RECOVERY OF VANADIUM, URANIUM, AND PHOSPHATE FROM IDAHO PHOSPHORITE ORES

By J. C. Judd,¹ R. G. Sandberg,² and J. L. Huiatt³

ABSTRACT

The Bureau of Mines investigated the recovery of vanadium, uranium, and phosphorus from low-grade phosphorite ores and concentrate by leaching with H_2SO_4 . Samples containing 0.12 to 0.23 pct V_2O_5 , 0.009 to 0.012 pct U_3O_8 , and 18 to 30 pct P_2O_5 were treated by batch-agitation leaching, roasting followed by acid leaching, salt-roasting followed by acid leaching, and leaching under pressure.

Maximum recoveries using leaching alone ranged from 78 to 98 pct of the V_2O_5 and 74 to 88 pct of the U_3O_8 . Leaching under pressure resulted in extractions of 88 to 95 pct of the V_2O_5 and 84 to 89 pct of the U_3O_8 . Leaching following roasting--with or without $NaCl$ --produced extractions of 97 to 99 pct of the V_2O_5 and 86 to 91 pct of the U_3O_8 . Depending on the technique(s) employed, phosphate extractions ranged from 89 to 99 pct.

Solvent extraction laboratory tests were conducted to selectively recover vanadium and uranium values from acid leach solutions. An average of 95 pct of the U_3O_8 was recovered using di(2-ethylhexyl)phosphoric acid, plus trioctylphosphinic oxide. Essentially all of the V_2O_5 was recovered with octylphenyl acid phosphate plus isodecanol. The phosphate remained in the raffinate.

INTRODUCTION

Vanadium is classified as a strategic and critical material because of its significant import dependence and essential use in equipment for defense, energy, and transportation (1).⁴ It is principally consumed by the iron and steel industry as ferrovandium or related vanadium-carbon ferroalloys. Vanadium significantly increases strength and improves toughness and ductility of carbon steels, which are used for constructing high-rise buildings, bridges, and pipelines. Other important applications for vanadium are as additives to titanium-based alloys, which are consumed in jet engines and other aircraft parts, and as catalysts, which are used in the manufacturing of sulfuric acid and other chemicals.

Vanadium is widely distributed throughout the earth but in rather low concentration. In the United States, particularly in the West, vanadium is found in uranium-bearing minerals and in certain phosphatic shales and phosphate rocks. One of these phosphatic deposits, located in Idaho, represents a large domestic vanadium reserve. The phosphorite beds, generally 3 to 20 ft thick, average 20 to 32 pct P₂O₅ and 0.14 pct V₂O₅. At least 125,000 short tons (st) of coproduct vanadium is contained in these deposits. An additional 1.6 million st of coproduct vanadium occurs in marginal reserves of phosphatic shale and low-grade phosphorite dispersed in the northern Rocky Mountains (1).

The western phosphate industry processes 2.6 million st/yr ore (2). Following beneficiation, the plus 325-mesh concentrate (30 to 32 pct P₂O₅) is leached with H₂SO₄, and the minus 325-mesh material is rejected to the tailings. A significant amount of vanadium and uranium is lost with the rejected tailings. Phosphoric acid (H₃PO₄) is produced from concentrates by either the dihydrate process (at temperatures of <80° C) or the hemihydrate process (at

>80° C). The P₂O₅ content of the acid is 28 to 30 pct with the dihydrate process and 45 to 54 pct with the hemihydrate process. If necessary, evaporation is used to increase the P₂O₅ content to 50 to 54 pct, regardless of which process is used (3-4). The chemical equation for the dihydrate (A) and hemihydrate (B) reactions are given below (4-6):

The approximate amount of H₂SO₄ used for maximum conversion to H₃PO₄ is the stoichiometric amount required to convert the CaO content of the concentrate to CaSO₄, plus an additional 2 to 3 pct. Acid concentration is very critical because, if the free sulfate content is too low, the gypsum (CaSO₄·2H₂O) crystals do not grow properly; this affects the rate of filtration (6). Also, the HPO₄ ions are substituted for SO₄ ions in the CaSO₄ lattice; this represents a significant P₂O₅ loss. The extent of substitution decreases with H₂SO₄ excess and increases with increased P₂O₅ concentration. Substitution of P₂O₅ in gypsum is also related to solids content in suspension. If the H₂SO₄ concentration is too high, an insoluble CaSO₄ layer forms around the particles to be digested (6).

