Recycling of plastics is urged by the need for closing material loops to maintain our natural resources when striving towards circular economy, but also by the concern raced by observations of plastic scrap in oceans and lakes. Packaging industry is the sector using the largest share of plastics, hence packaging dominates in the plastic waste flow. The aim of this paper was to sum up the recycling potential of post-consumer plastic packaging waste in Finland. This potential was evaluated based on the quantity, composition and mechanical quality of the plastic packaging waste generated by consumers and collected as a source-separated fraction, within the mixed municipal solid waste (MSW) or within energy waste. Based on the assessment 86,000-117,000 tons (18 kg/person/a) of post-consumer plastic packaging waste was generated in Finland in 2014. The majority, 84% of the waste was in the mixed MSW flow in 2014. Due to the launching of new sorting facilities and separate collections for post-consumer plastic packaging in 2016, almost 40% of the post-consumer plastic packaging could become available for recycling. However, a 50% recycling rate for post-consumer plastic packaging (other than PET bottles) would be needed to increase the overall MSW recycling rate from the current 41% by around two percentage points. The share of monotype plastics in the overall MSW plastics fraction was 80%, hence by volume the recycling potential of MSW plastics is high. Polypropylene (PP) and low density polyethylene (LDPE) were the most common plastic types present in mixed MSW, followed by polyethylene terephthalate (PET), polystyrene (PS) and high density polyethylene (HDPE). If all the Finnish plastic packaging waste collected through the three collection types would be available for recycling, then 19,000-25,000 tons of recycled PP and 6000-8000 tons of recycled HDPE would be available on the local market. However, this assessment includes uncertainties due to performing the composition study only on mixed MSW plastic fraction. In order to obtain more precise figures of the recycling potential of post-consumer plastic packaging, more studies should be performed on both the quantities and the qualities of plastic wastes. The mechanical and rheological test results indicated that even plastic wastes originating from the mixed MSW, can be useful raw materials. Recycled HDPE showed a smaller decline in the mechanical properties than recycled PP. The origin and processing method of waste plastic seemed to have less effect on the mechanical quality than the type of plastic. The applicability of a plastic waste for a product needs to be assessed case by case, due to product specific quality requirements. In addition to mechanical properties, the chemical composition of plastic wastes is of major importance, in order to be able to restrict hazardous substances from being circulated undesirably. In addition to quantity and quality of plastic wastes, the sustainability of the whole recycling chain needs to be assessed prior to launching operations so that the chain can be optimized to generate both environmental and economic benefits to society and operators.

Dai, X., et al. (2010). "Microbead electrochemiluminescence immunoassay for detection and identification of Venezuelan equine encephalitis virus." Journal of Virological Methods **169**(2): 274-281.
An electrochemiluminescence (ECL) immunoassay, incorporating chemically biotinylated and ruthenylated antibodies down-selected from a panel of monoclonal and polyclonal reagents, was developed to detect and identify Venezuelan equine encephalitis virus (VEEV). The limit of detection (LOD) of the optimized ECL assay was 10³ pfu/ml VEEV TC-83 virus and 1 ng/ml recombinant (r) VEEV E2 protein. The LOD of the ECL assay was approximately one log unit lower than that of a sandwich enzyme-linked immunosorbent assay (ELISA) incorporating the same immunoreagents. Repetition of ECL assays over time and by different operators demonstrated that the assay was reproducible (coefficient of variation 4.7-18.5% month-to-month; 3.3-8.8% person-to-person). The VEEV ECL assay exhibited no cross-reactivity with two closely related alphaviruses or with 21 heterologous biological agents. A genetically biotinylated recombinant VEEV antibody, MA116SBP, was evaluated for utility for detection of rE2; although functional in the ECL assay, the LOD was two log units higher (100 ng/ml vs 1 ng/ml) using MA116SBP than when chemically biotinylated antibody was used. The ECL assay detected VEEV at the lowest LOD (highest sensitivity) hitherto reported in the published literature and ECL assay results were generated in ~60 min compared to a 6-8 h period required for ELISA. Results have demonstrated a sensitive, rapid, and fully automated ECL immunoassay for detection and identification of VEEV.

Dai, Z., et al. (2018). "Occurrence of microplastics in the water column and sediment in an inland sea affected by intensive anthropogenic activities." Environmental Pollution **242**: 1557-1565.
Microplastics may lose buoyancy and occur in deeper waters and ultimately sink to the sediment and this may threaten plankton inhabiting in various water layers and benthic organisms. Here, we conduct the first survey on microplastics in the water column and corresponding sediment in addition to the surface water in the Bohai Sea. A total of 20 stations covering whole Bohai Sea were selected, which included 6 stations specified for water column studying. Seawater was sampled every 5 m, with maximal depth of 30 m in the water column

using Niskin bottles coupled with a ship-based conductivity, temperature and depth sensor (CTD) system and surface sediment samples were collected using box corer. The results indicated that higher microplastic levels accumulated at a depth range of 5–15 m in the water column in some stations, suggesting the surface water survey was not sufficient to reflect microplastics loading in a water body. Fibers predominated microplastic types in both seawater and sediment of the Bohai Sea, which accounted for 75%–96.4% of the total microplastics. However the relatively proportion of the fibers in the deeper water layers and sediment was lower than that in the surface water. Microplastic shapes are more diverse in the sediment than in the seawater in general. The microplastic sizes changed with depth in the water column and the proportion of the size-fraction < 300 μm increased with depth, probably as a result of rapid biofouling on the small microplastics due to their higher specific surface area. Such depth distribution also implied that sampling with manta net (>330 μm) that commonly used in the oceanographic survey might underestimate microplastics abundance in the water column. Further studies are recommended to focus on the sinking behavior of microplastics and their effects on marine organisms. Graphical abstract Image 1 Highlights • Microplastics levels in the surface sea were closely related with human activities. • A higher amount of microplastics accumulated in the depth of 5–15 m in the Bohai Sea. • Micropalstics with size <300 μm tended to sinking and presenting in the deeper water. • Microplastics abundance was not consistent between water and corresponding sediment. Substantial amount of microplastics accumulated in the deeper water rather than the surface water of the Baohai Sea. [ABSTRACT FROM AUTHOR]

Dakova, I., et al. (2009). "Ion-imprinted polymethacrylic microbeads as new sorbent for preconcentration and speciation of mercury." Talanta **78**(2): 523-529.

Metal ion-imprinted polymer particles have been prepared by copolymerization of methacrylic acid as monomer, trimethylolpropane trimethacrylate as cross-linking agent and 2,2'-azobisisobutyronitrile as initiator, in the presence of Hg(II)-1-(2-thiazolylazo)-2-naphthol complex. The separation and preconcentration characteristics of the Hg-ion-imprinted microbeads for inorganic mercury have been investigated by batch procedure. The optimal pH value for the quantitative sorption is 7. The adsorbed inorganic mercury is easily eluted by 2 mL 4 M HNO₃. The adsorption capacity of the newly synthesized Hg ion-imprinted microbeads is 32.0 micro mol g⁻¹ for dry copolymer. The selectivity of the copolymer toward inorganic mercury (Hg(II)) ion is confirmed through the comparison of the competitive adsorptions of Cd(II), Co(II), Cu(II), Ni(II), Pb(II), Zn(II) and high values of the selectivity and distribution coefficients have been calculated. Experiments performed for selective determination of inorganic mercury in mineral and sea waters showed that the interfering matrix does not influence the extraction efficiency of Hg ion-imprinted microbeads. The detection limit for inorganic mercury is 0.006 micro g L⁻¹ (3 sigma), determined by cold vapor atomic adsorption spectrometry. The relative standard deviation varied in the range 5-9% at 0.02-1 micro g L⁻¹ Hg levels. The new Hg-ion-imprinted microbeads have been tested and applied for the speciation of Hg in river and mineral waters: inorganic mercury has been determined selectively in nondigested sample, while total mercury

e.g. sum of inorganic and methylmercury, has been determined in digested sample.

Dakova, I., et al. (2012). "Synthesis and application of vinylpyridine containing ion-imprinted copolymer gel microbeads for Cu(II) solid-phase extraction." Journal of Separation Science **35**(20): 2805-2812.

The influence of polymer matrix on the extraction efficiency for Cu(II) and selectivity against metal ions such as Ni(II), Cd(II), Pb(II) of Cu(II) imprinted copolymer gels was described. The functional monomers investigated include the weakly basic 4-vinylpyridine (4-VP) and its mixure with the acidic and hydrogen binding methacrylic acid. Copolymer gels were prepared by dispersion cross-linking copolymerization using Cu(II)-4-(2-pyridylazo) resorcinol complex, Cu(II), or 4-(2-pyridylazo)resorcinol as templates. The chemical structure and morphology of the Cu(II)-imprinted microbeads are defined using elemental analysis, Fourier transform infrared spectroscopy, and scanning electron microscopy. Extraction efficiencies of newly synthesized sorbents were studied by batch procedure. The prepared copolymer gel with 4-VP as monomer and Cu(II)-4-(2-pyridylazo)resorcinol complex has higher capacity and selectivity toward Cu(II) than the copolymer gels prepared using the mixture of methacrylic acid and 4-VP. This new sorbent can be used as an effective SPE material for the highly selective preconcentration and separation of Cu(II) in sea water samples. It shows high mechanical and chemical stability. © 2012 WILEY-VCH Verlag GmbH & Co. KGaA, Weinheim.

Dakova, I., et al. (2007). "Solid phase selective separation and preconcentration of Cu(II) by Cu(II)-imprinted polymethacrylic microbeads." Analytica Chimica Acta **584**(1): 196-203.

Ion-imprinted polymer (IIP) particles are prepared by copolymerization of methacrylic acid as monomer, trimethylolpropane trimethacrylate as crosslinking agent and 2,2'-azo-bis-isobutyronitrile as initiator in the presence of Cu(II), a Cu(II)-4-(2-pyridylazo)resorcinol (Cu(II)-PAR) complex, and PAR only. A batch procedure is used for the determination of the characteristics of the Cu(II) solid phase extraction from the IIP produced. The results obtained show that the Cu(II)-PAR IIP has the greatest adsorption capacity (37.4 mumol g⁻¹ of dry copolymer) among the IIPs investigated. The optimal pH value for the quantitative preconcentration is 7, and full desorption is achieved by 1 M HNO<inf>3</inf>. The selectivity coefficients (S<inf>Cu/Me</inf>) for Me = Ni(II), Co(II) are 45.0 and 38.5, respectively. It is established that Cu(II)-PAR IIPs can be used repeatedly without a considerable adsorption capacity loss. The determination of Cu(II) ions in seawater shows that the interfering matrix does not influence the preconcentration and selectivity values of the Cu(II)-PAR IIPs. The detection and quantification limits are 0.001 mumol L⁻¹ (3sigma) and 0.003 mumol L⁻¹ (6sigma), respectively. © 2006 Elsevier B.V. All rights reserved.

D'Alessandro, M., et al. (2018). "Relationships between plastic litter and chemical pollutants on benthic biodiversity." Environmental Pollution **242**(Part B): 1546-1556.

Five Descriptors (D) of Marine Strategy Framework Directive (MSFD): marine litter (D10), non-indigenous species (D2) and organic and inorganic pollutants (D8), were estimated in a coastal area of GSA 16 (Augusta harbour, Central Mediterranean Sea) in order to study their effects on the biodiversity (D1) of the benthic community (D6) and to improve data for the MSFD. Investigation of plastic debris had led to the identification of 38 fragments divided into four categories, among which microplastics resulted as the most abundant. Six non-indigenous species, belonging to Polychaeta (Kirkegaardia dorsobranchialis, Notomastus aberans, Pista unibranchia, Pseudonereis anomala, Branchiomma bairdi) and Mollusca (Brachidontes pharaonis) were found. Biodiversity and benthic indices suggested a generalised, slightly disturbed ecological status. Anthracene, Zinc and Chrome were the most abundant chemical compounds in analysed sediments. Significant correlations were found between the abundance of trace elements vs biotic indices and between plastic debris vs biodiversity and benthic indices. This study represents the first report about the abundance of plastic debris and its relationship to contaminants and infauna in Augusta harbour. Our results can provide useful information for national and international laws and directives.

Dalu, T., et al. (2019). "Assessing factors driving the distribution and characteristics of shoreline macroplastics in a subtropical reservoir." Science of the Total Environment **696**: 133992.

Plastic pollution is a growing problem that threatens all habitat types globally. However, relatively little is known about the extent of macroplastics in African freshwater ecosystems. This study explored the distribution and concentration of different macroplastic debris types in Nandoni reservoir, South Africa over four sites (2 high household- and 2 low household-density) and two seasons (cool-dry, hot-dry). Similarities were observed for macroplastic debris numbers and weights across sites and seasons. Although slight insignificant differences in macroplastics abundances were observed, no significant relationships were recorded between household density (i.e. as proxy for human population density) and macroplastic debris abundances. The amount of plastic debris and 'species' (i.e. gamma-diversity value) decreased with distance from the shoreline, with the highest amount of plastic debris and 'species' being observed at the shoreline in all sites and seasons. Polypropylene was the most dominant (>45%) in terms of abundance for both seasons and sites. The information derived serves as a baseline for future studies on macroplastic distributions along freshwater reservoir shorelines.

Dam, A. H. and D. Kim (2008). "Metal ion-imprinted polymer microspheres derived from copper methacrylate for selective separation of heavy metal ions." Journal of Applied Polymer Science **108**(1): 14-24.

Microbeads of metal ion-imprinted polymers (MIIPs) were prepared by a novel precipitation polymerization technique, in which copper methacrylate monomer and ethylene glycol dimethacrylate crosslinker were copolymerized in a rotary evaporator. The prepared microbeads had mono- or narrow size dispersity, and their sizes increased from 1 to 4 m with decreasing solvent amount or increasing initiator concentration. The absorption capacity and selectivity of the imprinted polymer for copper ion were determined in the presence of various competitive metal ions. As results, adsorption equilibrium was quickly achieved in about 10 min with high absorbability (about 90%). The effects of pH, initial metallic ion concentration, and MIIP bead size on the absorption capacity were investigated. The Cu(II)-imprinted polymers exhibited extremely high selectivity, which was much higher than that of corresponding blank polymers.

Damelin, L. H., et al. (2015). "Alginate microbead-encapsulated silver complexes for selective delivery of broad-spectrum silver-based microbicides." International Journal of Antimicrobial Agents **46**(4): 394-400.

In sub-Saharan Africa, human immunodeficiency virus (HIV) infections are predominantly acquired via heterosexual contact, and women are at greatest risk of being infected. This region also has the highest rates of sexually transmitted infections (STIs) per capita worldwide; STIs are strongly associated with increased HIV transmission. Therefore, there is an urgent requirement for microbicides that are active against HIV and STIs. Silver compounds exhibit broad antimicrobial activity, making them potentially ideal broad-spectrum microbicides. However, for silver compounds to be effective microbicides, they must be active within seminal fluid and the

delivery vehicle used must protect the silver microbicide from vaginal fluid components but selectively release it during intercourse and/or following ejaculation. In this study, silver complexes were synthesised from the ligands saccharin, benzimidazole and 8-hydroxyquinoline and their microbicidal activity was assessed. We show that a silver saccharinate-benzimidazole complex (AgSB) exhibited activity against HIV-1, herpes simplex virus type 2 (HSV-2) and Neisseria gonorrhoeae at concentrations significantly below LD(50) levels for the vaginal mucosal cell line SiHa. Furthermore, we show that alginate microbeads are stable in vaginal fluid simulant but rapidly dissolve in seminal fluid simulant. Finally, we have established that microbead-encapsulated AgSB, dissolved in seminal fluid simulant, is active against the above pathogens, albeit at higher concentrations for HIV-1. This research therefore highlights, for the first time, the potential use of silver complexes encapsulated in alginate microbeads as a novel system for the delivery and selective release of broad-spectrum silver-based microbicides within the vaginal milieu during sexual intercourse/after ejaculation.

Damodar, R. and B. Movva (2014). "Preparation and in-vitro evaluation of metformin HCl tablets containing sustained release beads for increasing therapeutic window." Journal of Bioequivalence and Bioavailability **6**(3): 091-095.

The purpose of present investigation was to develop the dosage form containing metformin for both immediate and sustained release. The SR release tablets of metformin were not useful to control the fasting glucose levels whereas conventional metformin tablets cannot acts for prolonged time, But the tablets prepared by present method useful for control both fasting glucose levels and maintenance dose. Even though many combination therapies available in market as metformin for sustain release and other sulfonylureas for immediate release, The primary concern for considering metformin hydrochloride as monotherapy was its efficient activity, less cost and negligible cardiac risk factors. The immediate release dose was developed by direct compression method and sustained release beads were prepared by inotropic gelation method using sodium alginate and sodium CMC, CaCl<inf>2</inf>. The various batches of directly compressed tablets with different percentages of sustained release beads were prepared and evaluated for various physical properties and dissolution profile. Hardness (kg/cm²) of tablets was decreased and percentage loss in friability is increased as concentration of beads in tablet increased. All the parameters are within range for tablets containing micro beads up to 35% thereafter loss in friability and Hardness (kg/cm²) are not within range. © 2014 Damodar R, et al.

Dandachi, N., et al. (2005). "Critical evaluation of real-time reverse transcriptase-polymerase chain reaction for the quantitative detection of cytokeratin 20 mRNA in colorectal cancer patients." Journal of Molecular Diagnostics **7**(5): 631-637.

We evaluated the usefulness of cytokeratin 20 (CK20) mRNA expression in the quantitative detection of circulating tumor cells in the blood of patients with colorectal cancer (CRC). Blood samples from healthy volunteers (HVs; n = 37), patients with localized (n = 42) and metastatic colorectal cancer (n = 40), and patients with chronic inflammatory bowel disease (CID; n = 15) were examined. After immunomagnetic enrichment using microbeads against human epithelial antigen, total RNA was extracted, reverse transcribed, and analyzed by real-time reverse transcriptase-polymerase chain reaction using the LightCycler instrument. CK20 expression in peripheral blood was found in 46 of 82 (56%) patients with CRC, 8 of 37 (22%) HVs, and 9 of 15 (60%) patients with CID. Levels of CK20 mRNA were significantly higher in blood samples from CRC patients (median 681) than in blood samples from HVs (median 0) (P = 0.001), whereas no difference could be detected between patients with CRC and CID. Although the present technique could not distinguish CRC from CID, the method warrants further efforts to improve sample preparation and tumor cell enrichment, which may render real-time CK20 reverse transcriptase-polymerase chain reaction a feasible technique in identifying circulating tumor cells in peripheral blood of cancer patients.

Danese, E., et al. (2012). "High detection rate of genomic imbalances in CD138-positive enriched plasma cells from multiple myeloma patients." Biochimica Clinica **36 (6)**: 551.

Background: Multiple Myeloma (MM) is a heterogeneous disease, which is characterized by the occurrence of specific genomic abnormalities that are both of diagnostic and prognostic relevance. The detection of these abnormalities through molecular-genetic techniques is hampered by the overall low percentage of proliferating plasma cells (PCs) present in whole bone marrow (BM) aspirates. To overcome the risk of false-negative results, the International Myeloma Working Group has recently suggested to perform interphase FISH (i-FISH) on enriched PCs samples. Aim(s): (a) to develop and optimize a protocol of magnetic cell sorting (MACS) for the selection of CD138-positive PCs from whole BM aspirates; (b) to compare the diagnostic efficacy of i-FISH in enriched PCs with that in whole BM samples. Method(s): 140 samples from patients with MM (n=120) and benign monoclonal gammopathy of undetermined significance (MGUS, n=20) were divided into two groups representing two different phases for analysis: (1) 120 cases referred to our diagnostic centre before June 2012 were evaluated by i-FISH performed on unsorted BM cells from routine chromosomal preparations; (2) 20 cases collected after June 2012 were assessed by i-FISH performed on CD138+ sorted BM cells. Magnetic cell separation of PCs was performed using the Whole Blood CD138 MicroBeads (Miltenyi Biotec, Auburn, CA) according to the manufacturer's protocol. The MACS enrichment was verified by flow cytometric analysis. The i-FISH panel included probes for the identification of t(11;14)(q13;q32), t(4;14)(p16;q32) and 13q14/17p13 aberrations. 300 nuclei were scored for each sample. The detection threshold for gains, losses and translocations was set at 10% for all probes. Result(s): The percentage of plasma cells after magnetic cell separation varied between 30% and 78%. One or more genomic abnormalities were detected in enriched PCs in 10/20 (50%) cases, whereas in whole BM samples these abnormalities were detected in only 23/120 (19%) of the cases (P<0.001). Conclusion(s): MACS-enrichment technique results in a significantly increased detection rate of clinically relevant genomic abnormalities in intherphase cells.

Dangor, Z., et al. (2019). "The association between breastmilk group B Streptococcal capsular antibody levels and late-onset disease in young infants." Clinical Infectious Diseases **06**: 06.

BACKGROUND: Animal-model studies demonstrated less group B streptococcal (GBS) invasive disease and gastrointestinal colonization after enteral administration of serotype-specific capsular antibody. There is however a paucity of information on the association of breastmilk GBS serotype-specific capsular antibody and risk for invasive disease in infants. The aim of this study was to explore the association between natural secretory IgA (sIgA) capsular antibody in breastmilk, and the occurrence of late-onset disease (LOD) in young infants.

METHODS: A matched case-control study was undertaken in infants <3months of age in Johannesburg, South Africa. Breastmilk samples were collected on cases and controls matched for gestational age, maternal age and HIV-status at time of enrolment. Capsular serotype Ia, Ib, III and V sIgA antibody concentrations were measured using the fluorescence based micro-bead immunosorbent assay.

RESULTS: Breastmilk samples were available for 31 LOD (8 serotype Ia and 23 serotype III), 10 serotype Ia and 11 serotype III recto-vaginally colonized matched controls, and 84 and 105 non-colonized

matched controls. Using a Bayesian model to estimate the probability of disease, there was a 90% reduction in the risk of developing serotype Ia and III LOD with sIgA concentrations >=0.14 micro g/mL and >=2.52 micro g/mL, respectively.
CONCLUSION: Breastmilk sIgA capsular antibody was associated with lower risk for LOD in young infants. The ability of GBS polysaccharide-protein conjugate vaccines currently under development to induce sIgA responses warrant investigation as a potential mediator of protection against LOD.

Danhier, P., et al. (2013). "Influence of cell detachment on the respiration rate of tumor and endothelial cells." PLoS ONE [Electronic Resource] **8**(1): e53324.

Cell detachment is a procedure routinely performed in cell culture and a necessary step in many biochemical assays including the determination of oxygen consumption rates (OCR) in vitro. In vivo, cell detachment has been shown to exert profound metabolic influences notably in cancer but also in other pathologies, such as retinal detachment for example. In the present study, we developed and validated a new technique combining electron paramagnetic resonance (EPR) oximetry and the use of cytodex 1 and collagen-coated cytodex 3 dextran microbeads, which allowed the unprecedented comparison of the OCR of adherent and detached cells with high sensitivity. Hence, we demonstrated that both B16F10 melanoma cells and human umbilical vein endothelial cells (HUVEC) experience strong OCR decrease upon trypsin or collagenase treatments. The reduction of cell oxygen consumption was more pronounced with a trypsin compared to a collagenase treatment. Cells remaining in suspension also encounter a marked intracellular ATP depletion and an increase in the lactate production/glucose uptake ratio. These findings highlight the important influence exerted by cell adhesion/detachment on cell respiration, which can be probed with the unprecedented experimental assay that was developed and validated in this study.

Daniel, D. B., et al. (2020). "Assessment of fishing-related plastic debris along the beaches in Kerala Coast, India." Marine Pollution Bulletin **150 (no pagination)**(110696).

An assessment of quantity, composition and seasonal variation of fishing-related plastic debris was conducted in six beaches along the Kerala coast of India during 2017-2018. Plastic items were the most dominant type of waste constituting 73.8% by number and 59.9% by weight. In the total debris recorded, 5540 pieces (36%) weighing 198.4 kg (39.8%) were fishing related trash. On an average 14.4 +/- 12 fishing related items/100 m², corresponding to mean weight of 0.55 +/- 0.7 kg/100 m² was recorded from these beaches. Results indicated that the fishing-related plastic items were concentrated four times more in the beaches with higher fishing intensity, as compared to the other beaches. Also, the concentration of fishing-related plastic was recorded higher in the post-monsoon season compared to the lowest during monsoon, which was significant with p-value < 0.05. The results emphasize the role of fishing activities in the generation of marine litter. Copyright © 2019 Elsevier Ltd

Danis, O., et al. (2019). "Production of PHB from waste materials using Bacillus megaterium and development of electrospun composite nanomats." FEBS Open Bio **9 (Supplement 1)**: 211.

Along with the increasing world population the amount and variety of organic pollutants are continually increasing. Plastic waste is one of the major problems of today's world. Bioplastics are microbially produced polymers that are deposited in the form of storage granules by microorganisms under different conditions. Biopolymers are considered as an alternative to the environmental pollution caused by plastics. Polyhydroxyalkanoates (PHAs) are biodegradable polymers of biological origin. PHAs suggested as a solution to environmental pollution and they are mechanically similar to various thermoplastics. Poly (3-hydroxybutyrate) (PHB) is the most

studied and best characterized PHA derivative. PHB production from different microorganisms including Bacillus megaterium was reported by researchers. Bacillus megaterium is a gram-positive, endosporin-forming, rod-shaped bacterium which was found in the soil, has aerobic life span and considered as saprophytic. Collagen, the most abundant protein in animals, is a biopolymer that is present in all connective tissues of animals. As a result of its unique characteristics such as its biodegradability, weak antigenicity and its excellent biological compatibility, collagen is one of the most suitable biomaterial that can be used in biomedical areas. In this study Bacillus megaterium was screened for the production of PHB using fish industry waste materials. Fish skins and scales obtained from the local fish processing plant used for the isolation and characterization of collagen. Fatty waste material obtained from this process then used for the production of PHB. A nanofiber composite of collagen with PHB was prepared by electrospinning and characterized by FT-IR and SEM. Our results indicate that fish processing plant waste materials are excellent sources for the production of PHB. The obtained nanofiber mats displayed high potential to be used for various biomedical applications.

Danisker, M. (1989). "PLASTIC POLICY." Organic Gardening (08973792) **36**(2): 69-69.
Focuses on the U.S. government's policy regarding plastic materials and their disposal. Number of states requiring degradable plastics in six-pack ring binders or carriers; Proposal of legislation to tax and/or ban plastic packaging; Designation of Jefferson City, Missouri, as the first U.S. city to use degradable plastic bags in a citywide refuse program.

D'Anna, F., et al. (2014). "Effects of soil solarization with different plastic films on yield performance of strawberry protected plantations in Sicily." Acta Horticulturae.
Two main alternatives to replace methyl-bromide soil fumigation are soil solarization, which is feasible in geographical areas with high solar radiation, and the combination of the nematocide 1,3-dichloropropene (1,3-D) and the fungicide chloropicrin (Pic) applied through drip irrigation lines. The objective of this two-year study was to evaluate solarization and fumigation with 1,3-D + Pic as preplant soil treatments for plasticulture strawberry production in the northern coast of Sicily. Plots to be solarized were covered with transparent polyethylene (PE) or with green ethylene-vinylacetate (EVA) film mulches and left undisturbed for 69 and 77 days in 2009 and 2010, respectively. Freshly bare rooted plants and containerized plants were transplanted in the first and second year, respectively. Cultivars 'Candonga' and 'Nora' were tested using standard plasticulture practices. Soil temperatures recorded in PE solarized plots were higher than 37 degrees C for 792 and 750 hours, in 2009 and 2010 respectively, whereas cumulative exposure above 37 degrees C in green-EVA film solarized soil was 615 and 592 hours in the first and second year, respectively. These temperature are considered lethal for several soil pathogens. In both years, regardless of the cultivars tested, total marketable fruit yields in fumigated and solarised plots were significantly higher than in the untreated plots. Our results demonstrated the efficiency of solarization with either transparent-PE or green-EVA mulching films as alternative to 1,3-D + Pic soil preplant treatment. The green-EVA plastic mulch, was designed to be kept on soil after the end of soil solarization during the cropping season because it prevents infestation with weeds and therefore may need not to be replaced by traditional black plastic mulch. The green-EVA film induced both thermal regimes and fruit yields comparable to those obtained under conventional PE film. Therefore, it was concluded that its use would be a feasible option and a considerable reduction of plastic waste.

Danso, D., et al. (2019). "Plastics: Environmental and Biotechnological Perspectives on Microbial Degradation." Applied & Environmental Microbiology **85**(19): 01.

Plastics are widely used in the global economy, and each year, at least 350 to 400 million tons are being produced. Due to poor recycling and low circular use, millions of tons accumulate annually in terrestrial or marine environments. Today it has become clear that plastic causes adverse effects in all ecosystems and that microplastics are of particular concern to our health. Therefore, recent microbial research has addressed the question of if and to what extent microorganisms can degrade plastics in the environment. This review summarizes current knowledge on microbial plastic degradation. Enzymes available act mainly on the high-molecular-weight polymers of polyethylene terephthalate (PET) and ester-based polyurethane (PUR). Unfortunately, the best PUR- and PET-active enzymes and microorganisms known still have moderate turnover rates. While many reports describing microbial communities degrading chemical additives have been published, no enzymes acting on the high-molecular-weight polymers polystyrene, polyamide, polyvinylchloride, polypropylene, ether-based polyurethane, and polyethylene are known. Together, these polymers comprise more than 80% of annual plastic production. Thus, further research is needed to significantly increase the diversity of enzymes and microorganisms acting on these polymers. This can be achieved by tapping into the global metagenomes of noncultivated microorganisms and dark matter proteins. Only then can novel biocatalysts and organisms be delivered that allow rapid degradation, recycling, or value-added use of the vast majority of most human-made polymers.

Dantas, D. V., et al. (2019). "Ingestion of plastic fragments by the Guri sea catfish <i>Genidens genidens</i> (Cuvier, 1829) in a subtropical coastal estuarine system." Environmental science and pollution research international **26**(8): 8344-8351.

One of the most recognized anthropogenic impacts in marine environments is solid waste pollution, especially plastic, which can be ingested by fish, thus interfering with their health. In this context, the aim of this study is to describe the ingestion of plastic fragments and to identify the possible effect of this contamination in the condition factor of Genidens genidens in the Laguna Estuarine System. The stomach contents of 92 G. genidens (26 juveniles and 66 adults) were analyzed. The Index of Relative Importance was performed to identify the contribution of each prey item. Condition factor (CF) was used to analyze the effect of plastic ingestion on the fish's body condition (by comparing individuals in the same ontogenetic phase). For the juveniles, eight items were observed, the most important of which were Penaeidae, followed by Portunidae and plastic. For the adults, 12 items were observed, the most important of which were Penaeidae, Portunidae, Polychaeta, and plastic. The analysis of CF demonstrated higher values for individuals without plastic in the stomach, which indicated a better health condition. The CF of a fish may be affected by variations in the physiological condition, environmental stresses, and nutritional and biological variations, and could be used to compare the body condition or health of a fish species. The ingestion of plastic could significantly influence the worst body condition of the individuals that were analyzed in the present study. The plastic pollution in marine coastal waters is associated with the appropriate waste management levels.

D'Archivio, A. A., et al. (2015). "Artificial neural network prediction of multilinear gradient retention in reversed-phase HPLC: comprehensive QSRR-based models combining categorical or structural solute descriptors and gradient profile parameters." Analytical and bioanalytical chemistry **407**(4): 1181-1190.

Issue Title: A different way of looking at vibrational hyperspectral data/Micellar extraction for the analysis of Alzheimer's disease brain proteome/Quantification of polyolefin microplastics in personal-care products/Removal of Triton X-100 by microdialysis A multilayer artificial neural network (ANN) is used to model the reversed-phase liquid chromatography retention times of 16 selected compounds, including purines, pyrimidines and nucleosides. The analysed data,

taken from literature, were collected in acetonitrile-water eluents under the application of 16 different multilinear gradients. The parameters describing the gradient profile together with solute descriptors are considered as the independent variables of an ANN-based model providing the retention time as response. Categorical variables or, alternatively, a selected set of molecular descriptors of computational origin are adopted to represent the solutes. Network training, validation and testing are performed preliminarily using data of 12, 2 and 4 gradients, respectively and successively, to investigate model performance under more severe calibration conditions, with data of 9, 2 and 7 gradients. The proposed approach allows a quite accurate prediction of retention times of the target analytes in external multilinear gradients. Categorical variables can successfully represent the target solutes when the model is called to transfer retention data from calibration to external gradients. In particular, using a five-dimensional bit string to represent the analytes, mean errors on retention times are 2 and 3 % under the most and less favourable calibration conditions, respectively. A comparable performance is observed if the categorical variables are replaced by five molecular descriptors, selected by a genetic algorithm within a large set of structural variables of computational origin.

Darling, E. M. and D. Di Carlo (2015). "High-Throughput Assessment of Cellular Mechanical Properties." Annual Review of Biomedical Engineering **17**: 35-62.

Traditionally, cell analysis has focused on using molecular biomarkers for basic research, cell preparation, and clinical diagnostics; however, new microtechnologies are enabling evaluation of the mechanical properties of cells at throughputs that make them amenable to widespread use. We review the current understanding of how the mechanical characteristics of cells relate to underlying molecular and architectural changes, describe how these changes evolve with cell-state and disease processes, and propose promising biomedical applications that will be facilitated by the increased throughput of mechanical testing: from diagnosing cancer and monitoring immune states to preparing cells for regenerative medicine. We provide background about techniques that laid the groundwork for the quantitative understanding of cell mechanics and discuss current efforts to develop robust techniques for rapid analysis that aim to implement mechanophenotyping as a routine tool in biomedicine. Looking forward, we describe additional milestones that will facilitate broad adoption, as well as new directions not only in mechanically assessing cells but also in perturbing them to passively engineer cell state. Darmody, G., et al. (2015). "Tissue targeting of the European flat oyster, Ostrea edulis, using microencapsulated microbeads as a biological proxy." Aquaculture International **23**(2): 647-659.

Expansion of the aquaculture industry has been accompanied by outbreaks of disease from an ever increasing range of pathogens. Such outbreaks pose serious limitations to the growth and sustainability of the seafood industry, necessitating the development of alternative methods to combat disease. Immunostimulants are currently being pursued as an effective alternative to the use of traditional antibiotics. However, for suspension feeding bivalves, an effective system whereby immunostimulants can be successfully delivered to the site of infection at appropriate times is lacking. In recent years, the process of microencapsulation using non-toxic and biodegradable coatings has been an effective and stable delivery system for the administration of probiotics. In this study, SMA microbeads encapsulated in alginate were used as a biological proxy for the delivery of immunostimulants to the European flat oyster, Ostrea edulis. Chitosan- and poly-L-lysine-coated and uncoated alginate microcapsules were used, and the route of intake and transportation to the various oyster tissue types was assessed histologically.

Darquea, D., et al. (1997). "Development and characterization of a bioselective adsorption matrix for removal of Bacillus cereus spores from buffer and milk." Lebensmittel Wissenschaft & Technologie **30**(8): 786-792.

Cataphote Microbeads class -400 were derivatized. Carbohydrates on the Fc region of monoclonal antibody 183 against B. cereus T spores were oxidized to allow for an oriented antibody immobilization (270 nmsuperscript 2/molecule). The adsorption matrix was characterized for its ability to bind B. cereus in comparison with a control matrix. It was capable of removing 96% of spores in skim milk, compared with 90% removal for the control. It had excellent regeneration ability and was capable of removing 8 x 10⁶ spores/msuperscript 2.

Daryanto, S., et al. (2017). "Can ridge-furrow plastic mulching replace irrigation in dryland wheat and maize cropping systems?" Agricultural Water Management **190**: 1-5.

Dryland crop production requires significant water investments, but problems associated with irrigation have been observed in many dryland regions (e.g., China, Australia and the Mediterranean basin). A key strategy for maintaining crop yields without over-exploiting the scarce water resource is by increasing water use efficiency (WUE). Plastic mulching technology for wheat and maize has been commonly used in China, but their effect on yield, soil water content, evapotranspiration (ET), and WUE has not been compared with traditional irrigation. Using a meta-analysis approach, we quantitatively examined the efficacy of plastic mulching in comparison with traditional irrigation in the same region. By covering the ridges with plastic and channeling rainwater into a very narrow planting zone (furrow), our results showed that plastic mulching resulted in a yield increase comparable to irrigated crops but used 24% less water in comparison with irrigation due primarily to a much greater WUE and better retention of soil water. The higher WUE in plastic-mulched croplands was likely a result of a greater proportion of available water being used for transpiration (T) than evaporation (E). Currently production costs and residual plastic pollution hinder worldwide adoption of the technique, despite being a promising strategy for dryland cropping systems.

Das, A., et al. (2016). "Partial Obstruction of the Endotracheal Tube by the Plastic Coating Sheared from a Stylet." Case Reports in Pediatrics **2016**: 4373207.

A preterm with gestational age of 24 weeks was intubated at day of life 16. The intubation was done in a routine manner with the use of a stylet. It took a significant effort from the clinician to pull the stylet out after intubation. After intubation the respiratory status of the neonate deteriorated requiring significantly greater support. When ventilating and oxygenating the infant was getting progressively difficult, the decision was made to change the endotracheal tube (ETT). The cause for deterioration of respiratory status was then determined to be a sheared piece of plastic from the sheath of the stylet which was lodged in the lumen of the ETT. After removal of the plastic particle, the condition of the infant improved significantly.

Das, B., et al. (2014). "Zinc alginate-carboxymethyl cashew gum microbeads for prolonged drug release: development and optimization." International Journal of Biological Macromolecules **70**: 506-515.

Isoxsuprine HCl-loaded microbeads using sodium alginate (SA)-carboxymethyl cashew gum (CMCG) polymer-blends were developed through ionotropic-gelation technique using ZnSO4 as cross-linker. Effects of polymer-blend ratio and cross-linker concentration on drug encapsulation efficiency (DEE) and cumulative drug release at 7 h (R7 h) were optimized by 3(2) factorial design. Optimized microbeads were of excellent combination of high DEE (79.92+/-2.51%) and suitable sustained drug release pattern over a prolonged period of 7 h (58.67+/-2.26%). The

microbead surface morphology was analyzed by SEM. The physical state of isoxsuprine HCl within the optimized microbead matrix was analyzed by FTIR and DSC. In vitro isoxsuprine HCl release from alginate-CMCG microbeads in phosphate buffer (pH, 6.8) showed prolonged sustained drug release and Korsmeyer-Peppas model (R2=0.9959-0.9992) over 7 h.

Das, D. S., et al. (2014). "Anti-myeloma activity of a novel glutaminase inhibitor CB-839." Blood. Conference: 56th Annual Meeting of the American Society of Hematology, ASH **124**(21).

Background and Rationale: Cancer cells possess different metabolic requirements than normal cells, such as increased fatty acid synthesis and increased rates of glutamine metabolism, which facilitate their growth and survival. Glutamine is one of the key metabolites required by different cancer cell types for their survival. It is a precursor for alpha-keto glutarate (alphaKG) of tricarboxylic acid cycle. Intracellular glutamine is metabolized by a biochemical process glutaminolysis: glutamine is converted to glutamate by glutaminase (GLS), followed by glutamate conversion to alphaKG by glutamate dehydrogenase (GDH). Three mammalian GLS have been identified: the Liver-type (LGA or GLS2), the Kidney-type (KGA) and Glutaminase C (GAC). Elevated GAC mRNA levels have been detected in gliomas, colorectal carcinomas, adenomas and breast tumor cell lines. GLS activity is linked to tumor growth, since its inhibition by small molecule inhibitors or siRNA knockdown suppresses tumor growth in solid tumors. Elevated glutaminolysis confers drug resistance. These findings suggest that targeting GLS activity inhibits oncogenic transformation and overcomes drug resistance. Here we evaluated anti-MM activity of CB-839, a novel potent orally bioavailable inhibitor of both KGA and GAC splice variants of glutaminase Material(s) and Method(s): MM cell lines, patient MM cells, and peripheral blood mononuclear cells (PBMCs) from normal healthy donors were utilized to assess the anti-MM activity of CB-839. All studies involving human samples were performed under approved protocols at Dana-Farber Cancer Institute. Cell viability was assessed by WST-1 (Chemicon International) assay, as per manufacturer's instructions. MM cells from patients were isolated by CD138-positive selection using CD138 microbeads and the auto MACS magnetic cell sorter. Total cell lysates were subjected to immunoblot analysis. HUVEC cell angiogenesis assay and transwell cell migration assays were performed, as previously described (Chauhan et al., Blood, 2010, 115(4): 834-45). Glutamine and glutamate determination kit was purchased from Sigma, USA. Drug source: CB-839 was obtained from Calithera Biosciences, USA Results: KGA and GAC are highly expressed in MM cell lines than in normal PBMCs. We first confirmed the functional specificity of glutamines (GLS) inhibitor CB-839 using MM cells. Specifically, a significant increase in glutamine and a concomitant decrease in glutamate levels were observed in CB-839-treated RPMI-8226 MM cells ($p < 0.05$; n=3). Moreover, treatment of MM cells with CB-839 significantly decreased both basal and active alpha-keto glutarate levels ($p < 0.05$; n=3). Treatment of MM cell lines (MM.1S, MM.1R, RPMI-8226, Dox-40, U266, ARP-1, INA-6, ANBL6.WT, ANBL6.R, and LR5) and primary patient cells for 72h significantly decreased their viability (IC<inf>50</inf> range 1.25 muM-10 muM) ($p < 0.05$; n=3) without markedly affecting PBMCs from normal healthy donors, suggesting specific anti-MM activity and a favorable therapeutic index for CB-839. Conversely, pretreatment of MM cells with alpha-keto glutarate, a downstream product of glutamine breakdown abrogates anti-MM activity of CB-839. Moreover, CB-839 inhibits proliferation of MM cells even in the presence of BM stromal accessory cells. Mechanistic studies show that CB-839 triggered MM cell death occurs in a caspase-dependent manner, associated with induction of autophagy in MM cells via inhibition of PI3K/Akt/mTOR signaling pathway without concurrent activation of mTORC1. CB-839 induced autophagy was evident by increased levels of autophagy markers Beclin-1, Atg-7 and LC3B. Combining CB-839 with a biochemical inhibitor of autophagy 3-methyl adenine or chloroquine triggered

antagonism, suggesting that both autophagy and caspase-mediated apoptotic pathway contribute to anti-MM activity of CB-839. Furthermore, CB-839 blocked migration of MM cells and angiogenesis. Finally, combination of CB-839 with pomalidomide, bortezomib or SAHA induces synergistic anti-MM activity Conclusion(s): Our preclinical studies showing efficacy of CB-839 in MM disease models provide the framework for a clinical trial of CB-839, either alone or in combination, to improve outcome in relapsed and refractory MM patients.

Das, M. (2014). "ENVIRONMENTAL EDUCATION AND ATTITUDE TOWARDS SOCIAL AWARENESS ON PLASTIC POLLUTION OF HIGHER SECONDARY SCHOOL STUDENTS IN HOOGHLY DISTRICT." International Journal of Physical and Social Sciences **4**(7): 315.

Environmental education is the study of the relationships and interactions between natural and human systems. It is interdisciplinary, combining aspects of natural sciences such as ecology and geography with aspects of social sciences such as economics, law and public health. Two National Science Foundation boards have underscored the importance of environmental education and have called for a systematic approach to environmental education a report found that 95% of the public supports environmental education in schools. The present study aims to investigate the concept of environmental awareness in plastic pollution of higher secondary school students of Hooghly District. Concept and attitude of environment awareness in plastic pollution measure by questionnaire was used to assess their environment awareness. The result of analysis shows that there exists significant difference in plastic pollution awareness among higher secondary school student. Urban students are more aware in plastic pollution than rural school student in Hooghly district. Science students are more aware than commerce and arts students in plastic pollution.

Das, P. and P. Tiwari (2018). "The effect of slow pyrolysis on the conversion of packaging waste plastics (PE and PP) into fuel." Waste Management **79**: 615-624.

