POTENTIAL FOR RECOVERY OF RUTILE AND OTHER BYPRODUCTS FROM WESTERN COPPER TAILINGS

By E. G. Davis¹, G. V. Sullivan², and W. E. Lamont³

ABSTRACT

The Bureau of Mines studied tailings samples from 11 large-scale western copper operations to determine the potential for recovery of rutile and other critical and strategic minerals. Up to 15 pounds per short ton (lb/st) TiO₂ was found in these samples; however, only 9 to 44 pct of the TiO₂ was liberated rutile. For one sample, gravity preconcentration, grinding, and flotation recovered 34 pct of the TiO₂ in a 54.8-pct-TiO₂ concentrate. Over 0.38 lb/st W was found in some of the tailings samples. Scheelite was identified as the major W mineral. Nine of the eleven samples contained about 0.02 to 0.18 lb/st Co. Pyrite was the principal Co-bearing sulfide mineral, with Co contained in about one-fifth of the pyrite grains. Up to 30 pct of the Co was concentrated in a bulk sulfide flotation concentrate.

Two of the goals of the Bureau of Mines are to maximize mineral recovery from domestic resources and to conserve mineral resources. To help meet these goals, the Bureau has been investigating the recovery of valuable minerals from mineral processing tailings. One of the areas under study has been the recovery of rutile from western Cu mill tailings (1).4 Rutile (TiO₂) and ilmenite (FeTiO₃) are the two major Ti-bearing minerals utilized in the production of Ti metal and TiO₂ pigment. Rutile used domestically is imported at the rate of 170,000 st annually (2). In 1953, a survey by the U.S. Geological Survey (3) indicated that most of the western Cu deposits being mined at that time contained from 6 to 15 lb/st TiO_2 . The TiO_2 is present as rutile, anatase, ilmenite, and other Ti minerals. One such operation--San Manuel, a division of Magma Copper Co., a wholly owned subsidiary of Newmont Corp.--had ore reserves of nearly 1 billion st. In addition to 15 lb/st Cu, this reserve also contains 15 lb/st TiO₂ (4-6). More recently, Force (7) recorded the origin and mode of occurrence of

rutile in porphyry ore. He estimated the potential byproduct rutile resource in the active western copper mines to be in excess of 5 million mt, with a potential rutile recovery rate of 300 mt/d. Sullivan and Llewellyn (8) estimated that recovery of rutile from two of the tailings they investigated would amount to about 32 pct of 1980 U.S. imports.

A rutile flotation technique for rutile-bearing Cu mill tailings was developed by Llewellyn and Sullivan (1). The success of that investigation led to this research, which sought to determine the feasibility of rutile recovery from other western copper mines.

Eleven companies, some of which wished to remain anonymous, cooperated in this study, submitting a total of 15 flotation plant tailings samples and one leach plant waste product. Daily capacity of these 11 operations is substantially over 500,000 st (9). Consequently, recovery of rutile and/or other potentially valuable minerals in these plant waste materials could represent very significant tonnages.

DESCRIPTION OF SAMPLES

Samples of Cu mill tailings were requested from all major western copper producers so that the elements in their waste products could be inventoried. Most of the operating companies provided several barrels of tailings. However, at the time, the copper market was in a

⁴Underlined numbers in parentheses refer to items in the list of references at the end of this report. depressed state, so some of the properties were not operating. Several of these companies furnished samples of drill-hole composites of old tailings ponds or composites of monthly operating samples taken from storage.

Each sample was thoroughly mixed or slurried before a representative sample was taken for head analyses, sizing, and sink-float studies.

CHEMICAL ANALYSES

Representative samples of each waste tailings were analyzed by wet chemical means for several major elements and some of the minor elements such as Ti, Cu, Fe. and S. Trace elements were analyzed by neutron activation⁵ and X-ray fluorescence. The resulting analyses (table 1) indicated that the TiO2 content in the tailings products varied from 3.2 to 15 1b/st. The tailings also contained varying amounts of Cu that were not recovered in the original processing of the ore and trace amounts of Mo, W, Co, V, Zn. and Ni. The recovery of some of these elements may be of interest especially if they can be recovered in addition to the TiO2.

PHYSICAL ANALYSES

X-ray Diffraction

Representative samples of each waste tailings were analyzed using X-ray diffraction to determine the mineralogical composition of each sample. Results of

⁵The neutron activation was done in the University of Utah's TRIGA reactor, which operates with a flux density of 10¹² neutrons per square centimeter per second. The tests were performed on 1-g samples that were heat sealed in plastic capsules and irradiated for either 15 s or 10 min, depending on the amount of contained elements, their half lives, and their neutron-absorption cross sections. Flux monitors were Au for samples irradiated for 15 s and Fe for samples irradiated for 10 min. Counting was done with a Ge-Li detector coupled to a 4,096-channel analyzer.

the diffraction studies (table 2) indicated that the quartz was a major constitutent in 15 of the samples. Garnet, orthoclase, plagioclase, and mica were reported in minor to major amounts. The concentration of rutile was too low in the bulk tailings for detection using X-ray diffraction.