Acid processes for recovery of uranium and vanadium from the usual western resources are similar to those processes used in the production of H₃PO₄, except the feed generally has not been beneficiated prior to U₃O₈ and V₂O₅ recovery. One benefit of processing unbeneficiated phosphorite ore is the elimination of one solid waste stream and the significant problems in its handling (7-8). A second benefit is higher recoveries, as value losses during beneficiation are generally significant. A third benefit is conservation of the resource, as more

⁴Underlined numbers in parentheses refer to items in the list of references at the end of this report.

phosphate should be available per short ton of phosphorite ore mined. Therefore, processing of phosphorite to recover vanadium and uranium requires that phosphorus also be recovered, in order to offset the costs of additional H_2SO_4 consumption.

Because of the strategic importance of vanadium the Bureau of Mines conducted an investigation to recover vanadium, uranium, and phosphorus from unbeneficiated Conda and Fort Hall (Gay Mine) ores, a Conda high-magnesium material, and a Conda concentrate (Simplot Mill). Extraction techniques investigated were batch-agitation leaching alone; roasting or

salt-roasting followed by leaching; and leaching under pressure. Tests were performed to determine acid addition, temperature, solids content, and time requirements for optimum extractions. Complementary solvent extraction tests were conducted to selectively extract the vanadium and uranium from the leach solutions. Solvent extraction was selected because it has been used successfully in the past to recover uranium (4) and vanadium (9) with trioctylphosphinic oxide (TOPO) and to recover both vanadium and uranium (10) with trialkylphosphine oxide plus an alkyl-substituted diaryl phosphoric acid.

SAMPLE DESCRIPTION AND PROCEDURES

SAMPLE DESCRIPTION

The four samples used in this study were designated as Conda, Conda (high-Mg), and Fort Hall ores, and Conda concentrate. Conda and Fort Hall ore samples were from ore deposits that are presently being processed to produce phosphate fertilizer. The Conda concentrate, as received, was a deslimed, calcined product. Ninety-seven percent of this material was minus -35 mesh. The Conda (high-Mg) ore sample represents material that is presently being rejected because its high magnesium content causes processing problems. Chemical and inductively coupled plasma (ICP) analyses of the four samples are listed in tables 1 and 2, respectively.

Microscopic and X-ray diffraction examination identified the samples as calcium phosphate shale or phosphorite. X-ray diffraction also revealed that (1) Conda and Fort Hall samples contained illite clay, quartz, clinozoisite-epidote (a mineral with composition intermediate to these two minerals), limonite, calcite, plagioclase, pyrite, and apatite, and (2) the Conda (high-Mg) sample contained dolomite, apatite, quartz, calcite, and plagioclase. Neither fluorescence nor a Geiger counter could detect any uranium in the four samples, nor could specific vanadium or uranium minerals be identified.

Ore samples were prepared for leaching by pulverizing to minus 35 mesh and

splitting into 100-g samples. Concentrate samples were screened through minus 35 mesh; the oversize was pulverized to minus 35 mesh. The screen fractions were recombined and split into 100-g samples.

A wet-screen analysis was performed to determine the distribution of vanadium, uranium, and phosphate in the screen fractions from each of the samples. Results of the wet-screen analysis are listed in tables 3-6. The results show 59 to 73 pct of the V₂O₅, 27 to 42 pct of the U₃O₈, and 20 to 39 pct of the P₂O₅ in the ores were distributed to the fines (minus 200-mesh fraction). The Conda concentrate was not considered, as it had already been beneficiated and calcined. The analyses indicate that significant amounts of vanadium, uranium,

and phosphate could be lost if the fines are removed during beneficiation.

The Conda concentrate contains less vanadium but more phosphate than the Conda and Fort Hall ore samples. Vanadium and phosphate content are lowest in the Conda (high-Mg) ore. The magnesium content of the Conda (high-Mg) ore is twice the amount in the Conda ore, and five times the amount in the Fort Hall ore.

EXPERIMENTAL PROCEDURES

Leaching procedures used in this study were as follows: batch-agitation leaching; roasting, with and without salt addition, followed by leaching; and leaching under pressure. The lixiviant in all

tests was reagent-grade sulfuric acid (H₂SO₄).

Batch-agitated leach tests were performed using 100 g of minus 35-mesh samples. The samples were leached for 3 to 24 h in a 1,000-mL tall beaker equipped with a reflux tube and stopper. Agitation was accomplished using a custom-fabricated impeller rotated at sufficient speed to maintain particle suspension.