Packaging plastic waste consisting of low and high-density polyethylene and polypropylene were pyrolyzed in a lab scale semi-batch reactor at a very slow dynamic condition (1degreeCmin⁻¹). Gaseous and liquid products were collected at regular intervals starting from their inception during the degradation process. Detailed analysis was carried out to estimate the properties of plastic derive oil (PDO) obtained at different stages of the pyrolysis process. The pyrolysis temperature has a significant effect on the product compositions. The paraffin concentration increases with increasing pyrolysis temperatures. On the other hand, increased pyrolysis temperature decreases olefin concentration. Olefinic content in the PDO was found comparatively higher when PP was in the feed. Presence of polypropylene in the feed caused the production of PDOs with branch-chain hydrocarbon components with high isoparaffin index and research octane number (RON). The PDOs obtained (for all feed studied) at the early stages of the degradation process have light hydrocarbon liquid fractions belonging to light and middle distillates of petroleum (C₆ - C₂₀). The yield of both light and middle fractions decreased as the pyrolysis reactor temperature reached the maximum value (~400degreeC). Gas evolution pattern depends on both pyrolysis temperature and the feed composition. Propylene was found more dominating among other major components of gases like methane, ethane, ethylene, propane, n-butane, 1-butene, isobutylene and n-pentane etc.

Dasari, P., et al. (2014). "Hormonal regulation of the cytokine microenvironment in the mammary gland." Journal of Reproductive Immunology **106**: 58-66.

The mammary gland is a unique organ that undergoes hormone-driven developmental changes

over the course of the ovarian cycle during adult life. Macrophages play a role in regulating cellular turnover in the mammary gland and may affect cancer susceptibility. However, the immune microenvironment that regulates macrophage function has not been described. Hormonal regulation of the cytokine microenvironment across the ovarian cycle was explored using microbead multiplex assay for 15 cytokines in mammary glands from C57Bl/6 mice at different stages of the oestrous cycle, and in ovariectomised mice administered oestradiol and progesterone. The cytokines that were found to fluctuate over the course of the oestrous cycle were colony-stimulating factor (CSF)1, CSF2, interferon gamma (IFNG) and tumour necrosis factor alpha (TNFA), all of which were significantly elevated at oestrus compared with other phases. The concentration of serum progesterone during the oestrus phase negatively correlated with the abundance of cytokines CSF3, IL12p40, IFNG and leukaemia inhibitory factor (LIF). In ovariectomised mice, exogenous oestradiol administration increased mammary gland CSF1, CSF2, IFNG and LIF, compared with ovariectomised control mice. Progesterone administration together with oestradiol resulted in reduced CSF1, CSF3 and IFNG compared with oestradiol administration alone. This study suggests that the cytokine microenvironment in the mammary gland at the oestrus phase of the ovarian cycle is relatively pro-inflammatory compared with other stages of the cycle, and that the oestradiol-induced cytokine microenvironment is significantly attenuated by progesterone. A continuously fluctuating cytokine microenvironment in the mammary gland presumably regulates the phenotypes of resident leukocytes and may affect mammary gland cancer susceptibility.

Dasgupta, S., et al. (2011). "Characterization of the APC presenting a microbial polysaccharide toregulatory T cells." Inflammatory Bowel Diseases **2)**: S11-S12.

Commensal bacteria harbored in the mammalian gut are possibly reservoirs ofimmunomodulatory molecules having profound effects on the host immune system.Polysaccharide A (PSA) from the human symbiont Bacteroides fragilis is onesuch molecule and has been demonstrated to have potent anti-inflammatory propertiesin various murine models. Induced IL-10 liberated from CD4+T cells is a keyfeature of this immunoregulatory activity. However, little is known about how theseimmunoregulatory T cells are induced in order to control inflammation. Wehypothesized that a subset of Dendritic cells (DCs) may provide the cellular platformfor PSA action. This hypothesis was supported by our initial finding that followingoral gavage with B fragilis in healthy mice, PSA dependent augmentation ofCD4+CD25+FOXP3+ Tregs correlated with the frequency of B220+CD11cint nonconventionalDCs(R2=0.6993, p=0.038) in the MLN. The B220+CD11cint cell populationis primarily Plasmacytoid DCs (PDCs), which characteristically have surfaceexpression of PDCA-1, Siglec H, and Ly6c. These cells have been implicated as tolerogenicDCs in other inflammatory murine models. Interestingly, the tolerogenicrole of PDCs has been described in humans as well. However, while TLR2 ligationhas not been felt to be important to PDC activation, TLR2 ligation by PSA has beendescribed to be essential for this polysaccharide to activate the immune system.To investigate whether PDCs respond to PSA in a TLR2 dependent way, we investigatedthe in vitro interaction between PSA and DCs derived from bone marrowcells stimulated with Flt3L. After 36 hours of culture, PDCA-1+B220+CD11c+ PDCs in the presence of PSA showed substantially higher expression of TLR2compared to media controls. PDCs isolated with PDCA-1 microbeads from a poolof bone marrow derived DCs, significantly augmented the liberation of IL-10 fromCD4T cells in presence of PSA. In a co-culture assay, PSA stimulated liberation ofIL-10 from CD4T cells was significantly reduced when compared to PDCs derivedfrom TLR2^{-/-} mice (p=0.0046).In the intra-rectal TNBS colonic inflammation model, the frequency of SiglecH+B220+CD11b-CD11c+ PDCs and the GMFI of Siglec H correlated inversely withcumulative colitis score (R2=0.4377, p=0.0002 and R2=0.4255, p=0.0003) suggestinga possible immunoregulatory role for PDCs in PSA mediated protection. Interestingly, in TNBS treated TLR2^{-/-}mice who were not protected by PSA, no increasein GMFI of Siglec H was seen. In order to confirm a role for PDCs in PSA mediatedprotection in this colitis model, we depleted PDCs with a monoclonal antibody(anti-PDCA-1) and compared disease score to isotype controls. We observed thatamong control animals not treated with PSA, neither the cumulative disease scorenor the accumulation of potentially pathogenic CD11c-CD11b+ myeloid cells in thecolon was reduced in anti-PDCA-1 treated animals compared to isotype controls. Both these parameters (pathogenic CD11c-CD11b+ myeloid cells in the colon andclinical score) were significantly reduced in PSA treated animals compared to controls(p= < 0.01). However, PSA failed to protect mice when PDCs were depletedwith PDCA-1 mAb treatment. This suggests that in PSA-induced immunoregulationof a model colitis, PDCs have a tolerogenic or immunoregulatory role which maybe critical in generating regulatory features and function in T cells.

Datta, D. and G. Haider (2018). "Enhancing degradability of plastic waste by dispersing starch into low density polyethylene matrix." Process Safety & Environmental Protection: Transactions of the Institution of Chemical Engineers Part B **114**(Part B): 143-152.

The present investigation emphasizes the synthesis and characterization of an extruded biodegradable film developed by dispersion of corn starch in LDPE matrix. Biodegradable films of different composition were prepared and compared with virgin LDPE film. The effect of detergent solution, mustard oil, petroleum oil and saline water was determined as per ASTMD 543-67 to assess its durability. The chemical resistance of the film under 10% HC1 and 10% NaOH was also checked. The developed biodegradable film of composition 60:30:10 by weight of LDPE:starch:additive showed a tensile strength of 16.2 MPa and elongation at break of 140% indicating that only 10-12% loss of tensile strength and 15% loss in impact strength can be observed by incorporating just 30% starch as compared to virgin LDPE film. The application of the biodegradable film as an environmental friendly packaging material can be effectively judged by its decrease in tensile strength and elongation at break by 8% and 2% respectively by addition of just 10% starch under soil burial condition whereas the burst strength has increased by 16% which makes it to be extensively applicable for packaging. [ABSTRACT FROM AUTHOR]

Dauvergne, P. (2018). "Why is the global governance of plastic failing the oceans?" Global Environmental Change Part A: Human & Policy Dimensions **51**: 22-31.

On some measures, the global governance of plastic is improving. Curbside recycling and community cleanups are increasing. Companies like Toyota, Walmart, and Procter & Gamble are reducing waste to landfill. And all around the world, as research consolidates and activism intensifies, towns, cities, and legislatures are banning some uses of plastic, such as for grocery bags and as microbeads in consumer products. Yet the amount of plastic flowing into the oceans is on track to double from 2010 to 2025. Why? Partly, the dispersal, durability, and mobility of microplastics make governance extremely hard. At the same time, the difficulty of governing plastic has been rising as production accelerates, consumption globalizes, pollution sources

diversify, and international trade obscures responsibility. As pressures and complexities mount, the global governance of plastic – characterized by fragmented authority, weak international institutions, uneven regulations, uncoordinated policies, and business-oriented solutions – is failing to rein in marine plastic pollution. In large part, as this article demonstrates, this governance landscape reflects industry efforts to resist government regulation, deflect accountability, and thwart critics, coupled with industry advocacy of corporate self-regulation and consumer responsibility as principles of governance. These findings confirm the need for more hard-hitting domestic regulation of industry as well as an international plastics treaty to scale up local reforms. [ABSTRACT FROM AUTHOR]

Davalos, R. V., et al. (2008). "Performance impact of dynamic surface coatings on polymeric insulator-based dielectrophoretic particle separators." Analytical & Bioanalytical Chemistry **390**(3): 847-855.

Efficient and robust particle separation and enrichment techniques are critical for a diverse range of lab-on-a-chip analytical devices including pathogen detection, sample preparation, high-throughput particle sorting, and biomedical diagnostics. Previously, using insulator-based dielectrophoresis (iDEP) in microfluidic glass devices, we demonstrated simultaneous particle separation and concentration of various biological organisms, polymer microbeads, and viruses. As an alternative to glass, we evaluate the performance of similar iDEP structures produced in polymer-based microfluidic devices. There are numerous processing and operational advantages that motivate our transition to polymers such as the availability of numerous innate chemical compositions for tailoring performance, mechanical robustness, economy of scale, and ease of thermoforming and mass manufacturing. The polymer chips we have evaluated are fabricated through an injection molding process of the commercially available cyclic olefin copolymer Zeonor 1060R. This publication is the first to demonstrate insulator-based dielectrophoretic biological particle differentiation in a polymeric device injection molded from a silicon master. The results demonstrate that the polymer devices achieve the same performance metrics as glass devices. We also demonstrate an effective means of enhancing performance of these microsystems in terms of system power demand through the use of a dynamic surface coating. We demonstrate that the commercially available nonionic block copolymer surfactant, Pluronic F127, has a strong interaction with the cyclic olefin copolymer at very low concentrations, positively impacting performance by decreasing the electric field necessary to achieve particle trapping by an order of magnitude. The presence of this dynamic surface coating, therefore, lowers the power required to operate such devices and minimizes Joule heating. The results of this study demonstrate that iDEP polymeric microfluidic devices with surfactant coatings provide an affordable engineering strategy for selective particle enrichment and sorting.

Davarc, F., et al. (2017). "The influence of solution viscosities and surface tension on calcium-alginate microbead formation using dripping technique." Food Hydrocolloids **62**: 119-127.

Currently, there is a growing interest for encapsulation of bioactive ingredients using calcium alginate microspheres or beads. Diffusion of the Ca in the alginate droplets provokes an ionic gelation and their conversion to hydrogel beads. The main objective of this study is to

investigate the influence of physical properties of alginate and CaCl₂ solutions on alginate droplet formation and penetration into gelling bath, in size and shape of Ca-alginate beads. The droplet formation and penetration in the calcium bath was investigated using a high-speed video recording. Viscosity of alginate solution was modified by changing the alginate concentration (from 10 to 30 g/L) and the viscosity of the bath was modified by using different water/glycerol mixes (0-90% of glycerol) to prepare the CaCl₂ solution. Surface tension of CaCl₂ solution is reduced by adding different concentrations of surfactants (Tween 20) in a range of 0.01-1 g/L. Droplets detach from the tip with a tear shape. In all conditions tested, the droplets reach a spherical shape in less than 15 ms after detachment and less than 25 mm from the tip. Spherical beads are obtained when the kinetic energy is high enough to break the surface resistance of the calcium bath and droplet viscosity high enough to avoid deformations. Penetration depth of alginate droplets were mainly affected by viscosity and surface tension of CaCl₂ solution. When viscosity and surface tension of CaCl₂ solution increases, sphericity decrease and shape deformations are observed. The surfactant addition enhanced penetration and prevented shape deformations of Ca-alginate beads.

Davarpanah, E. and L. Guilhermino (2015). "Single and combined effects of microplastics and copper on the population growth of the marine microalgae Tetraselmis chuii." Estuarine, Coastal and Shelf Science **167**: 269-275.

As the accumulation of microplastics continues to rise in the marine environment, more knowledge on their potential toxic effects on marine organisms is needed to assess their risks to environmental and human health. Thus, the goal of the present study was to investigate the effects of fluorescent red polyethylene plastic micro-spheres 1-5 mu m diameter (used as microplastic model and hereafter indicated as MP), alone and in mixture with copper, on the population growth of the marine microalgae Tetraselmis chuii. Two null hypotheses were tested: (H01) Exposure to MP concentrations in ppb range does not affect the average specific growth rate of T. chuii; (H02) MP do not interact with the toxicity of copper to T. chuii. In laboratory bioassays, T. chuii cultures were exposed for 96 h to MP concentrations ranging from 0.046 to 1.472 mg/l), concentrations of copper alone ranging from 0.02 to 0.64 mg/l, and the same concentrations of copper in the presence of 0.184 mg/l of MP in test media. No significant effects of MP on T. chuii population growth were found ($p > 0.05$), leading to the acceptance of H01. Copper alone significantly decreased the population growth of T. chuii with EC10, EC20 and EC50 of 0.009, 0.023 and 0.139 mg/l, respectively. The corresponding values in the presence of MP were 0.012, 0.029 and 0.145 mg/l, respectively. Moreover, the study found no significant differences between the toxicity curves of copper in the presence and absence of MP ($p > 0.05$), leading to the acceptance of H02. Despite these findings, because microplastics are known to adsorb and accumulate copper, aged pellets more than virgin ones, and the toxicity of smaller particles may be higher, further studies on the combined effects of copper and microplastics on microalgae should be performed, especially under long-term exposures to nano-sized aged microplastics.

Davarpanah, E. and L. Guilhermino (2019). "Are gold nanoparticles and microplastics mixtures more toxic to the marine microalgae Tetraselmis chuii than the substances individually?" Ecotoxicology & Environmental Safety **181**: 60-68.

The widespread use of microplastics and nanomaterials resulting in environmental contamination is of high concern. Microplastics have been found to modulate the toxicity of other environmental contaminants. Thus, the hypothesis that microplastics increase the toxicity

of gold nanoparticles to the marine microalgae Tetraselmis chuii was tested. In a laboratory bioassay, T. chuii cultures were exposed for 96 h to ~5 nm diameter gold nanoparticles (AuNP) and to virgin 1-5 mum diameter microplastics (MP), alone and in mixture. The treatments were: control; citrate-control; AuNP alone (0.1, 0.3 and 3 mg/L); MP alone (0.3, 0.9 and 4 mg/L) and mixture of the two substances in three different concentrations (0.1 mg/L AuNP + 0.3 mg/L MP; 0.3 mg/L AuNP + 0.9 mg/L MP; 3 mg/l AuNP + 4 mg/L MP). The effect criterion was the inhibition of the average specific growth rate. AuNP alone and MP alone did not cause significant decrease of T. chui average specific growth rate up to 3 mg/L and 4 mg/L, respectively. The mixture containing 3 mg/L AuNP + 4 mg/L MP significantly reduced the average specific growth rate of the microalgae. Therefore, this mixture was more toxic to T. chuii than its components individually. Overall, the results of the present study indicated that the MP and AuNP tested have a relatively low toxicity to T. chuii, but the toxicity increases when they are in mixtures containing high concentrations of both substances. These proof-of-concept findings stress the need of more research on the toxicity of mixtures containing microplastics and nanomaterials.

Dave, D. and S. S. Katewa (2006). "Domestic solid waste generation and its disposal in Udaipur city, Rajasthan, India." Nature, Environment and Pollution Technology **5**(2): 225-228.

Domestic waste is becoming serious threat to urban environment especially in dense populated areas. Many diseases and contamination are the results of such pollutants. In light of the above problems, a study was conducted to access the quality and quantity of household waste generated and disposed off in urban areas of Udaipur city. The study was confined to randomly selected 300 families of Udaipur city. The survey revealed that daily disposal of kitchen waste, paper waste and plastic waste came out to be 29480g, 1003g and 1064g respectively. Kitchen waste being degradable does not pose much problems but paper and plastic, disposed in large quantities lead to serious environmental degradation.

Davenport, C., et al. (2016). "A Quick and Efficient Method for the Purification of Endoderm Cells Generated from Human Embryonic Stem Cells." Journal of Visualized Experiments **109**: 03.

The differentiation capabilities of pluripotent stem cells such as embryonic stem cells (ESCs) allow a potential therapeutic application for cell replacement therapies. Terminally differentiated cell types could be used for the treatment of various degenerative diseases. In vitro differentiation of these cells towards tissues of the lung, liver and pancreas requires as a first step the generation of definitive endodermal cells. This step is rate-limiting for further differentiation towards terminally matured cell types such as insulin-producing beta cells, hepatocytes or other endoderm-derived cell types. Cells that are committed towards the endoderm lineage highly express a multitude of transcription factors such as FOXA2, SOX17, HNF1B, members of the GATA family, and the surface receptor CXCR4. However, differentiation protocols are rarely 100% efficient. Here, we describe a method for the purification of a CXCR4+ cell population after differentiation into the DE by using magnetic microbeads. This purification additionally removes cells of unwanted lineages. The gentle purification method is quick and reliable and might be used to improve downstream applications and differentiations.

David, J., et al. (2018). "Quantitative Analysis of Poly(ethylene terephthalate) Microplastics in Soil via Thermogravimetry-Mass Spectrometry." Analytical Chemistry **90**(15): 8793-8799.

The use of plastic materials in daily life, industry, and agriculture can cause soil pollution with plastic fragments down to the micrometer scale, i.e., microplastics. Quantitative assessment of microplastics in soil has been limited so far. Until now, microplastic analyses in soil require laborious sample cleanup and are mostly restricted to qualitative assessments. In this study, we applied thermogravimetry-mass spectrometry (TGA-MS) to develop a method for the direct quantitative analysis of poly(ethylene terephthalate) (PET) without further sample pretreatment. For this, soil samples containing 1.61 +/- 0.15 wt % organic matter were spiked with 0.23-4.59 wt % PET bottle recyclate microplastics. dl-Cysteine was used as the internal standard (IS). Sample mixtures were pyrolyzed with a 5 K min⁻¹ ramp (40-1000 degreeC), while sample mass loss and MS signal intensity of typical PET pyrolysis products were recorded. We found MS signal intensities linearly responding to microplastic concentrations. The most-promising results were obtained with the IS-corrected PET pyrolysis product vinylbenzene/benzoic acid (m/ z = 105, adj. R² = 0.987). The limits of detection and quantification were 0.07 and 1.72 wt % PET, respectively. Our results suggest that TGA-MS can be an easy and viable complement to existing methods such as pyrolysis or thermogravimetry-thermal desorption assays followed by gas chromatography/mass spectrometry detection or to spectral microscopy techniques.

David, J., et al. (2018). "Quantitative Analysis of Poly(ethylene terephthalate) Microplastics in Soil via Thermogravimetry–Mass Spectrometry." Analytical Chemistry **90**(15): 8793.

The use of plastic materials in daily life, industry, and agriculture can cause soil pollution with plastic fragments down to the micrometer scale, i.e., microplastics. Quantitative assessment of microplastics in soil has been limited so far. Until now, microplastic analyses in soil require laborious sample cleanup and are mostly restricted to qualitative assessments. In this study, we applied thermogravimetry–mass spectrometry (TGA–MS) to develop a method for the direct quantitative analysis of poly(ethylene terephthalate) (PET) without further sample pretreatment. Our results suggest that TGA–MS can be an easy and viable complement to existing methods such as pyrolysis or thermogravimetry–thermal desorption assays followed by gas chromatography/mass spectrometry detection or to spectral microscopy techniques.

David, J., et al. (2019). "Introducing a soil universal model method (SUMM) and its application for qualitative and quantitative determination of poly(ethylene), poly(styrene), poly(vinyl chloride) and poly(ethylene terephthalate) microplastics in a model soil." Chemosphere **225**: 810-819.

Methods for analysis of microplastic in soils are still being developed. In this study, we evaluated the potential of a soil universal model method (SUMM) based on thermogravimetry (TGA) for the identification and quantification of microplastics in standard loamy sand. Blank and spiked soils (with amounts of one of four microplastic types) were analyzed by TGA. For each sample, thermal mass losses (TML) in 10degreeC intervals were extracted and used for further analysis. To explain and demonstrate the principles of SUMM, two scenarios were discussed. The first refers to a rare situation in which an uncontaminated blank of investigated soil is available and TML of spiked and blank soils are subtracted. The results showed that the investigated microplastics degraded in characteristic temperature areas and differences between spiked and blank soils were proportional to the microplastics concentrations. The second scenario reflects the more common situation where the blank is not available and needs to be replaced by the

previously developed interrelationships representing soil universal models. The models were consequently subtracted from measured TML. Sparse principal component analysis (sPCA) identified 8 of 14 modeled differences between measured TMLs and the universal model as meaningful for microplastics discrimination. Calibrating various microplastics concentrations with the first principal component extracted from sPCA resulted in linear fits and limits of detection in between environmentally relevant microplastics concentrations. Even if such an approach using calculated standards still has limitations, the SUMM shows a certain potential for a fast pre-screening method for analysis of microplastics in soils.

Davidson, K. and S. E. Dudas (2016). "Microplastic ingestion by wild and cultured Manila clams (Venerupis philippinarum) from Baynes sound, British Columbia." Archives of Environmental Contamination and Toxicology **71**(2): 147-156.

Microplastics, plastic particles <5 mm, are an emerging concern in aquatic ecosystems. Because microplastics are small, they are available to many filter-feeding organisms, which can then be consumed by higher trophic level organisms, including humans. This study documents the quantity of microplastics present in wild and cultured Manila clams (Venerupis philippinarum). Three active shellfish farms and three reference beaches (i.e., non-shellfish farm sites) in Baynes Sound, British Columbia were chosen to examine the microplastic concentrations in wild and cultured Manila clams. Microplastics were isolated using a nitric acid digestion technique and enumerated from 54 clams (27 farmed and 27 non-farmed). Qualitative attributes, such as colour and microplastic type (fiber, fragment, or film) also were recorded. There was no significant difference ($F=1.29$; $df=1,4$; $P=0.289$) between microplastic concentrations in cultured and wild clams. Microplastic concentrations ranged from 0.07 to 5.47 particles/g (from reference beach and shellfish farm clams, respectively). Fibers were the dominant microplastic (90%); colourless and dark gray fibers were the most common colours observed (36 and 26%, respectively). Although this indicates that microplastics are definitely present in seafood consumed by humans, shellfish aquaculture operations do not appear to be increasing microplastic concentrations in farmed clams in this region.

Davidson, T. M. (2012). "Boring crustaceans damage polystyrene floats under docks polluting marine waters with microplastic." Marine Pollution Bulletin **64**(9): 1821-1828.

Boring isopods damage expanded polystyrene floats under docks and, in the process, expel copious numbers of microplastic particles. This paper describes the impacts of boring isopods in aquaculture facilities and docks, quantifies and discusses the implications of these microplastics, and tests if an alternate foam type prevents boring. Floats from aquaculture facilities and docks were heavily damaged by thousands of isopods and their burrows. Multiple sites in Asia, Australia, Panama, and the USA exhibited evidence of isopod damage. One isopod creates thousands of microplastic particles when excavating a burrow; colonies can expel millions of particles. Microplastics similar in size to these particles may facilitate the spread of non-native species or be ingested by organisms causing physical or toxicological harm. Extruded polystyrene inhibited boring, suggesting this foam may prevent damage in the field. These results reveal boring isopods cause widespread damage to docks and are a novel source of microplastic pollution.

Davis, W. and A. G. Murphy (2015). "Plastic in surface waters of the Inside Passage and beaches of the Salish Sea in Washington State." Marine Pollution Bulletin **97**(1-2): 169-177.

We summarize results of two independent studies on plastic pollution in the marine environment that overlap in time and space. One study evaluated the abundance of anthropogenic debris on 37 sandy beaches bordering the Salish Sea in Washington State while the other characterized plastic debris in surface waters of the Salish Sea and the Inside Passage to Skagway, Alaska. Both studies concluded that foam, primarily expanded polystyrene was the dominant pollutant. Plastic was found in surface waters the full length of the Inside Passage but was concentrated near harbors. At the wrack line, an average square meter of Washington's 1180. km of sandy beaches in the Salish Sea had 61 pieces of anthropogenic debris weighing approximately 5. g. The total loading for the entire 1. m wide band is estimated to be 72,000,000 pieces and 5.8. metric tons. Most anthropogenic debris on beaches is generated within the region. Copyright © 2015 Elsevier Ltd.

Davison, P. and R. G. Asch (2011). "Plastic ingestion by mesopelagic fishes in the North Pacific Subtropical Gyre." Marine Ecology, Progress Series **432**: 173-180.

The oceanic convergence zone in the North Pacific Subtropical Gyre acts to accumulate floating marine debris, including plastic fragments of various sizes. Little is known about the ecological consequences of pelagic plastic accumulation. During the 2009 Scripps Environmental Accumulation of Plastics Expedition (SEAPLEX), we investigated whether mesopelagic fishes ingest plastic debris. A total of 141 fishes from 27 species were dissected to examine whether their stomach contents contained plastic particles. The incidence of plastic in fish stomachs was 9.2%. Net feeding bias was evaluated and judged to be minimal for our methods. The ingestion rate of plastic debris by mesopelagic fishes in the North Pacific is estimated to be from 12000 to 24000 tons yr⁻¹. Similar rates of plastic ingestion by mesopelagic fishes may occur in other subtropical gyres.

Davranche, M., et al. (2019). "Are nanoplastics able to bind significant amount of metals? The lead example." Environmental Pollution **249**: 940-948.

The nanoscale size of plastic debris makes them potential efficient vectors of many pollutants and more especially of metals. In order to evaluate this ability, nanoplastics were produced from microplastics collected on a beach exposed to the North Atlantic Gyre. The nanoplastics were characterized using multi-dimensional methods: asymmetrical flow field flow fractionation and dynamic light scattering coupled to several detectors. Lead (II) adsorption kinetics, isotherm and pH-edge were then carried out. The sorption reached a steady state after around 200min. The maximum sorption capacity varied between 97% and 78.5% for both tested Pb concentrations. Lead (II) adsorption kinetics is controlled by chemical reactions with the nanoplastics surface and to a lesser extent by intraparticle diffusion. Adsorption isotherm modeling using Freundlich model demonstrated that NPG are strong adsorbents equivalent to hydrous ferric oxides such as ferrihydrite (log K_{ads}^{freundlich}=8.36 against 11.76 for NPG and ferrihydrite, respectively). The adsorption is dependent upon pH, in response to the Pb(II) adsorption by the oxygenated binding sites developed on account of the surface UV oxidation under environmental conditions. They could be able to compete with Fe or humic colloids for Pb binding regards to their amount and specific areas. Nanoplastics could therefore be efficient vectors of Pb and probably of many other metals as well in the environment.

Dawood, S. (2016). "Sustainable, changeable, digital - the packaging trends of the future." Design Week (Online Edition): 1-1.

The article discusses designers' efforts with the medium to reduce their carbon footprint, help those who are partially-sighted or even immerse consumers in virtual reality specially in food Packaging. It mentions Harvard University professor David Edwards' ideas to wrap food or liquid in an edible coating to reduce packaging waste. It also mentions American start-up Loliware's a

gelatinous, flavoured cup made of seaweed, aimed to cut plastic pollution with its water bottle alternative.

Dawood, S. (2018). "Sadiq Khan's water fountains look to reduce London's plastic waste: The Mayor of London will install 20 water fountains across the capital and make tap water more freely available, in a social design project that aims to discourage the public from buying new bottles." Design Week (Online Edition): 1-1.

The article informs that Sadiq Khan, Mayor of London would install 20 water fountains across the capital and make tap water more freely available, in a social design project that aims to discourage the public from buying new bottles. It mentions campaign aim to eliminate the plastic waste. it also mentions the views of Shirley Rodrigues, deputy mayor for environment and energy, on the same.

Dawson, A., et al. (2018). "Uptake and Depuration Kinetics Influence Microplastic Bioaccumulation and Toxicity in Antarctic Krill (Euphausia superba)." Environmental Science & Technology **52**(5): 3195-3201.

The discarding of plastic products has led to the ubiquitous occurrence of microplastic particles in the marine environment. The uptake and depuration kinetics of ingested microplastics for many marine species still remain unknown despite its importance for understanding bioaccumulation potential to higher trophic level consumers. In this study, Antarctic krill (Euphausia superba) were exposed to polyethylene microplastics to quantify acute toxicity and ingestion kinetics, providing insight into the bioaccumulation potential of microplastics at the first-order consumer level. In the 10 day acute toxicity assay, no mortality or dose-dependent weight loss occurred in exposed krill, at any of the exposure concentrations (0, 10, 20, 40, or 80% plastic diet). Krill exposed to a 20% plastic diet for 24 h displayed fast uptake (22 ng mg-1 h-1) and depuration (0.22 h-1) rates, but plastic uptake did not reach steady state. Efficient elimination also resulted in no bioaccumulation over an extended 25 day assay, with most individuals completely eliminating their microplastic burden in less than 5 days post exposure. Our results support recent findings of limited acute toxicity of ingested microplastics at this trophic level, and suggest sublethal chronic end points should be the focus of further ecotoxicological investigation. Dawson, A. L., et al. (2018). "Turning microplastics into nanoplastics through digestive fragmentation by Antarctic krill." Nature communications **9**: 1-8.

Microplastics (plastics <5 mm diameter) are at the forefront of current environmental pollution research, however, little is known about the degradation of microplastics through ingestion. Here, by exposing Antarctic krill (Euphausia superba) to microplastics under acute static renewal conditions, we present evidence of physical size alteration of microplastics ingested by a planktonic crustacean. Ingested microplastics (31.5 µm) are fragmented into pieces less than 1 µm in diameter. Previous feeding studies have shown spherical microplastics either; pass unaffected through an organism and are excreted, or are sufficiently small for translocation to occur. We identify a new pathway; microplastics are fragmented into sizes small enough to cross physical barriers, or are egested as a mixture of triturated particles. These findings suggest that current laboratory-based feeding studies may be oversimplifying interactions between zooplankton and microplastics but also introduces a new role of Antarctic krill, and potentially other species, in the biogeochemical cycling and fate of plastic.

Dawson, I. G. J. (2019). "Taking responsibility: self-attribution for risk creation and its influence on the motivation to engage in risk management behaviors."

Many risks (eg, climate change, poor health, plastic pollution) can be the result of human behaviors. Although anthropogenic risk creation is rarely intentional, it is still possible that in many circumstances individuals will recognize some degree of personal responsibility for creating the risk and, therefore, may perceive a moral obligation to manage that risk (eg, reducing carbon emissions, eating a low-fat diet, boycotting single-use plastics). However, the extent to which risk management behaviors are motivated by self-attribution for risk creation has received little empirical attention. To address this issue, a study was conducted in which participants responded to three scenarios (road safety, environmental, animal welfare) that each described a situation in which a particular risk developed and in which the participants liability for creating the risk varied. Participants then responded to measures of self-attribution for risk creation, perceived risk, objective liability, guilt, moral standards and willingness to manage the risk. A multiple regression showed that the only significant predictor of the participants willingness to manage the risk was self-attribution for risk creation. Moreover, further analysis showed that the positive relationship between self-attribution for risk creation and the willingness to manage the risk was moderated by perceived risk. Hence, individuals who accept greater responsibility for creating a risk may be more willing to engage in actions to manage that risk, and his/her willingness is also likely to increase as his/her perception of the risk increases. These findings provide new insights into the motivational forces underlying risk management behaviors and highlights important directions for future research and risk communication strategies. 2019, 2019 Informa UK Limited, trading as Taylor & Francis Group.

Day, C. E., et al. (2009). "A novel method for isolation of human lung T cells from lung resection tissue reveals increased expression of GAPDH and CXCR6." Journal of Immunological Methods **342**(1-2): 91-97.

Lung T lymphocytes are important in pulmonary immunity and inflammation. It has been difficult to study these cells due to contamination with other cell types, mainly alveolar macrophages. We have developed a novel method for isolating lung T cells from lung resection tissue, using a combination of approaches. Firstly the lung tissue was finely chopped and filtered through a nylon mesh. Lymphocytic cells were enriched by Percoll density centrifugation and the T cells purified using human CD3 microbeads, resulting in 90.5%+/-1.9% (n=11) pure lymphocytes. The T cell yield from the crude cell preparation was 10.8+/-2.1% and viability, calculated using propidium iodide (PI) staining and trypan blue, was typically over 95%. The purification process did not affect expression of CD69 or CD103, nor was there a difference in the proportion of CD4 and CD8 cells between the starting population and the purified cells. Microarray analysis and real time RT-PCR revealed upregulation of GAPDH and CXCR6 of the lung T cells as compared to blood-derived T cells. This technique highly enriches lung T cells to allow detailed investigation of the biology of these cells.

de Bomfim, A. S. C., et al. (2019). "Effect of different degradation types on properties of plastic waste obtained from espresso coffee capsules." Waste Management **83**: 123-130.

In terms of large use of plastic products, a necessity exists to minimize effects of the waste produced on environment by recycling, reuse and application in new products. In Brazil, the espresso coffee capsules are an emerging plastic waste, representing 0.9% of the coffee

consumed in 2017. Therefore, Nescafe Dolce Gusto espresso coffee capsules were chosen in order to understand the polypropylene stabilization and degradation initiators with the purpose of recycling by applying in a composite material, as home composting product. In this context, the plastic capsule wastes were exposed to chemical, thermal, accelerated weathering (ultraviolet radiation+humidity) and natural weathering in order to analyze the influence of exposure and possibilities of a real application in a composting environment. Masses of the samples were monitored before and during the weathering conditions. Thermal (TGA and DSC) and chemical (FTIR) analysis were carried out before and after exposure. No changes in thermal stability were observed, however, samples conditioned in acid solution presented thermal degradation event beginning at 131degreeC. In addition, all samples presented a similar behavior of melting and crystallization points, which did not change with exposure. FTIR analysis showed a disappearance of CC and CO bonds on samples exposed to natural weathering and basic solution conditioning. It also showed formation of chromophores groups on samples exposed to accelerated weathering. The visual analysis showed huge differences in samples exposed to accelerated weathering and acid solution, which were the most damaged. On the other hand, samples exposed to natural weathering, thermal and basic conditioning did not presented significantly changes supported by the TGA and FTIR results.

De Carlo, R. M., et al. (2015). "Evaluation of different QuEChERS procedures for the recovery of selected drugs and herbicides from soil using LC coupled with UV and pulsed amperometry for their detection." Analytical and bioanalytical chemistry **407**(4): 1217-1229.

Issue Title: A different way of looking at vibrational hyperspectral data/Micellar extraction for the analysis of Alzheimer's disease brain proteome/Quantification of polyolefin microplastics in personal-care products/Removal of Triton X-100 by microdialysis Seven quick, easy, cheap, effective, rugged and safe (QuEChERS)-based procedures, differing in both the extraction and clean-up steps, were investigated for the recovery of bentazone (BTZ), atrazine (ATZ), carbamazepine (CBZ), phenytoin (PNT) and its metabolite 5-(p-hydroxyphenyl-),5-phenylhydantoin (HPPH) from soil. Target analytes were chosen for their extensive use and/or occurrence in soil, as well as for their medium-high polarity characteristics (log K ^sub OW^ values in the range 0.88-2.80), which have been reported as a critical parameter for the recovery from soil with QuEChERS approaches. Liquid chromatography coupled with UV and pulsed amperometric (PA) detection at a glassy carbon electrode was used as instrumental technique. The recovery data obtained within each tested procedure were discussed for each compound investigated, highlighting different behaviour depending on the specific physicochemical characteristics of the analytes. The optimized QuEChERS conditions consisted of the extraction of analytes with CH^sub 3^CN:H2O 70:30, 5 % CH^sub 3^COOH, followed by a dispersive solid-phase extraction (d-SPE) clean-up step with C18 sorbent. This method, in which water is directly added to the soil together with acetonitrile and salts, allowed the rehydration step to be avoided, which can be as long as 30 min. Matrix effects were evaluated for both the detection techniques at different concentration levels, and they were below 24 % for both the detection technique used. The recoveries were evaluated at three concentration levels by a matrix-matched calibration and were in the ranges of 83-113 % (relative standard deviations (RSD)[less than or equal to]14 %) and 88-109 % (RSD[less than or equal to]11 %) for UV and PA detection, respectively, highlighting very good performances of the method, even for the more polar analytes. Method detection limits ranged from 4 [mu]g/kg (BTZ) to 493 [mu]g/kg (PNT) and from 4 [mu]g/kg (HPPH) to 11 [mu]g/kg (BTZ) for UV and PA detection, respectively. The method was finally compared with a microwave-assisted extraction procedure which provided less satisfactory extraction performances than the optimized

QuEChERS procedure. [Figure not available: see fulltext.]

de Carvalho, D. G. and J. A. Baptista Neto (2016). "Microplastic pollution of the beaches of Guanabara Bay, Southeast Brazil." Ocean & Coastal Management **128**: 10-17.

Plastic debris is widely recognized as an important marine environmental pollutant. Plastics pollution of coastal areas is a growing concern, with research efforts focusing on macroplastic (>5 mm) and microplastic fractions. Currently, a large proportion of the plastics found in the ocean are in the form of microplastics (<5 mm). Due to their buoyant and persistent properties, microplastics have the potential to be widely dispersed via hydrodynamic processes and ocean currents. Guanabara Bay has been identified as one of the most polluted environments on the Brazilian coastline, mainly due to the presence of heavy metals and hydrocarbons. The aim of this work was to investigate, using field surveys, the abundance, composition and distribution of microplastics and small plastic fragments on the beaches of Guanabara Bay, located in southeastern Brazil. Microplastic concentrations ranged from 12 to 1300 particles per m2on the beaches. Fibres, fragments, styrofoam and pellets accounted for 8766 particles, with microplastic fragments representing 56% of the total detected debris, followed by styrofoam fragments (26.7%), pellets (9.9%) and fibres (7.2%).

de Chalain, T. and J. H. Phillips (1997). "Design and development of a fascioperiosteal flap for use in experimental cranial surgery in a porcine model." Journal of Craniofacial Surgery **8**(6): 501-505.

As part of an ongoing program of research on reconstructive techniques applicable to the growing craniofacial skeleton, this study aimed to characterize a pedicled fasciocutaneous flap on the scalp of a porcine model. Twelve juvenile Yorkshire white pigs were used. The anatomy of the porcine scalp was determined by fresh cadaveric dissection, radiocontrast dye injection, and resin casting of the vascular supply. No direct analogue of the human superficial temporal artery, the key to the superficial and deep temporal fascial flaps in humans, could be demonstrated in the pig. Thus, a fascioperiosteal flap, pedicled on an occipital leash of vessels, was designed. After a 14-day surgical delay, this flap, which covered the entire cranial width, from the nuchal crest to the glabella (7-10 cm long x 3-4 cm wide), could be elevated and split into a periosteal and a fascial layer. A cartilage construct placed between these layers could be kept alive for 4 weeks with no evidence of necrosis. The flap would allow mobilization of the construct to distant sites on the head and neck. An extensive literature survey showed a dearth of suitable cranial flap options in animal models. Accordingly, the pig cranium was examined with a view to finding a fascial flap analogous to the human temporoparietal flap, suitable for use in ear reconstruction. Cadaver dissections of the pig scalp, examining both the fascial layers and blood supply, were performed in three pigs; in an additional three pigs, the vascular supply to the scalp and cranium was injected with a radiocontrast gel, and, after dissecting suitable flaps, x-ray exposure was used to demonstrate the microvascular supply of these flaps. In an additional two pigs, the cranial vascular tree was filled with a plastic resin, and the soft tissues were then removed by thermal and chemical digestion. Finally, a group of three pigs were used to test the functional efficacy of a bilayered, occipitally based fascioperiosteal flap, whose design evolved from the foregoing work. Fluoresceine and disulphine blue were used to demonstrate the vascularity of these flaps before and after a surgical delay procedure. Function of these flaps, as carriers of a reconstructive construct, was shown by implanting autologous cartilage for 3 weeks and then demonstrating complete survival of the implant by fine section and histology. No clinically useful equivalent of the superficial temporal artery in humans could be identified in pigs, thus rendering the porcine superficial temporal artery flap of little use. However, a useful flap, comprising the pericranium and the subgaleal fascia, based on the

occipital vasculature, could be raised with relative ease.

De Coen, W. M., et al. (1998). "The use of biomarkers in Daphnia magna toxicity testing. III. Rapid toxicity testing of pure chemicals and sediment pore waters using ingestion and digestive enzyme activity." Chemosphere **37**(13): 2677-2694.

In this study, 4 rapid (90 min) toxicity tests were developed using ingestion and digestive enzyme activity of Daphnia magna juveniles. Ingestion activity was assessed using fluorescent labelled latex micro-beads and digestive enzyme activity (trypsin, beta -galactosidase and esterase) was measured in homogenates using chromogenic (N-benzoyl-L-arginine-4-nitroanilide) and fluorogenic (4-methylumbelliferyl-B-D-galactoside and fluorescein diacetate) substrates. All assays and toxicity endpoints were evaluated for their potential use as routine toxicity testing tools for pure chemicals and sediment pore waters. The observed high correlation coefficients (r super(2)>0.9) between the short-term toxicity values and the acute toxicity endpoint (24h EC sub(50)) for pure chemicals suggests that these biomarker-based assays are good predictors of acute toxicity levels to D. magna. In the sediment pore water toxicity tests, ingestion activity was generally more sensitive than the conventional endpoint, while the enzymatic endpoints were less sensitive than the 24h immobility criterion. The use and limitations of the developed toxicity tests are discussed in the light of their application in ecotoxicity monitoring programmes.

De Falco, F., et al. (2018). "Evaluation of microplastic release caused by textile washing processes of synthetic fabrics." Environmental Pollution **236**: 916-925.

A new and more alarming source of marine contamination has been recently identified in micro and nanosized plastic fragments. Microplastics are difficult to see with the naked eye and to biodegrade in marine environment, representing a problem since they can be ingested by plankton or other marine organisms, potentially entering the food web. An important source of microplastics appears to be through sewage contaminated by synthetic fibres from washing clothes. Since this phenomenon still lacks of a comprehensive analysis, the objective of this contribution was to investigate the role of washing processes of synthetic textiles on microplastic release. In particular, an analytical protocol was set up, based on the filtration of the washing water of synthetic fabrics and on the analysis of the filters by scanning electron microscopy. The quantification of the microfibre shedding from three different synthetic fabric types, woven polyester, knitted polyester, and woven polypropylene, during washing trials simulating domestic conditions, was achieved and statistically analysed. The highest release of microplastics was recorded for the wash of woven polyester and this phenomenon was correlated to the fabric characteristics. Moreover, the extent of microfibre release from woven polyester fabrics due to different detergents, washing parameters and industrial washes was evaluated. The number of microfibres released from a typical 5 kg wash load of polyester fabrics was estimated to be over 6,000,000 depending on the type of detergent used. The usage of a softener during washes reduces the number of microfibres released of more than 35%. The amount and size of the released microfibres confirm that they could not be totally retained by wastewater treatments plants, and potentially affect the aquatic environment.

De Felice, B., et al. (2018). "Polystyrene microplastics did not affect body growth and swimming activity in <i>Xenopus laevis</i> tadpoles." Environmental science and pollution research international **25**(34): 34644-34651.