Sizing Studies

The samples were wet sieved at 150 and 37 µm and sedimentation sized at 10 µm. The sized fractions from each sample were analyzed for TiO2 and Cu to determine the size distribution of the TiO₂ and Cu minerals. Results of this study are summarized in table 3. In some of the samples, the Cu concentrated slightly in the plus 150-um size fraction, probably as a result of not achieving liberation of the copper sulfide minerals during grinding. In most of the samples, the Cu also concentrated slightly in the minus 10-um fraction, possibly resulting from (1) ineffective flotation of fine copper sulfide in the original flotation process or (2) the presence of oxide Cu in the fine sizes. The TiO₂ concentrated slightly in the minus 37-plus 10-um fraction.

Sink-Float Studies

The plus $10-\mu m$ size fraction was sinkfloat separated at specific gravities of 2.93 and 3.3 using heavy liquids. Each specific gravity (sp gr) fraction was analyzed for TiO₂ to determine its liberation characteristics. The liberated Ti minerals were concentrated in the sink 3.3 sp gr product, and the partially liberated Ti minerals were concentrated in

the fraction between 2.93 and 3.3 sp gr. As shown in table 4, the three samples containing the smallest amount of TiO_2 also contained large quantities of garnet which reported to the highest specific gravity fraction of 3.3. In the other samples, between 9 and 44 pct of the TiO_2 was in the sink 3.3 sp gr fraction. For sample 1B, the size analysis of the sink 3.3 sp gr fraction showed that 82 pct of the TiO_2 in that high-density fraction was between 75 and 10 µm in size. Although the liberation size for the Ti minerals was smaller than many of the tailings particles, several of the tailings contained sufficient liberated TiO_2 to be potentially viable resources. As shown in table 5, half of the tailings samples contained more than 2 lb/st liberated TiO₂. The analyses for five other potentially valuable elements found in the sink 3.3 sp gr fraction are also shown in table 5.

Mineralogical Examination of High-Density Fractions

The Bureau analyzed samples of minus 150-, plus 37-um, high-density fractions to determine their mineralogical contents. Several representative fractions were prepared from each of the samples. One set was cast in methyl methacrylate buttons which were then briquetted in lucite. They were later polished and examined using a reflected-light polarizing microscope. Another set was examined in oils using a transmitted-light polarizing microscope. Finally, a third set was pulverized and analyzed with an X-ray powder diffractometer.

Table 6 presents the combined results of the three separate mineral examinations. No effort was made to quantify the mineral species because of the large size difference between the minus 150and plus 37-µm fractions. The presence of an unidentified oxide mineral was noted in several of the samples; further examinations and chemical analyses did not identify this mineral.

Microprobe Analyses of Two High-Density Fractions

The sink fractions of samples 1A and 9A were examined by electron beam microprobe to determine the amount and mode of occurrence of the TiO₂ minerals. The approximate mineral contents of the highdensity sink fractions were estimated as follows, in percent:

| Mineral | Sample 1A | Sample 9A |

TABLE 6. - Mineralogical identification of minus 150- plus 37-µm high-density fractions

NOTE. -- Sample 11 was not analyzed.

The miscellaneous minerals included chalcopyrite, covellite, xenotime, molybdenite, barite, galena, sphalerite, and other silicates and oxides. The modes of occurrence and associations of the Tibearing minerals were as follows, with content shown in percent:

| Sample 1A | Sample 9A |
|-----------|-----------|
| 65 | 65 |
| 30 | 10 |
| 5 | 15 |
| 1 | 10 |
| | 65 30 |

The rutile with silicate intergrowth, which was common in sample 1A, is shown

in figure 1. Figure 1A, a negative electron current image, shows the rutile as light gray and the silicate as dark gray. Figures 1B and 1C show the distributions of Ti and Si, respectively.

The complex composite common in sample 9A is shown in figure 2. Figure 2A is a negative electron current image, and figures 2B, 2C and 2D are the elemental distributions of Ti, Fe, and Al, respectively. In figure 2A, the rutile appears as dark gray, and the large, porous mineral grain consists of a composite of ilmenite, FeO_2 , and aluminium silicate. About 10 pct of the Ti appears to be tied up in this manner.

Beneficiation studies were conducted to further define the chemical and physical natures of the critical and strategic minerals in the tailings and to determine the feasibility of several beneficiation schemes for recovering these minerals. Virtually all of the beneficiation studies were conducted on sample 1B from the San Manuel operation. This sample contained 14.6 1b/st TiO_2 , mostly as rutile, 1.4 1b/st Cu, and 0.1 1b/st Co.