A hotplate equipped with a temperature probe was used to keep leach temperatures within $\pm 1^\circ$ C. After leaching, the slurry was filtered through a Buchner funnel and the residue washed three times using about 50 mL of wash solution per wash. The first wash solution was a dilute solution of H₂SO₄ (pH adjusted to 1.5). Deionized water was used for the second and third washes.

Roast-leach tests were performed by preroasting the ore sample, mixed with or without NaCl, in a muffle furnace. The samples were heated at a specific temperature for 4 h, removed from the furnace, cooled to ambient temperature, and leached for 18 h at 75° C using H₂SO₄ solution.

Pressure-leach tests were performed on 50-g charges of minus 35-mesh material using a glass-lined pressure reaction apparatus equipped with stirrer and temperature probe. The reactor was purged for 5 min with oxygen before heating to the operating temperature. At the end of

testing, the reactor was quenched in cold water. The slurry was filtered through a Buchner funnel and washed using a procedure similar to that described for the leach-only tests, except 25 mL of wash solution was used per wash.

The pH and emf values were measured on the terminal leach solution (leach filtrate before wash water was added). The emf values were determined with platinum and saturated-calomel electrodes; the highest values indicate the most highly oxidized solution. Leaching efficiency was assessed by determining and comparing V₂O₅, U₃O₈, and P₂O₅ extractions.

LEACH TESTS

BATCH-AGITATION LEACHING

Batch-agitation leach tests were performed using various acid concentrations, solids contents, temperatures, and leaching times. Good agitation with a well-designed impeller was important to obtain reproducible results. Improper mixing during leaching caused temperature gradients, which decreased mass transfer rates between ore particles and leach solutions.

Conda Ore

The best extractions using Conda ore were 97, 87, and 99 pct of the V₂O₅, U₃O₈, and P₂O₅, respectively. These results were achieved by leaching the ore at 40 pct solids for 18 h at 90° C using 2,000 lb/st H₂SO₄ (table 7). Most wet-process phosphoric acid plants operate at a temperature between 75° and 85° C; a range which is most practical for leaching the phosphorite ores (3). Leaching

		75	.9	340	78	74	89
		85	.7	290	84	78	96
		90	.9	350	89	89	98

¹Conditions: 100 g of minus 35-mesh samples leached for 18 h.

Conda ore at 75° C for 18 h at 40 pct solids using 2,000 lb/st H₂SO₄ extracted 94, 88, and 98 pct of the V₂O₅, U₃O₈, and P₂O₅, respectively (table 8). Increasing the temperature to 85° C had little effect on extraction.

Experiments performed at 75° C and 18-h leaching time (table 8) showed that increasing pulp density from 33-1/3 pct solids to 40 pct solids significantly improved V₂O₅ and P₂O₅ extraction from Conda ore for a given acid concentration, but had little effect on U₃O₈ extraction. Increasing pulp density to 50 pct solids had no significant effect on extraction.

Fort Hall Ore

The best extractions using Fort Hall ore were 89, 89, and 98 pct of the V₂O₅, U₃O₈, and P₂O₅, respectively. These results were achieved by leaching the ore at 40 pct solids for 18 h at 90° C using 1,500 lb/st H₂SO₄ (table 7). Higher temperatures and longer leaching times generally improved extraction from this ore (tables 7 and 9). However, leaching at 85° C lowered V₂O₅, U₃O₈, and P₂O₅ extractions to 84, 78, and 96 pct, respectively, and leaching at 75° C produced still lower results of 78, 74, and 89 pct V₂O₅, U₃O₈, and P₂O₅, respectively. Increasing the acid addition (table 10) from 1,500 to 2,500 lb/st H₂SO₄ (at 75° C) increased phosphate extraction from 89 to 93 pct but in turn reduced U₃O₈ extraction from 74 to 71 pct.

In general, temperature and time had greater effects on extraction than did acid addition. (See tables 7 and 9.) The ore was more difficult to agitate at 2,000 lb/st H₂SO₄ than at either 1,500 or 2,500 lb/st H₂SO₄, which may account for the lower extractions at 2,000 lb/st H₂SO₄ (table 10). The Fort Hall ore could not be agitated at 50 pct solids.

¹Conditions: 100 g of minus 35-mesh sample leached at 75° C for 18 h at 40 pct solids.

Conda (High-Mg) Material

The best extractions from this material were 95, 85, and 98 pct of the V₂O₅, U₃O₈, and P₂O₅, respectively (table 10). These results were achieved by leaching the material at 40 pct solids for 18 h at 75° C using 2,500 lb/st H₂SO₄.