A growing number of studies have highlighted the contamination and the effects towards organisms of diverse microplastics (μPs) in the marine environment. Surprisingly, although the

main sources of µPs for marine environments are inland surface waters, the information on the occurrence and the effects of µPs in freshwater ecosystems is still scant. Thus, the aim of the present work is to investigate the ingestion and possible adverse effects due to the exposure to polystyrene µPs (PSµPs; Ø = 3 µm) on tadpoles of the Amphibian Xenopus laevis. Larvae at the developmental stage 36, prior to mouth opening, were exposed under semi-static conditions to 0.125, 1.25, and 12.5 µg mL−1 of PSµPs, and allowed to develop until stage 46. At the end of the exposure, the digestive tract and the gills from exposed and control tadpoles were microscopically examined, as well as changes in body growth and swimming activity. PSµPs were observed in tadpoles' digestive tract, but not in the gills, from each tested concentration. However, neither body growth nor swimming activity were affected by PSµPs exposure. Our results demonstrated that PSµPs can be ingested by tadpoles, but they did not alter X. laevis development and swimming behavior at least during early-life stages, also at high, unrealistic concentrations.

de Haan, W. P., et al. (2019). "Floating microplastics and aggregate formation in the Western Mediterranean Sea." Marine Pollution Bulletin **140**: 523-535.

Pollution by large-sized plastics and microplastic debris is widespread in all Earth environments, also threatening marine ecosystems worldwide. In this study we determine the load of microplastics in the Western Mediterranean Sea and evaluate their aggregation potential into marine aggregates. We report average microplastic abundances of 0.10+/-0.09itemsm⁻² (max: 0.50itemsm⁻²). Abundances and chemical composition of microplastics are subject to temporal changes as a function of human activities in the areas of influence and shifting meteorological and sea-state conditions. We find that microplastics were on average smaller in mass than other studies conducted in the Mediterranean Sea indicating longer exposure times in the environment. The microplastic aggregation potential was determined by inspecting formed biogenic aggregates either during sample collection or in the laboratory. Smaller and more angular microplastics dominated in marine aggregates, representing an average 40% in abundance and 25% in mass of microplastics.

De Luca, L., et al. (2016). "Characterization and prognostic relevance of circulating microvesicles in chronic lymphocytic leukemia." Blood. Conference: 58th Annual Meeting of the American Society of Hematology, ASH **128**(22).

Background: Thecross talk between neoplastic cells and microenvironment is mediated by direct cell-to-cell contacts, secretion of soluble factors and release of extracellular vesicles (EVs). EVs deriving from tumor cells in chronic lymphocytic leukemia (CLL) may affect the surrounding microenvironment, playing a key role on survival of neoplastic clone. Of note, EVs are increased in CLL patients compared to normal subjects. In this study, we performed a comprehensive characterization of serum EVs from previously untreated CLL patients, investigating, in particular, phenotype and absolute number, in order to test their possible prognostic significance. Patients and Methods: Serum samples of 1 31 newly diagnosed CLL and from 28 healthy subjects were analyzed. One milliliter of serum was processed with serial ultracentrifugations. Each sample of EV-enriched pellet, from patients and controls, was freshly analyzed by FACS Calibur (Becton Dickinson BD) cytometer using Cell Quest software (BD). The system was calibrated using standard microbeads with a diameter of 0.3-0.9-3 mum to define the size limit for microvesicles (MV), a subtype of EVs. To determine the number of MV/muL serum, TruCOUNT beads (BD) were added immediately prior to analysis by flow cytometry. MV morphology was characterized by transmission electron microscope (TEM). MV were then

labeled with fluorochrome-conjugated monoclonal antibodies (anti-CD19, CD3, CD94, CD20, CD2, CD56, CD52, CD37) and their specific isotypic controls. Finally, MV were correlated with the main clinical and biological disease's characteristics, including clinical outcome. Result(s): Flow cytometric analysis of MVs showed a size within 1mm, based on forward and side scatter evaluation and the use of standard beads. The analysis was carried out on MV population isolated by the gating strategy. MV were also visualized by TEM, showing a spheroid morphology. We found a significantly higher mean number of MV in CLL patients with respect to healthy subjects (p<0.001) (Fig.1A). Moreover, by stratifying CLL patients for Rai stage, those with advanced clinical stages (III-IV) had a significantly higher number of MV with respect to patients with Rai stages 0 and I-II (p<0.01) (Fig.1B). To confirm the neoplastic cell source, MV were analyzed for the expression of lineage-specific antigens. In particular, B cells released preferentially CD19+ and CD37+ MV as compared to CD20. As observed for the total number of MV, significant increased amounts of CD19+, CD20+ and CD37+ MV were found in advanced clinical stages. Absolute MV number cut-off selected by ROC analysis distinguished Rai stage 0 patients with shorter time to treatment (TTT) from those with more stable disease (median 75 months vs not reached, P<0.01). Likewise, in the entire cohort, two groups of patients with different TTT (median 78 months vs not reached, P<0.01) (Fig.1C) and different overall survival (OS) (median 127 months vs not reached, P=0.02) (Fig.1D) were identified. At multivariate analysis, serum MV independently predicted for TTT (along with Rai stage, lymphocyte count and CD38 expression) and OS (along with Rai stage). Conclusion(s): Our study indicates that: (i) MV number is higher in CLL patients as compared to normal controls; (ii) CD19 and CD37 are the most represented B-cell antigens on CLL derived MV; (iii) total MV levels are associated with high tumor burden; (iv) total MV levels predict for TTT in Rai 0 patients, as well as for TTT and OS in all stage patients. These observations suggest that MV may represent a new biomarker for CLL.

De Lucia, C. and P. Pazienza (2019). "Market-based tools for a plastic waste reduction policy in agriculture: A case study in the south of Italy." Journal of Environmental Management **250**: 109468.

The 2018 European Strategy for Plastics in a Circular Economy identifies a set of actions to reduce plastic waste in the EU in the near future. To implement this strategic view, appropriate policy tools need to be identified within Member Countries. The present work aims at investigating farmers' attitudes towards the use of traditional market-based tools (i.e. subsidies and tax-credits) as well as other initiatives such as a pay-back mechanism under an Extended Producer Responsibility (EPR) to reduce plastic waste in agriculture. We analyse the case of the province of Foggia, an area which is recognised as being the largest plain in southern Italy. We consider a survey of 1,783 farmers and a multinomial regression model to infer on the probability of adopting the above policy tools. Key results suggest that the choice of each policy tool would be affected by the type of plastic waste generated. In particular, plastic packaging and plastic films would be likely to affect the probability to opt for a subsidy. In contrast, other types of plastic waste mainly generated by cereal crops activities (e.g. plastic bags and bottles for fertilisers and chemicals) would favour the adoption of a tax-credit mechanism. As for other aspects, horticulture production and the proximity to a collection site for waste disposal would increase the probability of adopting an EPR policy to contribute to plastic waste reduction.

de Lucia, G. A., et al. (2014). "Amount and distribution of neustonic micro-plastic off the western Sardinian coast (Central-Western Mediterranean Sea)." Marine Environmental Research **100**: 10-16.

A plethora of different sampling methodologies has been used to document the presence of micro-plastic fragments in sea water. European Marine Strategy suggests to improve standard

techniques to make future data comparable. We use Manta Trawl sampling technique to quantify abundance and distribution of micro-plastic fragments in Sardinian Sea (Western Mediterranean), and their relation with phthalates and organoclorine in the neustonic habitat. Our results highlight a quite high average plastic abundance value (0.15 items/m(3)), comparable to the levels detected in other areas of the Mediterranean. "Site" is the only factor that significantly explains the differences observed in micro-plastic densities. Contaminant levels show high spatial and temporal variation. In every station, HCB is the contaminant with the lowest concentration while PCBs shows the highest levels. This work, in line with Marine Strategy directives, represents a preliminary study for the analysis of plastic impact on marine environment of Sardinia.

De Pablo, J. L., et al. (2013). "What is the real cutoff for annexin v for capacitated sperm samples?" Fertility and Sterility **1)**: S448.

OBJECTIVE: To evaluate the Annexin V cutoff point for capacitated sperm samples. DESIGN: Analytic Retrospective Observational trial. MATERIALS AND METHODS: Participants age ranged from 18 to 45. All of them were involved in assisted reproduction treatments at Quiron Bilbao. The technique of double density gradient centrifugation has great potential in sperm preparation for assisted reproduction and was used to prepare the sperm samples. The proportion of apoptotic spermatozoa was assessed by using flow cytometry in 34 samples from fertile patients whose seminal values were above reference values established by WHO 2010. When the result is considered abnormal after the flow cytometry, colloidal super-paramagnetic microbeads conjugated with Annexin V may be applied to separate dead and apoptotic spermatozoa by using magnetic-activated cell soting (MACS). RESULT(S): Preliminary results show that the nonpathological percentage of sperm with apoptosis after capacitation is 15%. The cutoff point corresponds to the 90 percentile, with a mean value of 8% and a standard deviation of 4,47%. CONCLUSION(S): These preliminary results suggest that the ideal cutoff point to decide if we have to filter the sperm or not by using Annexin V columns is 15%. The filtrate in these pathological samples tries to reduce the percentage of apoptotic spermatozoa. The selection of nonapoptitic spermatozoa may be used to enhance sperm quality and could significantly improve the outcome of assisted fertilization. The Annexin V molecule has a specific affinity for phosphatidylserine and coupled with a fluorochrome such as FITC is used, together with Propidium Iodide (PI) as a supravital coloring. In our clinical practice, we consider using Annexin V FITC/PI instead of using Tunel since MACS uses Annexin V to separate dead and apoptotic cells. We do believe that is necessary to develop a protocol based on capacited samples because these are the samples that we use to perform ICSI. Moreover, an Annexin V cutoff point should be implemented.

de Poulpiquet, A., et al. (2016). "Dual Enzymatic Detection by Bulk Electrogenerated Chemiluminescence." Analytical Chemistry **88**(12): 6585-6592.

The combination of enzymes, as recognition elements for specific analytes, and of electrogenerated chemiluminescence (ECL) as a readout method has proven to be a valuable strategy for sensitive and specific analytical detection. However, ECL is intrinsically a 2D process which could potentially limit the analysis of inhomogeneous samples. Here, we show how a bulk ECL signal, generated by thousands of carbon microbeads remotely addressed via bipolar electrochemistry, are implemented as a powerful tool for the concomitant ECL sensing and imaging of two enzymatic substrates. We selected two enzymes (glucose dehydrogenase and choline oxidase) that react with their respective model substrates and produce in situ chemical species (beta-nicotinamide adenine dinucleotide (NADH) and H2O2) acting as coreactants for the ECL emission of different luminophores ([Ru(bpy)3](2+) at lambda = 620 nm and luminol at lambda = 425 nm, respectively). Both enzymes are spatially separated in the same capillary. We demonstrate thus the simultaneous quantitative determination of both glucose and choline over a wide concentration range. The originality of this remote approach is to provide a global chemical view through one single ECL image of inhomogeneous samples such as a biochemical concentration gradient in a capillary configuration. Finally, we report the first proof-of-concept of dual biosensing based on this bulk ECL method for the simultaneous imaging of both enzymatic analytes at distinct wavelengths.

De Smit, E., et al. (2016). "Longitudinal expression profiling of T lymphocytes in patients with active to quiescent giant cell arteritis." Clinical and Experimental Ophthalmology **44 (Supplement 1)**: 99-100.

Purpose: The immunopathogenesis of Giant Cell Arteritis (GCA) is poorly understood. The gold standard for diagnosis is a temporal artery biopsy. We aim to identify a less invasive method to diagnose GCA. Transcriptional profiling of blood measures the RNA in circulating nucleated cells. T Lymphocytes are key mediators of the adaptive immunity and are implicated in GCA. We sought to identify clinically useful predictive biomarkers by studying the transcriptome of purified T lymphocytes in patients with GCA. Method(s): Patients presenting with symptoms, signs and inflammatory markers consistent with GCA were enrolled. Serial blood samples were taken over 12 months. CD4+ and CD8+ T cells were isolated using magnetic antibody-coupled microbeads (Miltenyi). Samples were stored in RLT buffer (Qiagen). Aliquots were checked for cell purity. Batch RNA extractions were performed and sent for RNA sequencing. Result(s): Fifteen incident patients with active GCA and 15 age-matched controls were recruited. A total of 219 MACS events were performed, isolating between 2 and 10 million CD4+ and CD8+ cells (purity 94-99%). RNA extractions were performed using Qiagen RNAeasy kit, with good purity (A260/280 1.8-2.2). Samples were sent to the Translational Research Institute at QUT for sequencing using the illumina platform. Conclusion(s): This is the first translational study in GCA to investigate the T cell transcriptome. We have demonstrated good cell isolation technique, cell purity and RNA quality. It is likely that changes in the transcriptome over the course of the disease will provide insights into the pathogenesis and allow for a predictive biomarker for GCA diagnosis.

de Souza Machado, A. A., et al. (2019). "Microplastics Can Change Soil Properties and Affect Plant Performance." Environmental Science & Technology **53**(10): 6044-6052.

Microplastics can affect biophysical properties of the soil. However, little is known about the cascade of events in fundamental levels of terrestrial ecosystems, i.e., starting with the changes in soil abiotic properties and propagating across the various components of soil-plant interactions, including soil microbial communities and plant traits. We investigated here the effects of six different microplastics (polyester fibers, polyamide beads, and four fragment types: polyethylene, polyester terephthalate, polypropylene, and polystyrene) on a broad suite of proxies for soil health and performance of spring onion (Allium fistulosum). Significant changes were observed in plant biomass, tissue elemental composition, root traits, and soil microbial activities. These plant and soil responses to microplastic exposure were used to propose a causal model for the mechanism of the effects. Impacts were dependent on particle type, i.e., microplastics with a shape similar to other natural soil particles elicited smaller differences from control. Changes in soil structure and water dynamics may explain the observed results in which polyester fibers and polyamide beads triggered the most pronounced impacts on plant traits and function. The findings reported here imply that the pervasive microplastic contamination in soil may have consequences for plant performance and thus for

agroecosystems and terrestrial biodiversity.

de Souza Machado, A. A., et al. (2018). "Impacts of Microplastics on the Soil Biophysical Environment." Environmental Science & Technology **52**(17): 9656-9665.

Soils are essential components of terrestrial ecosystems that experience strong pollution pressure. Microplastic contamination of soils is being increasingly documented, with potential consequences for soil biodiversity and function. Notwithstanding, data on effects of such contaminants on fundamental properties potentially impacting soil biota are lacking. The present study explores the potential of microplastics to disturb vital relationships between soil and water, as well as its consequences for soil structure and microbial function. During a 5-weeks garden experiment we exposed a loamy sand soil to environmentally relevant nominal concentrations (up to 2%) of four common microplastic types (polyacrylic fibers, polyamide beads, polyester fibers, and polyethylene fragments). Then, we measured bulk density, water holding capacity, hydraulic conductivity, soil aggregation, and microbial activity. Microplastics affected the bulk density, water holding capacity, and the functional relationship between the microbial activity and water stable aggregates. The effects are underestimated if idiosyncrasies of particle type and concentrations are neglected, suggesting that purely qualitative environmental microplastic data might be of limited value for the assessment of effects in soil. If extended to other soils and plastic types, the processes unravelled here suggest that microplastics are relevant long-term anthropogenic stressors and drivers of global change in terrestrial ecosystems.

De Tullio, G., et al. (2013). "The functional attitude and the predictive role of an unconventional subset of T cells in clinical outcome of lymphoma patients: alphabeta-double negative T cells, preliminary data of a prospective study." Blood. Conference: 55th Annual Meeting of the American Society of Hematology, ASH **122**(21).

Graphic Background Many aspects of lymphoma pathophysiology indicate mutual interactions between the host immune system and lymphoma cells. These interactions may either promote or control lymphomagenesis. An unconventional subset of CD4-CD8- double-negative T cells (DNTs) has been recently described to contribute specifically to anti-tumor immunity. Indeed, DNTs are involved in immune regulation and tolerance as well as in host defense and inflammation, acting as regulatory T cells and/or cytotoxic T cells. DNTs are T lymphocytes which express either alphabeta or gammadelta T-cell receptors (TCR) and lack CD4, CD8 and CD56. In healthy human donors and murine models, they constitute about 1-5% of the lymphocytes in peripheral blood and in lymphoid organs. No data are available on the role of DNT cells in human anti-lymphoma immunity. Information from murine models suggests that expanded DNT cells would not impair host immunity against lymphoma and would perhaps stimulate it. DNT cells have also demonstrated to have a direct in vitro anti-tumor activity against lymphoma. Few data are available on the prognostic significance of DNTs in lymphomas, on their interaction with other immune cells, and on their functional attitude. Aims The aim of this study was to assess the frequency and the functional attitude of circulating DNTs in Lymphoma patients and healthy donors as controls, in order to assess the role of DNTs on clinical outcome and progression. Methods To test this population as prognostic factor on clinical outcome and progression of lymphoma disease, peripheral blood (PB) and bone marrow (BM) samples of 46 Lymphoma patients (pts), with non-Hodgkin's Lymphomas and classical Hodgkin Lymphoma were selected and prospectively collected at diagnosis and after one month till the end of chemo- or immuno-chemotherapy therapy. Blood samples were collected also at the time of relapse or progression. As control PB samples of 16 healthy donors were collected. Circulating

DNT subsets (TCRalphabeta+ and TCRgammadelta+) were characterized for their ontogeny, tolerogenic or cytotoxic attitude and TCR clonality by staining with the following conjugated monoclonal antibodies (MoAbs) for surface and intracellular markers: CD3, CD4, CD8, CD56, CD45, TCRalphabeta, CD45Ra, CD45Ro, CCR7, CD27, CD28, CD30, CD69, GITR, CD95, CD178, CD152, IFN-gamma, TNF-alpha, granzyme B, and perforin. Isotype-matched MoAbs were used as staining controls. For functional studies, DNTs were purified from PBMCs of patients through a negative selection by using specific MACS microbeads and then cultured for 2 weeks in complete medium supplemented with anti-CD3 (OKT3), rhIL-2 and rhIL-4. Data were acquired using an 8-colour flow cytometer and analyzed using Kaluza software. Data were compared among the groups using the Mann-Whitney non-parametric test or Kruskal-Wallis one-way analysis of variance. The study was approved by the local Ethics Committee and all patients provided their informed consent in accordance with the Declaration of Helsinki. Results The percentage (mean + SE) of DNTs in BM (2.367 +/- 0.5891) of Lymphoma pts was lower than in PB samples (3.421 +/- 0.981). Moreover we observed a significant decrease (p = 0.006) of circulating alphabeta-DNTs in pts with untreated lymphoma (23.7 +/- 3.7) as compared with healthy controls (31.3 +/- 3.4), and their number seemed to be modulated by disease relapse/progression or disease treatment. (fig.1). In Hodgkin's Lymphoma circulating alphabeta-DNTs were significantly increased as compared with other histotypes (p = 0.0001) (fig.2). Circulating alphabeta-DNTs were significantly decreased (p=0.006) in serial samples collected after treatment or at the time of disease relapse. Interestingly, after ex vivo expansion, DNTs acquired an immunomodulatory cytokine profile, characterized by the secretion of IFN-gamma and granzyme B which are known as central components of anti-tumor immune responses (fig.3). (Figure presented) Conclusions To date, no data have been reported on DNT phenotypic and functional charact rization in Lymphoma patients. Our study has demonstrated for the first time that alphabeta-DNTs could play an important role in both the development and the progression of lymphomas. In addition, based on our preliminary results, it is likely that ex-vivo expanded DNTs exert an anti-tumor activity thus suggesting their possible use as a new strategy for adoptive immune-therapy.

De Tullio, G., et al. (2013). "Role of circulating ab-double negative t cells (DNT) in lymphoma patients: Preliminary results of a prospective study." Haematologica **1)**: 416-417.

Background: Numerous aspects of lymphoma pathophysiology indicate mutual interactions between the host immune system and lymphoma cells. These interactions may either promote or control lymphomagenesis. An unconventional subset of CD4-CD8- double-negative T cells (DNTs) has been recently described to specifically contribute to anti-tumor immunity.Indeed, DNTs are involved in immune regulation and tolerance as well as in host defence and inflammation, acting as both regulatory T cells and/or cytotoxic T cells.DNTs are T lymphocytes expressing either abeta or gammadelta T-cell receptor (TCR) and lacking of CD4,CD8 and CD56.In healthy human donors and murine models, they constitute about the 1-5% of lymphocytes in the peripheral blood and in lymphoid organs. No data are available on the role of DNT cells in human anti-lymphoma immunity. Translating information from murine models expanded DNT cells would not impair host immunity against lymphoma and perhaps stimulate it.On the other hand,DNT cells also demonstrated to have a direct in vitro anti-tumor activity against lymphoma. Few data are available on the prognostic significance of DNTs in lymphomas,on their interaction with other immune cells and on their functional attitude. Aim(s): The aim of this study is to assess the frequency and the functional attitude of circulating DNTs in Lymphoma patients and healthy donors as controls, in order to evaluate the role of DNTs on clinical outcome Methods: For phenotypic and functional characterization of DNTs peripheral blood samples of 30 Lymphoma patients and 16 healthy donors wereprospectively collected.The staining of circulating DNT subset was performed with the following conjugated monoclonal antibodies (MoAbs) for surface and intracellular markers: CD3, CD4, CD8, CD56, CD45, TCRabeta, CD45Ra, CD45Ro, CCR7, CD27, CD28, CD30, CD69, GITR, CD95, CD178, CD152, IFN-gamma, TNF-a, granzymeB, perforin. Isotype-matched MoAbs will be used as staining controls. For functional studies, DNTs were purified from PBMCs of pts through a negative selection by using specific MACS microbeads and then cultured for 2 week in complete medium supplemented with anti-CD3 (OKT3), rhIL-2 and rhIL-4. Data was acquired using a 8-colour flow cytometer and analyzed using Kaluza software. Data were compared among the groups using the Mann-Whitney non parametric test or Kruskal-Wallis one-way analysis of variance.The study was approved by the local Ethics Committeeand all patients provided their informed consent in accordance with the Declaration of Helsinki. Result(s): We observed a significant decrease (P=0.006) of abeta-DNTs in the PB of patients with untreated lymphoma (20.5+/-4.8 SE,) (Mean+/-SE) as compared with healthy controls (31.3+/-3.4),and their number correlated with disease relapse/progression (Figure 1 A and B).In Hodgkin's Lymphoma patients the abeta-DNTs frequencies were significantly increased as compared with other histotypes (Figure 1 D). Interestingly, after ex vivo expansion, DNTs, acquired a immunomodulatory cytokine profile, characterized by the secretion of IFN-gamma and granzyme B which are known as central component of anti-tumor immune responses (Figure 1 C). Summary and Conclusion(s): To date,no data has been reported on DNTs phenotypic and functional characterization in Lymphoma pts. Our study has demonstrated for the first time that abeta-DNTs may play an important role in both the development and the progression of lymphomas. In addition, based on our preliminary results,it is likely that ex-vivo expanded DNTs exert an antitumor activity,thus suggesting their possible use as new strategy for adoptive immune-therapy. (Figure Presented).

De Vries, L., et al. (2016). "Tofacitinib and a selective Janus kinase 1 inhibitor are equally potent in suppressing human macrophage function and T-cell proliferation." Journal of Crohn's and Colitis **10 (Supplement 1)**: S96-S97.

Background: Nonselective Janus kinase (JAK) inhibitors such as tofacitinib have shown efficacy in treatment of ulcerative colitis. Tofacitinib inhibits JAK1, JAK2, JAK3, and TYK2. Side effects observed in patients (eg, neutropenia, anaemia) are attributed to JAK2 signalling. These side effects, have led to the development of selective JAK inhibitors. It is unclear whether selective JAK1 or JAK3 inhibition is sufficient in suppressing inflammatory responses. We aimed to investigate the potency of a selective JAK1 inhibitor (JAK1i, GSK2586186), a JAK3 inhibitor (JAK3i, GSK2864192A), and tofacitinib (CP-690,550-10, Pfizer) to supress innate and adaptive immune responses in vitro. Method(s): Peripheral blood mononuclear cells (PBMCs), monocytes, and lymphocytes were isolated from buffy coats using Ficoll and Percoll separation. CD14+ monocytes (n = 6) were isolated with CD14+ micro beads and stimulated with LPS (100 ng/ml) and IFNgamma (10 ng/ml) for 6 hours in presence or absence of JAK1i, JAK3i, or tofacitinib (10-1000 nM). Cytokine and chemokine production by monocytes was measured in the supernatant by ELISA. Lymphocytes (n = 3) were stimulated with anti-CD3/CD28 beads in the presence or absence of JAK1i, JAK3i, or tofacitinib in a concentration ranging from 10 to 10.000 nM. Cell viability was assessed using an MTS colorimetric assay. In addition, JAK1i, JAK3i, and tofacitinib (10- 10.000 nM) were added in a mixed lymphocyte reaction (MLR), in which PBMCs of 2 donors are mixed in a 1:1 ratio and cultured for 6 days. In both experiments, T-cell proliferation was measured with a Tritium proliferation assay. Result(s): In human CD14+ monocyte-derived macrophages, JAK1i and tofacitinib, but not JAK3i, decreased CXCL10 secretion at 1000 nM (resp. p = 0.021, p = 0.021, p = 0.416), whereas TNFalpha, and IL6 secretion was unaffected by all inhibitors. When assessing the effect of tofacitinib, JAK1i, and JAK3i on T-cell proliferation using anti-CD3/CD28 beads, JAK1i, and tofacitinib equally inhibited T-cell proliferation at 1000 nM (resp. p = 0.010 and p = 0.006). JAK3i inhibited T-cell proliferation at 4000 nM (p = 0.004). At these doses, T-cell viability was not affected. In a MLR, JAK1i, and tofacitinib inhibited T-cell proliferation at 100 nM (both p = 0.000). JAK3i to inhibited T-cell proliferation at 2000 nM (p = 0.022). Conclusion(s): In vitro, JAK1i and tofacitinib, but not JAK3i, inhibit CXCL10 secretion produced by IFNgamma/LPS triggered human monocyte- derived macrophages and proliferation of human T-cells in a dose-dependent manner. JAK3i inhibits T-cell proliferation at a higher dose, without affecting T-cell viability. (Table Presented).

De Vries, L. C., et al. (2016). "Tofacitinib and a selective janus kinase 1 inhibitor are equally potent in suppressing human macrophage function and T cell proliferation." Gastroenterology **1)**: S386-S387.

INTRODUCTION Non-selective Janus Kinase (JAK) inhibitors such as tofacitinib have shown efficacy in treatment of ulcerative colitis. Tofacitinib inhibits JAK1, JAK2, JAK3 and TYK2. Side effects observed in patients (e.g. neutropenia, anaemia) are attributed to JAK2 signalling. These side effects, have led to the development of selective JAK inhibitors. It is unclear whether selective JAK1 or JAK3 inhibition is sufficient in suppressing inflammatory responses. We aimed to investigate the potency of a selective JAK1 inhibitor (JAK1i, GSK2586186), a JAK3 inhibitor (JAK3i, GSK2864192A) and tofacitinib (CP-690,550-10, Pfizer) to supress innate and adaptive immune responses in vitro. METHODS peripheral blood mononuclear cells (PBMC's), monocytes and lymphocytes were isolated from buffy coats using Ficoll and Percoll separation. CD14+ monocytes (n=6) were isolated with CD14+ micro beads and stimulated with LPS (100 ng/ml) and IFNgamma (10 ng/ml) for 6 hours in presence or absence of JAK1i, JAK3i or tofacitinib (10-1000 nM). Cytokine and chemokine production by monocytes was measured in the supernatant by ELISA. Lymphocytes (n=3) were stimulated with anti-CD3/CD28 beads in the presence or absence of JAK1i, JAK3i or tofacitinib in a concentration ranging from 10 to 10.000 nM. Cell viability was assessed using an MTS colorimetric assay. In addition, JAK1i, JAK3i and tofacitinib (10-10.000 nM) were added in a mixed lymphocyte reaction (MLR), in which PBMC's of 2 donors are mixed in a 1:1 ratio and cultured for 6 days. In both experiments, T cell proliferation was measured with a Tritium proliferation assay. RESULTS In human CD14+ monocyte-derived macrophages, JAK1i and tofacitinib, but not JAK3i decreased CXCL10 secretion at 1000 nM (resp. p=0.021, p=0.021, p=0.416), while TNFalpha, and IL6 secretion was unaffected by all inhibitors. When assessing the effect of tofacitinib, JAK1i and JAK3i on T cell proliferation using anti- CD3/CD28 beads, JAK1i and tofacitinib equally inhibited T cell proliferation at 1000 nM (resp. p=0.010 and p=0.006). JAK3i inhibited T cell proliferation at 4000 nM (p=0.004). At these doses, T cell viability was not affected. In a MLR, JAK1i and tofacitinib inhibited T cell proliferation at 100 nM (both p=0.000). JAK3i to inhibited T cell proliferation at 2000 nM (p=0.022). CONCLUSION In vitro, JAK1i and tofacitinib, but not JAK3i inhibit CXCL10 secretion produced by IFNgamma/LPS triggered human monocyte-derived macrophages and inhibit proliferation of human T cells in a dose dependent manner. JAK3i inhibits T cell proliferation at a higher dose, without affecting T cell viability.

De Witte, M., et al. (2015). "Immune reconstitution and clinical outcome after alpha/beta T-cell depleted allogeneic stem cell transplantation from matched related and unrelated donors." Blood **126 (23)**: 4313.

Introduction: The outcome of allo-SCT in patients with hematological malignancies is still hampered by GVHD and relapse. Specific depletion of alphabeta T- cells is proposed to result in a decreased incidence of aGVHD, whereas the remaining innate cells such as NK cells and gammadeltaT cells may provide control of infected and transformed cells the first months post SCT. This strategy has been pioneered in haploindentical transplantation with promising results. Within this study, we extend alphabetaT- cell depleted allo-SCT to patients with a matched related and unrelated donor. The primary aim is to develop an allogeneic SCT protocol with a low incidence of aGVHD without an increased incidence of infections or relapse to serve as a platform for post-allo interventions such as a pre-emptive DLI or transfer of genetically modified T cells. Method(s): Patients with hematological malignancies (including AML, ALL, MM, NHL) who received an alphabetaT-cell depleted allo-SCT of a HLA matched sibling (MRD) or HLA matched (9 or 10/10) unrelated donor (MUD) were analysed. alphabetaT-cell reduction was performed by negative selection with anti-alphabetaTCR antibodies in combination with magnetic microbeads, using the automated CliniMACS device (Miltenyi Biotec, Bergisch Gladbach, Germany). The maximal contamination with alphabetaT-cells was 5x105/kg. The conditioning regimen consisted of: ATG (Genzyme) 6 mg/m² + fludarabine 120 mg/m² + busilvex AUC=90. Immune suppression consisted of 28 days of mycophenolic acid. A cohort of 32 patients was retrospectively analyzed for clinical parameters including immune reconstitution, engraftment, infections, GVHD, relapse, NRM and OS and compared to an historical control cohort of recipients of a T cell replete allo-SCT. In addition in a subset of patients NGS of the TCRbeta chain was performed using the Illumina/MiSeq sequencing platform after isolation diverse immune subsets within the alphabetaT-cell repertoire. Result(s): The combination of ATG/fludarabine/busilvex was well tolerated with hematological recovery within 3 weeks. Primary engraftment (chimerism > 95%) was observed in all patients (n=32). Immune reconstitution primarily consisted of NK cells. In addition, gammadeltaT cells were detectable at normal numbers the first half year post SCT, whereas the adaptive immune repertoire showed a delayed reconstitution. As compared to the historical control cohort, the incidence of CMV (54% vs 38%; p = 0,48) and EBV (32% vs 9%' p=0,148) infections did not show a significant increase. The incidence of aGVHD > grade II within 100 days in patients of a alphabetaT-cell depleted allo-SCT was 0%. During this relative short time of follow-up (1-14 months) 2 patients developed a relapse (both > 6 months) and 2 patients deceased (one with mucormycosis, one with GVHD post DLI). With NGS of the TCRbeta repertoire, a surprising diversity was observed in defined immune subsets ranging from clonal expansion of regulatory T cells to broad repertoires in effector memory cells. Conclusion(s): alphabetaT-cell depletion in MRD/MUD results in a swift reconstitution of innate cells (NK cells and gammadeltaT-cells) the first 6 months post transplantation, followed by a subsequent reconstitution of the adaptive immune repertoire. The diversity appears to be different for diverse subsets of the alphabetaT-cell repertoire, which remains to be confirmed in an extended pool of patients. The incidence of severe aGVHD is low, without a significant increase in infections or relapse shortly post allo-SCT. These results will be confirmed during extended follow-up and in a planned prospective multicenter study.

De Witte, M., et al. (2016). "Clinical outcome and immune reconstitution in alpha/beta T-cell depleted allogeneic stem cell transplantation from matched related and unrelated donors." Haematologica **101 (Supplement 1)**: 287-288.

Background: The outcome of allo-SCT in patients with hematological malignancies is still hampered by GVHD and relapse. Specific depletion of alphabeta Tcells is proposed to result in a decreased incidence of aGVHD, whereas the remaining innate cells such as NK cells and gammadeltaT cells may provide control of infected and transformed cells the first months post SCT. This strategy has been pioneered in haploindentical transplantation with encouraging results. Within this study, we extend alphabetaT- cell depleted allo-SCT to patients with a matched related and unrelated donor. Aim(s): The primary aim is to develop an allogeneic SCT protocol with a low incidence of aGVHD without an increased incidence of infections or relapse to serve as a platform for post-allo interventions such as a pre-emptive DLI or transfer of genetically modified T cells. Method(s): 55 Patients with hematological malignancies (including AML, ALL, MM, NHL, MPN) who received an alphabetaT-cell depleted allo-SCT of a HLA matched sibling (MRD) or HLA matched (9 or 10/10) unrelated donor (MUD) were analysed. alphabetaT-cell reduction was performed by negative selection with anti- alphabetaTCR antibodies in combination with magnetic microbeads, using the automated CliniMACS device (Miltenyi Biotec, Bergisch Gladbach, Germany). The maximal contamination with alphabetaT-cells was 5x105/kg. The conditioning regimen consisted of: ATG (Genzyme) 6 mg/m²+fludarabine 120 mg/m²+busilvex AUC=90. Part of the patients received mycophenolic acid as GVHD prophylaxis for 28 days. Patients were retrospectively analyzed for clinical parameters including immune reconstitution, engraftment, infections, GVHD, relapse, NRM and OS and compared to an historical control cohort of recipients of T cell replete allo-SCT. A retrospective cohort of recipients of T cell replete allografts was used for comparison. In addition in a subset of patients NGS of the TCRbeta chain was performed using the Illumina/MiSeq sequencing platform after isolation of diverse immune subsets within the alphabetaT-cell repertoire. Result(s): alphabetaT-cell depletion with anti-alphabetaTCR antibodies resulted in a 4.1 (1.7- 5.2) log depletion of alphabetaT cells and a recovery of 77% (43-98%) of the CD34+ cells. The median contamination with alphabetaT-cells was 16x10³/kg (0.8x10³/kg - 200x10³/kg) and infused number of CD34+ cells were 6.8x10⁶/kg (1.2 x10⁶/kg - 10.4x10⁶/kg). The combination of ATG/fludarabine/busilvex was well tolerated with hematological recovery within 3 weeks. Primary engraftment (chimerism >95%) was observed in all patients (n=55). Immune reconstitution primarily consisted of NK cells. In addition, gammadeltaT cells were detectable at normal numbers the first half year post SCT, whereas the adaptive immune repertoire showed a delayed reconstitution. The incidence of CMV infections was 54% in patients after alphabetaT cell depleted allo-SCT without MMF, 23% in patients after alphabetaT cell depleted allo-SCT with MMF and 38% in T cell replete allo-SCT control cohort. The incidence of EBV infections was 30,8%; 9,5% and 8,7% respectively. The incidence of aGVHD >grade II within 100 days in patients of a alphabetaT-cell depleted allo-SCT was 0%. During this short time of follow-up (1-20 months) we observed no significant differences in EFS, NRM and OS as compared to historical control cohorts. With NGS of the TCRbeta repertoire, a surprising diversity was observed in defined immune subsets ranging from clonal expansion of regulatory T cells to broad repertoires in effector memory cells. Summary/Conclusions: Here we present the clinical outcome of a large cohort (n=55) of patients having received an alphabetaT-cell depleted allograft of MRD/MUD. We observe a swift reconstitution of innate cells (NK cells and gammadeltaTcells) the first 6 months post transplantation, followed by a subsequent reconstitution of the adaptive immune repertoire. The incidence of severe aGVHD was 0%, without a significant increase in infections or relapse shortly post allo- SCT. These results will be confirmed during extended follow-up and in a planned prospective multicenter study.

De Witte, M., et al. (2015). "Alpha/beta T-cell depleted allogeneic stem cell transplantation from matched related and unrelated donor grafts in patients with poor risk leukemia." Biology of Blood and Marrow Transplantation **1)**: S277-S278.

Introduction: The outcome of allo-SCT in patients with poor risk leukemia is still hampered by GVHD and relapse. The innate immune system has been reported to contribute to tumor control, with lower incidence of GVHD. Specific depletion of alphabetaT-cells - key players in the development of GVHD - will render NK cells and gd T cells within the allograft. Recently reported results have shown the great promise of this approach in haploidentical transplantations. Within this study, we aim to extend alphabetaT-cell depleted allo- SCT to patients with a MRD or MUD. Method(s): Patients with either 'poor-risk' or 'very poor-risk' leukemia were included in this phase I study. Either HLA matched siblings (MRD) or HLA matched (9 or 10/10) unrelated donors (MUD) were eligible. abT-cell reduction was performed by negative selection with anti-abTCR antibodies in combination with magnetic microbeads, using the automated CliniMACS device (Miltenyi Biotec, Bergisch Gladbach, Germany). The maximal contamination with abT-cells for all dose levels was 5x10⁵/kg. The conditioning regimen consisted of: ATG (Genzyme) 4 or 6 mg/m² + fludarabine 120 mg/m² + busilvex AUC=90 followed by alphabetaT-cell depleted grafts from matched related or unrelated donors. No additional immune suppression was given after allo-SCT. Result(s): Products for 15 patients have been successfully processed and used for alphabetaT-cell depleted allo-SCT between 2013 and 2014. A ~4 log depletion of alphabetaT-cells has been observed in the product with a recovery of ~75% of CD34+ cells. The combination of ATG/fludarabine/busilvex was well tolerated with a hematological recovery within 3 weeks. Primary engraftment (chimerism > 95%) was observed in all patients. Immune reconstitution primarily consisted of innate cells (NK cells and gd T cells) the first 6 months post transplantation. In addition, no increase in CMV or EBV reactivations has been observed so far under the profound "innate control." Up to date, none of the patients developed aGVHD > grade II. Conclusion(s): ATG Busulfan Fludarabine is a low toxicity platform for abTCR-depleted transplantations, resulting in a swift reconstitution of innate cells (NK cells and gd T cells) the first 6 months post transplantation. This transplantation strategy can serve as a tool for future immunological interventions such as a pre-emptive DLI or transfer of genetically modified T cells.

De Witte, M. D., et al. (2016). "Clinical outcome and immune reconstitution in alphabeta T-cell depleted allogeneic stem cell transplantation from matched related and unrelated donors." <u>Bone Marrow Transplantation</u> **1)**: S335-S336.

Introduction: Specific depletion of alphabeta T- cells is proposed to result in a decreased incidence of aGVHD, whereas the remaining innate cells such as NK cells and gammadeltaT cells may provide control of infected and transformed cells the first months post SCT. This strategy has been pioneered in haploindentical transplantation with encouraging results (1). Here we extend alphabetaT- cell depleted allo-SCT to patients with a matched related and unrelated donor. Material (or patients) and methods: 55 patients with hematological malignancies (including AML, ALL, MM, NHL, MPN) received an alphabetaT-cell depleted allo-SCT of a HLA matched sibling (MRD) or HLA matched (9 or 10/10) unrelated donor (MUD). alphabetaT-cell reduction was performed by negative selection with anti-alphabetaTCR antibodies in combination with magnetic microbeads, using the automated CliniMACS device (Miltenyi Biotec, Bergisch Gladbach, Germany). The maximal contamination with alphabetaT-cells was 5x10⁵/kg. The conditioning regimen consisted of: ATG (Genzyme) 6 mg/m²+fludarabine 120 mg/ m²+busilvex AUC = 90. Part of the patients received mycophenolic acid as GVHD prophylaxis for 28 days. Patients were retrospectively analyzed for clinical parameters including immune reconstitution, engraftment, infections, GVHD, relapse, NRM and OS and compared to an historical control cohort of recipients of T cell replete allo-SCT. In addition in a subset of patients NGS of the TCRbeta chain was performed using the Illumina/MiSeq sequencing platform after isolation of diverse immune subsets within the alphabetaT-cell repertoire. Result(s): alphabetaT-cell depletion with anti-alphabetaTCR antibodies resulted in a 4.1 (range 1.7-5.2) log depletion of alphabetaT cells, resulting in a median contamination of 16x10³alphabetaT-cells/kg (0.8x10³/kg - 200x10³/kg). Primary engraftment (chimerism>95%) was observed in all patients (n = 55). Immune reconstitution primarily consisted of NK cells. In addition, gammadeltaT cells were detectable at normal numbers the first half year post SCT, whereas the adaptive immune repertoire showed a delayed reconstitution. The incidence of CMV infections was 54% in patients after alphabetaT-cell depleted allo-SCT without MMF, 23% in patients after alphabetaT cell depleted allo-SCT with MMF and 38% in T cell replete allo-SCT control cohort. The incidence of EBV infections was 30,8%; 9,5% and 8,7% respectively. The incidence of aGVHD>grade II within 100 days in patients of a alphabetaT-cell depleted allo-SCT was 0% (figure 1). During this short time of follow-up (1-20 months) we observed no significant differences in EFS, NRM and OS as compared to historical control cohorts. With NGS of the TCRbeta repertoire, a surprising diversity was observed in defined immune subsets ranging from clonal expansion of regulatory T cells to broad repertoires in effector memory cells. Conclusion(s): alphabetaT-cell depletion in allografts of MRD/MUD results in a swift reconstitution of innate cells (NK cells and gammadeltaT-cells), followed by a subsequent reconstitution of the adaptive immune repertoire. The incidence of severe aGVHD is 0%, without a significant increase in infections or relapse shortly post allo-SCT. These results will be confirmed during extended follow-up and in a planned prospective multicenter study. (Figure presented).

Dean, B. Y., et al. (2018). "Factors influencing microplastic abundances in nearshore, tributary and beach sediments along the Ontario shoreline of Lake Erie." Journal of Great Lakes Research **44**(5): 1002-1009.

Sediment samples were collected from nearshore, tributary and beach environments within and surrounding the northern part of Lake Erie, Ontario to determine the concentrations and distribution of microplastics. Following density separation and microscopic analysis of 29 samples, a total of 1178 microplastic particles were identified. Thirteen nearshore samples contained 0-391 microplastic particles per kg dry weight sediment (kg⁻¹), whereas 4 tributary samples contained 10-462 kg⁻¹ and 12 beach samples contained 50-146 kg⁻¹. The highest concentrations of nearshore microplastics were from near the mouths of the Detroit River in the western basin and the Grand River in the eastern basin, reflecting an urban influence. The highest microplastic concentrations in beach samples were determined from Rondeau Beach in the central basin where geomorphology affects plastics concentration. The Welland Canal sample in the eastern basin contained the greatest concentration of microplastics of the tributary samples, which is consistent with high population density and shipping traffic. The overall abundance of microplastic in northern Lake Erie nearshore, tributary and beach samples is 6 times lower than in sediment sampled from northern Lake Ontario. The nearshore and beach sample results potentially reflect the transport patterns of floating plastics modeled for Lake Erie, which predict that the majority of plastic particles entering the lake are transported to southern shoreline regions rather than northern areas.

Dean, J. M., et al. (2010). "Microglial MyD88 signaling regulates acute neuronal toxicity of LPS-stimulated microglia in vitro." Brain, behavior, and immunity **24**(5): 776-783.