RUTILE RECOVERY

Llewellyn and Sullivan devised a flotation method for recovering the rutile from San Manuel Cu tailings (8). First. the as-received tailings were deslimed at After adjusting the pH to 9.8 10 µm. with Na₂Co₃, the sulfide minerals were floated using sodium ethyl xanthate as Then the carbonaceous the collector. minerals were floated at pH 9.8 using sodium oleate as the collector and dextrin as a rutile depressant. After thickening to remove most of the high-pH water, H₂SO₄ was used to lower the pH to 2.4 followed by rutile flotation using petroleum sulfonate as the collector and HF as a silicate depressant. Both the sulfide and carbonate flotations significantly lowered the acid consumption required to maintain the 2.4 pH for rutile After three cleaning flotaflotation. tion stages, the rutile concentrate contained $34.7 \text{ pct } \text{TiO}_2$, and the method recovered 31 pct of the TiO2. Size analysis of the rutile concentrate showed that only the minus 75-µm rutile was recovered. Grinding the original tailings through 75 µm increased the TiO2 recovery However, the grinding costs to 34 pct. for these tailings would greatly exceed the benefit of the increased rutile recovery.

FIGURE 2.—Electron microprobe photographs of high-density fraction of sample 9A (X 200). *A*, Negative electron current image; *B*, Ti distribution; C, Fe distribution; *D*, Al distribution.

Sizing and Flotation

Llewellyn and Sullivan pointed out that preconcentration of the plus $75-\mu m$ rutile might prove to be an economical alternative to bulk grinding for increased rutile recovery. Building upon their research, three additional beneficiation schemes were studied.

The first alternate method classified the tailings at 75 μ m and discarded the plus 75- μ m material. A flow diagram of this method is shown in figure 3. The minus 75- μ m material was treated

according to the method devised by Llewellyn and Sullivan, except for the substitution of an anionic sulphosuccinate for the petroleum sulfonate in the rutile flotation. About 30 pct of the TiO₂ was recovered in a 55.7-pct-TiO₂ concentrate. Heavy-liquid analysis of the rutile flotation tailings indicated that 87 pct of the liberated rutile was recovered in the rutile concentrate. A summary of the TiO₂ distribution is shown in table 7. Nearly all of the TiO₂ lost in the flotation tailings was in the form of small grains locked with silicate minerals.

FIGURE 3.—Flow diagram, first alternate to Llewellyn and Sullivan method for rutile recovery.

(2 1,000-g charges)

NAp Not applicable. '83 pct of available TiO₂.

Preconcentration and Flotation

The second alternate method employed gravity preconcentration on the plus $75-\mu m$ portion of the tailings. Figure 4 shows the flow diagram for this method. Using a concentrating table, the plus 150-µm fraction and minus 150- plus 75-µm fraction were independently treated to form a heavy-mineral concentrate containing 17 pct of the plus 75-µm TiO₂ and rejecting over 96 pct of the gangue. Heavy-liquid analysis showed that 69 pct of the plus 75-µm liberated rutile was recovered in the table concentrate. After combining the gravity concentrate with the minus $75-\mu m$ material, the modified Llewellyn and Sullivan flotation method (anionic sulphosuccinate substituted for the petroleum sulfonate) produced a 30.2-pct-Ti02 concentrate, but recovered only 24 pct of the TiO2.

Preconcentration, Grinding, and Flotation

The third alternate method employed gravity preconcentration followed by grinding. As shown in figure 5, the plus $150-\mu m$ fraction and the minus 150-plus 75- μm fraction were individually tabled

and the combined gravity concentrate was ground in a ball mill to minus 75 μm . The ground concentrate was combined with the original minus 75- μm fraction and deslimed at 10 μm . The final flotation concentrate recovered 34 pct of the TiO_2 in a 54.8-pct-TiO_2 concentrate.

Comparison of Flotation Methods

To compare the efficiency of the flotation methods, consideration must be given to both reagent consumption and rutile grade and recovery. A summary of the reagent requirements for each method is shown in table 8. These data show that significant savings in reagent consumption can be made by lowering the amount of material sent to flotation.

A summary of the results from the beneficiation schemes tested is shown in table 9. Several physical characteristics of the TiO_2 found in the tailings can be determined by comparing these results. For each method, the rutile in the flotation feed was never liberated. About 31 pct of the TiO_2 was liberated and recovered in the as-received minus 75- plus $10-\mu m$ fraction. Only 4 pct of the rutile was recovered from the ground

¹Over 30 pct of the rutile was recovered in the rougher flotation. Subsequent cleaner flotations lost significant amounts of rutile.

gravity concentrate. Although 32 pct of the TiO₂ was in the plus 75- μ m portion of the tailings, at most only 4 pct was recovered by any of the three alternative methods. This information coupled with the heavy-liquid analysis showed that only 34 pct of the TiO₂ was liberated and recoverable in tailings sample 1B. Even at this low recovery potential, the quantity of recoverable rutile being discarded annually at the mill that supplied this sample approaches 18 pct of U.S. domestic rutile consumption.