Conda Concentrate

The best extractions from the Conda concentrate were 98, 78, and 99 pct of the V₂O₅, U₃O₈, and P₂O₅, respectively (table 10). These results were achieved by leaching the concentrate at 40 pct solids for 18 h at 75° C using 2,000 lb/st H₂SO₄. This should be similar to the actual mill result.

ROAST AND SALT-ROAST LEACHING

Because roast-leach methods have been effective in treating uranium ore in which the uranium could not be extracted by leaching alone, and because salt-roasting has been a viable process used in vanadium extraction (11), tests were performed to determine if vanadium and uranium extractions could be improved by these methods.

In roast-leaching, the samples were roasted for 4 h at 500° or 800° C; in salt-roasting, the samples were first combined with 10 pct NaCl, then roasted for 4 h at 800° C only. After roasting (or salt-roasting), the calcines were leached at 75° C for 18 h with additions of 1,000 to 2,500 lb/st H₂SO₄. Calcines from the Conda and Fort Hall ores were leached at 40 and 50 pct solids; calcines from the Conda (high-Mg) ore and Conda concentrate were leached at 40 pct solids.

Conda Ore

The following tabulation (from tables 7 and 11) shows that 500 lb/st less acid produced almost identical extraction levels following roasting or salt-roasting than from leaching alone.

U ₃ O ₈	89	88	91	90	78
P ₂ O ₅	98	97	99	99	99

Nap Not applicable.

As can be seen, salt-roasting produced slightly higher V₂O₅ values, but surprisingly, leaching the salt-roasted calcine lowered the U₃O₈ extraction considerably at the higher acid and solids content. (See columns 4 and 5 above.) Values are nearly as high after roasting without

salt at only 500° C and 50 pct solids. Note that roasting enabled leaching the ore at 50 pct solids.

Conda (High-Mg) Material

Nearly identical results (tables 10 and 13) were achieved following roasting and salt-roasting at 800° C as with leaching alone, but with lower acid additions, as shown in the following tabulation:

Conditions:	Leaching alone	Roast-leach	Salt-roast and leach

Salt-roasting and leaching with 1,500 lb/st H₂SO₄ produced even higher V₂O₅ extraction (of 98 pct), but P₂O₅ extractions were much lower (78 pct) (table 13).

Conda Concentrate

The major benefit from roasting or salt-roasting this material was an 11-pct gain in U₃O₈ extraction, under essentially the same leaching conditions as for leaching alone. There was no apparent benefit

with regard to lowering acid requirements, as shown in tables 10 and 13.

LEACHING UNDER PRESSURE

Leaching tests were performed under pressure to determine if improved vanadium and uranium extraction could be achieved without affecting phosphate extraction and to determine the conditions required for optimum extractions.

Conda ore, Fort Hall ore, Conda (high-Mg) ore, and Conda concentrate samples were pressure leached in a 2-L, glass-lined Parr⁵ pressure vessel. The 50-g charges were leached for 3 h at 20 pct solids under an oxygen atmosphere. The

⁵Reference to specific products does not imply endorsement by the Bureau of Mines.

total pressure, temperature, and acid addition levels were varied. Combinations of temperature and pressure were 90° C, 50 psi; 140° C, 90 psi; and 200° C, 260 psi. (Oxygen overpressure was 50 psi.) Acid additions were varied from 1,000 to 2,500 lb/st H₂SO₄. Test results are given in table 14.

Compared with other methods, leaching under pressure generally produced lower extractions; however, this may be due to the shortened leach time for these tests (3 h compared with 18 h for all previous test series). For two of the samples, fairly comparable results were produced at lower acid addition levels than for the 18-h leach tests--Conda ore and Conda concentrate.

	200	260	.3	612	95	79	91

¹Conditions: Samples leached for 3 h at 20 pct solids under 49 to 50 psi O₂.

Conda Ore

Preferred leaching conditions were 140° C, 90 psi, and 1,500 lb/st H₂SO₄; this resulted in extractions of 92, 88, and 92 pct, respectively of the V₂O₅, U₃O₈, and P₂O₅ (table 14). Acid requirement was 500 lb/st less than with leaching alone.

Fort Hall Ore

Highest V₂O₅ extraction of 88 pct resulted from using the following conditions: 200° C, 260 psi, and 1,500 lb/st H₂SO₄ (90 and 78 pct P₂O₅ and U₃O₈, respectively); but much higher U₃O₈ and P₂O₅ extractions were obtained by

leaching at 140° C, 90 psi, and acid additions of 2,000 lb/st. (See table 14.) The extractions were 84, 89, and 96 pct of the V₂O₅, U₃O₈, and P₂O₅, respectively. These extractions were higher than those from leaching alone, but lower than those from roasting plus leaching.