Although the role of microglial activation in neural injury remains controversial, there is increasing evidence for a detrimental effect in the immature brain, which may occur in response to release of neurotoxic substances including pro-inflammatory cytokines. However, the signaling mechanisms involved in microglial-induced neuronal cell death are unclear. Microglia

isolated from the brains of wild-type (WT) or MyD88 knockout (KO) mice were exposed to PBS or the TLR4-ligand LPS (100 ng/mL) for 2, 6, 14, or 24 h, and the microglia-conditioned medium (MCM) collected. Detection of multiple inflammatory molecules in MCM was performed using a mouse 22-plex cytokine microbead array kit. Primary neuronal cultures were supplemented with the 14 or 24 h MCM, and the degree of neuronal apoptosis examined after exposure for 24 h. Results showed a rapid and sustained elevation in multiple inflammatory mediators in the MCM of WT microglia exposed to LPS, which was largely inhibited in MyD88 KO microglia. There was a significant increase in apoptotic death measured at 24 h in cultured neurons exposed to CM from either 14 or 24 h LPS-stimulated WT microglia ($p<.05$ vs. WT control). By contrast, there was no increase in apoptotic death in cultured neurons exposed to CM from 14 or 24 h LPS-stimulated MyD88 KO microglia ($p=.15$ vs. MyD88 KO control). These data suggest that MyD88-dependent activation of microglia by LPS causes release of factors directly toxic to neurons.

Decker, T. (2018). "Achtung Plastik! Wie Verbraucher(innen) beim Einkaufen Plastikmüll reduzieren können." Gaia **27**(3): 330-331.

Das Plastikproblem und die damit verbundenen Umweltauswirkungen werden von der Öffentlichkeit rege diskutiert. Wie Plastik schon beim Einkaufen von Lebensmitteln und Kleidung vermieden werden kann, untersucht das Projekt Verbraucherreaktionen bei Plastik und dessen Vermeidungsmöglichkeiten am Point of Sale, das im Rahmen der Sozial-ökologischen Forschung vom Bundesministerium für Bildung und Forschung gefördert wird.

Decordier, I., et al. (2002). "Elimination of micronucleated cells by apoptosis after treatment with inhibitors of microtubules." Mutagenesis **17**(4): 337-344.

Two major mechanisms responsible for chromosome segregation errors are non-disjunction and chromosome loss, both leading to aneuploidy. Previous studies in our laboratory showed the existence of thresholds for the induction of chromosome non-disjunction and chromosome loss and the induction of apoptosis by microtubule inhibitors. From a mechanistic point of view one can expect that apoptosis contributes to the elimination of cells with premutagenic/mutagenic lesions. If aneuploid cells were eliminated by the induction of apoptosis below the threshold concentrations for chromosome loss and non-disjunction, the defined thresholds would not be applicable to cells unable to undergo apoptosis. The aim of this study was to investigate whether apoptosis was induced directly or indirectly as a response to aberrant chromosome segregation below the thresholds for the induction of chromosome loss and non-disjunction, as previously defined by us. Therefore, human lymphocytes were exposed in vitro to five concentrations of nocodazole and five concentrations of carbendazim representing the threshold concentrations for chromosome non-disjunction and chromosome loss, two concentrations below the lowest threshold and one concentration between the two threshold values. After 48 h exposure to the aneugens, induction of apoptosis was analysed by the annexin-V test. The frequencies of chromosome non-disjunction and chromosome loss were estimated in cytokinesis-blocked human lymphocytes in combination with FISH; this methodology was applied to whole cell cultures as well as to apoptotic and viable cell fractions obtained using magnetic annexin microbead cell sorting. Our results suggest that elimination of aneuploid cells does occur. However, the efficiency of disappearance of micronucleated cells is higher than for cells presenting chromosome non-disjunction. The correlation found between early apoptotic events and micronucleus formation could account, at least in part, for the specific elimination of aneuploid cells.

Decrop, D., et al. (2016). "Optical Manipulation of Single Magnetic Beads in a Microwell Array on a Digital Microfluidic Chip." Analytical Chemistry **88**(17): 8596-8603.

The detection of single molecules in magnetic microbead microwell array formats revolutionized the development of digital bioassays. However, retrieval of individual magnetic beads from these arrays has not been realized until now despite having great potential for studying captured targets at the individual level. In this paper, optical tweezers were implemented on a digital microfluidic platform for accurate manipulation of single magnetic beads seeded in a microwell array. Successful optical trapping of magnetic beads was found to be dependent on Brownian motion of the beads, suggesting a 99% chance of trapping a vibrating bead. A tailor-made experimental design was used to screen the effect of bead type, ionic buffer strength, surfactant type, and concentration on the Brownian activity of beads in microwells. With the optimal conditions, the manipulation of magnetic beads was demonstrated by their trapping, retrieving, transporting, and repositioning to a desired microwell on the array. The presented platform combines the strengths of digital microfluidics, digital bioassays, and optical tweezers, resulting in a powerful dynamic microwell array system for single molecule and single cell studies.

Deegan, A. J., et al. (2015). "Tracking calcification in tissue-engineered bone using synchrotron micro-FTIR and SEM." Analytical and bioanalytical chemistry **407**(4): 1097-1105.

Issue Title: A different way of looking at vibrational hyperspectral data/Micellar extraction for the analysis of Alzheimer's disease brain proteome/Quantification of polyolefin microplastics in personal-care products/Removal of Triton X-100 by microdialysis One novel tissue engineering approach to mimic in vivo bone formation is the use of aggregate or micromass cultures. Various qualitative and quantitative techniques, such as histochemical staining, protein assay kits and RT-PCR, have been used previously on cellular aggregate studies to investigate how these intricate arrangements lead to mature bone tissue. However, these techniques struggle to reveal spatial and temporal distribution of proliferation and mineralization simultaneously. Synchrotron-based Fourier transform infrared microspectroscopy (micro-FTIR) offers a unique insight at the molecular scale by coupling high IR sensitivity to organic matter with the high spatial resolution allowed by diffraction limited SR microbeam. This study is set to investigate the effects of culture duration and aggregate size on the dynamics and spatial distribution of calcification in engineered bone aggregates by a combination of micro-FTIR and scanning electron microscopy (SEM)/energy-dispersive X-ray spectroscopy (EDX). A murine bone cell line has been used, and small/large bone aggregates have been induced using different chemically treated culture substrates. Our findings suggest that bone cell aggregate culturing can greatly increase levels of mineralization over short culture periods. The size of the aggregates influences mineralisation rates with larger aggregates mineralizing at a faster rate than their smaller counterparts. The micro-FTIR mapping has demonstrated that mineralization in the larger aggregates initiated from the periphery and spread to the centre, whilst the smaller aggregates have more minerals in the centre at the early stage and deposited more in the periphery after further culturing, implying that aggregate size influences calcification distribution and development over time. SEM/EDX data correlates well with the micro-FTIR results for the total mineral content. Thus, synchrotron-based micro-FTIR can accurately track mineralization process/mechanism in the engineered bone. [Figure not available: see fulltext.]

Deepak, A., et al. (2019). "Awareness of plastic hazards among dental students." Drug Invention Today **11**(7): 1556-1558.

Aim: The aim of this study is to create and assess the awareness of plastic hazards among dental students. Material(s) and Method(s): A prospective, cross-sectional questionnaire-based survey study was carried out at Saveetha Dental College on the awareness of plastic hazards. A well-structured questionnaire was prepared, distributed, and collected when it was filled by the undergraduate student. The questionnaire mainly evaluated the undergraduates basic awareness of the subject of plastic hazards, its effects and management of the hazard. The result was then statistically analyzed and processed. Result(s): Most of the participants in the settings had the awareness of hazards of plastic bag usage. Plastics are commonly used by the people due to their easy availability and ease of handling goods. Females were found to use plastics more often than males in shopping, carrying goods, etc. The results were graphically represented and then analyzed. Conclusion(s): Plastic pollution can lead to various health problems such as lung diseases, skin diseases, reproductive problems, and growth and maturation problems. Therefore, reducing the use of plastic and increasing the use of biodegradable and jute bags can reduce plastic pollution. However, there is a need for spreading the awareness of using alternative strategies. Copyright © 2019 JPR Solutions. All rights reserved.

Deepak, S. (2013). "Generation of hospital waste: an awareness impact on health and environmental protection." National Journal of Community Medicine **4**(1): 185-188.

World is generating more and more waste as the population of people in the world & Hospitals are increasing day by day. Health care activities are a means of protecting health, curing patients and saving lives. Waste generating from hospitals, health centers and medicals are no exceptions. Medical waste contains toxic chemicals, can be infectious and pose contamination risks both to public health and environment. But they also generate waste, out of which 25 percent entail risks, either of infection, of trauma or radiation exposure. In addition the inappropriate treatment or disposal of the waste can lead to environmental contamination or pollution. Seventy five percent of the hospital waste is similar to household waste and do not entail any particular hazard. In general, PVC plastic waste represents the large amount in hospital waste. In this paper we are addressing the issue of incineration of medical waste and to control the surface water mercurial pollution, their impacts on health, environment and their remediation.

DeGregory, P. R., et al. (2016). "Quantitative electrochemical metalloimmunoassay for TFF3 in urine using a paper analytical device." Analyst **141**(5): 1734-1744.

We report a paper-based assay platform for the detection of the kidney disease marker Trefoil Factor 3 (TFF3) in human urine. The sensor is based on a quantitative metalloimmunoassay that can determine TFF3 concentrations via electrochemical detection of environmentally stable silver nanoparticle (AgNP) labels attached to magnetic microbeads via a TFF3 immunosandwich. The paper electroanalytical device incorporates two preconcentration steps that make it possible to detect concentrations of TFF3 in human urine at the low end of the target TFF3 concentration range (0.03-7.0 mug mL(-1)). Importantly, the paper device provides a level of accuracy for TFF3 determination in human urine equivalent to that of a commercial kit. The paper sensor has a dynamic range of ~2.5 orders of magnitude, only requires a simple, one-step incubation protocol, and is fast, requiring only 10 min to complete. The cost of the materials at the prototypic laboratory scale, excluding reagents, is just US$0.42.

Dehaut, A., et al. (2016). "Microplastics in seafood: benchmark protocol for their extraction and characterization." Environmental Pollution **215**: 223-233.

Pollution of the oceans by microplastics (<5 mm) represents a major environmental problem. To date, a limited number of studies have investigated the level of contamination of marine organisms collected in situ. For extraction and characterization of microplastics in biological samples, the crucial step is the identification of solvent(s) or chemical(s) that efficiently dissolve organic matter without degrading plastic polymers for their identification in a time and cost effective way. Most published papers, as well as OSPAR recommendations for the development of a common monitoring protocol for plastic particles in fish and shellfish at the European level, use protocols containing nitric acid to digest the biological tissues, despite reports of polyamide degradation with this chemical. In the present study, six existing approaches were tested and their effects were compared on up to 15 different plastic polymers, as well as their efficiency in digesting biological matrices. Plastic integrity was evaluated through microscopic inspection, weighing, pyrolysis coupled with gas chromatography and mass spectrometry, and Raman spectrometry before and after digestion. Tissues from mussels, crabs and fish were digested before being filtered on glass fibre filters. Digestion efficiency was evaluated through microscopical inspection of the filters and determination of the relative removal of organic matter content after digestion. Five out of the six tested protocols led to significant degradation of plastic particles and/or insufficient tissue digestion. The protocol using a KOH 10% solution and incubation at 60 degrees C during a 24 h period led to an efficient digestion of biological tissues with no significant degradation on all tested polymers, except for cellulose acetate. This protocol appeared to be the best compromise for extraction and later identification of microplastics in biological samples and should be implemented in further monitoring studies to ensure relevance and comparison of environmental and seafood product quality studies.

Dehaut, A., et al. (2019). "Current frontiers and recommendations for the study of microplastics in seafood." TrAC - Trends in Analytical Chemistry **116**: 346-359.

For seventy years, mass plastic production and waste mismanagement have resulted in huge pollution of the environment, including the marine environment. The first mention of seafood contaminated by microplastics was recorded in the seventies, and to date numerous studies have been carried out on shellfish, fish and crustaceans. Based on an ad hoc corpus, the current review aims to report on the numerous practices and methodologies described so far. By examining multiple aspects including problems related to the definition of the term microplastic, contamination at the laboratory scale, sampling and isolation, and quantification and identification, the aim was to point out current limitations and the needs to improve and harmonise practices for future studies on microplastics in seafood. A final part is devoted to the minimum information for publication of microplastics studies (MIMS). Based on the aspects discussed, MIMS act as a starting point for harmonisation of analyses. Dehghan, R., et al. (2016). "Evidence for decreased expression of APPL1 associated with reduced insulin and adiponectin receptors expression in PCOS patients." Journal of Endocrinological Investigation **39**(9): 1075-1082.

Purpose: To investigate the expression of Adaptor protein containing a PH domain, PTB domain and leucine zipper motif 1 (APPL1), insulin receptor (INSR), adiponectin and adiponectin receptors (adipoR1 and R2) and their possible associations in granulosa cells (GCs) of 22 polycystic ovary syndrome (PCOS) women compared to the 22 non-PCOS controls with normal ovulatory function matched for BMI (body mass index). Method(s): In this study, 44 infertile women aged 18-40 years undergoing in vitro fertilization (IVF) protocol were recruited. After follicular fluid collection, GCs were isolated and then purified with MACS (Micro Beads conjugated to monoclonal anti-human CD45 antibodies). RNA was extracted from GCs and quantitative real-time PCR (qRT-PCR) was performed to assess APPL1 gene expression. Result(s): Expression of APPL1, insulin receptor and adiponectin system genes was significantly decreased in PCOS group compared to the controls. Conclusion(s): Reduction of APPL1, insulin receptor and adiponectin system genes in GCs could be involved in the development of PCOS. Copyright © 2016, Italian Society of Endocrinology (SIE).

Dehghani, S., et al. (2017). "Microplastic pollution in deposited urban dust, Tehran metropolis, Iran." Environmental Science & Pollution Research **24**(25): 20360-20371.

Environmental pollutants such as microplastics have become a major concern over the last few decades. We investigated the presence, characteristics, and potential health risks of microplastic dust ingestion. The plastic load of 88 to 605 microplastics per 30 g dry dust with a dominance of black and yellow granule microplastics ranging in size from 250 to 500 mum was determined in 10 street dust samples using a binocular microscope. Fluorescence microscopy was found to be ineffective for detecting and counting plastic debris. Scanning electron microscopy, however, was useful for accurate detection of microplastic particles of different sizes, colors, and shapes (e.g., fiber, spherule, hexagonal, irregular polyhedron). Trace amounts of Al, Na, Ca, Mg, and Si, detected using energy dispersive X-ray spectroscopy, revealed additives of plastic polymers or adsorbed debris on microplastic surfaces. As a first step to estimate the adverse health effects of microplastics in street dust, the frequency of microplastic ingestion per day/year via ingestion of street dust was calculated. Considering exposure during outdoor activities and workspaces with high abundant microplastics as acute exposure, a mean of 3223 and 1063 microplastic particles per year is ingested by children and adults, respectively. Consequently, street dust is a potentially important source of microplastic contamination in the urban environment and control measures are required.

Dehnad, A., et al. (2016). "Development of immune-biomarkers of pulmonary tuberculosis in a rabbit model." Tuberculosis **101**: 1-7.

Tuberculosis (TB) causes extensive morbidity and mortality worldwide with approximately 10 million new cases of active disease emerging mostly from a pool of two billion individuals latently infected with Mycobacterium tuberculosis (M. tb) every year. The underlying host immune responses that drive M. tb infection to active disease or latency are not well understood. We propose that identification and characterization of host immune biomarkers will be helpful to better understand the mechanisms that drive this process, and may, in addition, lead to the development of better diagnostic tools for TB. We have previously reported the profiles of plasma immune biomarkers in pulmonary TB patients in endemic countries, and in M. tb-infected nonhuman primates. However, biomarker profiling for a cost-effective and user-friendly animal model relevant to human disease, such as rabbit, has not been developed. One challenge in the analysis of circulating cytokines/chemokines for rabbit model of TB is the limited availability of validated immune-reagents. Here we report the use of a commercially available multiplex microbead human cytokine/chemokine panels as development platform for rabbit immune reagents. The results demonstrate their utility to determine circulating analytes and define their profiles related to TB in the rabbit model. In addition, we report the profiles of circulating anti-M. tb antibodies in the plasma of rabbits with active pulmonary TB. These studies show that the pattern of expression of circulating immune biomarkers correlate with TB pathology in rabbits, and are similar to those defined in pulmonary TB patients.

Deibel, D. (1988). "Filter feeding by Oikopleura vanhoeffeni : Grazing impact on suspended particles in cold ocean waters." Marine biology. Berlin, Heidelberg **99**(2): 177-186.

Because of the abundance and size of Oikopleura vanhoeffeni its quantitative role as a suspension feeder in cold ocean waters needs to be defined. To minimize the effect of manipulation and containment, and to assess the effect of naturally occurring factors on clearance rate, the author used an in situ latex microbead technique in Logy Bay, Newfoundland, from February 1985 to June 1986. Individual clearance rates ranged from 8-944 ml h super(-1), increasing exponentially with increasing trunk length. At densities of 4-110 m super(-3), O. vanhoeffeni populations removed from < 1 to 13% of the standing stock of ingestible food particles each day. The median percentage daily ration (mu g C x mu g C super(-1) x d super(-1) x 100%) of 64% accounted for observed house production rates (1 to 2 d super(-1), with each house = 23% of body carbon).

Dekiff, J. H., et al. (2014). "Occurrence and spatial distribution of microplastics in sediments from Norderney." Environmental Pollution **186**: 248-256.

The spatial distribution of small potential microplastics (SPM) (<1 mm) in beach sediments was studied on a 500 m stretch of the North Sea island of Norderney. Their correlation with visible plastic debris (VPD) (>1 mm) was also examined. Small microparticles were extracted from 36 one kg sediment samples and analysed by visual microscopic inspection and partly by thermal desorption pyrolysis gas chromatography/mass spectrometry. The smallest particle size that could be analysed with this method was estimated to be 100 mum. The mean number of SPM at the three sampling sites (n = 12) was 1.7, 1.3 and 2.3 particles per kg dry sediment, respectively. SPM were identified as polypropylene, polyethylene, polyethylene terephthalate, polyvinylchloride, polystyrene and polyamide. The organic plastic additives found were benzophenone, 1,2-benzenedicarboxylic acid, dimethyl phthalate, diethylhexyl phthalate, dibutyl phthalate, diethyl phthalate, phenol and 2,4-di-tert-butylphenol. Particles were distributed rather homogenously and the occurrence of SPM did not correlate with that of VPD.

Del Angel-Mosqueda, C., et al. (2015). "Epidermal growth factor enhances osteogenic differentiation of dental pulp stem cells in vitro." Head & Face Medicine **11**: 29.

INTRODUCTION: Epidermal growth factor (EGF) and basic fibroblast growth factor (bFGF) play an important role in extracellular matrix mineralization, a complex process required for proper bone regeneration, one of the biggest challenges in dentistry. The purpose of this study was to evaluate the osteogenic potential of EGF and bFGF on dental pulp stem cells (DPSCs).

MATERIAL AND METHODS: Human DPSCs were isolated using CD105 magnetic microbeads and characterized by flow cytometry. To induce osteoblast differentiation, the cells were cultured in osteogenic medium supplemented with EGF or bFGF at a low concentration. Cell morphology and expression of CD146 and CD10 surface markers were analyzed using fluorescence microscopy. To measure mineralization, an alizarin red S assay was performed and typical markers of osteoblastic phenotype were evaluated by RT-PCR.

RESULTS: EGF treatment induced morphological changes and suppression of CD146 and CD10 markers. Additionally, the cells were capable of producing calcium deposits and increasing the mRNA expression to alkaline phosphatase (ALP) and osteocalcin (OCN) in relation to control groups (p < 0.001). However, bFGF treatment showed an inhibitory effect.

CONCLUSION: These data suggests that DPSCs in combination with EGF could be an effective stem cell-based therapy for bone tissue engineering applications in periodontics and oral implantology.

del Moral, P. M. and D. Warburton (2010). "Explant Culture of Mouse Embryonic Whole Lung, Isolated Epithelium, or Mesenchyme Under Chemically Defined Conditions as a System to Evaluate the Molecular

Mechanism of Branching Morphogenesis and Cellular Differentiation." Methods in Molecular Biology **633**: 71-79.

Lung primordial specification as well as branching morphogenesis, and the formation of various pulmonary cell lineages, requires a specific interaction of the lung endoderm with its surrounding mesenchyme and mesothelium. Lung mesenchyme has been shown to be the source of inductive signals for lung branching morphogenesis. Epithelial-mesenchymal-mesothelial interactions are also critical to embryonic lung morphogenesis. Early embryonic lung organ culture is a very useful system to study epithelial-mesenchymal interactions. Both epithelial and mesenchymal morphogenesis proceed under specific conditions that can be readily manipulated in this system (in the absence of maternal influence and blood flow). More importantly this technique can be readily done in a serumless, chemically defined culture media. Gain and loss of function can be achieved using expressed proteins, recombinant viral vectors, and/or analysis of transgenic mouse strains, antisense RNA, as well as RNA interference gene knockdown. Additionally, to further study epithelial-mesenchymal interactions, the relative roles of epithelium versus mesenchyme signaling can also be determined using tissue recombination (e.g., epithelial and mesenchymal separation) and microbead studies.

Del Sole, A. and A. Fonda (2004). "[Disposal of waste glass in sanitary departments: a sample survey in the Lazio region]." Annali di Igiene **16**(4): 569-578.

As a result of Italian law, DPR 15/7/2003 n. 254, about hospital waste, and given that little has been written about recycling waste glass in hospitals, a survey of 28 health departments in Lazio was performed. The objectives were: to estimate the mean quantity of clear vitreous waste in one year, to estimate how vitreous waste is administered, to estimate the extent of the use of plastic instead of glass, to analyse the costs and benefits of glass use and/or plastic use and to evaluate staff training about hospital waste disposal. The average production of clear vitreous waste was 0.28 kilogram per day per hospital bed occupied. (This would be the theoretical maximum quantity of glass to be recycled). Among the 28 departments studied, 82% separated waste products but only 36% disposed of glass in accordance with the law. The estimated possible savings on glass phleboclysis in 2002 year were 35,000 euro. Staff training could avoid this conspicuous waste of money. Fifteen departments also used plastic phleboclysis; of these, in 2 departments plastic waste is separated in the wards, but unfortunately this material is later disposed of in the bins for general solid urban waste. The other thirteen hospitals dispose of waste plastic as infectious material. Using glass phleboclysis instead of plastic phleboclysis would save about 680,000 euros per year. The disposal of glass waste material in practice was not found to follow the principles taught in the training courses. Theoretic data about glass production, estimated in this survey, refers only to clear glass and it is an underestimate of that of all glass used in departments. The quantity of glass actually recycled has been about 0.14 kilogram per day per hospital bed occupied and thus only 50% of the theoretical quantity (0.28 kilogram per day per hospital bed occupied). This percentage could be improved by effective training. Ideally, the disposal of waste glass would follow the legal requirements and be monitored locally.

Delamaire, M., et al. (1997). "Impaired leucocyte functions in diabetic patients." Diabetic Medicine **14**(1): 29-34.

This study evaluates polymorphonuclear neutrophil (PMN) cell performance in 61 diabetic patients free of infection (40 Type 1, 21 Type 2), using tests that explore all the functional steps of PMN: (1) adherence: expression of adhesion molecules, CD 11a, CD 11b, CD 11c; nylon fiber adherence test; (2) chemotaxis under agarose towards the bacterial oligopeptide FMLP and complement fractions, used as attracting agents; (3) phagocytosis of opsonized latex microbeads; (4) bactericidal activity: chemiluminescence assessment of the oxidative killing potential before and after stimulation by opsonized zymosan and PMA; nitroblue tetrazolium reduction test.

De-la-Torre, G. E. (2019). "Microplastics: an emerging threat to food security and human health." Journal of Food Science and Technology.

Microplastic presence in seafood and foodstuff have been documented globally in recent studies. Consequently, human exposure to microplastics through the ingestion of contaminated food is inevitable and pose a risk to food security and human health. In this review, microplastics and related xenobiotics are defined, global evidence of microplastic pollution in seafood is reviewed, the impacts to commercial marine species and food security are discussed, and the current knowledge of its direct effects on human health is reviewed. In addition, limited information regarding food security and scientific gaps are identified. Although microplastics in the marine environment and its effects on marine organisms have been well documented, more research is needed to completely understand the implications of microplastics over food security and human health. Further research must focus on monitoring and eliminating microplastics along the food supply chain and determining the extent to which food security is affected by microplastic pollution. © 2019, Association of Food Scientists & Technologists (India).

Delgado-Blanca, I., et al. (2019). "Novel sequential separation and determination of a quaternary mixture of fungicides by using an automatic fluorimetric optosensor." Food Additives & Contaminants. Part A, Chemistry, Analysis, Control, Exposure & Risk Assessment **36**(2): 278-288.

A versatile flow-through multi-optosensor is proposed for the separation and spectrofluorimetric determination of mixtures of four widely used pesticides: carbendazim, thiabendazole, carbaryl and o-phenylphenol at micro g g⁻¹ levels in fruits. The flow system is based on the online pre-concentration and separation of the pesticides on a solid sensing microzone, followed by the sequential measurement of their native fluorescence. The separation of the pesticides takes place on a solid support located in the same flow cell, on which analytes are temporarily immobilized and separated from the matrix due to their different retention/desorption kinetics when they interact with the C₁₈ silica gel microbeads. Suitable analytical parameters were obtained for the selected analytes, with method detection and quantification limits ranging between 0.1-0.5 and 0.2-1.6 micro g g⁻¹, respectively. These values comply with the maximum residue limits (MRLs) established by the Codex Alimentarius for these commodities; in addition, carbendazim, thiabendazole and ortho-phenylphenol comply with the MRLs of The European Union. The developed method was applied to the analysis of citrus fruits by performing recovery studies. Recoveries between 85% and 115% were obtained in all cases, and the results were confirmed by a liquid chromatography-mass spectrometry reference method.

Delion, M., et al. (2019). "CFTR malfunction is linked to mucus abnormal properties in cystic fibrosis." Journal of Cystic Fibrosis **18 (Supplement 1)**: S5.

Objectives: Gel-forming mucins (mainly MUC5B and MUC5AC in the lungs) are high-molecular-weight glycoproteins responsible for the viscoelastic properties of mucus and play a key role in CF pathogenesis. In CF airways, abnormal mucus properties drive mucus stasis and airway obstruction but the pathophysiologic link with CFTR malfunction is unclear.

Understanding the biochemical changes caused by CFTR malfunction is critical to identify therapeutic targets aimed to reverse mucus abnormalities in CF. Method(s): Human bronchial epithelial (HBE) and nasal epithelial (HNE) cells were collected from normal and CF subjects. Modulation of CFTR activity was ensured by either correction by small molecules (Vx770-Vx809) or inhibition with the inhibitor CFTR<inf>Inh172</inf>. Impact on mucin properties was assessed using biochemical assays (Western blotting, HPLC, IHC) and scanning electron microscopy (SEM). Change in mucociliary transport (MCT) was assessed using fluorescent microbeads tracking. Result(s): CFTR rescue in HBE cells significantly decreased total mucin concentration and increased ciliary beat amplitude suggesting a physical change in the mucin network surrounding the cilia. MUC5B crosslinking was also decreased as shown by electrophoretic mobility. In CF-HBE cells, duration and velocity of MCT were significantly reduced compared to non-CF cells but partially restored by Vx770-809 treatment. In addition, changes in CFTR function strongly affected mucin secretion in HNE cells. CFTR rescue significantly reduces mucins secretion. Inversely, CFTR inhibition resulted in mucin hyperconcentration in non-CF nasal cells, with a change in MUC5B/MUC5AC ratio and a tighter mucus network. Conclusion(s): CFTR function affects mucin secretion and molecular weight/size. Alteration of MUC5B/MUC5AC ratio and mucin network organization both likely affect the biophysical properties of airway mucus. Hence, treatments directly targeting mucus like mucolytics could be a promising therapeutic strategy.

Delva, L., et al. (2018). "EVALUATION OF POST-CONSUMER MIXED POLYOLEFINES AND THEIR INJECTION MOULDED BLENDS WITH VIRGIN POLYETHYLENE." Environmental Engineering & Management Journal (EEMJ) **17**(2): 427-434.

Recycling of solid plastic waste composed of post-consumer mixed polyolefines (polypropylene and polyethylene) was carried out by injection moulding of secondary material streams. The materials have been characterized by melt flow index (MFI), tensile, bending and impact measurements, density and differential scanning calorimetry (DSC). The sink-float technique was used to separate the polyethylene fraction, which was then blended into virgin polyethylene at different ratios and processed anew. The mechanical and physicochemical properties were likewise determined and these results were compared to theoretical values, predicted by the law-of-mixtures. It was found that the different postconsumer mixed polyolefines were of similar quality and had comparable properties. Furthermore, it was demonstrated that the tensile and bending properties of blends consisting of recycled separated polyethylene and virgin polyethylene follow the law-of-mixtures, while the impact strength does not and is in fact strongly reduced by the presence of different phases within the injection moulded part. [ABSTRACT FROM AUTHOR]

Delves, A. K. (1996). "INDUSTRIAL WASTE WATER MINIMISATION AND TREATMENT." Recycling Textile & Plastic Waste: 43-50.

The article discusses industrial approaches for waste water minimization in the textile industries in Great Britain. It covers topics including the production of nylon 6.6 yarn, end of pipe solutions, water and waste management at source, environmental systems and auditing, waste

water minimization on infinity dyeing and planning for continuous improvement. It is emphasized that the quality management system should be made to work and be subject to frequent audits to maintain the status qou. The water supplies must be metered at each function for energy conservation.

Demitri, C., et al. (2017). "Encapsulation of Lactobacillus kefiri in alginate microbeads using a double novel aerosol technique." Materials Science & Engineering. C, Materials for Biological Applications **77**: 548-555.

Alginate micro beads containing Lactobacillus kefiri (the principal bacteria present in the kefir probiotic drink) were produced by a novel technique based on dual aerosols spaying of alginate based solution and CaCl₂ as cross linking agent. Carboxymethylcellulose (CMC) has been also added to the alginate in order to change the physic-chemical properties (viscosity and permeability) of the microbeads. Calcium alginate and CMC are biopolymers that can be used for developing oral drug-delivery systems. These biopolymers have been reported to show a pH-dependent swelling behaviour. Calcium alginate and CMC have also been known to possess an excellent mucoadhesive property. The loaded microbeads have been characterized in terms of morphology, chemical composition and stability in different conditions mimicking the gastric environment. In this study, we demonstrate the feasibility of a continuous fabrication of alginate microbeads in a range of 50-70mum size, encapsulating L. kefiri as active ingredient. The technique involves the use of a double aerosols of alginate based solution and CaCl₂ as crosslinking agent. Moreover, the encapsulation process was proved to be effective and not detrimental to bacteria viability. At the same time, it was verified the protective efficacy of the microcapsules against the gastric environment using both SGF pH1.2 (fasted state) and pH2.2 (feed state).

Deng, G., et al. (2010). "Single cell analysis of primary and disseminated tumor cells isolated from tissue and blood." Cancer Research. Conference: 101st Annual Meeting of the American Association for Cancer Research, AACR **70**(8 SUPPL. 1).

Background: Cancer evolves through the accumulation of multiple genetic alterations. How such alterations are related to tumor growth and metastatic dissemination is being widely investigated. Tissue level analyses, however, may be confounded by tumor cell heterogeneity and contamination by wildtype stromal and immune cells. Single cell analysis of tumor cells may contribute to a better understanding of tumorigenesis and metastasis. Single cell analyses using flow cytometry or microdissected cells from tissues require large numbers of cells, expensive equipment, laborious technical training, and the analyzed single cell information may be impacted by technical processing artifacts. We developed an efficient, reliable and simple new method to isolate fresh single tumor cells from tissues and blood for mutational analysis and to evaluate additional biomarkers. Material(s) and Method(s): Tumor tissues and blood samples were obtained from breast cancer patients after informed consent. Primary or metastatic tissue was used for preparation of single cell suspensions for subsequent isolation. Single cells were isolated using EpCAM-conjugated microbeads and the MagSweeper, a device invented by our group. Individual microbead-labeled single cells were easy to observe and extract. Single cells were placed into individual PCR tubes for further DNA and RNA analyses. Single cell DNA mutational analysis was performed by sequencing using multiplex pre-amplification followed by PCR amplification. Multiplex RNA expression analyses were performed by qRT-PCR from single tumor cells. Enriched and unenriched single cell suspensions were used for biomarker evaluation and results were compared with normal tissues. Tumor cells with mutations were compared on a single cell level among multiple compartments: primary tumor, blood, and metastatic tumor. Results and Discussion: Single cells were isolated from suspensions prepared from primary and metastatic tumor tissues, EpCAM-enriched and unenriched single cells microscopically observed without requiring additional treatment and used for immunostaining for tumor cells identification. Some single cells not bound to EpCAM microbeads still met tumor cell criteria (cytokeratin positive, CD45 negative, and DAPI positive). The percentage of EpCAM -positive and cytokeratin-positive was determined in the single cell suspensions. Single cell DNA showing a single nucleotide mutation in the PIK3CA gene was identified in individual tumor cells from different tissues but not white blood cells. Results from our model indicate that isolating single tumor cells from tumor tissues or blood provides more detailed information about different tumor compartments in individual cancer patients. Comparison of individual tumor cells from primary and/or metastatic sites to tumor cells in blood should provide further insight into the metastatic process.

Deng, M., et al. (2000). "Immunomagnetic separation of Cryptosporidium parvum oocysts using MACS MicroBeads and high gradient separation columns." Journal of Microbiological Methods **40**(1): 11-17.

The MACS immunomagnetic separation (IMS) system was evaluated for concentrating Cryptosporidium parvum. Oocysts were first labelled with fluorescein isothiocyanate (FITC) or rabbit anti-C. parvum antibodies, then linked to MicroBeads coated with anti-FITC or anti-rabbit IgG, and separated through a high gradient separation column. Results indicated that over 95% of oocysts were recovered and their fluorescence and infectivity were retained. The presence of MicroBeads showed no effect on genomic DNA extraction and subsequent polymerase chain reaction (PCR)-based analyses, as sensitivity of PCR (10 oocysts) and the band pattern of randomly amplified polymorphic DNA (RAPD) were identical to those using DNAs extracted from normally purified oocysts. IMS-PCR consistently detected as few as 10 oocysts from 100 ml of apple juice or homogenized milk and IMS-IFA could detect 100 oocysts from 1 g of deer manure, demonstrating the efficiency of IMS in recovering oocysts from environmental and food samples.

Deng, Y. and Y. Zhang (2019). "Response to Uptake of microplastics and related health effects: a critical discussion of Deng et al., Scientific reports 7: 46687, 2017." Archives of Toxicology **93**(1): 213-215.

Deng, Y., et al. (2017). "Tissue accumulation of microplastics in mice and biomarker responses suggest widespread health risks of exposure." Scientific Reports **7**: 46687.

Microplastics (MPs) are a significant environmental health issue and increasingly greater source of concern. MPs have been detected in oceans, rivers, sediments, sewages, soil and even table salts. MPs exposure on marine organisms and humans has been documented, but information about the toxicity of MPs in mammal is limited. Here we used fluorescent and pristine polystyrene microplastics (PS-MPs) particles with two diameters (5 μm and 20 μm) to investigate the tissue distribution, accumulation, and tissue-specific health risk of MPs in mice. Results indicated that MPs accumulated in liver, kidney and gut, with a tissue-accumulation kinetics and distribution pattern that was strongly depended on the MPs particle size. In addition, analyses of multiple biochemical biomarkers and metabolomic profiles suggested that MPs exposure induced disturbance of energy and lipid metabolism as well as oxidative stress. Interestingly, blood biomarkers of neurotoxicity were also altered. Our results uncovered the distribution and accumulation of MPs across mice tissues and revealed significant alteration in several biomarkers that indicate potential toxicity from MPs exposure. Collectively, our data provided new evidence for the adverse consequences of MPs.

Deng, Y., et al. (2018). "Evidence that microplastics aggravate the toxicity of organophosphorus flame retardants in mice (Mus musculus)." Journal of Hazardous Materials **357**: 348-354.

This study was performed to reveal the health risks of co-exposure to organophosphorus flame retardants (OPFRs) and microplastics (MPs). We exposed mice to polyethylene (PE) and polystyrene (PS) MPs and OPFRs [tris (2-chloroethy) phosphate (TCEP) and tris (1,3-dichloro-2-propyl) phosphate (TDCPP)] for 90 days. Biochemical markers and metabolomics were used to determine whether MPs could enhance the toxicity of OPFRs. Superoxide dismutase (SOD) and catalase (CAT) increased ($p < 0.05$) by 21% and 26% respectively in 10 µg/L TDCPP + PE group compared to TDCPP group. Lactate dehydrogenase (LDH) in TDCPP + MPs groups were higher (18%-30%) than that in TDCPP groups ($p < 0.05$). Acetylcholinesterase (AChE) in TCEP + PE groups were lower (10%-19%) than those in TCEP groups ($p < 0.05$). These results suggested that OPFR co-exposure with MPs induced more toxicity than OPFR exposure alone. Finally, in comparison to controls we observed that 29, 41, 41, 26, 40 and 37 metabolites changed significantly ($p < 0.05$; fold-change > 1.2) in TCEP, TCEP + PS, TCEP + PE, TDCPP, TDCPP + PS and TDCPP + PE groups, respectively. Most of these metabolites are related to pathways of amino acid and energy metabolism. Our results indicate that MPs aggravate the toxicity of OPFRs and highlight the health risks of MP co-exposure with other pollutants.

Denizli, A., et al. (1999). "Diamine-plasma treated and Cu(II)-incorporated poly(hydroxyethylmethacrylate) microbeads for albumin adsorption." Journal of Biomaterials Science, Polymer Edition **10**(3): 305-318.

Poly(2-hydroxyethylmethacrylate) (PHEMA) microbeads prepared by suspension polymerization were treated with diamine-plasmas (i.e. ethylene-diamine (EDA) and hexamethylene diamine (HMDA)) in a glow-discharge reactor in which the exposure time and glow-discharge power were changed between 5 and 30 min and 5 and 20 W, respectively. The amount of nitrogen deposition increased both with increase in exposure time and glow-discharge power. The maximum amounts of nitrogen deposition on the microbeads were 22.3 and 23.4 micromol g(-1) with the EDA- and HMDA-plasmas. Then, Cu(II) ions were incorporated onto the PHEMA microbeads by chelating with the nitrogen-carrying functional groups. Different amounts of Cu(II) ions (2.4-6.8 mg g(-1)) were incorporated on the PHEMA microbeads by changing the initial concentration of Cu(II) ions. Bovine serum albumin (BSA) adsorption onto the unmodified PHEMA, diamine-plasma treated PHEMA, and diamine-plasma treated Cu(II)-incorporated PHEMA microbeads was investigated. The non-specific adsorption of BSA on the unmodified microbeads was very low (0.22 mg BSA g(-1)). Deposition of nitrogen increased the BSA adsorption (9.3 mg g(-1) for EDA-plasma and 12.7 mg g(-1) for HMDA-plasma). Cu(II)-incorporation significantly increased the BSA adsorption (154 mg g(-1) for EDA-plasma and 178 mg g(-1) for HMDA-plasma). Further increases in the albumin adsorption capacities of the polymer microbeads (185 mg g(-1) for EDA-plasma and 208 mg g(-1) for HMDA-plasma) were observed when human plasma was used. More than 92% of the adsorbed albumin molecules was desorbed in 1 h in the desorption medium containing 0.5 M NaSCN at pH 8.0. Repeated adsorption-desorption cycles showed the feasibility of these plasma-modified polymer microbeads.

Denizli, A., et al. (1993). "Nonspecific adsorption and covalent coupling of heparin on polyacrylate based microbeads." Biomaterials, Artificial Cells, & Immobilization Biotechnology **21**(2): 183-198.

Polyacrylate based microbeads were prepared by copolymerization of four different acrylate monomers, namely 2-hydroxyethylmethacrylate (HEMA), ethyleneglycoldimethacrylate (EGDMA), methylmethacrylate (MMA) and dimethylaminoethylmethacrylate (DMEAMA). These beads were further activated with CNBr at alkaline pH. The extend of nonspecific adsorption and covalent coupling of heparin on these beads were investigated in a batch reactors at different temperatures. The effects of initial concentrations of activation agent and heparin were also studied. Nonspecific heparin adsorption on the microbeads containing DMAEMA was significantly higher than the others. Nonspecific adsorption decreased with increasing temperature. Heparin was covalently coupled on CNBr activated microbeads. The amount of coupled heparin increased by increasing concentration of CNBr.

Denizli, A., et al. (1998). "Bilirubin removal from human plasma in a packed-bed column system with dye-affinity microbeads." Journal of Chromatography. B, Biomedical Sciences & Applications **707**(1-2): 25-31.

A dye-ligand. Cibacron Blue F3GA. was covalently coupled with the poly(EGDMA-HEMA) microbeads. The affinity sorbent carrying 16.5 micromol Cibacron Blue F3GA per gram polymer was then used to remove bilirubin from human plasma in a packed-bed column system. Bilirubin adsorption from human plasma on the unmodified poly(EGDMA-HEMA) microbeads was 0.32 mg/g, while much higher adsorption values, up to 24.2 mg/g, were obtained with the dye-attached microbeads. The bilirubin adsorption capacity of the microbeads decreased with an increase in the recirculation rate of plasma. Bilirubin adsorption increased with increasing temperature, and the maximum adsorption achieved at 37 degrees C (32.5 mg bilirubin/g polymer). Bilirubin molecules interacted directly with the immobilized Cibacron Blue F3GA molecules. Contribution of albumin adsorption on bilirubin adsorption was also significant.

Denizli, A. and E. Piskin (1995). "DNA-immobilized polyhydroxyethylmethacrylate microbeads for affinity sorption of human immunoglobulin G and anti-DNA antibodies." Journal of Chromatography B: Biomedical Applications **666**(2): 215-222.

Polyhydroxymethacrylate (PHEMA) microbeads were prepared by a suspension polymerization technique and activated by CNBr in an alkaline medium (pH 11.5). DNA molecules were immobilized onto CNBr-activated PHEMA beads. The amount of immobilized DNA was controlled by changing the medium pH and the initial concentrations of CNBr and DNA. The maximum DNA immobilization was observed at pH 5.0. Non-specific adsorption on the plain PHEMA microbeads was less than 0.1 mg/g. Much higher values, up to 2.75 mg/g, were achieved with the CNBr-activated PHEMA microbeads. Human immunoglobulin G (HIgG) adsorption onto PHEMA microbeads containing different amounts of DNA on their surfaces from aqueous solutions containing different amounts of HIgG at different pH values was investigated. The maximum HIgG adsorption was observed at pH 7.0. Non-specific HIgG adsorption onto the plain PHEMA microbeads was low (about 0.167 mg/g). Higher adsorption values, up to 7.5 mg/g, were obtained with the DNA-PHEMA beads. HIgG and anti-DNA antibody removal from the blood plasma obtained from a healthy donor and a patient with systemic lupus erythematosus (SLE) were also investigated. The maximum amounts of HIgG adsorbed from aqueous solution and human plasma onto the DNA-PHEMA microbeads were 7.35 and 23.46 mg/g, respectively. Anti-DNA antibody adsorption value was 40 mg/g.

Denizli, A., et al. (1995). "Protein A immobilized polyhydroxyethylmethacrylate beads for affinity sorption of human immunoglobulin G." Journal of Chromatography B: Biomedical Applications **668**(1): 13-19.

Protein A immobilized polyhydroxyethylmethacrylate (PHEMA) microbeads were investigated for the specific removal of HIgG from aqueous solutions and from human plasma. PHEMA microbeads were prepared by a suspension polymerization technique and activated by CNBr in an alkaline medium (pH 11.5). Protein A was then immobilized by covalent binding onto these microbeads. The amount of immobilized protein A was controlled by changing pH and the initial concentrations of CNBr and protein A. The maximum protein A immobilization was observed at pH 9.5. Up to 3.5 mg protein A/g PHEMA was immobilized on the CNBr activated PHEMA microbeads. The maximum HIgG adsorption on the protein A immobilized PHEMA microbeads was observed at pH 8.0. The non-specific HIgG adsorption onto the plain PHEMA microbeads was low (about 0.167 mg of HIgG/g PHEMA). Higher adsorption values (up to 6.0 mg of HIgG/g PHEMA) were obtained in which the protein A immobilized PHEMA microbeads were used. Much higher amounts of HIgG (up to 24.0 mg of HIgG/g PHEMA) were adsorbed from human plasma.