OTHER BYPRODUCT ELEMENTS RECOVERY

Several other important elements and minerals were discovered in the Cu tailings samples studied. In several cases, beneficiation techniques were utilized to concentrate these elements and minerals so their modes of occurrence could be further characterized. Tungsten values in the samples ranged from trace amounts to 0.38 lb/st. Scheelite was identified as the primary W mineral. Beneficiation tests were conducted on the sample with the highest W values. After screening sample at 150, 75, and the tailings and desliming at 10 µm each size 37 um, fraction was tabled to concentrate the The sulfide minerals heavy minerals. were removed from the table concentrates by flotation. Finally, the nonmagnetic

17

W concentrate was separated from the magnetic sulfide flotation tailings on a high-intensity wet magnetic separator. A W concentrate analyzing 2.4 pct WO₅ was produced by this treatment with about 87 pct recovery of the WO₃. A small portion of the scheelite was finer than $10-\mu m$ size and was not readily recovered by this method.

In nine of the eleven samples, Co ranged from 0.02 to 0.18 lb/st. From 7 to 25 pct of the Co was concentrated in the sink 3.3 sp gr fraction by heavyliquid separation. The sulfide flotation concentrate from sample 1B contained 1.2 lb/st Co, which was 30 pct of the Co in the sample. Although no specific Co mineral was identified, microprobe analysis indicated that about one-fifth of the pyrite grains contained Co. There was little hope for improved Co concentration by physical beneficiation techniques. Α preliminary test utilizing amminoacal leaching of oxidized sulfide concentrate followed by ion-exchange treatment showed that the Co could be extracted from the Cu tailings. This test recovered 15 pct the Co from the tailings sample 1B. of At 20 million st annual capacity from this mine, over 300,000 lb of Co could be recovered by this method. This represents 2 pct of U.S. domestic consumption (10) of this important element.

ACID LEACHING

The head samples and the minus 10-um fractions of 10 of the porphyry Cu tailings were leached with H_2SO_4 to determine the solubility of various elements. Sample 11 was not received in time to be included in this study. Twenty-five-gram samples were leached for 4 h on a steam bath using 50 mL of 25 pct H_2SO_4 . The leached samples were filtered and washed five times with hot distilled water. Leach and wash solutions were combined and analyzed for 20 elements by plasma spectrometry techniques. Arsenic, boron, and antimony were not detected in any of the leach solutions. Results for the remaining 17 elements are shown in table 10.

All solutions analyzed represented a 10:1 dilution of the original 50-mL leach solution. Analyses of the leach solutions from the minus $10\text{-}\mu\text{m}$ fractions for Al and P were omitted because significant quantities of tetrasodium pyrophosphate as a dispersant and Al₂(SO₄)₃ as a flocculant were used to obtain these slimes. These soluble salts may remain with the dried solids and report in the leach solution, giving erroneous results.

The Bureau chemists who performed the plasma spectrometry analyses (table 10) cautioned that spectral and background interferences create uncertainty about the presence of elements in the lower concentration ranges, particularly below about 0.01 g/L. Aluminum and calcium, for example, give major interference with W and U, respectively, and small programmed correction errors in the factors can give a false indication of the presence of these elements.

ND Not determined.

¹Multiply values by 40 to obtain pounds of material leached per ton of solids. ²Al₂(SO₄)₃ used as flocculant during sizing caused error in analysis. ³Tetra-sodium phrophosphate used as dispersant during sizing caused error in analysis.

CONCLUSIONS

Among the Cu tailings samples investigated, nine contained more than 2.0 lb/st TiO_2 as rutile. Only about 9 to 44 pct of this rutile was liberated. Flotation of the minus 75- plus $10-\mu m$ material from one sample recovered 30 pct of the TiO_2 in a 55.7-pct- TiO_2 concentrate.

Tungsten was found at levels as high as 0.4 lb/st in some tailings samples. Scheelite was identified as the principal W mineral. Gravity concentration, flotation, and magnetic separation of the sample W values_ significantly concentrated the plus $10-\mu$ m scheelite to 2.4 pct WO₃ with 87 pct WO₃ recovery. Cobalt in 9 of the 11 tailings samples ranged from 0.02 to 0.18 1b/st. Sulfide flotation, oxidation roasting, ammoniacal leaching, and ion exchange recovered about 15 pct of the Co in a Co-rich solution.