Conda (High-Mg) Material

Best extractions required 2,500 lb/st H₂SO₄, which is no better than from leaching alone or from roasting followed by leaching. This acid addition level at 90° C at 50 psi enabled extractions of 90, 84, and 99 pct, respectively of V₂O₅, U₃O₈, and P₂O₅.

Conda Concentrate

Preferred leaching conditions were 200° C, 260 psi, and 1,500 lb/st H₂SO₅.

This resulted in extractions of 94, 88, and 89 pct, respectively of the V₂O₅, U₃O₈, and P₂O₅ (table 14).

SOLVENT EXTRACTION TESTS

Subsequently, tests were performed to investigate methods to obtain separate products of vanadium and uranium from the various leach solutions. Table 15 summarizes the results of these tests, which involved adjusting the solution emf prior to contacting the pregnant solution with extractants.

In the first step, U₃O₈ values were extracted by contacting the pregnant solution with 0.5M D2EHPA (di(2-ethylhexyl) phosphoric acid) plus 0.125M TOPO (tri-octylphosphinic oxide), using a kerosene diluent. Contact was made at 25° C

for 5 min at an aqueous-to-organic (A/O) ratio of 4:1 following adjustment of the emf on all aqueous samples. Depending upon the aqueous material, the emf adjustment involved oxidation, using NaClO₃, or reduction via addition of iron filings. The emf must be adjusted to the value given in table 15 or coextraction of V₂O₅ will occur. The only pregnant solution that would extract only U₃O₈ over a range of emf values was the pregnant solution produced from leaching Conda ore alone. The range was 500±20 mV.

The second step, which extracted V_2O_5 values, involved contacting the raffinate from the first contact with 0.3M OPAP (octylphenyl acid phosphate) plus 5 vol pct IDA (isodecanol), using a kerosene diluent. Contact was made for 30 min at 25° C at an A/O ratio of 1:1, following adjustment of the emf downward. The emf values are given in table 15, but in most cases V_2O_5 could be extracted when the emf was less than 212 mV.

This method generally worked for all sample solutions, but small amounts of V_2O_5 were extracted during the uranium separation step for three of the four Conda (high-Mg) material solutions (table 15). Typical single contact results (leach only for Conda ore) extracted 98 pct of the U_3O_8 and none of the V_2O_5 in the first step, and 95 pct of the V_2O_5 during the second step. In all cases the P_2O_5 remained in the raffinate.

SUMMARY AND CONCLUSIONS

Extractions of 91 to 99 pct of the V_2O_5 , 78 to 89 pct of the U_3O_8 , and 89 to 99 pct of the P_2O_5 were achieved by processing Conda, Conda (high-Mg) material, and Conda concentrate samples using the following methods: leaching only; roasting with or without salt, followed by leaching; and leaching under pressure. Metal extractions required 1,500 to 2,000 lb/st H_2SO_4 for all samples except the Conda (high-Mg) material, which required 2,000 to 2,500 lb/st. All tests involved leaching for 18 h except the pressure test, for which time was reduced to 3 h. Roasting was done for 4 h, with or without salt.

V_2O_5 extraction from Fort Hall ore was (1) 78 pct when the ore was leached at 75° C for 18 h, (2) 78 to 88 pct when leached under pressure for 3 h at 90° to 200° C with an oxygen overpressure of about 50 psi, and (3) 97 to 98 pct when roasted without salt at 500° or 800° C or roasted with salt at 800° C for 4 h, followed by leaching for 18 h. U_3O_8 and P_2O_5 extractions were 74 to 91 pct and

89 to 99 pct, respectively. The required acid addition for this ore was 1,500 lb/st H_2SO_4 .

Preliminary solvent extraction tests showed that vanadium and uranium products could be separated from these leach solutions. Tests conducted at ambient temperature showed that when the emf of the leach solutions was adjusted to approximately 500 mV, an average of 95 pct of the U_3O_8 and none of the V_2O_5 was extracted using D2EHPA plus TOPO. Adjusting the raffinate emf to less than 200 mV and contacting with OPAP plus IDA enabled extraction of 79 pct or more of the V_2O_5 after one contact. All of the phosphate values were contained in the final raffinate, and therefore were available for H_3PO_4 production.

Work needs to be done on a continuous basis to determine the effect of impurity buildup on metal recovery. In addition, an economic evaluation must be conducted to determine which leaching procedures are cost effective.