Denizli, A., et al. (1996). "Congo red and Cu(II) carrying poly(ethylene glycol dimethacrylate-hydroxyethyl methacrylate) microbeads as specific sorbents. Albumin adsorption/desorption." Journal of Chromatography A **731**(1-2): 57-63.

Poly(ethylene glycol dimethacrylate-hydroxyethyl methacrylate) [poly(EGDMA-HEMA)] microbeads, in the size range 150-200 mum, were produced by a modified suspension copolymerization of EGDMA and HEMA. Congo Red was attached covalently to the poly(EGDMA-HEMA) microbeads, then Cu(II) ions were incorporated within the microbeads by chelating with the immobilized dye molecules. Different amounts of Cu(II) ions [0.5-2.9 mg Cu(II)/g polymer] were conjugated on the microbeads by changing the initial concentration of Cu(II) ions, pH and ionic strength. Bovine serum albumin (BSA) adsorption on these microbeads from aqueous solutions containing different amounts of BSA at different pH and ionic strengths was investigated in batch reactors. The non-specific BSA adsorption on the poly(EGDMA-HEMA) microbeads was almost zero. Congo Red derivatization significantly increased the BSA adsorption (up to 90 mg BSA/g polymer). A further increase in the adsorption capacity (up to 136 mg BSA/g polymer) was observed when Cu(II) ions were incorporated. More than 90% of the adsorbed BSA was desorbed in 1 h in a desorption medium containing 0.5 M NaSCN at pH 8.0.

Denkbas, E. B., et al. (1995). "Silicone-based microcarriers: preparation and BHK cell culture." CHEM ENG J BIOCHEM ENG J **58**(1): 65-70.

Spherical polymeric microbeads were produced by suspension cross-linking of hydroxyl-terminated polydimethylsiloxane prepolymers. Dimethylsiloxane-ethyleneoxide copolymer, dibutyltin dilaurate and methyltriethoxysilane were used as surfactant, catalyst and cross-linker, respectively. The surfaces of the microbeads were further modified by exposure of 3-amino-propyltriethoxysilane plasma in a glow-discharge apparatus. These silicone-based microbeads were used as microcarriers in culturing of baby hamster kidney (BHK) cells both in stationary and in submerged culture conditions. High attachment and growth were achieved on the glow-discharge treated silicone microbeads with moderate surface wettabilities (contact angle: 43-46 degree).

Deokar, S., et al. (2017). "Adsorptive Removal of Diuron Herbicide on Carbon Nanotubes Synthesized from Plastic Waste." Journal of Polymers & the Environment **25**(2): 165-175.

In this study, carbon nanotubes (CNTs) were synthesized from waste polyethylene bottles and their use as an adsorbent for the removal of diuron herbicide from aqueous solution was evaluated. Batch adsorption was performed by varying adsorbent dosage, initial concentration, contact time, and temperature. Kinetic models applied to experimental data indicated that the pseudo-second-order model had the best fit. The equilibrium data were analyzed using different

isotherm models. The adsorption capacity of CNTs for diuron removal, determined using the Hill isotherm, was approximately 40.37 mg/g at 303 K. From thermodynamic studies, the values of ΔH° (kJ/mol) and ΔS° [kJ/(mol K)] were calculated as −17.307 and −0.0528, respectively, which suggested that the adsorption process was exothermic. The negative values of ΔG° at three different temperatures indicated that adsorption of diuron on CNTs was favorable. [ABSTRACT FROM AUTHOR]

Deplaine, G., et al. (2011). "The sensing of poorly deformable red blood cells by the human spleen can be mimicked in vitro." Blood **117**(8): e88-95.

Retention of poorly deformable red blood cells (RBCs) by the human spleen has been recognized as a critical determinant of pathogenesis in hereditary spherocytosis, malaria, and other RBC disorders. Using an ex vivo perfusion system, we had previously shown that retention of Plasmodium falciparum-infected RBCs (Pf-RBCs) occur in the splenic red pulp, upstream from the sinus wall. To experimentally replicate the mechanical sensing of RBCs by the splenic microcirculation, we designed a sorting device where a mixture of 5- to 25-mum-diameter microbeads mimics the geometry of narrow and short interendothelial splenic slits. Heated RBCs, Pf-RBCs, and RBCs from patients with hereditary spherocytosis were retained in the microbead layer, without hemolysis. The retention rates of Pf-RBCs were similar in microbeads and in isolated perfused human spleens. These in vitro results directly confirm the importance of the mechanical sensing of RBCs by the human spleen. In addition, rigid and deformable RBC subpopulations could be separated and characterized at the molecular level, and the device was used to deplete a stored RBC population from its subpopulation of rigid RBCs. This experimental approach may contribute to a better understanding of the role of the spleen in the pathogenesis of inherited and acquired RBC disorders.

Derakhti, S., et al. (2017). "A new strategy for the Ca-alginate microbeads synthesis with the similar physical characteristics to the microcarriers in cell culture." Iranian Journal of Biotechnology **ISSUE)**: 142.

Background and Aim: Ca-alginate hydrogels have been widely applied in cell culture due to advantages they have such as biocompatibility, low cost and simplicity of preparation procedures. Small size gel beads (<300mum) are favored for anchorage dependent cell culture, as they undergo a lower level of shear stress and provide a higher surface area to volume ratio. However, production of the small microbeads has been failed by conventional techniques. In this study, we aimed to develop a strategy in the traditional electro spray method to produce the Ca-alginate microbeads with the sizes similar to the commercial microcarriers. Method(s): We employed electro spray method to create micro droplets of high viscous sodium alginate solution by applying constant DC voltage. The droplets fell into the calcium chloride solution and formed the hydrogels. The beads sizes were measured under various conditions of the flow rate and concentration of alginate solution and also the DC voltage to meet the conditions, which led us to obtain the microbeads with the desired sizes. Result(s): Among the tested variables, the flow rate of alginate solution was found to be the predominant factor, since the sizes of the beads significantly decreased by reducing this parameter. The reduction of the alginate solution concentration also led to decrement in the microbeads sizes but in lesser extent compared to flow rate. In the voltage range we worked (7-12 KV), the beads sizes were approximately independent of the voltage. Finally, we could produce spherical microbeads with the proximate mean size of 210mum by incorporation of alginate solution 1.25 % (w/v) with the flow rate of 0.5 ml/h under the voltage of 8kV in calcium chloride solution. Conclusion(s): Our findings suggested that it is possible to synthesis Ca-alginate hydrogels with the sizes similar to the commercial microcarriers by electro spray method. Further decrease in the beads sizes would be reachable by application of apparatus which could provide lower flow rates.

Derman, B. A., et al. (2019). "Pilot Study of Regulatory T-Cell Depletion in the Setting of Autologous Stem Cell Transplantation for Multiple Myeloma." Biology of Blood and Marrow Transplantation **25 (3 Supplement)**: S405-S406.

Introduction: High dose melphalan with autologous stem cell transplantation (ASCT) is a therapy mainstay in multiple myeloma (MM). However, the median PFS after ASCT is under 5 years even with contemporary agents. This may be due to immune dysfunction after ASCT. Regulatory T cells (Tregs, CD4⁺CD25⁺FoxP3⁺) reconstitute rapidly after ASCT, can inhibit antitumor immune responses, and are a target for non-cross-resistant therapy in the MRD-positive state. Method(s): We conducted a randomized pilot study to evaluate 2 methods of Treg depletion in MM patients undergoing ASCT. No Treg depletion was performed in the control ASCT arm. An anti-CD25 mAb (basiliximab 20 mg IV) was given day +1 post-ASCT in the in vivo Treg depletion (IVTRD) arm. In the ex vivo Treg depletion (EVTRD) arm, CD4⁺CD25⁺ Tregs were depleted from ASC grafts with anti-CD25 microbeads and CliniMACS device (Miltenyi). Primary endpoints were: 1) evaluate efficiency of Treg depletion, 2) measure kinetics of Treg depletion and recovery and 3) determine toxicities with the two methods of Treg depletion. Secondary endpoints were engraftment rates and disease response. Result(s): Fifteen patients were enrolled, 5 in each arm. One patient in the IVTRD arm was removed from study due to mobilization failure. ASC were collected following filgrastim/plerixafor. The conditioning regimen consisted of melphalan 200 mg/m². All patients engrafted; median times to neutrophil/platelet engraftment were similar between arms. 4/5 patients in the EVTRD arm had neutropenic fever (vs 2/5 in control ASCT arm and 2/4 in IVTRD arm). Engraftment syndrome occurred in 1 patient in the EVTRD arm. Conclusion(s): Median ex vivo depletion of CD4⁺CD25⁺ Tregs from 5 ASC grafts was 93% (figure 1). Baseline frequencies of peripheral blood (PB) CD4⁺FoxP3⁺ Tregs were similar between all arms (p=NS). A reduction in Treg frequency was seen in the EVTRD arm compared to controls at day +14 (p=0.0001) and +21 (p=0.025, figure 2). The IVTRD arm had lower Treg frequency at day +28 compared to controls (p=0.053). These data suggest that in vivo and ex vivo Treg depletion are feasible and result in significant reduction and delay in Treg recovery post-ASCT for MM. These methods could serve as a platform for using post-transplant immunotherapies to improve post-ASCT outcomes. Copyright © 2018

DeRomano, O. (1978). "Irrigation Apparatus." U.S. Patent No. 4 094,466, 3 p, 5 fig, 8 ref; Official Gazette of the United States Patent Office, Vol 971, No 2, p 590, June 13, 1978.

A device for underground drainage and irrigation of soil includes a porous element which can be engaged about a distribution pipe at a perforation or opening in the pipe. Apertures in a pipe distribution system can be provided in two ways. In the first instance, a space may be provided between the ends of two separate, aligned pieces of pipe. The porous filter or diffusion member can be in the form of a flange connector joining the two adjacent pipe sections. Or the flow passages or apertures are formed by perforating a pipe at selected locations. The location and

size of the perforations are selected according to the desired characteristics of the system. The apertures are selected according to the desired characteristics of the system. The apertures are then covered by a porous element permitting flow to be dispersed across the aperture and through the element. The individual porous elements are comprised of a quantity of small plastic particles, as for example, pellets of polyvinylchloride, sintered by application of heat, pressure or a bonding agent. The sintering leaves interstitial spaces to allow passage of fluid through the element. (Sinha-OEIS)

Derraik, J. G. B. (2002). "The Pollution of the Marine Environment by Plastic Debris: A Review." Marine Pollution Bulletin **44**(9): 842.

An overview is provided of the extent of plastic debris contamination of the marine environment. Data from the literature are cited to illustrate the ingestion of plastics by marine biota, the ingestion of PCBs via ingestion of plastics, the problem of marine mammal entanglement in plastic debris, and the possible pathway for alien species invasion due to drifting plastic debris. The data show that there is overwhelming evidence that plastic pollution is a threat to marine biodiversity, which is also threatened by overfishing, climate change, and other forms of marine pollution. Efforts to address the problem through international legislation are discussed briefly, and recommendations for reducing the amount of plastic debris are proposed.

Desai, S., et al. (2008). "Biomanufacturing of Microcapsules for Drug Delivery and Tissue Engineering Applications." IIE Annual Conference. Proceedings: 507.

This paper presents a biomanufacturing approach for generating bio-polymer microbeads that can be used for localized drug delivery and tissue engineering applications. Calcium alginate microbeads were produced using specialized micro jetting technique with tight size distributions. The rheological properties of the polymer were studied to gain a better understanding of the fluid's behavior during the jetting process. A designed experiment with multiple levels of bio-polymer concentrations was conducted to ascertain the significant factors affecting the diameter and stability of the microbeads. This study demonstrates a method of utilizing specialized micro jetting technology to manufacture consistent microbeads for variety of biomedical applications.

Desaules, C., et al. (2008). "A new HLA-DR4 allele, DRB1*0474, with an unusual residue at position 77." Tissue Antigens **72**(5): 500-501.

We report here a new DR4 allele, DRB1*0474, identified in a volunteer hematopoietic stem cell donor of the Swiss National Registry. DRB1*0474 differs from DRB1*040701 by two nucleotide residues resulting in a single Thr -> Asn substitution at codon 77. © 2008 The Authors.

Desbois, L., et al. (2012). "A microfluidic device for on-chip agarose microbead generation with ultralow reagent consumption." Biomicrofluidics **6**(4): 44101.

Water-in-oil microdroplets offer microreactors for compartmentalized biochemical reactions with high throughput. Recently, the combination with a sol-gel switch ability, using agarose-in-oil microdroplets, has increased the range of possible applications, allowing for example the capture of amplicons in the gel phase for the preservation of monoclonality during a PCR reaction. Here, we report a new method for generating such agarose-in-oil microdroplets on a microfluidic device, with minimized inlet dead volume, on-chip cooling, and in situ monitoring of biochemical reactions within the gelified microbeads. We used a flow-focusing microchannel network and successfully generated agarose microdroplets at room temperature using the "push-pull" method. This method consists in pushing the oil continuous phase only, while suction is applied to the device outlet. The agarose phase present at the inlet is thus aspirated in the device, and segmented in microdroplets. The cooling system consists of two copper wires embedded in the microfluidic device. The transition from agarose microdroplets to microbeads provides additional stability and facilitated manipulation. We demonstrate the potential of this method by performing on-chip a temperature-triggered DNA isothermal amplification in agarose microbeads. Our device thus provides a new way to generate microbeads with high throughput and no dead volume for biochemical applications.

DesBordes, C. K. and J. G. Welch (1984). "Influence of specific gravity on rumination and passage of indigestible particles." Journal of Animal Science **59**(2): 470-475.

Indigestible plastic particles (0.5 x 0.16 cm) with different specific gravities (0.90, 0.96, 1.17, 1.42, 1.77 and 2.15) were given in single doses of 4000 particles of each sp. gr. intraruminally to 4 fistulated steers and orally to 4 dry cows. With steers the average total 10-day recoveries differed and values in increasing order of sp. gr. were 17.1, 22.4, 85.2, 58.6, 58.8 and 60.4%. The ruminated fractions also differed and were 12.9, 17.1, 52.1, 1.7, 5.3 and 2.4% of the particles ingested. With cows the average total 10-day particle recovery varied with sp. gr. and was 46.2, 46.1, 92.2, 93.7, 96.2 and 78.6% with increasing sp. gr. The ruminated particles differed and averaged 39.2, 39.5, 53.4, 12.9, 11.7 and 5.5% of the ingested particles. In experiment 3 (cows), the average total 10-day particle recovery reflected sp. gr. and was 37.8, 35.4, 87.4, 94.2, 96.6 and 85.0%. Recovery percentages of ruminated particles differed and were 31.4, 30.2, 71.5, 29.5, 18.7 and 8.4. Highest recovery of particles of sp. gr. 1.17, 1.42, 1.77 and 2.15 occurred on day 2. In all three experiments the particles of lower sp. gr. of 0.90 and 0.96 showed low and relatively uniform passage during the entire 10-day recovery period.

Desforges, J.-P., et al. (2015). "Ingestion of Microplastics by Zooplankton in the Northeast Pacific Ocean." Archives of Environmental Contamination & Toxicology **69**(3): 320-330.

Microplastics are increasingly recognized as being widespread in the world's oceans, but relatively little is known about ingestion by marine biota. In light of the potential for microplastic fibers and fragments to be taken up by small marine organisms, we examined plastic ingestion by two foundation species near the base of North Pacific marine food webs, the calanoid copepod Neocalanus cristatus and the euphausiid Euphausia pacifia. We developed an acid digestion method to assess plastic ingestion by individual zooplankton and detected microplastics in both species. Encounter rates resulting from ingestion were 1 particle/every 34 copepods and 1/every 17 euphausiids (euphausiids > copepods; $p = 0.01$). Consistent with differences in the size selection of food between these two zooplankton species, the ingested particle size was greater in euphausiids (816 ± 108 µm) than in copepods (556 ± 149 µm) ($p = 0.014$). The contribution of ingested microplastic fibres to total plastic decreased with distance from shore in euphausiids ($r = 70$, $p = 0.003$), corresponding to patterns in our previous observations of microplastics in seawater samples from the same locations. This first evidence of microplastic ingestion by marine zooplankton indicate that species at lower trophic levels of the marine food web are mistaking plastic for food, which raises fundamental questions about potential risks to higher trophic level species. One concern is risk to salmon: We estimate that consumption of microplastic-containing zooplankton will lead to the ingestion of 2-7 microplastic particles/day by individual juvenile salmon in coastal British Columbia, and ≤91 microplastic particles/day in returning adults. [ABSTRACT FROM AUTHOR]

Desforges, J. P. W., et al. (2014). "Widespread distribution of microplastics in subsurface seawater in the NE Pacific Ocean." Marine Pollution Bulletin **79**(1-2): 94-99.

We document the abundance, composition and distribution of microplastics in sub-surface seawaters of the northeastern Pacific Ocean and coastal British Columbia. Samples were acid-digested and plastics were characterized using light microscopy by type (fibres or fragments) and size (<100, 100-500, 500-100 and >1000mum). Microplastics concentrations ranged from 8 to 9200particles/m³; lowest concentrations were in offshore Pacific waters, and increased 6, 12 and 27-fold in west coast Vancouver Island, Strait of Georgia, and Queen Charlotte Sound, respectively. Fibres accounted for ~75% of particles on average, although nearshore samples had more fibre content than offshore (p<0.05). While elevated microplastic concentrations near urban areas are consistent with land-based sources, the high levels in Queen Charlotte Sound appeared to be the result of oceanographic conditions that trap and concentrate debris. This assessment of microplastics in the NE Pacific is of interest in light of the on-coming debris from the 2011 Tohoku Tsunami. © 2013 Elsevier Ltd.

Deshmukh, S., et al. (2014). "Acoustic radiation forces at liquid interfaces impact the performance of acoustophoresis." Lab on a Chip **14**(17): 3394-3400.

Acoustophoresis is a method well suited for cell and microbead separation or concentration for downstream analysis in microfluidic settings. One of the main limitations that acoustophoresis share with other microfluidic techniques is that the separation efficiency is poor for particle-rich suspensions. We report that flow laminated liquids can be relocated in a microchannel when exposed to a resonant acoustic field. Differences in acoustic impedance between two liquids cause migration of the high-impedance liquid towards an acoustic pressure node. In a set of experiments we charted this phenomenon and show herein that it can be used to either relocate liquids with respect to each other, or to stabilize the interface between them. This resulted in decreased medium carry-over when transferring microbeads (4% by volume) between suspending liquids using acoustophoresis. Furthermore we demonstrate that acoustic relocation of liquids occurs for impedance differences as low as 0.1%.

Deshmukh, S. S., et al. (2013). "Formulation and Evaluation of Mucoadhesive Microbeads of Domperidone." Journal of Current Pharma Research **3**(4): 999-1009.

Hydroxy propyl methyl cellulose and citric acid were used in preparation of solid dispersion by kneading method. The drug release was found to be dependent on concentration of polymer in solid dispersion and modification of micro environmental pH by citric acid in dissolution medium. Amorphous dispersed form of domperidone was due to homogeneous dispersion of drug in carriers by kneading method. Mucoadhesive microbeads containing domperidone was prepared by Ionotropic gelation method. Beads was prepared, employing mucoadhesive polymer carbopol 934 in different ratio with sodium alginate. The drug release from formulation C10 was almost zero order which favors development of a sustained release formulation to improve short biological half life of drug which is 7 hour. Deshpande, A., et al. (2015). "An attempt to study the bacterialdegradation of polythene bag and rubber band using Vellore (Dumpsites) enriched soil." International Journal of Pharmacy and Technology **7**(3):

9623-9629.

Plastic materials pose a major problem despite being used in day to day lives. They cannot be degraded in a short span of time and thus plastic pollution is a matter of concern all over the world. A thin plastic bag itself requires 10-20 years to degrade, while a plastic bottle requires about 100 years for biodegradation (http://cmore.soest.hawaii.edu/cruises/super/biodegradation.htm). There is a need to understand in depth about the natural processes involved in breaking down of plastic so that new and better methods can be introduced based on the preexisting methods which speed up the process of degradation ^[1]. A thorough experimentation was carried out to find out if the microorganisms in soil can help in the process. The end result was the appearance of small pores on the plastic materials ^[2]. This proved that microorganisms play an important role in the degradation and breakdown of the bonds of plastic materials. Copyright © 2015, International Journal of Pharmacy and Technology. Detert, S., et al. (2018). "The atrial appendage as a suitable source to generate cardiac-derived adherent proliferating cells for regenerative cell-based therapies." Journal of Tissue Engineering and Regenerative Medicine **12**(3): e1404-e1417.

Cardiac-derived adherent proliferating (CardAP) cells obtained from endomyocardial biopsies (EMBs) with known anti-fibrotic and pro-angiogenic properties are good candidates for the autologous therapy of end-stage cardiac diseases such as dilated cardiomyopathy. However, due to the limited number of CardAP cells that can be obtained from EMBs, our aim is to isolate cells with similar properties from other regions of the heart with comparable tissue architecture. Here, we introduce the atrial appendage as a candidate region. Atrial appendage-derived cells were sorted with CD90 microbeads to obtain a CD90low cell population, which were subsequently analysed for their surface marker and gene expression profiles via flow cytometry and micro array analysis. Enzyme-linked immunosorbent assays for vascular endothelial growth factor and interleukin-8 as well as tube formation assays were performed to investigate pro-angiogenic properties. Furthermore, growth kinetic assays were performed to estimate the cell numbers needed for cell-based products. Microarray analysis revealed the expression of numerous pro-angiogenic genes and strong similarities to CardAP cells with which they also share expression levels of defined surface antigens, that is, CD29+, CD44+, CD45−, CD73+, CD90low, CD105+, and CD166+. High secretion levels of vascular endothelial growth factor and interleukin-8 as well as improved properties of vascular structures in vitro could be detected. Based on growth parameters, cell dosages for the treatment of more than 250 patients are possible using one appendage. These results lead to the conclusion that isolating cells with regenerative characteristics from atrial appendages is feasible and permits further investigations towards allogenic cell-based therapies.

However, due to the limited number of CardAP cells that can be obtained from EMBs, our aim is to isolate cells with similar properties from other regions of the heart with comparable tissue architecture. Here, we introduce the atrial appendage as a candidate region. Atrial appendage-derived cells were sorted with CD90 microbeads to obtain a CD90^{low} cell population, which were subsequently analysed for their surface marker and gene expression profiles via flow cytometry and micro array analysis. Enzyme-linked immunosorbent assays for vascular endothelial growth factor and interleukin-8 as well as tube formation assays were performed to investigate pro-angiogenic properties. Furthermore, growth kinetic assays were performed to estimate the cell numbers needed for cell-based products. Microarray analysis revealed the expression of numerous pro-angiogenic genes and strong similarities to CardAP cells with which they also share expression levels of defined surface antigens, that is, CD29⁺ , CD44⁺ , CD45⁻ , CD73⁺ , CD90^{low} , CD105⁺ , and CD166⁺ . High secretion levels of vascular endothelial growth factor and interleukin-8 as well as improved properties of vascular structures in vitro could be detected. Based on growth parameters, cell dosages for the treatment of more than 250 patients are possible using one appendage. These results lead to the conclusion that isolating cells with regenerative characteristics from atrial appendages is feasible and permits further investigations towards allogenic cell-based therapies.

Detree, C. and C. Gallardo-Escarate (2018). "Single and repetitive microplastics exposures induce immune system modulation and homeostasis alteration in the edible mussel Mytilus galloprovincialis." Fish & Shellfish Immunology **83**: 52-60.

Seashore invertebrates such as mussels are exposed to multiple bouts of pollution related to human activities. Plastic debris originating from land-based activities are a concerning issue as they may be fragmented in smaller pieces (microplastics, <5 mm diameter) which have an excellent potential for uptake by a large variety of animals. Here, we set out to explore the whole transcriptome profiling of Mytilus galloprovincialis associated with temporal variability of microplastics concentrations. Mussels were submitted to (i) a single 18 days-exposure to a concentration of microplastics found during pollution events (4.6 E+5 polyethylene microbeads L⁻¹), (ii) a recovery period to investigate the reversibility of microplastics effects and (iii) a repeated exposure to microplastics to evidence acclimation to microplastics pollution events. Overall, 18 days-exposure to microplastics was mostly associated with disruption of mussel global homeostasis resulting in the production of stress and immune-related proteins and as a consequence, a diminution of energy allocated to growth. During the recovery period, a contrasting response was observed with the activation of apoptotic processes and the up-regulation of immune-receptors and stress-related proteins (glutathione peroxidase, hsp70) in mussels previously exposed to microplastics. These divergent responses, suggest that the establishment of compensatory mechanism as an attempt to recover, is not sufficient to counteract physiological stress induced by the first exposure. Finally, the differences observed in gene expression between single and repeated exposures to microplastics suggest, under the experimental conditions tested, that mussels may be able to establish a stress-memory upon microplastics exposure.

Deun, K. V., et al. (2008). "Short-chain fatty acids and l-lactate as feed additives to control Campylobacter jejuni infections in broilers." Avian Pathology **37**(4): 379.

The usefulness of butyrate, acetate, propionate and l-lactate for the control of Campylobacter jejuni infections in broilers was assessed. For this purpose, the effect of these acids on the growth of C. jejuni in broth and intestinal mucous was determined, as well as their influence on the invasiveness of C. jejuni in intestinal epithelial cells. From these in vitro obtained results, one acid was retained for use as a feed additive in an in vivo trial. Butyrate was the most successful of the short-chain fatty acids, with 12.5 mM being bactericidal for C. jejuni at pH 6.0. Propionate and acetate had a bacteriostatic effect at 50mM. None of the short-chain fatty acids had a bactericidal effect at pH 7.5 at a maximum concentration of 50 mM. Mucous increased the minimum bactericidal concentration of butyrate, but not the bacteriostatic concentrations of propionate or acetate. When C. jejuni was incubated in growth subinhibitory concentrations of butyrate, acetate or propionate or 25 mM l-lactate, no alteration in the invasive capabilities of C. jejuni in Caco-2 cells was observed. The addition of butyrate-coated micro-beads to the feed was unsuccessful to reduce C. jejuni caecal colonization in a seeder model using 2-week-old broilers. In conclusion, despite the marked bactericidal effect of butyrate towards C. jejuni in vitro, butyrate-coated micro-beads do not protect broilers from caecal colonization with C. jejuni in the applied test conditions. This might be partially ascribed to the protective effect of mucous and the rapid absorption of butyrate by the enterocytes. [PUBLICATION ABSTRACT]

Devriese, L. I., et al. (2015). "Microplastic contamination in brown shrimp (Crangon crangon, Linnaeus 1758) from coastal waters of the Southern North Sea and Channel area." Marine Pollution Bulletin **98**(1/2): 179-187.

This study assessed the capability of Crangon crangon (L.), an ecologically and commercially important crustacean, of consuming plastics as an opportunistic feeder. We therefore determined the microplastic content of shrimp in shallow water habitats of the Channel area and Southern part of the North Sea. Synthetic fibers ranging from 200 micro m up to 1000 micro m size were detected in 63% of the assessed shrimp and an average value of 0.68+or-0.55 microplastics/g w. w. (1.23+or-0.99 microplastics/shrimp) was obtained for shrimp in the sampled area. The assessment revealed no spatial patterns in plastic ingestion, but temporal differences were reported. The microplastic uptake was significantly higher in October compared to March. The results suggest that microplastics >20 micro m are not able to translocate into the tissues.

Devriese, L. I., et al. (2017). "Bioaccumulation of PCBs from microplastics in Norway lobster (Nephrops norvegicus): an experimental study." Chemosphere **186**: 10-16.

Plastic debris acts as a sorbent phase for hydrophobic organic compounds like polychlorinated biphenyls (PCBs). Chemical partitioning models predict that the ingestion of microplastics with adsorbed chemicals in the field will tend not to result in significant net desorption of the chemical to the organism's tissues. This is expected due to the often limited differences in fugacity of the chemical between the indigestible plastic materials and the tissues, which are typically already exposed in the same environment to the same chemicals as the plastic. However laboratory trials validating these model predictions are scarce. In this study, PCB-loaded microplastics were offered to field-collected Norway lobsters (Nephrops norvegicus) during in vivo feeding laboratory experiments. Each ingestion experiment was repeated with and without loading a mixture of ten PCB congeners onto plastic microspheres (MS) made of polyethylene (PE) and polystyrene (PS) with diameters of either 500-600 micro m or 6 micro m. We observed that the presence of chemicals adsorbed to ingested microplastics did not lead to significant bioaccumulation of the chemicals in the exposed organisms. There was a limited uptake of PCBs in Nephrops tail tissue after ingestion of PCB-loaded PE MS, while almost no PCBs were detected in animals exposed to PS MS. In general, our results demonstrated that after 3 weeks of exposure the ingestion of plastic MS themselves did not affect the nutritional state of wild Nephrops.

Dewan, P. A., et al. (2002). "Plastic particle migration during intravenous infusion assisted by a peristaltic finger pump in an animal model." Pediatric Surgery International **18**(5-6): 310-314.

The contamination of intravenously administered fluid with foreign material has always been of

major concern, but the in-vivo impact of silicone embolisation from administration of fluid via a peristaltic finger pump (PFP) has not previously been assessed. To determine whether silicone particles enter the lungs and to review the histological response, 10 rabbits received an IV infusion of 0.9% saline at 10 ml/kg per hour over a 72-h period, via an IVAC 591 PFP. The lungs were analysed for silicone particles with scanning electron microscopy (SEM) and energy-dispersive X-ray analysis (EDXA). These results were compared with a control group of non-infused animals. Silicone particles were found in 8 of 10 animals in the experimental group and in 2 of 9 control animals, indicating that silicone particles are dislodged during pump-assisted IV infusions. The difference between the control and infused animals was statistically significant using Fisher's exact test (P = 0.023). However, silicone plastic particles in control animals suggest that there is also environmental exposure to silicone in addition to those particles that come from a therapeutic source. The additional finding of elemental silicon (which is one of the constituents of silicone plastic) in both infused and control animals in which silicone plastic was not found indicates that not all elemental silicon in animals reflects the presence of silicone plastic. The clinical significance of each of these two findings is yet to be determined. © Springer-Verlag 2002.

DeWitte, M. A., et al. (2014). "Development of an alpha/beta T-cell depleted allogeneic stem cell transplantation protocol form matched related and unrelated donor grafts in patients with poor risk leukemia." Blood. Conference: 56th Annual Meeting of the American Society of Hematology, ASH **124**(21).

Introduction: The outcome of allo-SCT in patients with poor risk leukemia is still hampered by GVHD and relapse. The innate immune system has been reported to contribute to tumor control, with lower incidence of GVHD. Specific depletion of alphaalpha T- cells - key players in the development of GVHD - will render NK cells and gammadelta T cells within the allograft. Recently reported results have shown the great promise of this approach in haploindentical transplantations. Within this study, we aim to extend alphaalphaT- cell depleted allo-SCT to patients with a MRD or MUD. Method(s): Patients with either 'poor-risk' or 'very poor-risk' leukemia were included in this phase I study. Either HLA matched siblings (MRD) or fully matched HLA matched (10/10) unrelated donors (MUD) were eligible. abT-cell reduction was performed by negative selection with anti-abTCR antibodies in combination with magnetic microbeads, using the automated CliniMACS device (Miltenyi Biotec, Bergisch Gladbach, Germany). The maximal contamination with alphaalphaT-cells for all dose levels was 5x10⁵/kg. Three conditioning regimens have been investigated (I): fludarabine 120 mg/m² + cyclophosfamide 4800 mg/m², (II): fludarabine 120 mg/m² + busilvex AUC=90 and (III): ATG (Genzyme) 4 mg/m² + fludarabine 120 mg/m² + busilvex AUC=90 followed by alphaalphaT- cell depleted grafts from matched related or unrelated donors. Within cohort II and III, no additional immune suppression was given after allo-SCT. Result(s): Products for 14 patients have been successfully processed and used for alphaalphaT-cell depleted allo-SCT between 2011 and 2013. A ~4 log depletion of alphaalphaT-cells has been observed in the product with a recovery of ~75% of CD34⁺ cells. In cohort I and cohort II, 60% and 25% primary graft failures were observed, whereas in cohort III primary engraftment (chimerism > 95%) was observed in all patients. The combination of ATG/fludarabine/busilvex was well tolerated with a hematological recovery of within 3 weeks. In all 14 patients immune reconstitution primarily consisted of innate cells (NK cells and gammadelta T cells) the first 6 months post transplantation. In addition, no increase in CMV or EBV reactivations has been observed so far under the profound "innate control". Conclusion(s): ATG Busulfan Fludarabine is a low toxicity platform for

abTCR-depleted transplantations, resulting in a swift reconstitution of innate cells (NK cells and gammadelta T cells) the first 6 months post transplantation. This transplantation strategy can serve as a tool for future immunological interventions such as a low dose DLI or genetically modified T cells.

Dey, P., et al. (2012). "Locust bean gum and its application in pharmacy and biotechnology: An overview." International Journal of Current Pharmaceutical Research **4**(1): 7-11.

Locust bean gum is a versatile biopolymer which finds its application in various fields. The conventional use of Locust bean gum as an excipient in drug products generally depends on the thickening, gel forming and stabilizing properties. A need for prolonged and better control of drug administration has increased the demand for tailor made polymers. Various significant works have been carried out in combination with the other polymers to make the formulation sustained and targeted. Recently a new work has been carried out by its chemical modification specifically its carboxymethylation derivative to improve its physico -chemical characteristics in terms of increased aqueous solubility. This derivatized gum can be used for the preparation of sustained release micro beads. Even locust bean gum has also finds its application in the field of biotechnology specifically in tissue engineering for the manufacturing of tissue scaffolds. Thus the gum has wide application in the both pharmaceutical and biotechnological field.

Dhall, R. and D. L. Kreitzman (2016). "Advances in levodopa therapy for Parkinson disease: Review of RYTARY (carbidopa and levodopa) clinical efficacy and safety." Neurology **86**(14 Suppl 1): S13-24.

Parkinson disease (PD) is a slowly progressive, incurable, neurodegenerative disorder with progressive motor symptoms that can be managed with treatments. Levodopa is generally recognized as the most effective and widely used treatment for PD. It improves function and quality of life, morbidity, and mortality, and therefore reduces individual and societal costs. Levodopa has a relatively short half-life, however, and is quickly metabolized in the plasma, leading to fluctuations, including wearing-off of effect and inconsistent symptomatic relief as well as development of dyskinesias, with both wearing off and dyskinesias worsening with advancing disease. Immediate-release and controlled-release formulations have been used with success, but motor fluctuations remain a problem. RYTARY (levodopa and carbidopa, IPX066) is an oral extended-release therapy composed of carbidopa-levodopa microbeads designed to dissolve at various rates that allows for quick absorption and sustained levodopa release over an extended period. In development studies, RYTARY improved symptoms in patients with both early and advanced PD and offered significantly improved Unified Parkinson Disease Rating Scale scores and "on" times, without worsening troublesome dyskinesias when compared to other levodopa formulations. Tolerability and safety were comparable to other formulations. This section reviews the data that support the use of RYTARY in the treatment of PD.

Dhanda, A., et al. (2012). "Is primary biliary cirrhosis a steroid sensitive autoimmune disease?" Gut **2)**: A118.

Introduction: Primary biliary cirrhosis (PBC) is a classic T cell mediated autoimmune disease: an autoantigen has been described and high levels of antigen specific liver infiltrating auto-reactive CD4+ T cells found. However, unlike in other autoimmune conditions steroid therapy is not considered effective in PBC although there is existing evidence that it can improve histological and biochemical parameters.1 We sought further evidence that PBC is a steroid sensitive disease by using two in vitro measures of steroid sensitivity. Method(s): We have applied an in vitro dexamethasone (Dex) inhibition of lymphocyte proliferation assay (DILPA), which correlates well with clinical steroid sensitivity and outcome in ulcerative colitis2 and alcoholic hepatitis,3 to 20 patients with PBC diagnosed by liver biochemistry, antibodies and liver histology (when performed). The DILPA assesses peripheral blood mononuclear cell (PBMC) sensitivity to treatment with steroids in vitro. We also examined the role of CD14+ monocytes, which produce pro-inflammatory cytokines to recruit T cells to the tissue of inflammation. PBMCs were isolated from peripheral blood by density gradient centrifugation over Ficoll. CD14+ cells were obtained by positive microbead selection and cultured with 300?ng/ml lipopolysaccharide in the presence or absence of Dex 1x10-6M for 24 h. Supernatants were then collected and interleukin (IL)-1beta, IL-6 and TNFalpha were measured by cytokine bead array (BD biosciences) according to manufacturer's instructions. Suppression of cytokine production by Dex was calculated. Result(s): In 20 patients with PBC, just one individual demonstrated in vitro steroid resistance by DILPA, and peripheral lymphocytes were sensitive to steroids in all other study subjects. Suppression of lymphocyte proliferation by Dex was significantly greater in patients with PBC compared to 37 healthy volunteer controls (86% vs 76%, p=0.04). Furthermore, Dex induced a 40%-100% suppression of IL-1beta, IL-6 and TNFalpha (mean 75%, 74% and 79%, respectively) in the supernatants of CD14+ monocyte cultures. This suggests that both peripheral blood lymphocytes and monocytes in patients with PBC are steroid sensitive. Conclusion(s): Using a validated measure of lymphocyte steroid sensitivity and a further assessment of monocyte steroid sensitivity we have demonstrated that PBC is a steroid sensitive disease. Together with existing clinical studies of glucocorticoids in PBC1 our in vitro evidence suggests that steroid treatment should not be dismissed outright as it may provide a useful option in selected patients with PBC.

Dhawan, A. (2015). "Clinical human hepatocyte transplantation: Current status and challenges." Liver Transplantation **21**(Supplement 1): S39-S44.

Dhawan, R., et al. (2019). "Recycling of plastic waste into tiles with reduced flammability and improved tensile strength." Process Safety & Environmental Protection: Transactions of the Institution of Chemical Engineers Part B **124**: 299-307.

• Lightweight tiles were inventively fabricated by simple and novel process. • Utilization of waste plastic bags as matrix reinforced with fly ash as filler. • The obtained tiles demonstrates good thermal stability and tensile strength of 9.68 MPa. • Composites tiles possess linear burning rate of 4.36 mm/min. • Resistance to acids and bases with negligible water absorption. This paper is focused on finding effective alternative for disposal of waste plastic bags by designing tiles with better mechanical strength, reduced flammability level, resistant against strong acids and bases and organic solvents, so that tiles can be used for designing structures for paver tiles for societal usage. In recent years the plastic consumption has increased manifolds leading to accumulation of plastic waste in large amount. Waste plastic bags being non-biodegradable and its extreme durability make its disposal process difficult. Plastic solid waste (PSW) present challenges and opportunities to the societies regardless of their technological advances and sustainability awareness. Traditional technologies for waste plastic disposal have failed to cope up with the increased generation of plastic waste. Also, the disposal of fly ash, waste by-product generated by combustion of coal in thermal power plants, is a serious problem both in terms of land use and environmental pollution. In this study, waste plastic matrix reinforced with fly ash (FA) and a flame retardant at different loadings (wt %) 5, 10, 15, 20 using twin screw extruder were molded into composite tiles and their characteristics were evaluated. Effect of different filler loading on waste plastic matrix was investigated. Composite (LFTP3) having appropriate ratios of fly ash and flame retardant showed reduced flammability with linear burning rate of 4.36 mm/minute and improved tensile strength of 9.68

MPa. Morphological and structural properties of all the composites were also investigated along with their flammability, resistance to different acids and bases and organic solvents, water absorption and mechanical strength. [ABSTRACT FROM AUTHOR]

Di, G., et al. (2013). "Phagocytosis and respiratory burst activity of haemocytes from the ivory snail, Babylonia areolata." Fish & Shellfish Immunology **35**(2): 366-374.

Haemocytes from the ivory snail, Babylonia areolata phagocytized Saccharomyces cerevisiae and Vibrio parahaemolyticus after 30 min. Haemocytes phagocytized V. parahaemolyticus at a greater rate than they phagocytized S. cerevisiae. The phagocytic rate (PP) of V. parahaemolyticus by granulocytes to was a little higher than that of S. cerevisiae. The phagocytic index (PI) of V. parahaemolyticus by granulocytes was significantly higher than that of S. cerevisiae. The same was true of hyalinocytes. The PP of granulocytes was significantly higher than that of hyalinocytes for each pathogen. No difference in PI was observed in granulocytes and hyalinocytes. Two defense mechanisms of B. areolata were quantified using flow cytometry. Haemocyte phagocytosis was quantified using fluorescent microbeads and respiratory burst activity was measured using H₂O₂ increases detected by 2', 7'-dichlorofluorescein diacetate. Both phagocytosis and respiratory burst activity of the haemocytes increased over time. After 90 min the phagocytic rate no longer increased. In the case of respiratory burst, the greatest increase in fluorescence occurred between 30 and 120 min, no further increase was seen after 120 min. These results showed unequivocally that a native (unstimulated) haemocyte oxidative burst was active in B. areolata. The aim of this study was to further the knowledge of immunology in gastropods.

Di, M., et al. (2019). "Corrigendum to "Pollution in drinking water source areas: Microplastics in the Danjiangkou Reservoir, China" [Environ. Toxicol. Pharmacol. 65 (January) 2019 82-89]." Environmental Toxicology & Pharmacology **66**: 133.

Di, M., et al. (2019). "Manuscript prepared for submission to environmental toxicology and pharmacology pollution in drinking water source areas: Microplastics in the Danjiangkou Reservoir, China." Environmental Toxicology & Pharmacology **65**: 82-89.

As the source of water for the South-to-North Water Diversion Project of China, the water quality of the Danjiangkou Reservoir (DJKR) is related to the safety of drinking water for billions of residents. Consequently, microplastics in surface water and sediment samples of the DJKR were investigated in this study. Microplastics were observed in all water and sediment samples with abundances varying from 467 to 15,017 n/m3 and 15 to 40 n/kg wet weight, respectively. Microplastics were rich in colour and dominated by fibrous items. Small-sized particles (< 2 mm) were more frequently observed than other sizes. Analysis by micro-Raman spectroscopy showed that polypropylene was the major polymer type. These systematic results demonstrated that the DJKR is suffering from the pollution of microplastics, which should be paid more attention based on its potential threat to the aquatic organisms and residents impacted by the drinking water source pollution. [ABSTRACT FROM AUTHOR]

Di, M. and J. Wang (2018). "Microplastics in surface waters and sediments of the Three Gorges Reservoir, China." Science of the Total Environment **616-617**: 1620-1627.

We investigated microplastic pollution levels in surface waters and sediments from the Three Gorges Reservoir (TGR). The TGR is the largest reservoir in China and is located across the Chongqing municipality and Hubei Province. Microplastic abundance in the surface water ranged from 1597 to 12,611n/m³ and in the sediments was 25 to 300n/kg wet weight (ww). In the surface waters, the contamination was more serious in urban areas, and in the sediments, countrysides were the most heavily polluted areas. Fibers were the most abundant microplastics, the dominant color was transparent, and small-sized particles were predominant. Of all the microplastics identified by micro-Raman spectroscopy, polystyrene was the most common type (38.5%) followed by polypropylene (29.4%) and polyethylene (21%). Compared with low-density microplastics, the high-density ones were more likely to be deposited from the water into the sediment. Several contaminants adsorbed by microplastics, such as organic solvents and pharmaceutical intermediates, were observed and qualitatively analyzed by Raman spectroscopy. The results of this study could provide valuable background information for microplastic pollution in the TGR.

Di Maio, F., et al. (2010). "The W2Plastics Project: Exploring the Limits of Polymer Separation." Open Waste Management Journal **3**: 90-98.

The efficient large-scale recycling of plastic waste is of increasing interest from an ecological and economic point of view but it represents a goal that has yet to be achieved by the recycling industry. The W2Plastics project aims at a fundamental change of the present status of plastics recycling by creating a breakthrough technology for the recycling of polyolefin's from complex wastes, i.e., wastes such as Waste from Electric and Electronic Equipment (W II), Construction and Demolition Waste (CDW), household waste and Automotive Shredder Residue (ASR). Polyolefin's are a very important family of polymers, constituting more than a third of the total plastics consumption in Europe (EU) and complex wastes provide the vastest, presently unused potential resource of secondary polyolefin's. In spite of that, Polyolefin's (PP, LDPE, HDPE) are the least recycled plastics materials. Only one million ton out of 14 million tons yearly sold in EU is being recycled. Nowadays, Polyolefin recyclers focus mainly on the relatively pure post-industrial or single-product wastes, since these wastes can be made into high-purity product materials by existing and cost-effective process technology. Post-industrial wastes are increasingly exported outside the EU, however, and so the Polyolefin recycling industry and their end-users are forced to look for alternative resources. In principle, post-consumer wastes, such as W II, CDW, household waste and ASR provide such a resource. They are a five to ten times larger reservoir of polyolefin's than do post-industrial wastes, but these wastes are also much more complex mixtures of materials and hence much more difficult to recycle. Technologies that are to address these resources need to be extremely powerful, since they must be relatively simple to be cost-effective, but also accurate enough to create high-purity products and able to valorise a substantial fraction of the materials that are present in the waste into useful products of consistent quality in order to be economical. The European FP7 Project: W2Plastics is developing a number of novel concepts, in particular Magnetic Density Separation (MDS) and

Ultrasound process and quality control by HyperSpectral Imaging (HSI), into a new technology to recover high-purity polyolefin's from complex wastes at low cost. The unique promise of this new concept derives from its ability to accurately separate many different materials in a single process step, resulting in an environmentally friendly and cheap process.

Di Maio, L., et al. (2018). "Data on thermal conductivity, water vapour permeability and water absorption of a cementitious mortar containing end-of-waste plastic aggregates." Data in Brief **18**: 1057-1063.

The data presented in this article are related to the research article entitled "Hygro-thermal and durability properties of a lightweight mortar made with foamed plastic waste aggregates" (Coppola et al., 2018) [1]. This article focuses the attention on thermal conductivity, water vapour permeability and water absorption of a lightweight cementitious mortar containing foamed end-of-waste plastic aggregates, produced via foam extrusion process [2]. Thermal conductivity, water vapour permeability and water absorption data are made available to allow comparison and/or extend the analysis. Experimental investigations showed that the presence of plastic aggregates decreased thermal conductivity, water vapour resistance and capillary water absorption.

Di Mauro, R., et al. (2017). "Abundant plankton-sized microplastic particles in shelf waters of the northern Gulf of Mexico." Environmental Pollution **230**: 798-809.

Accumulation of marine debris is a global problem that affects the oceans on multiple scales. The majority of floating marine debris is composed of microplastics: plastic particles up to 5 mm in diameter. With similar sizes and appearances to natural food items, these small fragments pose potential risks to many marine organisms including zooplankton and zooplanktivores. Semi-enclosed seas are reported to have high concentrations of microplastics, however, the distribution and concentration of microplastics in one such system, the Gulf of Mexico, remains unknown. Our study documented and characterized microplastics in continental shelf waters off the Louisiana coast in the northern Gulf of Mexico, using bongo nets, neuston nets, and Niskin bottles. Additionally, we compared the size distributions of microplastics and zooplankton collected using the nets. Plastics were manually sorted from the samples, documented, and measured using digital microscopy. Confirmation of putative plastics was carried out by hydrofluoric acid digestion and a subsample was analyzed using FTIR microscopy. Estimated concentrations of microplastics collected on the inner continental shelf during this study are among the highest reported globally. Total microplastic concentrations ranged from 4.8 to 8.2 particles m⁻³ and 5.0-18.4 particles m⁻³ for the bongo and neuston samples, respectively. Niskin bottles collected smaller plastic particles than the nets and indicated total microplastic concentrations (primarily fibers) from 6.0E4 - 15.7E4 particles m⁻³. Microplastic concentrations were greater than the abundances of all but four of the five most abundant taxa from bongo nets and were not statistically different from the abundances of any of the most numerous taxa from neuston nets. Sizes of microplastics and zooplankton partially or completely overlapped, suggesting the potential for confusion with natural prey. Copyright © 2017 Elsevier Ltd

Dias, B. F. d. S. Marine debris: understanding, preventing and mitigating the significant adverse impacts on marine and coastal biodiversity. CBD Technical Series; 2016. (83):78 pp. many ref. Montreal, Convention on Biological Diversity.

This document provides an update to the review of the impacts of marine debris that was previously undertaken by the Scientific and Technical Advisory Panel of the GEF (GEF-STAP) in

collaboration with the Secretariat of the Convention on Biological Diversity (SCBD), and published as CBD Technical Series 67 in 2012. This document follows a similar format and should be referred to in combination with the aforementioned document. The first chapter of this document reviews the state of knowledge of the various impacts of marine debris on marine and coastal biodiversity. It provides an update of the total number of species known to be affected by marine debris, which is now almost 800 (including effects of ghost fishing reported in recent years). The proportion of cetacean and seabird species affected by marine debris ingestion has risen substantially to 40 and 44%, respectively. The latest research on the physical and toxicological effects of microplastic is summarized along with evidence of trophic transfer in planktonic food chains in the laboratory and direct uptake of microplastics by invertebrates in the marine environment. Results of studies of plastic marine debris as a novel habitat for unique microbial communities and a potential vector for disease are also provided. The report also addresses the ability of large macrodebris items to transport invasive alien species across oceans, based on evidence from recent records of tsunami debris stranding along the west coast of North America. The impacts of lost, abandoned or discarded fishing gear on marine biodiversity, including long-term effects of ghost fishing and habitat degradation mainly from plastic-based gear, are also discussed. Recent estimates of the socioeconomic costs of marine debris are also provided to complement the information available in CBD Technical Series 67. The second chapter provides a review of policy options and approaches that are in place or have been proposed to address the impacts of marine debris. This includes a summary of the latest research to monitor and model the distribution and abundance of debris in the marine environment. The responses of management and regulatory bodies at the global or regional level indicate that the issue of marine debris is gaining recognition as a significant ecological and socioeconomic problem that may also have implications for human health. Different types of policy approaches and research needs to tackle predominantly land-based sources of marine debris are described. These include, among others: (i) packaging and plastics reduction; (ii) improved product and packaging design; (iii) potential use of waste as a resource; (iv) deposit return programmes; (v) economic instruments such as fees for single-use items; (vi) regulatory measures to prevent marine debris; (vii) bans for certain items (e.g., plastic bags, microbeads); (viii) engaging with industry and corporations on sustainability, including plastics disclosure policies; and (ix) support for innovation in new materials, manufacturing, recycling and product design using alternatives.

Dias, B. Z., et al. (2017). "PHYSICAL, MECHANICAL AND FIRE PROPERTIES OF THERMOPLASTIC COMPOSITES PRODUCED FROM RECYCLED PLASTIC MATRICES AND FILLED WITH LIGNOCELLULOSIC RESIDUES: A REVIEW." The Journal of Solid Waste Technology and Management(2).

Recycled plastic matrices and lignocellulosic residues are currently used to produce thermoplastic composites on a commercial scale. Nevertheless, some of the effects of these residues are unknown or not completely understood. Thus, the aim of this study was to investigate the effects of using recycled plastic matrices and incorporating lignocellulosic residues into thermoplastic composites on their mechanical properties, water absorption, discolouration, oxidation and flammability. The method used consisted of a review of scientific papers, prioritising studies published after the year 2000. Papers were grouped by the type of composite analysed (produced from recycled plastic matrices and filled with lignocellulosic residues) as well as the properties studied. The analysed studies indicate that plastic waste is a promising source of raw material for thermoplastic composite production as it imparts with respect to several properties (such as flexural and tensile strength and stability against discoloration) the same performance achieved by virgin plastic-based composites. On the other

hand, increasing the composites' lignocellulosic filler content tends to improve their stability against oxidation, for example, but appears to decrease their time to ignition, which in turn is of major interest because such materials are currently used as building components.

Dickinson, C. H. and D. Parkinson (1970). "Effects of mechanical shaking and water tension on survival and distribution of fungal inoculum in glass microbead media." Canadian Journal of Microbiology **16**(7): 549-552.

Dickson, A., et al. (2017). "Fluorescence imaging of cambial zones to study wood formation in Pinus radiata D. Don." Trees: Structure and Function **31**(2): 479-490.
Stem microcores from fast-growing trees, such as Pinus radiata (D. Don) with wide zones of cambium and differentiating xylem and very wide growth rings, pose a challenge for microscopy, as they are difficult to handle and easily damaged compared to slower growing species. A novel procedure has been developed which captures high-resolution images directly from the block face of large samples embedded in plastic resin without the need for sectioning or staining. Microcores of differentiating xylem of P. radiata growing in the central North Island of New Zealand were embedded in a low viscosity acrylic resin. The surface of the entire resin block was abraded and polished to expose cross sections of the wide zone of wood formation in these fast-growing trees without damage or distortion. Autofluorescence imaging was performed using a confocal laser scanning microscope. This avoided the need for staining and allowed the determination of the beginning of lignification based on lignin autofluorescence. Image analysis was used to determine the widths of: (a) the cambium, cell expansion, and wall-thickening zone (CET) and (b) the wall lignification zone (LT). A fast-growing tree had wider CET and LT zones than a slow-growing tree. This was due to the fast-growing tree producing more tracheids than the slow-growing tree, rather than by the production of larger tracheids.

Diepens, N. J. and A. A. Koelmans (2018). "Accumulation of Plastic Debris and Associated Contaminants in Aquatic Food Webs." Environmental Science & Technology **52**(15): 8510-8520.
We present a generic theoretical model (MICROWEB) that simulates the transfer of microplastics and hydrophobic organic chemicals (HOC) in food webs. We implemented the model for an Arctic case comprised of nine species including Atlantic cod and polar bear as top predator. We used the model to examine the effect of plastic ingestion on trophic transfer of microplastics and persistent HOCs (PCBs) and metabolizable HOCs (PAHs), spanning a wide range of hydrophobicities. In a scenario where HOCs in plastic and water are in equilibrium, PCBs biomagnify less when more microplastic is ingested, because PCBs biomagnify less well from ingested plastic than from regular food. In contrast, PAHs biomagnify more when more microplastic is ingested, because plastic reduces the fraction of PAHs available for metabolization. We also explore nonequilibrium scenarios representative of additives that are leaching out, as well as sorbing HOCs, quantitatively showing how the above trends are strengthened and weakened, respectively. The observed patterns were not very sensitive to modifications in the structure of the food web. The model can be used as a tool to assess prospective risks of exposure to microplastics and complex HOC mixtures for any food web, including those with relevance for human health.

Dierkes, G., et al. (2019). "Quantification of microplastics in environmental samples via pressurized liquid extraction and pyrolysis-gas chromatography." Analytical & Bioanalytical Chemistry **411**(26): 6959-6968.
The quantification of microplastics (MP) in environmental samples is currently a challenging

task. To enable low quantification limits, an analytical method has been developed combining pressurized liquid extraction (PLE) and pyrolysis GC-MS. The automated extraction includes a pre-extraction step via methanol followed by a subsequent PLE using tetrahydrofuran. For the most frequently used synthetic polymers polyethylene (PE), polypropylene (PP), and polystyrene (PS), limits of quantification were achieved down to 0.007 mg/g. Recoveries above 80% were attained for solid matrices such as soil and sediments. The developed method was applied for MP quantification in environmental samples such as sediment, suspended matter, soil, and sewage sludge. In all these matrices, PE and PP were detected with concentrations ranging from 0.03 to 3.3 mg/g. In sewage sludge samples, all three polymers were present with concentration levels ranging between 0.08 +/- 0.02 mg/g (PP) and 3.3 +/- 0.3 mg/g (PE). However, especially for solid samples, the analysis of triplicates revealed elevated statistical uncertainties due to the inhomogeneous distribution of MP particles. Thus, care has to be taken when milling and homogenizing the samples due to the formation of agglomerates. Graphical abstract.

Digka, N., et al. (2018). "Microplastics in mussels and fish from the Northern Ionian Sea." Marine Pollution Bulletin **135**: 30-40.

Microplastic ingestion by marine organisms presents an emerging threat to marine ecosystems; microplastics in different marine species are currently reported worldwide. This study aims to assess microplastic ingestion in four, highly commercial, marine species from Greek waters in the Northern Ionian Sea (Mediterranean Sea). Microplastics were found in mussels (Mytilus galloprovincialis) and all three fish species (Sardina pilchardus, Pagellus erythrinus, Mullus barbatus) examined. The frequency of occurrence of ingested microplastics was 46.25% in mussels, while among fish species, S. pilchardus showed the highest frequency of microplastic ingestion (47.2%). Microplastic abundance ranged from 1.7-2 items/individual in mussels and from 1.5-1.9 items/individual in fish. The majority of ingested microplastics were fragments, while their color and size varied. Fourier Transform Infrared Spectroscopy (FT-IR) indicated polyethylene as the most common polymer type in mussels and fish. Results can be used to set baseline levels for the assessment of microplastic pollution in the Ionian Sea.

Dignum, H. M., et al. (2004). "Quantification of CD38 expression in B-cell chronic lymphocytic leukemia (B-CLL): a comparison between antibody binding capacity (ABC) and relative median fluorescence (RMF)." Leukemia & Lymphoma **45**(6): 1167-1173.

We have previously shown that quantification of CD38 expression using microbeads of specific antibody binding capacity (ABC) improves the prognostic value of CD38 expression in B-cell chronic lymphocytic leukemia, particularly for Binet Stage A patients. Quantification of CD38 expression using beads is expensive, time consuming and could be difficult to implement in a routine clinical laboratory. The calculation of relative median fluorescence (RMF) using the median fluorescence intensities of the test and control samples, is even more simply and cheaply obtained by flow cytometry and could be used as an alternative way of quantifying antigen expression. The present study demonstrates that RMF is an effective prognostic indicator in B-CLL that correlates closely with ABC in predicting disease-specific survival and time to progression for all patients. RMF predicted overall survival and time to progression in all patients (P < 0.0001 for both), in Binet Stage A patients (P < 0.0001 for both) and in Stage A patients under 60 years (P = 0.0299 and P = 0.0143, respectively). ABC predicted overall survival and time to progression in all patients (P < 0.0001 for both) in Stage A patients (P = 0.0024 and P < 0.0001, respectively) and in Stage A patients under 60 (P = 0.0379 and P = 0.0032, respectively). RMF is more effective than percentage CD38 positivity > 30% or > 20% in predicting disease-specific survival in Stage A patients of all ages (CD38 < > 30%: P = 0.0853, CD38 < > 20%: P = 0.0894) and in those under 60 years old (CD38 < > 30%: P = 0.5438, CD38 < > 20%: P = 0.2872). Also, RMF is more effective in predicting time to progression of Binet Stage A patients less than 60 years (P = 0.0143), while percentage CD38 positivity of 30%, 20% or 7% did not achieve statistical significance (P = 0.1103, = 0.0547, = 0.3399, respectively). We suggest that CD38 RMF could be used clinically as an alternative to ABC to identify patients with B-CLL that are likely to progress and require early treatment.

Dikareva, N. and K. S. Simon (2019). "Microplastic pollution in streams spanning an urbanisation gradient." Environmental Pollution **250**: 292-299.

Microplastic pollution has received considerable attention in marine systems, but recent work shows substantial plastic pollution also occurs in freshwater ecosystems. Most freshwater research has focused on large rivers and lakes, but small streams are the primary interface between land, where plastic is used, and drainage networks. We examined variation in the amount and form of plastic occurring in small streams spanning an urbanisation gradient. All streams contained microplastics with concentrations similar to that found in larger systems (up to 303 particles m^{-3} in water and 80 particles kg^{-1} in sediment). The most abundant types were fragments and small particles (63–500 µm). Chemical types of plastic were quite variable and often not predictable based on size, form and colour. Variation in microplastic abundance across streams was high, but only partially explained by catchment scale parameters. There was no relationship between human population density or combined stormwater overflows and microplastic abundance. Residential land cover was related to microplastic abundance, but explanatory power was low. Our results suggest local-scale factors may be more important than catchment-scale processes in determining microplastic pollution in small streams. Image 1 • Sediments and water of urban streams were assessed for microplastic pollution. • Level of contamination of small streams is comparable to large rivers. • Catchment scale parameters can partially explain patterns of spatial distribution. • Local-scale processes might be important factors at predicting microplastic pollution. Small urban streams deliver microplastics from land to the sea at the level comparable with large rivers but factors that contribute the most to the pollution are not evident. [ABSTRACT FROM AUTHOR]

Dilek, Y., et al. (2016). "The detection of circulating tumor cells (CTCs) in patients with colorectal cancer by flow cytometry." FEBS Journal **283 (Supplement 1)**: 300.

Colorectal cancer (CRC) is one of the leading causes of mortality worldwide. Metastasis is associated with the presence of circulating tumor cells (CTCs) in the peripheral blood of cancer patients. CTC cut-off values have been shown to predict for poorer overall survival in metastatic breast (>=5), prostate (>=5), and colorectal (>=3) cancer based on assessment of 7.5 ml of blood. In our study, CTCs were detected in blood samples of colorectal cancer patients, using with our modified convenient method for the strategies of CTC enrichment and detection. 7.5 mL peripheral blood samples were firstly collected and peripheral blood mononuclear cells (PBMCs) were isolated from the fresh blood samples by ficoll gradient separation. Next, the leukocytes in PBMCs were removed by magnetic microbeads conjugated with CD45 for a negative selection. Finally, the retained cells were labeled with anti-epithelial cell adhesion molecule (anti-EpCAM), cytokeratins (CK8, CK19) and the leukocyte-specific marker as anti-CD45. All samples were analyzed by BD FACS Aria III flow cytometry. In total, 10 patients and 7 healthy people were included in this study. The results showed that CTCs were not detected in the blood samples of healhty volunteers, but 3-13 CTCs were detected with CK14, 15, 16, 19-based gating strategy in the blood samples of colorectal cancer patients. It is accepted that the cut off value is 3 CTCs for colorectal cancer and CTC is negative if it is below this value or CTC is considered as a positive, if it is equal to or above this value, which might be an indication for poor prognosis. Thus CTC's detection may serve a representative surrogate tumor biomarker for real-time monitoring of disease status and tailoring personalized therapy.

Dilkes-Hoffman, L., et al. (2019). "Public attitudes towards bioplastics – knowledge, perception and end-of-life management." Resources, Conservation & Recycling **151**: N.PAG-N.PAG.

• The general public's knowledge of bioplastics is low. • However, the perception, particularly of biodegradable plastics, is positive. • Biodegradable plastics are rated as better for the environment than normal plastics and easily recyclable plastics. • The majority of respondents would dispose of biodegradable plastics in the recycling bin. • Potential issues associated with the introduction of bioplastics are discussed. The aim of this research was to understand current knowledge and perceptions regarding bioplastics. Results were gathered through an online survey of 2518 nationally representative Australians. The results indicate that the Australian public's knowledge of bioplastics is low, but perception, particularly of biodegradable plastics, is positive. Biodegradable plastics were perceived as better for the environment than 'normal plastics' and even 'easily recyclable' plastics. The majority of respondents (58%) said they were unsure whether biodegradable plastics can have negative environmental impacts. Sixty-eight percent of people say they would like to see more of the plastic items they use be biodegradable. If this becomes the case, there will be an increased stream of bioplastics entering the recycling system with 62% of people saying they would dispose of bioplastic items in the recycling bin. In light of the results presented in this work, potential issues relating to the introduction of bioplastics are raised and the role that governments and local councils can play in driving the development of the standards, labelling and waste management options that will need to be introduced alongside the introduction of wider bioplastic materials use are discussed. [ABSTRACT FROM AUTHOR]

Dilkes-Hoffman, L. S., et al. (2019). "Public attitudes towards plastics." Resources, Conservation and Recycling **147**: 227-235.

Understanding and engaging the public is key for ensuring the success of government and industry initiatives aimed at addressing the problem of plastic waste. However, there has been little focus on documenting the general public's attitudes towards plastics. This study examines public beliefs and attitudes towards plastics in Australia and provides insight on a global level. The research was conducted using an online survey of a nationally representative sample (2518 respondents). Overall, the survey results indicate that the public view plastics as a serious environmental issue. Plastic in the ocean had the highest mean rating for seriousness out of nine environmental issues, followed by two other issues relating to plastic waste production and

disposal. Whilst there was an association of plastics with food packaging and convenience, there was more of a negative association with the use of plastic overall. Eighty percent of respondents indicated a desire to reduce plastic use and the majority of respondents believe that paper and glass are more environmentally friendly packaging materials than plastics. However, the results showed that many respondents do not translate their aspiration to reduce plastic use into action. Overall, while a majority of the Australian public are concerned about plastics as an environmental issue, they place the bulk of the responsibility for reducing the use of disposable plastic on industry and government. DiMinno, G., et al. (1986). "A myeloma paraprotein with specificity for platelet glycoprotein IIIa in a patient with a fatal bleeding disorder." Journal of Clinical Investigation **77**(1): 157-164.

Impaired platelet aggregation, normal shape change, and agglutination and normal ATP secretion and thromboxane synthesis in response to high concentrations of thrombin or arachidonic acid were found in a patient with multiple myeloma and hemorrhagic tendency. The purified IgG1 kappa or its F(ab1)2 fragments induced similar changes when added in vitro to platelet-rich plasma from normal subjects. In addition, the paraprotein inhibited adhesion to glass microbeads, fibrin clot retraction, and binding of radiolabeled fibrinogen or von Willebrand factor to platelets exposed to thrombin or arachidonic acid without affecting intraplatelet levels of cAMP. The radiolabeled para-protein bound to an average of 35,000 sites on normal platelets but it bound to less than 2,000 sites on the platelets from a patient with Glanzmann's thrombasthenia. Immunoprecipitation studies showed that the platelet antigen identified by the paraprotein was the glycoprotein IIIa. Furthermore, binding of radiolabeled prostaglandin E1 (PGE1) to resting platelets as well as binding of von Willebrand factor to platelets stimulated with ristocetin were entirely normal in the presence of patient's inhibitor. These studies indicate that bleeding occurring in dysproteinemia may be the result of a specific interaction of monoclonal paraproteins with platelets. In addition, our data support the concept that the interaction of fibrinogen and/or von Willebrand factor with the platelet glycoprotein IIb-IIIa complex is essential for effective hemostasis.

Dimitrakakis, E., et al. (2009). "Determination of heavy metals and halogens in plastics from electric and electronic waste." Waste Management **29**(10): 2700-2706.

Abstract: The presence of hazardous substances and preparations in small waste electrical and electronic equipment (sWEEE) found in the residual household waste stream of the city of Dresden, Germany has been investigated. The content of sWEEE plastics in heavy metals and halogens is determined using handheld X-ray fluorescence analysis (HXRF), elemental analysis by means of atomic absorption spectrometry (AAS) and ion exchange chromatography (IEC). Mean value of results for heavy metals in samples (n =51) by AAS are 17.4mg/kg for Pb, 5.7mg/kg for Cd, 8.4mg/kg for Cr. The mass fraction of an additive as shown by HXRF (n =161) can vary over a wide range. Precise deductions as regards sWEEE plastics content in hazardous substances and preparations cannot be made. Additional research would be expedient regarding the influence of hazardous substances to recycling processes, in particular regarding the contamination of clean fractions in the exit streams of a WEEE treatment plant. Suitable standards for calibrating HXRF for use on EEE plastics or complex electr(on)ic components do not exist and should be developed. [Copyright &y& Elsevier]

Ding, J., et al. (2019). "Microplastics in the Coral Reef Systems from Xisha Islands of South China Sea." Environmental Science & Technology **53**(14): 8036.

The impacts of microplastics on coral reefs are gaining attention due to findings that microplastics affect coral health. This work investigated the distribution and characteristics of microplastics in the seawater, fish, and corals in 3 atolls from the Xisha Islands of South China Sea. In the seawater samples, microplastics were detected in the outer reef slopes, reef flats, and lagoons with abundances ranging from 0.2 to 11.2, 1.0 to 12.2, and 1.0 to 45.2 items L–1, respectively. Microplastic abundance was 0–12.0 items individual–1 (0–4.7 items g–1) in fish and 1.0–44.0 items individual–1(0.02–1.3 items g–1) in coral. The predominant shape and polymer of microplastics in seawater, fish, and coral were fibrous rayon and polyethylene terephthalate (PET). Microplastic sizes primarily ranged from 20–330 μm in both the seawater and fish, while there were relatively more 1–5 mm microplastics in the corals. The shape, size, color, and polymer type distribution patterns of microplastics in seawater more closely resembled those in fish gills than those in fish gastrointestinal tracts or coral samples. This study shows that microplastics are abundant in these coral reef systems and they are captured by fish or "trapped" by corals.

Ding, J., et al. (2018). "Accumulation, tissue distribution, and biochemical effects of polystyrene microplastics in the freshwater fish red tilapia (Oreochromis niloticus)." Environmental Pollution **238**: 1-9.

While the presence of microplastics (MPs) in marine environments has been detected worldwide, the importance of MPs pollution in freshwater environments has also been emphasized in recent years. However, the body of knowledge regarding the biological effects of MPs on freshwater organisms is still much more limited than on marine organisms. The aim of the present study was to evaluate the accumulation and tissue distribution of MPs in the freshwater fish red tilapia (Oreochromis niloticus), as well as the biochemical effects of MPs on O. niloticus. During 14 days of exposure to 0.1 micro m polystyrene-MPs at concentrations of 1, 10, and 100 micro g L⁻¹, the MPs concentrations in various tissues of O. niloticus generally increased over time following the order gut > gills > liver ~ brain. Moreover, the acetylcholinesterase (AChE) activity in the fish brain was inhibited by MPs exposure, with a maximum inhibition rate of 37.7%, suggesting the potential neurotoxicity of MPs to freshwater fish. The activities of cytochrome P450 (CYP) enzymes [7-ethoxyresorufin O-deethylase (EROD) and 7-benzyloxy-4-trifluoromethyl-coumarin O-dibenzyloxylase (BFCOD)] in the fish liver exhibited clear temporal variabilities, with significant decreases followed by elevations compared to the control. The alterations of the EROD and BFCOD activities indicate the potential involvement of CYP enzymes for the metabolism of MPs. The activity of antioxidative enzyme superoxide dismutase (SOD) in the liver was significantly induced throughout the exposure period, while the malondialdehyde (MDA) content did not vary with MPs exposure, suggesting that the antioxidative enzymatic system in O. niloticus could prevent oxidative damage. These results highlight the ingestion and accumulation of MPs in different tissues of freshwater fish, which lead to perturbations in fish biological systems and should be considered in environmental risk assessment.

Ding, L., et al. (2019). "Microplastics in surface waters and sediments of the Wei River, in the northwest of China." Science of the Total Environment **667**: 427-434.

Microplastic pollution is an increasingly important environment problem. Many studies show the occurrence of microplastics in our environmental system. However, the freshwater system is less understood, especially in northwest China. We investigated the occurrence and characteristics of microplastics in the Wei River Basin, which is located in northwestern China. The Wei River is the largest tributary of the Yellow River and runs through three major provinces. In the Wei River, the concentration of microplastics in the surface waters varied from 3.67 to 10.7 items /L and in the sediments, the abundance of microplastics varied from 360 to 1320 items/kg. Fiber (50.1%)was the dominant types in water samples and sediments. The small size (<0.5mm)(68.1%)were the main size of microplastics in Wei River. The types of microplastics were polyethylene, Polyvinyl chloride and polystyrene, as identified using a Fourier transform infrared spectrometer. This study could be a valuable reference for better understanding the microplastics pollution in inland northwestern China.

Ding, X., et al. (2005). "Inducible nitric oxide synthase-dependent DNA damage in mouse model of inflammatory bowel disease." Cancer science **96**(3): 157-163.

Increased cancer risk occurs in inflammatory bowel disease (IBD) undergoing long-term chronic inflammation. To evaluate whether inducible nitric oxide synthase (iNOS)-dependent DNA damage plays a role in the carcinogenic process triggered by IBD, we prepared a mouse model of IBD induced by transfer of CD45RBhighCD4+ T cells lacking regulatory T cells to female severe combined immunodeficiency (SCID) mice. CD45RBhighCD4+ T cells were isolated from mouse spleen after staining with fluorescein isothiocyanate (FITC)-conjugated anti-CD45RB monoclonal antibody, followed by anti-FITC-conjugated microbeads. This IBD mouse model showed that the bodyweight increased with aging to a lesser extent than non-treated controls, and that the intestine was shortened. Pathological findings of this mouse model, which showed severe inflammation in colon tissues, were similar to IBD patients. Double immunofluorescence technique revealed that both 8-nitroguanine and 8-oxo-7,8-dihydro-2'-deoxyguanosine (8-oxodG) were formed mainly in epithelial cells of the IBD mouse model. 8-Nitroguanine was formed in most of 8-oxodG-immunoreactive nuclei of epithelial cells. iNOS, proliferating cell nuclear antigen and p53 protein were also expressed in the colon epithelium. These results indicate that nitrative DNA damage, as well as oxidative DNA damage, is induced in colon epithelial cells of the IBD mouse model followed by proliferation of these cells, which may contribute to colon carcinogenesis.

Ding, X., et al. (2004). "Fabrication of microarrays on fused silica plates using the laser-induced backside wet etching method." Langmuir **20**(22): 9769-9774.

A novel approach in the fabrication of microarrays of dye and protein on fused silica plates using the laser-induced backside wet etching (LIBWE) technique is described. The surface of fused silica plates was initially precoated using trimethoxysilane self-assembled monolayers (SAMs) and then etched using the LIBWE method to obtain the desired microstructures on the plate surface. Using this technique, the SAMs on the nonirradiated areas were able to survive the LIBWE process and were used as templates for the subsequent deposition of dye molecules or proteins via chemical bonding or physical adsorption. In the case of fused silica plates precoated with fluorinated SAMs, the LIBWE method is used to remove the SAMs to expose the etched silica surfaces, on which a thin layer of pyranine molecules can be site-selectively deposited using an aqueous solution of pyranine. In another application, an ethanol solution of rhodamine 6G was preferentially deposited onto the nonirradiated areas. In yet another application, bovine serum albumin was preferentially deposited onto the laser-irradiated areas; in this case, the fused silica plates were precoated with poly(ethylene oxide) SAMs. Interestingly, when an aqueous suspension of polystyrene (PS) microbeads was cast onto the fused silica precoated with the fluorinated SAMs, hexagonally close-packed PS microbeads were deposited into the etched cavities. Depositions of the dye, protein, and microbeads were confirmed by visualization using a fluorescence microscope and scanning electron microscope.

Ding, Y., et al. (2019). "Numerical prediction of the short-term trajectory of microplastic particles in Laizhou Bay." Water **11**(11).

Microplastic particles are easily captured by microorganisms and enter the food chain, which poses a threat to ecological health. These particles are abundant in coastal areas because of the influence of anthropic activities and the interaction between the sea and land. Although much research on microplastics has been done, predicting the transportation of microplastic particles in coastal zones is still a challenge. In this paper, the trajectories of microplastic particles released from four river mouths around Laizhou Bay are investigated using the lattice Boltzmann method coupled with the Lagrangian particle-tracking method, involving inter-particle and particle-wall collisions. The trajectories of particles released from four river mouths are recorded within 30 days.

Dini, C., et al. (2014). "Characterization and stability analysis of biopolymeric matrices designed for phage-controlled release." Applied Biochemistry & Biotechnology **174**(6): 2031-2047.

Alginate and low methoxylated pectin gel matrices emulsified with oleic acid were studied for phage oral delivery. Matrix structural analysis revealed that emulsified pectin (EP) gel microbeads were harder and more cohesive than those of emulsified alginate (EA). EP showed high swelling capacity and slower matrix degradation in aqueous media, suggesting that oleic acid is mainly located on the surface of EP microbeads. EA and EP matrices having p-nitrophenyl palmitate (C-16 ester) as tracer dissolved into oleic acid and in the presence of lipase confirmed this hypothesis which is consistent with EP better phage protective capability. Surface analysis of gel microbeads by scanning electron microscopy revealed strong differences between EP and EA gel microbeads. Phage release kinetics was tested using semi-empirical mathematical models. Experimental curve best fitted the Korsmeyer-Peppas model, predicting transport mechanisms according to the high swelling and degradation of EP. The proposed encapsulation model represents an innovative technology for phage therapy, which can be extrapolated to other therapeutic purposes, using a simple environmentally friendly synthesis procedure and cheap food-grade raw materials.

Dinsdale, R. M. and M. Almemark (1999). "Composition and biodegradability of products of wet air oxidation of polyester." Environmental Science & Technology **33**(22): 4092.

Examines the composition and biodegradability of products of wet air oxidation (WAO) of polyester. Concepts on the chemical and biological systems to treat polluting organic compounds; Use of the WAO system in the treatment of waste and prevent air pollution; Legislations and increasing environmental concerns on plastic recycling.

Dinter, F., et al. (2019). "Simultaneous detection and quantification of DNA and protein biomarkers in spectrum of cardiovascular diseases in a microfluidic microbead chip." Analytical & Bioanalytical Chemistry **411**(29): 7725-7735.

The rapid and simultaneous detection of DNA and protein biomarkers is necessary to detect the outbreak of a disease or to monitor a disease. For example, cardiovascular diseases are a major cause of adult mortality worldwide. We have developed a rapidly adaptable platform to assess biomarkers using a microfluidic technology. Our model mimics autoantibodies against three

proteins, C-reactive protein (CRP), brain natriuretic peptide (BNP), and low-density lipoprotein (LDL). Cell-free mitochondrial DNA (cfmDNA) and DNA controls are detected via fluorescence probes. The biomarkers are covalently bound on the surface of size- (11-15 mum) and dual-color encoded microbeads and immobilized as planar layer in a microfluidic chip flow cell. Binding events of target molecules were analyzed by fluorescence measurements with a fully automatized fluorescence microscope (end-point and real-time) developed in house. The model system was optimized for buffers and immobilization strategies of the microbeads to enable the simultaneous detection of protein and DNA biomarkers. All prime target molecules (anti-CRP, anti-BNP, anti-LDL, cfmDNA) and the controls were successfully detected both in independent reactions and simultaneously. In addition, the biomarkers could also be detected in spiked human serum in a similar way as in the optimized buffer system. The detection limit specified by the manufacturer is reduced by at least a factor of five for each biomarker as a result of the antibody detection and kinetic experiments indicate that nearly 50 % of the fluorescence intensity is achieved within 7 min. For rapid data inspection, we have developed the open source software digilogger, which can be applied for data evaluation and visualization. Graphical abstract.

Diogene, J., et al. (2015). "Special Issue: Non-regulated environmental contaminants in seafood: contributions of the ECsafeSEAFOOD EU project. (Special Issue: Non-regulated environmental contaminants in seafood: contributions of the ECsafeSEAFOOD EU project.)." Environmental Research **143**(Part B): 1-137.

This special issue contains 15 articles focusing on marine environmental contamination; consumers' health risk-benefit perception of seafood and attitude toward the marine environment; environmental contaminants of emerging concern in seafood; a critical view on microplastic quantification in aquatic organisms; occurrence of pharmaceuticals and endocrine disrupting compounds in macroalgaes, bivalves, and fish from coastal areas in Europe; toxic elements and speciation in seafood samples from different contaminated sites in Europe; Ostreopsis cf. ovata dynamics in the NW Mediterranean Sea in relation to biotic and abiotic factors; contribution to the risk characterization of ciguatoxins; integrated risk index for seafood contaminants (IRISC); exposure of the population of Catalonia (Spain) to musk fragrances through seafood consumption; benefits and risks associated with consumption of raw, cooked, and canned tuna (Thunnus spp.) based on the bioaccessibility of selenium and methylmercury.

Dionne, S., et al. (2017). "The effect of vitamin D on macrophage function and polarization in Crohn's disease." Journal of Crohn's and Colitis **11 (Supplement 1)**: S119-S120.

Background: Defective bacterial clearance by macrophages is be-lieved to play an important role in Crohn's disease (CD). Phenotypes of macrophages include inflammatory M1 and anti-inflammatory M2. Vitamin D has been shown to reduce colitis severity but the mechanisms remain unclear. The effect of Vitamin D on M1 and M2 macrophages in IBD has not been investigated. The aim was to identify possible differences in M1 and M2 macrophages between CD patients and controls and to determine the effect of 1,25 vit D on macrophage function and phenotype markers. Method(s): PBMC were isolated from peripheral blood of 45 CD patients and 33 controls not taking vitamin D supplements. REB approval and patient consent was obtained. Monocytes were isolated using CD14 microbeads. M1 and M2 type macrophages were generated by culturing of monocytes in the presence of GM-CSF and M-CSF, respectively. Cytokines were determined by ELISA following stimulation with 100 ng/ml LPS. Phagocytosis was determined by measuring the uptake of FITC-latex beads using flow cytometry. Chemotaxis assays were performed in transwell plates. Expression of M1 and M2 markers was determined by qPCR. Result(s): No difference in chemotaxis or phagocytosis was observed in CD macrophages compared to controls. M2 displayed greater phagocytic activity than M1 (94.6% vs 80.3%). Phagocytosis was not altered after treatment with 1,25D. M1 migrated in slightly higher numbers toward CCL2 and fMLP compared to M2. Vit D slightly increased migration of both types toward fMLP (+18-26%). LPS-induced production of TNFalpha, IL-12p40 and IL-10 was comparable between macrophages in CD and controls. M1 produced higher amounts of IL-12p40 and TNFalpha compared to M2 (p<0.0005 and p<0.05, respectively) whereas IL-10 production was greater in M2 (1566 vs 152 pg/ml, p<0.005). Preincubation with 1,25D greatly decreased IL-12p40 production by M1 (-64.9%, p<0.0005) as well as that by M2 (-100%, p<0.05). 1,25D also decreased TNFalpha production by M1 (-49.6%, p<0.05) and IL-10 by M2 (-28.2%, p<0.05). M2 macrophages preferentially express F13A1, PTGS2, CD163, CXCL10, CD14 and MMP2, whereas TGFbeta, CCL1 and CYP27B1 expression was higher in M1. Marker expression was similar between CD and control macrophages. M1 and M2 markers were not differentially modulated by vit D. Conclusion(s): Peripheral blood derived macrophage chemotaxis and phagocytosis in CD is similar to those from controls. The main effect of 1,25D was to markedly decrease pro-inflammatory cytokine pro-duction from M1 macrophages. However, 1,25D did not modulate macrophage polarization to the anti-inflammatory M2 phenotype. This study was supported by a grant from the Dairy Farmers of Canada.

DiPaolo, B. C., et al. (2010). "Stretch magnitude and frequency-dependent actin cytoskeleton remodeling in alveolar epithelia." American Journal of Physiology - Cell Physiology **299**(2): C345-353.

Alveolar epithelial cells (AEC) maintain integrity of the blood-gas barrier with gasket-like intercellular tight junctions (TJ) that are anchored internally to the actin cytoskeleton. We hypothesize that stretch rapidly reorganizes actin (<10 min) into a perijunctional actin ring (PJAR) in a manner that is dependent on magnitude and frequency of the stretch, accompanied by spontaneous movement of actin-anchored receptors at the plasma membrane. Primary AEC monolayers were stretched biaxially to create a change in surface area (DeltaSA) of 12%, 25%, or 37% in a cyclic manner at 0.25 Hz for up to 60 min, or held tonic at 25% DeltaSA for up to 60 min, or left unstretched. By 10 min of stretch PJARs were evident in 25% and 37% DeltaSA at 0.25 Hz, but not for 12% DeltaSA at 0.25 Hz, or at tonic 25% DeltaSA, or with no stretch. Treatment with 1 muM jasplakinolide abolished stretch-induced PJAR formation, however. As a rough index of remodeling rate, we measured spontaneous motions of 5-mum microbeads bound to actin focal adhesion complexes on the apical membrane surfaces; within 1 min of exposure to DeltaSA of 25% and 37%, these motions increased substantially, increased with increasing stretch frequency, and were consistent with our mechanistic hypothesis. With a tonic stretch, however, the spontaneous motion of microbeads attenuated back to unstretched levels, whereas PJAR remained unchanged. Stretch did not increase spontaneous microbead motion in human alveolar epithelial adenocarcinoma A549 monolayers, confirming that this actin remodeling response to stretch was a cell-type specific response. In summary, stretch of primary rat AEC monolayers forms PJARs and rapidly reorganized actin binding sites at the plasma membrane in a manner dependent on stretch magnitude and frequency.

Dipper, A., et al. (2018). "Reducing plastic waste, carbon footprint and cost: Inhaler recycling at Musgrove Park Hospital." European Respiratory Journal. Conference: European Respiratory Society International Congress, ERS **52**(Supplement 62).

Background: Wasted medication costs the NHS 300 million per year (Trueman, P et al. Evaluation of the Scale, Causes and Costs of Waste Medicines. YHEC/School of Pharmacy, University of London. 2010). As potent greenhouse gases, hydrofluorocarbons (HFCs) in metered

dose inhalers (MDIs) produce 8% of the NHS' carbon footprint (Hillman, T et al. BMJ 2013; 346: f3359). Aim(s): To collect inhaler devices for recycling, quantify wasted doses and their environmental impact. Method(s): We collected inhalers over 90 days at our district general hospital. Number, device type and remaining doses were recorded. Devices without a counter were listed as either 'empty' or 'doses remaining'. We calculated the financial cost of wasted doses and the carbon footprint of MDIs. All devices were sent to the 'Complete the Cycle' recycling scheme. Result(s): There were 481 inhalers collected with 34 device types. 41 capsule devices were excluded. Of returned inhalers, 77.3% had doses remaining. 43 (9.8%) were full, costing 1209. There were 8546 unused doses from 201 inhalers with counters. 71.8% of dry powder inhalers (DPIs) and 79.9% of MDIs had doses remaining. Assuming the MDIs as 50% full on average, our collection represented 2.63 tonnes of equivalent CO2 (CO2e) emissions which may otherwise have been released into the environment, equivalent to 120 return journeys from London to Paris by Eurostar, or 10.8 return flights. Conclusion(s): There were significant remaining doses in returned inhalers, likely underestimating true inhaler waste. Waste prevention and considering alternatives to inhaled HFCs in addition to recycling are essential as healthcare systems strive to reduce carbon emissions with everconstrained budgets.

Direskeneli, H., et al. (2010). "Identification of JAK1 as a candidate inflammatory signalling pathway by genome-wide expression profiling in monocytes from patients with Behcet's disease." Arthritis and Rheumatism **10)**: 2200.

Purpose: Both innate and adaptive immune responses are observed in Behcet's Disease (BD). We aimed to obtain a global view of the immune/inflammatory activity in BD compared to Familial Mediterranean Fever (FMF), a classical, autoinflammatory disease. Method(s): Twenty-eight patients with BD (F/M: 9/19, mean age: 33.4 years), 13 with FMF (F/M: 9/4, mean age: 30.4 years) and 21 healthy controls (HC) (F/M: 11/10, mean age: 30.6 years) were enrolled to the study. Whole-genome microarray profiling was performed with human U133 (Plus 2.0) microarrays on an Affymetrix platform using CD14+ monocyte and CD4+T lymphocyte subsets isolated by microbeads from peripheral blood mononuclear cells. Data was analysed with Genespring (Version 10.0) software. RT-PCR was performed for the validation of JAK1 expression. Result(s): Among 28792 transcripts analysed, in CD14+ monocytes, 1188 transcripts reached a significant difference level with a minimum 2-fold difference observed in 279 genes. In CD4+T-lymphocytes, 2880 transcripts showed significant difference with at least 2-fold difference in 109 genes. In CD14+ monocytes of BD patients, oxysterol binding protein-like-8 (OSBPL8)(3.8 fold), cell-division-cycle-27 homolog (S. cerevisiae) (CDC27)(3.1 fold), myeloid/lymphoid or mixed-lineage leukemia-3 (MLL3) (3.1 fold), PHD finger protein-3 (PHF3)(2.9 fold) and BCL2-associated x protein (BAX)(2.7 fold) had the highest expressions. However, in principal component analysis, Januse-kinase-1 (JAK1)(2.6 fold) and metallothionein 1X, (MT1X)(2.1 fold) appeared to be the dominant molecules associated with immune/inflammatory signalling pathways. Validation by RT-PCR also showed an increased JAK1 expression (fold increase compared to GAPDH: BD: 9.5 vs FMF: 5.1 vs HC: 7.3, p=0.07, BD vs FMF: p=0.04). Discussion(s): Whole-genome microarray analysis demonstrated a selective activation of BD monocytes compared to FMF, suggesting their critical role between innate and adaptive immune responses. Activation of JAK1 through various cytokines such as IL-2, IL-6, IL-15 and interferon-gamma may be one of the dominant signaling pathways driving inflammation in BD.

Dirks, C. G., et al. (2013). "Lung transplant recipients suspected of antibody mediated rejection treated with plasmapheresis have a poor prognosis." Journal of Heart and Lung Transplantation **1)**: S264.

Purpose: No standard criteria exists for antibody mediated rejection (AMR) in lung transplant recipients and there is no consensus of treatment of suspected AMR. We report the outcome in patients suspected of AMR, based on radiological, pathological and immunological criteria, treated with plasmapheresis. Methods and Materials: Retrospective single center study of lung transplant recipients who were treated with plasmapheresis from 2007 to 2011 due to the suspicion of AMR. A tentative diagnosis of AMR was based on 1) >20% decline in FEVi, 2) transbronchial biopsies showing diffuse alveolar or interstitial damage with or without acute cellular rejection, 3) No infection as a plausible cause of damage, 4) Presence of extensive ground-glass pattern on HR-CT, 5) detection of Donor specific HLA antibodies (DSA) by solid-phase HLA microbead assay (Luminex). Result(s): Eleven patients were identified with suspicion of AMR and treatment with plasmapheresis. 7/11 patients had more than 20% decline in FEV1. All patients fulfilled criteria 2, 3, and 4 and Luminex analysis was performed in 8/11 patients with detection of Donor specific HLA antibodies and with a positive Donor specific B-cell cross-match in 4/11 patients. Biopsies demonstrated a wide spectrum of morphology: DAD (4),NSIP (3), COP (3), OB (3), AIP (1), positive C4D (1). Two patients with DAD and one with COP had grade A2/ A3. All 11 transplant recipients were treated with plasmapheresis and subsequently Rituximab or Alemtuzumab. Eight patients died within 9 months from the last plasmapheresis. Conclusion(s): Although treated aggressively with plasmapheresis and other immunmodulating therapies the outcome of suspected AMR was poor. No specific pathological pattern was found in this small study and a tentative diagnosis of AMR based solely on CT and transbronchial biopsies is probably difficult to distinguish from the recently defined Restrictive Allograft Syndrome. More specific criteria for AMR in lung transplantation are needed.

Dittlein, D., et al. (2012). "Keratinocyte derived mediators and their influence on T cell effector functions." Experimental Dermatology **21 (3)**: e30.

Regarding the important role of human skin in host defence, a clear knowledge about the crosstalk of keratinocytes and infiltrating immune cells is of great relevance. Especially the secretion of mediators may provide keratinocytes a tool to influence specifically the fate of T cells. Recent data demonstrated that co-cultures of keratinocytes and CD4+ T cells result in a differed cytokine profile and proliferation potential. However, nothing is known about possible individual effects on the CD4+ T cell subtypes. This prompted us to study the modulating effect of keratinocyte derived mediators on three different T cell lines Th1, Th2, and Th17. For this purpose primary human keratinocytes were cultured under steady state as well as under inflammatory conditions provoked by IFN-gamma stimulation (300 U/ml). Cell free supernatants were collected and to eliminate donor specific effects the supernatants of three different keratinocyte donors were mixed. For generation of T cell lines, naive CD4+ T cells were isolated by microbead untouch technique from human blood and subsequently polarised to Th1, Th2 and Th17 cells within 7 days. Keratinocyte supernatants were added to the fully polarised T cell lines and after 72 h of incubation T cell supernatants were taken to quantify cytokine production by ELISA (IFN-gamma, IL-10, IL-4, IL-17 and IL-22). To determine the proliferation potential of the T cells 3H thymidine incorporation assays were performed. Especially in the case of supernatants generated by unstimulated keratinocytes the results showed a strikingly clear inhibitory effect on IL-10 as well as IL-22 production in all T cell lines. For the Th2 cell line an inhibition of IL-4 secretion was observed as well as for Th1 cells the tendency of a decreased IFN-gamma secretion was seen when co-incubated with keratinocyte supernatants. In contrast secretion of IL-17 by Th17 cells seems to be supported by the presence of keratinocyte supernatant. In conclusion, keratinocytes are critically involved in defining the threshold of inflammatory processes in the skin by inhibiting T cell proliferation and cytokine production.

Diwakar, G., et al. (2012). "Evaluation of melanin transfer mechanism in keratinocytes using fluorescent microbeads." <u>Pigment Cell and Melanoma Research</u> **25 (5)**: 682.

Melanin uptake by keratinocytes is a physiological response triggered by environmental or hormonal stimuli. The mechanism of melanin transfer that is accepted by most is the process of melanosome phagocytosis by the keratinocytes. Many attempts have been made to capture this process using melanocytekeratinocyte cocultures, however, quantification of melanosomes captured by keratinocytes remains a challenging task. Reliable and accurate quantification of captured melanosomes is essential to discover and compare efficacy of novel inhibitors of this process. Here we describe a novel approach using fluorescent microbeads to understand melanosome phagocytosis by keratinocytes. XB-2 keratinocytes were incubated with carboxylate-modified 1 lmred fluorospheres (103 beads/cell) for 4 h and washed 3x in PBS and subjected to flow cytometric analysis. The number of fluorescent events accounted for nearly 50% of total events, indicating keratinocytes were ingesting the fluorospheres, i.e. pseduomelanosomes. Niacinamide, a known phagocytosis inhibitor, was used as a control to evaluate pseudomelanosome transfer. Pretreatment with niacinamide prior to microbead treatment resulted in significantly reduced microbead uptake by the keratinocytes, as evidenced by decreased fluorescent events and fluorescence intensity. Combining Artemisia extract previously shown to inhibit microbead uptake (Barnet) with niacinamide enhanced microbead transfer inhibition. Fluorescence and time lapse microscopy of keratinocyte ingested beads further revealed that the beads localized around the keratinocyte perinuclear cytoplasmic area similar to the nuclear capping of keratinocytes by melanosomes. We conclude that this fluorophore-keratinocyte model could be used as an initial screening method to find novel ingredients that inhibit the melanosome phagocytosis mechanism.

Djalilian, A. R., et al. (2018). "Exosomes from corneal mesenchymal stem cells modulate the immunophenotype of macrophages." <u>Investigative Ophthalmology and Visual Science. Conference</u> **59**(9).

Purpose : Mesenchymal stem cells (MSCs) have been under study for their therapeutic immunomodulatory properties. At ARVO 2017 we reported that cornea derived mesenchymal stem cells can modulate the immunophenotype of macrophages in a distinct manner. We demonstrated that the modulatory effects are mediated through MSC secreted factors. In this study, we focused on exosomes / extra-cellular vesicles derived from MSCs to determine their specific modulatory effects on macrophages. Methods : Peripheral blood mononuclear cells were isolated from the buffy coats by density-gradient separation. Monocytes were isolated using anti-human CD14 microbeads. Purified CD14+ monocytes were plated in cell culture plates at a concentration of 10 per well in IMDM media supplemented with 10% human serum blood type AB. Monocytes were cultured for 7 days to differentiate into macrophages. On day +7, macrophages were supplemented with fresh media and either co-cultured with human corneal MSCs (in transwells) to obtain MSC educated macrophages (MEMs), or else treated with exosomes isolated from human corneal MSCs to get exosome educated macrophages (EEMs). After 3 days, the macrophages were collected and subjected to flow cytometry. Results : Corneal MSCs were found to produce extracellular vesicles that primarily consisted of exosome-sized vesicles. By flow cytometry, macrophages educated using corneal MSCs (cMEM) or corneal exosomes (cEEM) showed similar but a distinct surface marker profile. For the M2 markers, the mean fluorescent intensity (MFI) of CD206, PD-L2 and CD39 for both MEM and EEM were significantly elevated compared to controls, however CD206, PDL1, PD-L2 was also significantly higher in the EEMs compared to the MEMs. Interestingly, in contrast both CD163

and CD16 were significantly lower in the EEMs compared to the MEMs. For the M1 markers, HLA-DR, there was no difference in surface expression in either the MEMs or EEMs, while CD86 was significantly lower in the MEMs compared to both controls and EEMs. Conclusions : These results demonstrate the distinct modulatory effects of cornea MSCs and cornea MSC derived exosomes on macrophages. Further functional and gene expression studies are underway to better characterize the exosomes and exosome educated macrophages. Likewise, additional studies are needed to determine the therapeutic potential of cornea MSC exosomes in ocular inflammatory disorders.

Dmytriw, A. A. (2019). "The microplastics menace: An emerging link to environment and health." Science of the Total Environment: 135558.

do Sul, J. A. I. and M. F. Costa (2013). "Plastic pollution risks in an estuarine conservation unit." Journal of Coastal Research **1**(65): 48.

Plastics enter the marine environment mostly from land-based sources, often via estuaries. However, studies related to plastic debris pollution remain rare within these environments. An estuarine beach comprised within a Marine Conservation Unit (MCU) in the Northeast coast of Brazil was studied during one year regarding plastic pollution. Petroleum derived products were >95% of all items, as commonly reported for other coastal and marine habitats. Monthly totals of marine debris presented an average of 10.8 plus or minus 1.63 items.100m super(-2), much lower than reported in the literature for other estuarine beaches. Three main sources were identified: fisheries, local users and human settlements along the river basin. The most frequent (56%) size category was 11-100cm super(2), but fragmented items alone were 83% of observed items. The main impact on the estuarine and visiting biota expected is the ingestion of plastic items and fragments, which was corroborated by recent works on estuarine fishes. Interactions with fishing gear are highlighted in the context of this MCU. To protect the traditional livelihoods in the Goiana Estuary, the guarantee of a healthy ecosystem, inclusive free from plastic pollution, must be included in management plans.

Dobaradaran, S., et al. (2018). "Characterization of plastic debris and association of metals with microplastics in coastline sediment along the Persian Gulf." Waste Management **78**: 649-658.

This study reports number, size and color distribution, and metal contents of microplastics as well as adherent sediments along the Persian Gulf. Samples were collected from 9 stations in summer 2015 with a sampling time interval of 10 days. Plastic size of 2-5 mm, and <=0.25 mm with 45 and 33% and white and colorless plastics with 62 and 33% had the highest abundance considering number per m², respectively. In general, the majority of collected plastics (79%) were smaller than 5 mm (defined size for microplastics). The mean Al, Fe, Mn, Cd, Cr, Ni, Pb, Cu contents of plastic fragments were 115, 531, 32.2, 0.035, 0.915, 2.03, 4.59, and 3.6 mug g⁻¹, respectively while the mean Al, Fe, Mn, Cd, Cr, Ni, Pb, Cu contents of sediments were 186, 3050, 127, 0.81, 5.01, 14.5, 48.6 and 5.43 mug g⁻¹ respectively. There were significant differences between the abundance of plastic items as well as the all examined metal concentrations of microplastics and sediments at different sampling times. As there is no regular cleanup program in the studied areas, significant differences between plastic items number at different sampling times (with higher plastic items number at the first day of sampling) showed that a large number of plastic items may enter from beaches to the sea and become available to marine organisms. Doberstein, S. K., et al. (1995). "Fluorescent erythrocyte ghosts as standards for quantitative flow cytometry." Cytometry **20**(1): 14-18.

We report here a quick and inexpensive method for preparing standards of known fluorochrome content for calibration and quantitation of flow cytometry fluorescence signals. Erythrocyte ghosts prepared by hypotonic lysis are filled with solutions containing fluorescently labeled dextran. Standards prepared by this technique have a narrow range of fluorescence and a linear response of fluorescence to fluorochrome content up to 2 x 10(6) fluorochrome molecules/cell. The volume of ghost standard particles is roughly 70 femtoliters (fl)/cell. The fluorescence of ghost standards is nearly identical to that of commercially available microbead standards of similar fluorochrome content. Ghost standards have stable fluorescence for at least 3 weeks at 4 degrees C. These standards can be made with any fluorochrome or combination of fluorochromes over a wide concentration range.

Dock, J., et al. (2017). "Human immune compartment comparisons: Optimization of proliferative assays for blood and gut T lymphocytes." Journal of Immunological Methods **445**: 77-87.

The accumulation of peripheral blood late-differentiated memory CD8 T cells with features of replicative (cellular) senescence, including inability to proliferate in vitro, has been extensively studied. Importantly, the abundance of these cells is directly correlated with increased morbidity and mortality in older persons. Of note, peripheral blood contains only 2% of the total body lymphocyte population. By contrast, the gut-associated lymphoid tissue (GALT) is the most extensive lymphoid organ, housing up to 60% of total body lymphocytes, but has never been assessed with respect to senescence profiles. We report here the development of a method for measuring and comparing proliferative capacity of peripheral blood and gut colorectal mucosa-derived CD8 T cells. The protocol involves a 5-day culture of mononuclear leukocyte populations, from blood and gut colorectal mucosa respectively, labeled with 5-(and 6)-carboxyfluorescein diacetate succinimidyl ester (CFSE) and 5-bromo-2'-deoxyuridine (BrdU) and stimulated with anti-CD2/3/28-linked microbeads. Variables tested and optimized as part of the protocol development include: mode of T cell stimulation, CFSE concentration, inclusion of a second proliferation marker, BrdU, culture duration, initial culture concentration, and inclusion of autologous irradiated feeder cells. Moving forward, this protocol demonstrates a significant advance in the ability of researchers to study compartment-specific differences of in vitro proliferative dynamics of CD8 T cells, as an indicator of replicative senescence and immunological aging. The study's two main novel contributions are (1) Optimization and adaptation of standard proliferative dynamics blood T cell protocols for T cells within the mucosal immune system. (2) Introduction of the novel technique of combining CFSE and BrdU staining to do so.

Dodson, G. Z., et al. (2020). "Microplastic fragment and fiber contamination of beach sediments from selected sites in Virginia and North Carolina, USA." Marine Pollution Bulletin **151 (no pagination)**(110869).

Microplastic particles (<5 mm) constitute a growing pollution problem within coastal environments. This study investigated the microplastic presence of estuarine and barrier island beaches in the states of Virginia and North Carolina, USA. Seventeen sediment cores were collected at four study sites and initially tested for microplastic presence by pyrolysis-gas chromatography-mass spectrometry. For the extraction, microplastic particles were first separated from the sediment using a high-density cesium chloride solution (1.88 g/mL). In a second step, an oil extraction collected the remaining microplastic particles of higher densities. Under the light microscope, the extracted microplastic particles were classified based on their morphologies into fragments and fibers. Raman microspectroscopy chemically identified a subset of microplastic particles as polypropylene, polyethylene terephthalate, poly(4-vinylbiphenyl), polystyrene, polyethylene, and nylon. The results show a concentration of microplastic particles (1410 +/- 810 per kg of dry sediment) even in protected and ostensibly unpolluted estuarine and beach sediments of Virginia and North Carolina. Doh, I. J., et al. (2019). "A Portable Spark-Induced Breakdown Spectroscopic (SIBS) Instrument and its Analytical Performance." Applied Spectroscopy **73**(6): 698-708.

A compact spark-induced plasma spectroscopic device was developed to detect elements used in a variety of applications. The system consists of a spark generator connected to tungsten electrodes, a custom-built delay generator, and two spectrometers that together cover the ultraviolet visible (UV-Vis) range (214-631 nm). The system was evaluated by qualitatively and quantitatively sampling copper standards. Prominent spectral peaks were identified using the NIST database for atomic emissions. The effectiveness of the proposed system was also tested with a lanthanide sample (gadolinium) and provided qualitative identification of the characteristic peaks. A semi-quantitative measurement for silicon and gold was performed using variable amounts of each particulate. Silica microbeads in solution were applied to paper wafers, while gold nanoparticles were sputter-coated onto silicon wafers.

Doherty, S. B., et al. (2012). "Application of whey protein micro-bead coatings for enhanced strength and probiotic protection during fruit juice storage and gastric incubation." Journal of Microencapsulation **29**(8): 713-728.

Context: Coated whey protein micro-beads may improve probiotic protection and provide delayed cell-release mechanisms. Objective(s): Lactobacillus rhamnosus GG was encapsulated in whey protein micro-beads by droplet extrusion with coating via electrostatic deposition: primary-polysaccharide and secondary-whey protein. Material(s) and Method(s): Storage studies were performed in cranberry and pomegranate juice (pH 2.4; 28 days; 4 and 25degreeC) followed by simulated ex vivo porcine gastric (pH 1.6) and intestinal (pH 6.6) digestion. Results and discussion: After storage and simulated gastro-intestinal digestion, free cells, cells suspended in protein and cells encapsulated in alginate micro-beads, illustrated complete probiotic mortality, while coated micro-beads enhanced probiotic viability after juice storage (8.6+/-0.1 log10CFUmL ⁻¹). Beads also showed significant binding of hydrophobic molecules. Coated micro-beads illustrated high gastric survival (9.5+/-0.1 log10CFUmL⁻¹) with 30min delayed intestinal release relative to non-coated micro-beads. Conclusion(s): Micro-bead coatings could be applied in delayed cell-release for targeted intestinal probiotic delivery. © 2012 Informa UK Ltd All rights reserved.

Doherty, S. B., et al. (2011). "Development and characterisation of whey protein micro-beads as potential matrices for probiotic protection." Food Hydrocolloids **25**(6): 1604-1617.

This study evaluated the efficacy of whey protein isolate (WPI) as an encapsulation matrix for the maintenance of Lactobacillus rhamnosus GG viability during simulated gastro-intestinal studies. Micro-bead characteristics were investigated using microscopy, chromatography, laser diffractometry and zeta potential analysis. Heat-treated WPI (11%, w/v) blended with stationary phase cultures demonstrated an instant gelation impetus in acetate buffer (0.5 M), tempered to 35 degrees C in the presence of Tween-20 (0.04%). Atomic force microscopy (AFM) demonstrated that micro-bead extrusion at pH 4.6 fuelled strong cohesive interactions within protein-probiotic amalgams; an electrostatic alliance further highlighted by zeta potential analysis. Optimization of encapsulation conditions generated self-supporting structures (200+or-1.2 micro m) with high micro-bead strength and individual loading capacity of

2.7x10⁴ cfu/micro-bead. Plate enumeration demonstrated that micro-bead extrusion had no detrimental effect on cell viability due to the perpetuation of stationary phase concentrations (10⁹ cfu/mL). This finding was further validated by LIVE/DEAD microscopy staining, which visualized the homogenous distribution of live probiotics throughout micro-bead matrices. Following 3 h in vitro stomach incubation (pH 1.8; 37 degrees C), micro-beads laden with 10¹⁰ cfu demonstrated acid-stability and peptic-resistance, characteristics required for optimum probiotic refuge. However, enzyme-activated intestinal conditions catalysed a synergistic response engaging rapid matrix disintegration and controlled probiotic release. Matrix digestion was monitored by chromatography, which witnessed the sequential release of peptides <2 kDa after 30 min. In conclusion, this study led to the development and design of a protein encapsulation polymer based on congruent matrix interactions for reinforced probiotic protection during challenging situations for their targeted delivery to intestinal absorption sites.

Dohnert, N., et al. (2010). "The proliferation behaviour of human vascular umbilical cord cells for cardiovascular tissue engineering under static and dynamic conditions." European Journal of Medical Research **1)**: 226.

Background: A crucial factor for the tissue engineering of heart valves is to establish the optimal conditions for cell culture. In our laboratory, we are trying to improve the proliferation of human vascular umbilical cord cells, the myofibroblasts. This is very important for the planning of follow-up studies and ultimately for the construction of a heart valve from these cells. In this study we compared the possibillity of dynamic cultivation with the common static cultivation method. Further, we tested whether the static cell culture could be improved by modifying the culture medium. Mat erial s und Methods: To compare the static and dynamic cell culture methods the adherent myofibroblasts were seeded onto micro beads in a rotating bioreactor (RCCS-D, Synthecon) and cells were counted at defined intervals. In parallel a static culture from the same cell source was seeded and counted. In a further analysis the cells were seeded in culture flasks for three passages with five different concentrations of ascorbic acid as additive to the culture medium (from 0.1 to 5 mmol/L); one flask remained without the additive. Every passage (n=6) was tested using a WST assay, which showed the cell proliferation as an absorbtion difference calculated by an ELISA reader. The procedure was carried out during four consecutive days for every passage. Result(s): The results showed that the dynamic cell culture did not improve the cell proliferation. The myofibroblasts were not suited to this method of cultivation. We also found a significant difference in cell proliferation between the myofibroblasts with and without ascorbic acid in the medium in static culture. A concentration of 0.1 mmol/l proved to be the best possible concentration out of the five, although every result in proliferation was better with ascorbic acid than in its absence. Conclus ion: We found that myofibroblasts do not proliferate in an adequate way when seeded onto micro beads in a rotating bioreactor. The use of ascorbic acid is important for further studies to improve the cell proliferation in vitro, which would upgrade the process and reduce the time required for the fabrication of heart valves. In addition these results can be taken into account in protocols for future experiments, thus improving the handling of myofibroblasts from the umbilical cord in tissue engineering.

Doker, S., et al. (2013). "Arsenic speciation in water and snow samples by adsorption onto PHEMA in a micro-pipette-tip and GFAAS detection applying large-volume injection." Talanta **103**: 123-129.

A miniaturized solid phase extraction procedure has been developed for ultra-trace determination of inorganic arsenic species. Arsenic(III) as pyrrolidinedithiocarbamate complex was selectively adsorbed on 30 mg poly(hydroxyethyl methacrylate) (PHEMA) micro beads, which is simply packed into a micro-pipette-tip. The adsorbed arsenic was quantitatively eluted by 700 muL 0.25 M NH(3) and determined by graphite furnace atomic absorption spectrometry (GFAAS). Injection of larger volume (i.e., 50 muL v.s. conventional 10-20 muL) eluent into graphite furnace and the use of Mg(NO(3))(2) as chemical modifier have improved atomic absorption signal intensity (sensitivity as characteristic mass of 25 pg) and precision (RSD of 2.6%, c=10 mug L(-1), n=11). Total arsenic amount was determined after reduction of arsenic(V) to arsenic(III) by thiourea-HCl system. As(V) concentration was calculated by the difference between As(III) and total arsenic. The detection limit (3s) of the method was found as 10 ng L(-1) As(III) with an enrichment factor of 86. The relative standard deviation and relative error for six replicate determinations of 0.5 mug L(-1) As(III) were found to be 4.0% and -0.7%, respectively. The method was successfully applied to drinking water, snow and reference water (SEM-2011) samples. When the samples were spiked with 0.5 and 1.0 mug L(-1) As(III) and As(V), the recoveries varied between 96 and 100%.

Dolci, L. S., et al. (2009). "Development of a new device for ultrasensitive electrochemiluminescence microscopy imaging." Analytical Chemistry **81**(15): 6234-6241.

Electrochemiluminescence (ECL) is widely used in biosensors and immunoassays thanks to the high sensitivity and specificity of the electrochemically triggered luminescence signal. So far, no applications have been reported on the use of ECL as a probe for ultrasensitive low-light microscope imaging. This work reports the development of a new transparent electrochemical cell for ECL imaging suitable for single cell analysis. The system is based on the use of a microscope placed in a dark box equipped with a CCD camera and a potentiostat. Transparent conducting glass coated with fluorine-doped tin oxide (FTO) has been used, and a three electrode configuration has been designed. The electrochemical cell was optimized using 8 microm diameter polystyrene beads coated with a Ru(bpy)(3)(2+) complex in order to simulate living cells. The Ru(bpy)(3)(2+) immobilized on the microbeads can be imaged and quantified at a concentration as low as 1 x 10(-19) mol/microm(2). Microscope imaging showed that the ECL signal was detected only in correspondence to the beads present on the electrode surface, and the probe could be accurately localized with a spatial resolution of 0.4 microm. The new ECL imaging device can be used in conjunction with other chemiluminescence-based imaging methods for ultrasensitive multiplex imaging on cells and tissues.

Dominghetti, A. W., et al. (2016). "Nitrogen loss by volatilization of nitrogen fertilizers applied to coffee orchard." Ciencia e Agrotecnologia **40**(2): 173-183.

Ammonia volatilization (N-NH₃) is one of the main pathways of Nitrogen loss reducing nitrogen use efficiency in coffee orchard. This work aimed at quantifying ammonia volatilization (N-NH₃) losses from N-sources to be used in coffee plantations fertilization in Brazil. The experiment was conducted in the field on a dystrophic red latosol (Ferralsol in FAO's classification) at the Coffee Research Sector, University of Lavras, MG, Brazil. The experimental design was of complete randomized blocks with three repetitions of the following treatments: conventional urea, ammonium nitrate and urea + 0.15% Cu and 0.4% B, urea + anionic polymers, urea + elementary sulfur (S⁰) + polymers, and urea + plastic resin. These N sources were split into three doses of 150 kg ha⁻¹ and band applied. The N-NH₃ losses by volatilization and variations of pH (H₂O) were measured, before and after N application. The N-sources contributed to reduce the soil pH, measured after the third nitrogen fertilization. The N-NH₃ losses by volatilization (average from three applications) was as follows: urea + anionic polymers (35.8%)

> conventional urea (31.2%)=urea + S⁰ + polymers (31.0%) > urea + 0.15% Cu + 0.4% B (25.6%) > urea + plastic resin (8.6%)=ammonium nitrate (1.0%).

Domingues, M. T., et al. (2014). "Short-term effect of alginate-biochar microbeads in corn germination." International Proceedings of Chemical, Biological and Environmental Engineering **77**: 31-34.

Biochar is the solid by-product of biomass pyrolysis. It is a promising soil conditioner and can be a material with high aggregate economic value, since its performance can improve plant's nutrient utilization and reduce the usage of conventional fertilizers. Biochar can be used in the formulation of new types of fertilizers as polymeric microbeads. These microbeads can be enriched with biochar and nutrients in its matrix to form fertilizers of slow release of nutrients. Thus, as a promising agricultural material, it is important to assess the environmental hazards caused by the implementation of these microbeads. In this context, seeds were sown in a soil-less Petri dish with microbeads produced with biochar from sugarcane enriched with or without phosphate. The seeds germination and its vitality were evaluated by the first germination count (FGC) and the germination speed index (GSI). The short-term effects showed that the microbeads, in general, assessed by the means of FGC, GSI and mass gain showed the best performance, suggesting that the environment created by these materials provided the best chemical and physical interaction with the embryonic axes.

Domogalla-Urbansky, J., et al. (2019). "Raman microspectroscopic identification of microplastic particles in freshwater bivalves (<i>Unio pictorum</i>) exposed to sewage treatment plant effluents under different exposure scenarios." Environmental science and pollution research international **26**(2): 2007-2012.

We investigated the uptake of microplastic (MP, <5 mm) particles by using freshwater bivalves (Unio pictorum) as biological samplers in the environment. They were exposed either directly to the biologically purified sewage of a North Bavarian sewage treatment plant (STP) or placed in a small river up- and downstream of the wastewater discharge for 28 days and 6 months, respectively. A control group was maintained in a pond. After acid digestion, the soft tissue was analyzed for MP particles by means of Raman microspectroscopy (RM, over 3000 particles individually measured), which allows for identification and quantification of particles down to 1 μm. Only in the bivalve collective exposed to STP effluents MP was found, however a very small amount (maximum of nine MP particles in the bivalve sample exposed for 6 months). In the bivalves up- and downstream of the wastewater discharge and in control organisms from a pond, no microplastic was identified. The amount of microplastic particles was small in absolute terms and small in relative terms (ca. 1:100 (6 months) and below 1:1000 (28 days)) as hundreds of particles per sample were analyzed which turned out to be non-plastic. Including the results for the river, this indicates a rather low MP contamination level for organisms in close vicinity to a sewage treatment plant.

Dong, C. D., et al. (2020). "Polystyrene microplastic particles: In vitro pulmonary toxicity assessment." Journal of Hazardous Materials **385**: 121575.

Microplastics (MPs) have become a global environmental concern. Recent studies have shown that MPs, of which the predominant type is often polystyrene (PS; known as PS-MPs), can extend to and affect remote, sparsely inhabited areas via atmospheric transport. Although exposure to inhaled MPs may induce lung dysfunction, further experimental verification of the pulmonary toxic potential of MPs and the mechanism underlying the toxicity is needed. Here we used normal human lung epithelial BEAS-2B cells to clarify the association between pulmonary toxicity and PS-MPs.

Dong, H., et al. (2016). "A microchip for integrated single-cell genotoxicity assay." Talanta **161**: 804-811.

With the development of large-scale biologic databases, precision medicine is becoming a frontier in biomedical research. As a main focus of precision medicine study, cancer has been widely accepted as a disease born out of inherited genetic variations or accumulating genomic damage. At the single-cell level, microfluidics or lab-on-a-chip technology for cancer study is an emerging tool for improving risk assessment, diagnostic categories and therapeutic strategies. This work presents a multi-layer microchip for single-cell gene expression profiling. Treated by three drug reagents (i.e. methyl methanesulfonate, docetaxel and colchicine) with varied concentrations and time lengths, individual human breast cancer cells (MCF-7) are then lysed on-chip, and the released mRNA templates are captured and reversely transcribed into cDNA on microbead surface. Three genes (GAPDH, CDKN1A, AURKA) are amplified and quantified simultaneously through triplex real-time polymerase chain reactions (qPCR). Readout per run is set to be eighteen, and can be further improved following same approach. The microchip is able to integrate all steps of single-cell gene expression profiling, and provide precision study of drug induced genotoxicity with reduced reagents consumption per reaction and instrumental cost.

Dong Huy, G., et al. (2011). "A novel separation and enrichment method of 17beta-estradiol using aptamer-anchored microbeads." Bioprocess and Biosystems Engineering **34**(2): 189-195.

The estrogenic compound 17beta-estradiol (E2) is widely studied for its potential endocrine disruption effects. Due to the low level of E2 present in the environment, it is highly desirable to develop a sensitive and efficient separation and enrichment method for E2 analysis. In this paper, we proposed a novel E2 preconcentration method using anti-E2 aptamer-anchored isothiocyanate-modified beads (NCS beads). The glass beads are chemically modified with primary amino group, and then treated with phenylene diisothiocyanate (PDITC) to generate an isothiocyanate group, which is reactive towards the amine group. The amino-modified anti-E2 aptamer can be easily covalently immobilized onto the as-prepared NCS beads. The experimental results demonstrated that the aptamer affinity microbeads could selectively retain and separate E2 compound. The effects of the operation parameters on retention of E2, including washing condition, eluting condition, the number of beads, and the incubation time were investigated. Moreover, high-performance liquid chromatography with preconcentration of E2 on the aptamer affinity microbeads was applied to detect the E2 in the spiked water samples and obtained a good recovery. © 2010 Springer-Verlag.

Dong, L., et al. (2018). "Reversible and long-term immobilization in a hydrogel-microbead matrix for high-resolution imaging of Caenorhabditis elegans and other small organisms." PLoS ONE **13**(3).

The nematode Caenorhabditis elegans is an important model organism for biomedical research and genetic studies relevant to human biology and disease. Such studies are often based on high-resolution imaging of dynamic biological processes in the worm body tissues, requiring well-immobilized and physiologically active animals in order to avoid movement-related artifacts and to obtain meaningful biological information. However, existing immobilization methods employ the application of either anesthetics or severe physical constraints, by using glue or specific microfluidic on-chip mechanical structures, which in some cases may strongly affect physiological processes of the animals. Here, we immobilize C. elegans nematodes by taking advantage of a biocompatible and temperature-responsive hydrogel-microbead matrix. Our gel-based immobilization technique does not require a specific chip design and enables fast and reversible immobilization, thereby allowing successive imaging of the same single worm or of small worm populations at all development stages for several days. We successfully demonstrated the applicability of this method in challenging worm imaging contexts, in particular by applying it for high-resolution confocal imaging of the mitochondrial morphology in worm body wall muscle cells and for the long-term quantification of number and size of specific protein aggregates in different C. elegans neurodegenerative disease models. Our approach was also suitable for immobilizing other small organisms, such as the larvae of the fruit fly Drosophila melanogaster and the unicellular parasite Trypanosoma brucei. We anticipate that this versatile technique will significantly simplify biological assay-based longitudinal studies and long-term observation of small model organisms.

Dong, L., et al. (2013). "Promoting low-carbon city through industrial symbiosis: A case in China by applying HPIMO model." Energy Policy **61**: 864-873.

Abstract: China launched low-carbon city strategy to respond global climate change. Industrial symbiosis (IS) could generate both economic and environmental benefits in clustered industries and communities. This research shed light on how industrial symbiosis contributes to city's low-carbon development. An urban-level hybrid physical input and monetary output (HPIMO) model which covers physical energy inputs and air pollutants emissions, is established for addressing case study in a Chinese typical industrial city (Liuzhou). Based on current energy consumption and industrial symbiosis and the application of HPIMO model, scenarios related to industrial symbiosis, including waste plastics recycling, scrap tires recycling, flying ash recycling and biomass utilization are explored. Results show that compared with business-as-usual (BAU) scenario, IS can reduce solid wastes and further contribute to the co-benefits of energy saving, CO2 emissions reduction and air pollutants reduction. The finding is critical for national low-carbon strategy. Finally, policy implications to support the ever-improvement of IS promotion in China are proposed and discussed. [Copyright &y& Elsevier]

Dong, S., et al. (2018). "Combinational effect of titanium dioxide nanoparticles and nanopolystyrene particles at environmentally relevant concentrations on nematode Caenorhabditis elegans." Ecotoxicology and Environmental Safety **161**: 444-450.

The possible adverse effects of nanoplastics have received the great attention recently; however, their effects at environmentally relevant concentration on organisms are still largely unclear. We here employed Caenorhabditis elegans to investigate the combinational effects of titanium dioxide nanoparticles (TiO₂-NPs) and nanopolystyrene particles at environmentally relevant concentrations on organisms. In wild-type nematodes, prolonged exposure to nanopolystyrene particles (1 micro g/L) could enhance the toxicity of TiO₂-NPs (1 micro g/L) in decreasing locomotion behavior and in inducing intestinal reactive oxygen species (ROS) production. Meanwhile, combinational exposure to TiO₂-NPs (1 micro g/L) and nanopolystyrene particles (1 micro g/L) altered the molecular basis for oxidative stress in wild-type nematodes. Moreover, prolonged exposure to nanopolystyrene particles (0.1 micro g/L) could further enhance the toxicity of TiO₂-NPs (1 micro g/L) in decreasing locomotion behavior and in inducing intestinal ROS production in sod-3 mutant nematodes. Our data suggest the potential role of nanopolystyrene particles at environmentally relevant concentrations in enhancing the toxicity of ENMs in the environment.

Dong, X., et al. (2019). "Controlled delivery of basic fibroblast growth factor (bFGF) using acoustic droplet vaporization stimulates endothelial network formation." Acta Biomaterialia **97**: 409-419.
The challenge of translating pro-angiogenic growth factors for therapeutic purposes has stimulated a myriad of biomaterials-based, delivery approaches. Many techniques rely on incorporating a growth factor into a hydrogel. The kinetics of release can be tuned based on the physiochemical properties of the growth factor and scaffold. We have developed an acoustically-responsive scaffold (ARS), whereby release of a growth factor is non-invasively and spatiotemporally controlled in an on-demand manner using focused ultrasound. An ARS consists of a fibrin matrix doped with a growth factor-loaded, sonosensitive emulsion. In this study, we used an ARS to investigate the impact of basic fibroblast growth factor (bFGF) release on endothelial tubule formation. The co-culture model of angiogenic sprouting consisted of endothelial cell-coated microbeads and dispersed fibroblasts. bFGF release correlated with the acoustic pressure applied while sprout length correlated with both the volume of bFGF-loaded emulsion in the ARS and acoustic pressure. Minimal bFGF release and sprouting were observed in the absence of ultrasound exposure. Staggering the release of bFGF via multiple ultrasound exposures did not affect sprouting. Additionally, sprouting did not display a dependence on the distance between each microbead and the ARS. Overall, these results highlight the potential of using ultrasound to control regenerative processes via the controlled delivery of a growth factor. STATEMENT OF SIGNIFICANCE: Due to the ineffectiveness of conventional routes of administration, implantable hydrogels are often used as matrices to deliver growth factors (GFs). Spatial control of release is typically realized using anisotropic constructs while temporal control is obtained by modifying matrix properties and GF-scaffold interactions. In this study, we demonstrate how focused ultrasound can be used to non-invasively and spatiotemporally control release of basic fibroblast growth factor (bFGF), in an on-demand manner, from a composite hydrogel. The acoustically-responsive scaffold (ARS) consists of a bFGF-loaded, monodispersed double emulsion embedded within a fibrin matrix. We demonstrate how controlled release of bFGF can stimulate endothelial network formation. These results may be of interest to groups working on controlled release strategies for GFs, especially in the context of stimulating angiogenesis.

Dong, X., et al. (2019). "Sorption of Tonalide, Musk Xylene, Galaxolide, and Musk Ketone by microplastics of polyethylene and polyvinyl chloride." Marine Pollution Bulletin **144**: 129-133.
The effects of time, temperature, and salinity on the adsorption of Tonalide (AHTN), Musk Xylene (MX), Galaxolide (HHCB), and Musk Ketone (MK) by microplastics of polyethylene (PE) and polyvinyl chloride (PVC) are studied.

Dong, Y., et al. (2019). "Adsorption mechanism of As(III) on polytetrafluoroethylene particles of different size." Environmental Pollution **254**: N.PAG-N.PAG.
Microplastics exhibit active environmental behavior and unique surface characteristics, and act as carriers for the migration of trivalent arsenic (As(III)) in the environment. Herein, the mechanism by which polytetrafluoroethylene (PTFE) microplastic particles adsorb As(III) is systematically determined. The larger the size of PTFE particles, the smaller the specific surface area, the higher the point of zero charge (PZC), and the more unfavorable adsorption of As(III); the highest adsorption amount can reach 1.05 mg g^{-1}. The adsorption process can be divided into three stages by the intraparticle diffusion model: external mass transfer, intraparticle diffusion, and dynamic equilibrium, of which the external mass transfer stage is the adsorption

rate-limiting stage. The Langmuir isotherm model better represented the equilibrium adsorption results. The adsorption of As(III) by PTFE was an exothermic process, and because the increase in temperature broke the hydrogen bond, the amount of adsorption was decreased, which was not conducive to spontaneous adsorption. In the pH range of 3–7, as the pH value increased, the amount of As(III) adsorbed by PTFE gradually decreased, which may be related to the change in PZC for PTFE and the protonation of As(III). The H on the surface hydroxyl group of the PTFE exhibited a very large positive potential (+82.37 kcal mol−1). Thus, it can attract the arsenic oxyanion, and As(III) was subsequently adsorbed on the surface of the PTFE through the hydrogen bond on the hydroxyl group. Electrostatic force and non-covalent interaction were the key mechanisms affecting the PTFE adsorption. Image 1 • Polytetrafluoroethylene (PTFE) microplastic particles have high adsorption capacity on As(III) (1.05 mg g−1). • The adsorption of As(III) by PTFE is an exothermic process. • The hydrogen atom in the surface hydroxyl group of the PTFE exhibited a very large positive electrostatic potential. • Electrostatic force and non-covalent interaction are the key mechanisms affecting the As(III) adsorption by PTFE. The key mechanisms of As(III) adsorption by PTFE is electrostatic force and non-covalent interaction. [ABSTRACT FROM AUTHOR]

Dong, Y., et al. (2019). "Microplastic particles increase arsenic toxicity to rice seedlings." Environmental Pollution **259**: 113892.

Hydroponic experiments were conducted to study the effects of microplastic particles of polystyrene (PS) and polytetrafluoroethylene (PTFE) on arsenic (As) content in leaves and roots of rice seedlings, and the changes in root vigor and physiological and biochemical indicators under single or combined PS and PTFE with As(III) treatment. Rice biomass decreased with increasing concentrations of PS, PTFE, and As(III) in the growth medium. The highest root (leaf) biomass decreases were 21.4% (10.2%), 25.4% (11.8%), and 26.2% (16.2%) with the addition of 0.2 g L⁻¹ PS, 0.2 g L⁻¹ PTFE, and 4 mg L⁻¹ As(III), respectively. Microplastic particles and As(III) inhibited biomass accumulation by inhibiting root activity and RuBisCO activity, respectively. The addition of As(III) and microplastic particles (PS or PTFE) inhibited photosynthesis through non-stomatal and stomatal factors, respectively; furthermore, net photosynthetic rate, chlorophyll fluorescence, and the Chl a content of rice were reduced with the addition of As(III) and microplastic particles (PS or PTFE). Microplastic particles and As(III) induced an oxidative burst in rice tissues through mechanical damage and destruction of the tertiary structure of antioxidant enzymes, respectively, thereby increasing O₂⁻ and H₂O₂ in roots and leaves, inducing lipid peroxidation, and destroying cell membranes. When PS and PTFE were added at 0.04 and 0.1 g L⁻¹, respectively, the negative effects of As(III) on rice were reduced. Treatment with 0.2 g L⁻¹ PS or PTFE, combined with As(III), had a higher impact on rice than the application of As(III) alone. PS and PTFE reduced As(III) uptake, and absorbed As decreased with the increasing concentration of microparticles. The underlying mechanisms for these effects may involve direct adsorption of As, competition between As and microplastic particles for adsorption sites on the root surface, and inhibition of root activity by microplastic particles.

Dong, Y., et al. (2020). "As(III) adsorption onto different-sized polystyrene microplastic particles and its mechanism." Chemosphere **239 (no pagination)**(124792).

We systematically investigated the surface characteristics of polystyrene microplastic particles (PSMPs) prepared by ball milling to impart a porous surface structure and special surface characteristics, and studied the mechanism of adsorption of As(III) onto PSMPs. The sizes of the PSMPs prepared by ball milling for 2, 4, and 8 h were in the ranges of 0.1-1, 1-10, and 10-100 mum, respectively. That is, the longer the milling time is, the larger the specific surface area of the particles is. Moreover, the higher the point of zero charge is, the higher the adsorbed amount of As(III) is. The highest adsorption rate of As(III) onto PSMPs was found to be 1.12 mg g⁻¹. After 1200 min, the adsorption reached equilibrium, and a pseudo-second-order model better fitted the As(III) adsorption kinetics. The Langmuir and Freundlich models could well describe the adsorption isotherms. Furthermore, hydrogen bonds between As(III) and PSMPs were broken at high temperatures, resulting in a decrease in As(III) adsorption onto PSMP, which indicated that the adsorption process was exothermic. Increases in the pH and concentrations of interfering nitrate and phosphate ions in the solution led to inhibited As(III) adsorption of PSMPs. The electrostatic potential of most areas of the PSMP surface was positive, and the H atom on the carboxyl group exhibited a very large positive potential (+56.6 kcal/mol), and thus attracted arsenic oxyanions. Thus, it was determined that As(III) adsorbed to the surface of PSMPs through hydrogen bonding with the carboxyl group. Electrostatic forces and non-covalent interactions are the key mechanisms affecting the adsorption of As(III) onto PSMPs. This work provides a clear theoretical basis for the behavior of the PSMP as an arsenic carrier and might aid to improve the environmental toxicity of arsenic. Copyright © 2019 Elsevier Ltd

Dong, Y., et al. (2014). "Determination of Cattle Foot-and-Mouth Disease Virus by Micro-ELISA Method." Analytical Sciences **30**(3): 359.

The development of foot-and-mouth disease virus (FMDV) detection methods is crucial for animal food security, tackling regional FMDV epidemic, and global FMDV prognostic control. For these purposes, a fast and sensitive analysis method is required. In this study, we developed a microchip-based ELISA (enzyme-linked immunosorbent assay), micro-ELISA, to realize FMDV detection. Nickel(II) chelating chemistry was utilized to immobilize recombinant protein (antigen) on polystyrene micro-beads in order to determine FMDV antibodies in cattle serum samples. In addition, reaction protocol and conditions were investigated. As a result, the FMDV detection was successfully demonstrated with only a 10-µL sample volume in 25-minute assay time. Analytical sensitivity was evaluated by a maximum nominal positiveness percentage value (NPPV) of 303 and a dilution factor of 32×. The method's inter-run and intra-run CV (coefficients of variance) values were 15.5 and 17.1%, respectively, which were fully compatible with the OIE (World Organization for Animal Health) principle of validation of diagnosis assays for infectious diseases. The developed method should become a powerful tool for determining other animal contagious diseases and/or zoonosis.

Dong, Z., et al. (2018). "Size-dependent transport and retention of micron-sized plastic spheres in natural sand saturated with seawater." Water Research **143**: 518-526.

A series of one-dimensional column experiments were conducted to investigate the transport and retention of micron-sized plastic spheres (MPs) with diameters of 0.1-2.0mum in seawater-saturated sand. In seawater with salinity of 35 PSU (practical salinity units), the mass percentages recovered from the effluent (M_{eff}) of the larger MPs increased from

13.6% to 41.3%, as MP size decreased from 2.0mum to 0.8mum. This occurred because of the gradual reduction of physical straining effect of MPs in the pores between sands. The smaller MPs (0.6, 0.4, and 0.1mum) showed the stronger inhibition of MPs mobility, with M_{eff} values of 11.5%, 11.9%, and 9.8%, respectively. This was due to the lower energy barriers (from 108 k_BT to 16 k_BT) between the smaller MPs and the sand surface, when compared with the larger MPs (from 296 k_BT to 161 k_BT). In particular, the aggregation of MPs (0.6 or 0.4mum) triggered a progressive decrease in MP concentration in the effluent. Retention experiments showed that the vertical migration distance of most MP colloids was 0-4cmat the inlet of column. For 0.6 or 0.4mumMPs, the particles were concentrated over a 0-2cm vertical distance. Moreover, the salinity (35-3.5 PSU) did not affect the transport of the larger MPs (2.0-0.8mum). However, as seawater salinity decreased from 35 PSU to 17.5 or 3.5 PSU, the aggregation of the smaller MPs (0.6-0.1mum) was dramatically inhibited or completely prevented. Meanwhile, ripening of the sand surface by the MPs (0.6 and 0.4mum) no longer occurred. By contrast, all MPs in deionized water (0 PSU) achieved complete column breakthroughs because of the strong repulsive energy barrier (from 218 k_BT to 4192 k_BT) between the MPs and the sand surface. Consequently, we find that the transport and retention of MPs in sandy marine environment strongly relies on both the MP size and the salinity levels.

Dong, Z., et al. (2019). "Cotransport of nanoplastics (NPs) with fullerene (C₆₀) in saturated sand: Effect of NPs/C₆₀ ratio and seawater salinity." Water Research **148**: 469-478.

Nanoplastics (NPs) have been identified as newly emerging particulate contaminants. In marine environments, the interaction between NPs and other engineered nanoparticles remains unknown. This study investigated the cotransport of NPs with fullerene (C₆₀) in seawater-saturated columns packed with natural sand as affected by the mass concentration ratio of NPs/C₆₀ and the hydrochemical characteristics. In seawater with 35 practical salinity units (PSU), NPs could remarkably enhance C₆₀ dispersion with a NPs/C₆₀ ratio of 1. NPs behaved as a vehicle to facilitate C₆₀ transport by decreasing colloidal zeta-potential and forming stable primary heteroaggregates. As the NPs/C₆₀ ratio decreased to 1/3, NPs mobility was progressively restrained because of the formation of large secondary aggregates. When the ratio continuously decreased to 1/10, the stability and transport of colloids were governed by C₆₀ rather than NPs. Under this condition, the transport trend of binary suspensions was similar to that of single C₆₀ suspension, which was characterized by a ripening phenomenon. Seawater salinity is another key factor affecting the stability and associated transport of NPs and C₆₀. In seawater with 3.5 PSU, NPs and C₆₀ (1:1) in binary suspension exhibited colloidal dispersion, which was driven by a high-energy barrier. Thus, the profiles of the cotransport and retention of NPs/C₆₀ resembled those of single NPs suspension. This work demonstrated that the cotransport of NPs/C₆₀ strongly depended on their mass concentration ratios and seawater salinity.

Dong, Z., et al. (2019). "Role of surface functionalities of nanoplastics on their transport in seawater-saturated sea sand." Environmental Pollution **Part 1. 255 (no pagination)**(113177).

Capsule: Surface functionalities of nanoplastics (NP) strongly influenced NP transport and retention in seawater-saturated sea sand. The transport and retention of nanoplastics (NP, 200 nm nanopolystyrene) functionalized with surface carboxyl (NPC), sulfonic (NPS), low-density amino (negatively charged, NPA⁻), and high-density amino (positively charged, NPA⁺) groups in seawater-saturated sand with/without humic acid were examined to explore the role of NP surface functionalities. The mass percentages of NP recovered from the effluent (M<inf>eff</inf>) with a salinity of 35 practical salinity units (PSU) were ranked as follows: NPC (19.69%) > NPS (16.37%) > NPA⁺ (13.33%) > NPA⁻ (9.78%). The homoaggregation of NPS and NPA⁻ was observed in seawater. The transport of NPA⁻ exhibited a ripening phenomenon (i.e., a decrease in the transport rate with time) due to the high attraction of NP with previously deposited NP, whereas monodispersed NPA⁺ presented a low M<inf>eff</inf> value because of the electrostatic attraction between NPA⁺ and negatively charged sand. Retention experiments showed that the majority of NPC, NPS and NPA⁺ accumulated in a monolayer on the sand surface, whereas NPA⁻ accumulated in multiple layers. Suwannee River humic acid (SRHA) could remarkably improve the transportability of NPC, NPS, and NPA⁻ by increasing steric repulsion. The strong attraction between NPA⁺ and the deposited NPA⁺ in the presence of SRHA triggered the weak ripening phenomenon. As seawater salinity decreased from 35 PSU to 3.5 PSU, the increase in electrostatic repulsion of NP-NP and NP-sand enhanced the transport of NPC, NPS, and NPA⁻, and the ripening of NPA⁻ breakthrough curves disappeared. In deionized water, NPC, NPS, and NPA⁻ achieved complete column breakthrough because the electrostatic repulsion between NP and sand intensified. However, the M<inf>eff</inf> values of NPA⁺ in 3.5 PSU seawater and deionized water presented limited increments of 15.49% and 23.67%, respectively. These results indicated that the fate of NP in sandy marine environments were strongly affected by NP surface functionalities, seawater salinity, and coexisting SRHA. Copyright © 2019 Elsevier Ltd

Donnelly, E. L. (2012). Prey and plastic ingestion of Pacific Northern Fulmars (Fulmarus glacialis) collected in Monterey Bay, California.

Marine plastic pollution affects seabirds that mistake it for prey or incidentally ingest it with prey. Northern Fulmars (Fulmarus glacialis) and seabirds that feed at the water's surface ingest the most plastic. This can cause health issues, including satiety that possibly leads to inefficient foraging. The objectives of this study were to examine fulmar body condition, identify cephalopod diet and ingested plastic, predict foraging areas, and determine if prey number and size was correlated with ingested plastics in Pacific Northern Fulmars (Fulmarus glacialis rodgersii). Cephalopod prey were identified, measured, and enumerated; plastic and marine debris were categorized, enumerated, and weighed from beach-cast Northern Fulmars wintering in Monterey Bay, California, during 2003 and 2007. Fulmars ate mostly Gonatid squids (Gonatus pyros, G. onyx , and G. californiensis) in similar size classes for both years. There was a significant negative correlation between pectoral muscle index and average size of cephalopod beaks per stomach, a significant increase in multiple plastic categories between years, and no significant correlation between the number and mass of plastic compared with the number and size of prey for either year. Although there was no correlation between plastic and prey, other issues with ingested plastics (contaminant accumulation, endocrine disruption, and micro plastics) should be further examined as plastic pollution increases in the world's oceans.

Donnelly-Greenan, E. L., et al. (2014). "Prey and plastic ingestion of Pacific Northern Fulmars (Fulmarus glacialis rogersii) from Monterey Bay, California." Marine Pollution Bulletin **85**(1): 214-224.

Marine plastic pollution affects seabirds, including Pacific Northern Fulmars (Fulmarus glacialis rodgersii), that feed at the surface and mistake plastic for prey or incidentally ingest it. Direct and indirect health issues can result, including satiety and possibly leading to inefficient foraging. Our objective was to examine fulmar body condition, identify cephalopod diet to species, enumerate and weigh ingested plastic, and determine if prey number and size were correlated with ingested plastics in beach-cast fulmars wintering in Monterey Bay California (2003, n=178: 2007, n=185). Fulmars consumed mostly Gonatus pyros, G. onyx, and G. californiensis of similar size for both years. We found a significant negative correlation between pectoral muscle index and average size of cephalopod beaks per stomach; a significant increase in plastic categories between 2003 and 2007; and no significant correlation between number and mass of plastic compared with number and size of prey for either year.

Donohue, M. J., et al. (2019). "Evaluating exposure of northern fur seals, Callorhinus ursinus, to microplastic pollution through fecal analysis." Marine Pollution Bulletin **138**: 213-221.

Environmental microplastics are widely documented in marine life and bioaccumulation may present risks to marine predators. Investigations of microplastics in marine mammals are increasing, though none have examined animals routinely consumed by humans. Here, we investigate microplastic exposure in the northern fur seal (Callorhinus ursinus), a species consumed by humans, using fecal material. We examined 44 feces (scat) at sites encompassing the seals' eastern Pacific range. Multiple contamination control measures were implemented, including field and laboratory controls. Fragments were the most common microplastic recovered, in 55% (24/44) of scat and no controls (range 1 to 86 fragments/scat, mean 16.6, sd 19.1). Microplastic fibers were recovered from 41% of scats (18/44), though some controls contained fibers confounding fiber results. Fecal analysis documented northern fur seal exposure to microplastics throughout their eastern Pacific range. Copyright © 2018

Doring, M. and F. A. Siebert (2010). "A method to check the design and specification of seeds in low-dose-rate brachytherapy." Brachytherapy **1)**: S61-S62.

Purpose: Using ¹²⁵Ior ¹⁰³Pd in LDR brachytherapy for prostate implants is a worldwide well-established method. An important factor for the success of the treatment is the exact knowledge of the dose distribution. Each seed type has its own dosimetric characteristics. These can be expressed for example by the TG-43 calculation method that allow for an accurate dose calculation. Due to the different design of the seed models they have an own dosimetric characterization. When using a modern seed treatment planning system the user must rely on that the design of the seeds and the TG-43 data set that is based on this design. It is a consumption that the individual seeds are within the seed types hardware specification. The internal design of six different seed models (Bebig S06, Bebig S17, BrachySeed, IBt, Oncura 6734, Theragenics Modell 200) was investigated and the resulting dimensions can be compared with their specifications. Material(s) and Method(s): To analyze the design of the sources non- radioactive seeds were at first casted in a plastic resin in a cuboid form of about 20 mm x 10 mm x 5 mm size. The casted seeds were manually grinded in longitudinal direction of the seeds until the half of the source was cut. In this way it was possible to visualize the internal design of the seeds over the whole source length. To check that the seed is grinded exactly halfway and consistently over the whole seed length thin marker plates with well known thickness were casted directly beneath the sources. When the grinding procedure reaches the marker this was an indicator that the source was cut halfway. After this process a microscope with an attached digital camera was used to take pictures of the cut seed. Because the images were scaled, absolute dimensions could be obtained. The measurements were carried out three times per seed by one observer and the mean value was used for further analysis. To ensure that the preparation method is reproducible the procedure of casting and grinding was performed four times by the same observer for one seed model (IBt Intersource-125). Result(s): The four times replicated investigations of the IBt seed type resulted in a mean length of 4.41

mm (SD: 0.06 mm) and 0.80 mm (SD: 0.01 mm) for the diameter. These values are close to the source specifications of 4.5 mm length and 0.8 mm diameter. The following seed lengths and diameters were measured for the other seed types: Bebig S06: (4.51 mm, 0.80 mm), Bebig S17: (4.53 mm, 0.82), BrachySeed: (4.22 mm, 0.79 mm), IBt: (4.44 mm, 0.80 mm), Oncura 6734: (4.62 mm, 0.78 mm), Theragenics: (4.43 mm, 0.90 mm). Some of the internal seed dimensions were already analyzed and compared with published data. For example, the length and diameter of the gold marker in the Bebig S06 model are specified with 3.5 and 0.17 mm. In this study 3.51 mm (SD: 0.00) respectively 0.18 mm (SD: 0.01) were obtained from the opened sources. In Figure 1 the cut Bebig S06 seed is shown for illustration. For the titanium wall thickness of this seed model the dimension of 0.05 mm was determined what exactly corresponds with the specification published in the TG-43 report. Conclusion(s): In this study we presented a method to check the internal dimensions of the design of LDR ¹²⁵I and ¹⁰³Pd sources. The preliminary results show no difference to the specification of the seeds.

Doros, A. (2010). "[Interventional radiological treatment of hepatocellular carcinoma]." Orvosi Hetilap **151**(30): 1204-1208.

During the last years, interventional radiological treatment of hepatocellular cancer has changed dramatically. The percutaneous ethanol infiltration is partly replaced by thermoablative methods, mainly by radiofrequency ablation. Cooled-tip electrodes and volumetric therapy planning increased the treatment success. Embolisation beads made vessel occlusion more precise and predictable, while the development of the drug eluting beads led to the most effective way of chemoembolisation. The so called radioembolisation with Yttrium 90 isotopes filled into glass microbeads is slowly gaining acceptance worldwide. Thermoablation and embolisation or chemoembolisation are the main tools for downstaging tumors, or avoiding disease progression in liver transplant recipients on the waiting list. All of these therapeutic options have their well established places in well known and worldwide accepted protocols, such as the algorithm of the Barcelona group (BCLC). In the near future, further results can be expected from the combination of available treatments, including sorafenib medication. [References: 17]

Dorr, I., et al. (1994). "Selecting somatic hybrid plants using magnetic protoplast sorting." Bio/Technology **12**(5): 511-515.

A magnetic cell sorter (MACS) technique designed for animal cells was used to produce large numbers of potato somatic hybrids. Selected biotinylated lectins are used to mediate, via streptavidin, the binding of superparamagnetic microbeads to the protoplasts of one fusion partner. The other partner contains the selectable marker neomycin phosphotransferase II (NPT II). After fusion, the protoplast mixture is sorted by MACS, which retains protoplasts labelled with magnetic microbeads. This fraction is incubated on kanamycin-containing medium, where only hybrid cells grow into calluses. The protoplast staining with lectins, the protoplast separation with MACS and the regeneration of hybrid calluses into plants were optimized. With MACS treatment, the percentage among regenerated plants of hybrids between two clones of Solanum tuberosum increased from 8 to 36%. In the interspecific somatic hybridization S. tuberosum x S. bulbocastanum, the increase was from 28 to 82%. Hybrid plants were identified by DNA fingerprinting and had the morphology and cytology expected for fusion products. The large number of plants which can be obtained should enable selection of hybrids with desired chromosome number, morphology and seed fertility.

Doucette, A., et al. (2000). "Protein concentration and enzyme digestion on microbeads for MALDI-TOF

peptides mass mapping of proteins from dilute solutions." Analytical Chemistry **72**(14): 3355-3362.

A method for generating peptide mass maps from dilute protein samples is presented. The method involves the concentration of proteins from aqueous solution by adsorption onto reversed-phase polymeric microbeads. These beads are then washed extensively to remove contaminants, after which the bound proteins are digested with trypsin. Analysis of the digestion products is performed by MALDI-TOF mass spectrometry following direct deposition of the beads on a MALDI target, along with the matrix solution. The procedure is demonstrated using solutions of cytochrome c, lysozyme, and bovine serum albumin. The results of these digests are compared to trypsin digestions of the protein samples without sample preconcentration. Comparative results are also presented for protein solutions contaminated with 2 M NaCl, 2 M urea, or sodium dodecyl sulfate at concentrations up to 0.02%. These results reveal that, with the microbead preconcentration procedure, peptide mass maps can routinely be generated from highly contaminated samples with a protein concentration of only 100 nM.

Douglas, A. C., et al. (2013). "Akt2 regulates mitophagy in breast cancer cell lines." Cancer Research. Conference: 104th Annual Meeting of the American Association for Cancer Research, AACR **73**(8 SUPPL. 1).

The PI3K-Akt signaling pathway is involved in the regulation of cell growth, proliferation, metabolism, and death by apoptosis and autophagy. There are three isoforms of Akt (1, 2, and 3) that share over 70% sequence identity and two activating phosphorylation sites. The activation of Akt by insulin or insulin-like growth factor (IGF-1) results in rapid phosphorylation of two amino acid residues that are conserved among all three Akt isoforms. Phosphorylation of threonine 308 (Thr308) leads to roughly 100-fold higher activity, while phosphorylation at serine 474 (Ser474) potentiates the activity another 10-fold. The two phosphorylation events are independent of one another and while phosphoinositide-dependent kinase 1 (PDK1) is accepted as the activating kinase for Thr308, the kinase that phosphorylates Ser474 has only recently been confirmed as the target of rapamycin in complex with Rictor and Sin1 (mTORC2). Among the three Akt isoforms, Akt2 is a particularly promising breast cancer therapeutic target, as its ablation most profoundly affects the long-term cell survival rate. Ablation of Akt2 induces autophagy, which increases cancer cell survival and resistance in response to chemotherapy. In this work, we examined the possibility that Akt2 may specifically regulate autophagic destruction of the mitochondria (mitophagy) via the mitophagy activator PINK1. This point of regulation may represent an attractive therapeutic target to decrease autophagy and increase cancer cell death. Insulin signaling promotes the phosphorylation of Akt by mTORC2 via the PTEN-induced putative kinase (PINK1). PINK1 is a serine/threonine mitochondrial kinase that has been linked to familial Parkinson's disease. PINK1 was originally classified in a screen for transcriptional upregulation of genes upon overexpression of PTEN in two endometrial cancer cell lines, but in the same publication high levels of PINK1 mRNA were present in ovarian tumours that were lacking PTEN. No further investigations into this relationship have been described and it remains unclear as to the relationship between PTEN, Akt, and PINK1, and how regulation occurs at the transcriptional or posttranslational level. Normally PINK1 regulates mitochondrial quality control by targeting defective mitochondria for autophagy (referred to as mitophagy) via the ubiquitin E3 ligase Parkin. We have identified an interaction between Akt2 and the major regulator of mitophagy (PINK1). We suggest that Akt2 normally inhibits mitophagy, and that inhibition of Akt leads to selective autophagic destruction of the mitochondria. We next wanted to determine whether Akt2 activation is required for its mitochondrial localization. Mitochondria isolations were performed using magnetic labelling of the mitochondria with Anti-TOM22 microbeads. The results suggest that the key activating

residues of Akt2 may not be required for mitochondrial localization.

Doyen, P., et al. (2019). "Occurrence and identification of microplastics in beach sediments from the Hauts-de-France region." Environmental Science & Pollution Research **26**(27): 28010-28021.
The present work was carried out to quantify microplastics (MP) from three sandy beaches along the Cote d'Opale coastline located in the Hauts-de-France region of northern France. Three different study sites located along the English Channel were investigated due to different levels of anthropopression and hydrodynamic conditions. Sediments were collected at three different tide lines: high tide line (HTL), middle of the intertidal zone (IZ), and low tide line (LTL), to investigate the effects of tide line on microplastic contamination. Particles and fibers were counted and colors were recorded; polymer identification was then performed using pyrolysis-gas chromatography-mass spectrometry (Py-GC/MS). Particle and fiber abundances ranged from 23.4 +/- 18.9 to 69.3 +/- 30.6 items kg⁻¹ dry weight sediment, with a trend towards fiber predominance, were observed. No difference in particle and fiber abundance was found between the different beaches and tide lines, except for Boulogne-sur-Mer, where the particle number was significantly different between tide lines. Major polymers identified were polyethylene (36.6%) and polypropylene (10.7%). This citizen science project provided preliminary data about the abundance and polymeric nature of MP along the Cote d'Opale coastline.

Doyle, D., et al. (2019). "Low levels of microplastics recorded from the common periwinkle, Littorina littorea on the west coast of Ireland." Marine Pollution Bulletin **149 (no pagination)**(110645).
Microplastics (MPs) are an environmental pollutant of increasing concern. However, little research has assessed MP levels in intertidal gastropods. The authors explored MP abundance in the gastropod Littorina littorea from four sites within Galway Bay, West Ireland. To do this, 50 L. littorea were collected from four rocky shores of varying wave exposure, with two sites located in the north of the bay and two in the south. An additional 50 individuals were taken from a commercial exporter, to determine MP levels in L. littorea intended for human consumption. MPs were recovered from 60.4% of the individuals and the average MP level was 2.14 MPs/gram of wet soft body mass. MP levels differed significantly between sites, with the two northern sites having the highest levels. Oceanographic conditions within Galway Bay are likely responsible for the observed variation in MP abundance, with the North Sound of the bay potentially facilitating deposition. Copyright © 2019

Doyle, M. J., et al. (2011). "Plastic particles in coastal pelagic ecosystems of the Northeast Pacific ocean." Marine Environmental Research **71**(1): 41-52.
The purpose of this study was to examine the distribution, abundance and characteristics of plastic particles in plankton samples collected routinely in Northeast Pacific ecosystems, and to contribute to the development of ideas for future research into the occurrence and impact of small plastic debris in marine pelagic ecosystems. Plastic debris particles were assessed from zooplankton samples collected as part of the National Oceanic and Atmospheric Administration's (NOAA) ongoing ecosystem surveys during two research cruises in the Southeast Bering Sea in the spring and fall of 2006 and four research cruises off the U.S. west coast (primarily off southern California) in spring, summer and fall of 2006, and in January of 2007. Nets with 0.505 mm mesh were used to collect surface samples during all cruises, and sub-surface samples during the four cruises off the west coast. The 595 plankton samples processed indicate that plastic particles are widely distributed in surface waters. The proportion of surface samples from each cruise that contained particles of plastic ranged from 8.75 to

84.0%, whereas particles were recorded in sub-surface samples from only one cruise (in 28.2% of the January 2007 samples). Spatial and temporal variability was apparent in the abundance and distribution of the plastic particles and mean standardized quantities varied among cruises with ranges of 0.004-0.19 particles/m3, and 0.014-0.209 mg dry mass/m3. Off southern California, quantities for the winter cruise were significantly higher, and for the spring cruise significantly lower than for the summer and fall surveys (surface data). Differences between surface particle concentrations and mass for the Bering Sea and California coast surveys were significant for pair-wise comparisons of the spring but not the fall cruises. The particles were assigned to three plastic product types: product fragments, fishing net and line fibers, and industrial pellets; and five size categories: <1 mm, 1-2.5 mm, >2.5-5 mm, >5-10 mm, and >10 mm. Product fragments accounted for the majority of the particles, and most were less than 2.5 mm in size. The ubiquity of such particles in the survey areas and predominance of sizes <2.5 mm implies persistence in these pelagic ecosystems as a result of continuous breakdown from larger plastic debris fragments, and widespread distribution by ocean currents. Detailed investigations of the trophic ecology of individual zooplankton species, and their encounter rates with various size ranges of plastic particles in the marine pelagic environment, are required in order to understand the potential for ingestion of such debris particles by these organisms. Ongoing plankton sampling programs by marine research institutes in large marine ecosystems are good potential sources of data for continued assessment of the abundance, distribution and potential impact of small plastic debris in productive coastal pelagic zones.

Drain, S., et al. (2010). "Multidrug resistance gene expression in plasma cell myeloma." Haematologica **2)**: 387-388.

Background: Multi-drug resistance (MDR) is a phenomenon that can lead to impaired treatment efficacy in all forms of malignancy. The most prominent forms of MDR are mediated by the drug effluxing actions of certain adenosine tri-phosphate binding cassette (ABC) transport proteins. Recent debates in plasma cell myeloma (PCM) have questioned which of the many ABC transporters are to be implicated in the course of this disease and also in the treatment of PCM post relapse. rs1045642 is a SNP within ABCB1 which is thought to affect the activity of the protein product (P-glycoprotein) and has demonstrated significant associations with overall survival in PCM1. Aims. This study was designed to investigate the expression of the MDR associated genes; ABCB1, ABCB4, LRP, ABCC1 and ABCG2 in PCM. We also wished to determine the impact of rs1045642 on ABCB1 mRNA levels in PCM. Method(s): 89 patients with a confirmed diagnosis of PCM were studied with ethical consent approved via ORECNI. Of these patients, 81 were biopsied at diagnosis of either MGUS or MM and 8 at relapse. Tumour cells were separated from bone marrow biopsies using CD138+magnetic microbeads and RNA was extracted using Trizol. mRNA expression was determined for each gene using relative quantification and taqman validated assays. Results are expressed as a fold change from expression in normal plasma cells. Result(s): Of the 5 genes investigated, ABCB4 (MDR-3) has demonstrated the greatest increase in PCM patients at diagnosis with a mean fold change of 26. In relapsed samples, all genes apart from ABCB1 have demonstrated a substantial decrease in mean fold change with ABCB4 mean fold change reduced to 9. ABCB1 mean fold change was increased from 0.6 at diagnosis to 2.8 in relapsed samples. MDR gene expression was not significantly associated with currently available prognostic factors in PCM (B2M, Albumin, Ig class and light chain restriction). rs1045642 does not affect ABCB1 mRNA levels in PCM patient samples. Conclusion. This study suggests that ABCB4 may be the most prominent contributor to MDR and initial treatment failure in newly diagnosed PCM. ABCB1, however, appears to haveincreased mRNA levels in relapsed samples suggesting that P-gp may be a more prominent

contributor to treatment strategies, post relapse, in PCM. MDR gene expression may be an independent factor affecting treatment within this patient cohort. rs1045642 does not alter ABCB1 mRNA levels in PCM suggesting that effects of this SNP manifest at the protein level. Further work will investigate the expression and activity of P-glycoprotein in PCM and will determine the clinical effect of rs1045642 on P-gp.

Driedger, A. G. J., et al. (2015). "Plastic debris in the Laurentian Great Lakes: a review." Journal of Great Lakes Research **41**(1): 9-19.

Pollution by plastic debris is an increasing environmental concern in the Laurentian Great Lakes where it affects open-water, shoreline, and benthic environments. Open-water surveys reveal that, in certain areas of the Great Lakes, surface water densities of plastics are as high as those reported for areas of litter accumulation within oceanic gyres. Data from volunteer beach cleanups show that typically more than 80% of anthropogenic litter along the shorelines of the Great Lakes is comprised of plastics. The distribution of plastics in bottom sediments of the Great Lakes is essentially unknown. Sources of plastic debris to the Great Lakes include microplastic beads from consumer products, pellets from the plastic manufacturing industry, and waste from beach-goers, shipping, and fishing activities. Many plastics degrade slowly in the environment and may have long-term adverse ecological and economic impacts, including the dispersal of persistent organic pollutants. Plans to combat and curtail plastic debris pollution in the Great Lakes will come at a significant economic cost, likely in excess of $400 million annually. Here, we review the current state of knowledge on plastic pollution in the Great Lakes, identify knowledge gaps, and suggest future research directions.

Dris, R., et al. (2017). "A first overview of textile fibers, including microplastics, in indoor and outdoor environments." Environmental Pollution **221**: 453-458.

Studies about microplastics in various environments highlighted the ubiquity of anthropogenic fibers. As a follow-up of a recent study that emphasized the presence of man-made fibers in atmospheric fallout, this study is the first one to investigate fibers in indoor and outdoor air. Three different indoor sites were considered: two private apartments and one office. In parallel, the outdoor air was sampled in one site. The deposition rate of the fibers and their concentration in settled dust collected from vacuum cleaner bags were also estimated. Overall, indoor concentrations ranged between 1.0 and 60.0 fibers/m³. Outdoor concentrations are significantly lower as they range between 0.3 and 1.5 fibers/m³. The deposition rate of the fibers in indoor environments is between 1586 and 11,130 fibers/day/m² leading to an accumulation of fibers in settled dust (190-670 fibers/mg). Regarding fiber type, 67% of the analyzed fibers in indoor environments are made of natural material, primarily cellulosic, while the remaining 33% fibers contain petrochemicals with polypropylene being predominant. Such fibers are observed in marine and continental studies dealing with microplastics. The observed fibers are supposedly too large to be inhaled but the exposure may occur through dust ingestion, particularly for young children.

Dris, R., et al. (2015). "Microplastic contamination in an urban area: a case study in Greater Paris. (Special Issue: Microplastics in the environment.)." Environmental Chemistry **12**(5): 592-599.

This study investigates the microplastic contamination of both urban compartments (wastewater and total atmospheric fallout) and surface water in a continental environment. These first investigations on an urban environment confirm the presence of microplastics in sewage, fresh water and total atmospheric fallout and provide knowledge on the type and size distribution of microplastics in the 100-5000- micro m range. For the first time, the presence of

microplastics, mostly fibres, is highlighted in total atmospheric fallout (29-280 particles m⁻² day⁻¹). High levels of fibres were found in wastewater (260-320x10³ particles m⁻³). In treated effluent, the contamination significantly decreased to 14-50x10³ particles m⁻³. In the River Seine, two sampling devices were used to collect both large and small microplastic particles: (i) a plankton net (80- micro m mesh), and (ii) a manta trawl (330- micro m mesh). Sampling with the plankton net showed a predominance of fibres, with concentrations ranging from 3 to 108 particles m⁻³. A greater diversity of both microplastic shapes and types was found during manta trawl sampling but at much lower concentrations (0.28-0.47 particles m⁻³). This combined approach could be relevant and implemented in future studies to provide an accurate overview of microplastic distribution in freshwater.

Dris, R., et al. (2018). "Synthetic and non-synthetic anthropogenic fibers in a river under the impact of Paris Megacity: Sampling methodological aspects and flux estimations." Science of the Total Environment **618**: 157-164.

Processed fibers are highly present in our daily life and can be either natural, artificial (regenerated cellulose) and synthetic (made with petrochemicals). Their widespread use lead inevitably to a high contamination of environment. Previous studies focus on plastic particles regardless of their type or shape as long as they are comprised between 330mum and 5mm. On the contrary, this study focuses exclusively on fibers using a smaller mesh size net (80mum) to sample freshwater. Moreover, all processed organic fibers are considered, irrespective to their nature. First, the short term temporal variability of the fibers in the environment was assessed. While exposing the sampling net during 1min a coefficient of variation of approx. 45% (with n=6) was determined. It was of only 26% (n=6) when the exposure was of 3min. The assessment of the distribution through the section showed a possible difference in concentrations between the middle of the water surface and the river banks which could be attributed to the intense river traffic within the Paris Megacity. The vertical variability seems negligible as turbulence and current conditions homogenize the distribution of the fibers. A monthly monitoring showed concentrations of 100.6+/-99.9fibers.m⁻³ in the Marne River and of: 48.5+/-98.5, 27.9+/-26.3, 27.9+/-40.3 and 22.1+/-25.3fibers.m⁻³ from the upstream to downstream points in the Seine River. Once these concentrations are converted into fluxes, it seems that the impact generated by the Paris Megacity cannot be distinguished. Investigations on the role of sedimentation and deposition on the banks are required. This study helped fill some major knowledge gaps regarding the fibers in rivers, their sampling, occurrence, spatial-temporal distribution and fluxes. It is encouraged that future studies include both synthetic and none synthetic fibers.

Dris, R., et al. (2016). "Synthetic fibers in atmospheric fallout: A source of microplastics in the environment?" Marine Pollution Bulletin **104**(1-2): 290-293.

Sources, pathways and reservoirs of microplastics, plastic particles smaller than 5mm, remain poorly documented in an urban context. While some studies pointed out wastewater treatment plants as a potential pathway of microplastics, none have focused on the atmospheric compartment. In this work, the atmospheric fallout of microplastics was investigated in two different urban and sub-urban sites. Microplastics were collected continuously with a stainless steel funnel. Samples were then filtered and observed with a stereomicroscope. Fibers accounted for almost all the microplastics collected. An atmospheric fallout between 2 and 355 particles/m(2)/day was highlighted. Registered fluxes were systematically higher at the urban than at the sub-urban site. Chemical characterization allowed to estimate at 29% the proportion

of these fibers being all synthetic (made with petrochemicals), or a mixture of natural and synthetic material. Extrapolation using weight and volume estimates of the collected fibers, allowed a rough estimation showing that between 3 and 10 tons of fibers are deposited by atmospheric fallout at the scale of the Parisian agglomeration every year (2500 km(2)). These results could serve the scientific community working on the different sources of microplastic in both continental and marine environments.

Dris, R., et al. (2015). "Beyond the ocean: contamination of freshwater ecosystems with (micro-)plastic particles. (Special Issue: Microplastics in the environment.)." Environmental Chemistry **12**(5): 539-550.

Massive accumulation of plastic particles has been reported for marine ecosystems around the world, posing a risk to the biota. Freshwater ecosystems have received less attention despite most plastic litter being produced onshore and introduced into marine environments by rivers. Some studies not only report the presence of microplastics in freshwater ecosystems, but show that contamination is as severe as in the oceans. In continental waters, microplastics have been observed in both sediments (predominantly lake shores but also riverbanks) and water samples (predominantly surface water of lakes and rivers). This review highlights recent findings and discusses open questions, focussing on the methodology of assessing this contaminant in freshwater ecosystems. In this context, method harmonisation is needed in order to obtain comparable data from different environmental compartments and sites. This includes sampling strategies (at spatial and temporal scales), sample treatment (taking into consideration high levels of organic matter and suspended solids) and reliable analytical methods to identify microplastics.

Drury, W. J., et al. (1993). "Interactions of 1 um latex particles with Pseudomonas aeruginosa biofilm." Water Research **27**(7): 1119-1126.

Some of the ways in which particles and biofilms might react in water and waste treatment are indicated, and results are reported from experiments to study such interactions in a well-characterized model system, with fluorescently-labelled latex microbeads and biofilms of Pseudomonas aeruginosa in a continuous flow annular reactor. The microbeads attached readily to the biofilm and could be easily identified and enumerated separately from the bacteria. The particles penetrated the full 34 um depth of the biofilm. Capture of the microbeads by the biofilm was proportional to the biofilm cell carbon concentration and to the standard deviation

in biofilm thickness measurements. The microbeads formed aggregates on the biofilm but not in the associated bulkwater. The retention period for the beads in the biofilm was much longer than that for suspended particles in the reactor. These experiments simulated the fate of quiescent (non-producing) micro-organisms in biological reactors.

Dryden, G. W., et al. (2011). "EGCG reduces pro-inflammatory cytokine production and induces apoptosis in activated CD14+ macrophages, CD4+Cd45+RO T cells, and mixed macrophage/T cell populations, but not CD4+Cd45+RA T cells from IBD patients and controls." Gastroenterology **1)**: S838.

Introduction: Due to its anti-oxidant, anti-inflammatory and pro-apoptotic effects, (-)epigallo-catechin 3-gallate (EGCG), the major green tea polyphenol, has sparked considerable interest as a potential therapeutic agent for chronic inflammatory diseases, including the inflammatory bowel diseases (IBD) Crohn's disease and ulcerative colitis. Aim(s): To analyze the ability of EGCG to inhibit production of pro-inflammatory cytokines and to induce apoptosis in subpopulations (CD14⁺ macrophages, CD4⁺CD45⁺RO T cells and CD4⁺CD45⁺RA T cells) of human peripheral blood mononuclear cells from IBD patients and controls. Method(s): CD14⁺ macrophages, CD4⁺CD45⁺RO and CD4⁺CD45⁺RA T cells were isolated by microbead technology from the peripheral blood of 5 IBD patients and 3 normal controls. Varying levels of EGCG were introduced into the supernatant for 24h with LPS-stimulated CD14⁺ macrophages, CD4⁺CD45⁺RO or CD4⁺CD45⁺RA T cells alone or mixed with CD14⁺ macrophages and the two T cell subpopulations. Supernatants were collected to assay IBD related cytokines, including IFNgamma, IL-6, and IL-17. Under similar conditions, apoptosis of the cells was assessed by Annexin V/propidium iodide staining immediately following the 24 hr culture. Result(s): In IBD patients, EGCG administration (5mug/ml) clearly diminished the production of pro-inflammatory cytokines in cultures of LPS-stimulated CD14⁺ macrophages alone or mixtures of macrophages co-cultured with CD4⁺CD45⁺RO T cells (see table for % reduction from LPS-stimulated baseline). However, EGCG had little or no effect on cultures of CD4⁺CD45⁺RA T cells. In cultures of cells from healthy control individuals, EGCG showed a similar inhibitory pattern. In IBD patients, EGCG (5mug/ml) induced significant apoptosis in 24 h cultures of LPS-stimulated CD14⁺ macrophages and CD4⁺CD45⁺RO T cells alone, while no apoptosis was detected (0.9%) in CD4⁺CD45⁺RA T cell cultures. In mixed cultures of LPS stimulated CD14+ macrophages and CD4⁺CD45⁺RO T cells, the same EGCG concentration induced significant apoptosis. No significant apoptosis (0.42%) was observed when CD4⁺CD45⁺RA T cells were substituted. Interestingly, cells from healthy control (normal) individuals showed similar patterns of response to EGCG, but reduced levels of apoptosis, whether examining LPS-stimulated CD14⁺ macrophages or CD4⁺CD45⁺RO T cells stimulated with anti-CD3. Discussion(s): These results reveal that EGCG administration imparts significant anti-inflammatory and proapoptotic effects, as evidenced by its capacity to reduce production of several pro-inflammatory cytokines and induce significant rates of apoptosis in LPS-stimulated CD14+ macrophages and CD4⁺CD45⁺RO T cells. The latter effect seemed to be more pronounced in cells from IBD patients compared to healthy controls. We are currently evaluating this therapy in patients with active colitis. (Table presented).

Dryden, G. W., et al. (2009). "EGCG, a green tea catechin, reduces pro-inflammatory cytokine production

by CD14⁺ macrophages, CD4⁺Cd45⁺RO⁺ T cells, and mixed macrophage/T Cell populations from IBD patients and controls." Gastroenterology **1)**: A687.

Introduction: Green tea polyphenols, particularly -(-) epigallocatechin 3-gallate (EGCG), have sparked considerable interest as potential therapeutic agents for chronic inflammatory diseases due to their anti-oxidant and anti-inflammatory effects. Aim(s): Analyze the ability of EGCG to inhibit production of pro-inflammatory cytokines in human peripheral blood mononuclear cells (PBMCs) In Vitro to gauge its anti-inflammatory effects in immune cells from IBD patients. Method(s): PBMCs were obtained from 4 colitis patients and 4 normal controls and enriched for monocytes or lymphocytes by plastic adherence. CD14+ macrophages, CD4⁺CD45⁺RO⁺ and CD4⁺CD45⁺RA⁺ T cells were isolated respectively by microbead technology. Three experiments were performed: 1) Lipopolysaccharide (LPS) stimulated CD14⁺ macrophages alone, 2) co-cultured with CD4⁺CD45⁺RO⁺ or CD4⁺CD45⁺RA⁺ T cells, or 3) anti-CD3 Ab stimulated CD4⁺CD45⁺RO⁺ T cells were incubated in the presence of EGCG (0-10 ng/mul) for 3 and 6 days. Supernatants were collected for cytokine analysis by ELISA. Result(s): LPS stimulated CD14⁺macrophages, orCD4⁺CD45⁺RO⁺T cells co-cultured with LPS stimulated macrophages experienced a dose-dependent reduction in pro-inflammatory cytokine production as shown in table 1. Co-culture of CD14⁺ macrophages with CD4⁺CD45⁺RO⁺ T cells resulted in a 92% reduction of IL-17 production. There was no change in IL-17 production when CD4⁺CD45⁺RA⁺T cells were substituted. When evaluated in LPS stimulated CD14⁺ macrophages alone, EGCG elicited a similar reduction in cytokine production. Reduced cytokine levels were not due to loss of cell viability. Discussion(s): These results reveal that EGCG produces a significant anti-inflammatory effect by reducing the production of the pro-inflammatory cytokines TNFalpha, IL-1beta, IL-6, and IFNgamma. The ability of EGCG to increase apoptosis in lymphocytes from colitis patients, but not from healthy controls, suggests that it may offer a clinical benefit by this mechanism, as well. We are currently conducting a clinical trial in patients with ulcerative colitis to evaluate the clinical correlation of these findings. {Table presented}.

Drzyzga, O. and A. Prieto (2019). "Plastic waste management, a matter for the ‘community’." Microbial Biotechnology **12**(1): 66-68.

[...]according to all current expert reports, if the advantages of plastics are to be enjoyed in full, we also need to promote the most sustainable waste management alternatives, encourage recycling, use energy recovery as a complementary option and restrict the dumping in landfills of all recoverable plastic waste. By screening natural microbial communities exposed to PET in the environment, Yoshida et al. ( ) isolated a novel bacterium (Ideonella sakaiensis strain 201-F6) that can use PET as its major energy and carbon source. Natural or designed microbial communities might also be used for the biodegradation of petroleum-based plastic waste, with a balanced set of enzymes attacking the carbon backbones under favourable abiotic conditions (e.g. at controlled industrial composting facilities; Bhardwaj et al.,). [...]it may be possible to design efficient microbial communities able to degrade plastic waste – even those types currently recalcitrant to biologically driven breakdown.

Du, P., et al. (2009). "Construction of DNA sandwich electrochemical biosensor with nanoPbS and

nanoAu tags on magnetic microbeads." Biosensors & Bioelectronics **24**(11): 3223-3228.

A novel and sensitive sandwich electrochemical biosensor based on the amplification of magnetic microbeads and Au nanoparticles (NPs) modified with bio bar code and PbS nanoparticles was constructed in the present work. In this method, the magnetic microspheres were coated with 4 layers polyelectrolytes in order to increase carboxyl groups on the surface of the magnetic microbeads, which enhanced the amount of the capture DNA. The amino-functionalized capture DNA on the surface of magnetic microbeads hybridized with one end of target DNA, the other end of which was hybridized with signal DNA probe labelled with Au NPs on the terminus. The Au NPs were modified with bio bar code and the PbS NPs were used as a marker for identifying the target oligoncleotide. The modification of magnetic microbeads could immobilize more amino-group terminal capture DNA, and the bio bar code could increase the amount of Au NPs that combined with the target DNA. The detection of lead ions performed by anodic stripping voltammetry (ASV) technology further improved the sensitivity of the biosensor. As a result, the present DNA biosensor showed good selectivity and sensitivity by the combined amplification. Under the optimum conditions, the linear relationship with the concentration of the target DNA was ranging from 2.0 x 10(-14) M to 1.0 x 10(-12)M and a detection limit as low as 5.0 x 10(-15)M was obtained.

Du, X., et al. (2009). "The epidemiological study on cryptosporidiosis in outpatients of Nanjing children's hospital." Journal of Tropical Medicine **9**(4): 382-385.

The prevalence of cryptosporidiosis among the paediatric outpatients of the Nanjing Children's Hospital, Jiangsu, China, was investigated. 2268 faecal samples collected from July to August and September to October were screened for Cryptosporidium using modified acid-fast staining and then sequentially diagnosed using auramine phenol fluorescence-modified acid-fast complex straining. In addition, 207 serum samples were randomly obtained from the outpatients to detect specific IgG to the Cryptosporidium recombinant SA35 protein using the microbead immunoassay (MIA). The prevalence of cryptosporidiosis based on faecal parasitological examination was 0.97%. The positive rate of anti-SA35 IgG was 29.95%. The prevalence was not significantly different between the male and female patients (P>0.05) by faecal examination, whereas there was a significant difference between children under and above one year old (P<0.05) by MIA. It is concluded that children in Nanjing and surrounding regions are still at risk of cryptosporidiosis in the summer and autumn.

Du, X., et al. (2009). "The application of microbead immunoassay in the research and diagnosis of parasitology." Zhongguo Bingyuan Shengwuxue Zazhi / Journal of Pathogen Biology **4**(9): 712-715.

The development and application of medical experimental methods are fundamental to medical research and disease diagnosis. Microbead immunoassay (MIA) can be used to detect specific proteins including cytokines and pathogenic antigen, as well as nucleic acids etc. MIA, which utilizes microbeads as solid support, can measure simultaneously up to 100 different analytes in a single reaction well and its predominance includes high sensitivity, specificity, reliability, and rapid multiplex detection capability. In recent years, MIA has been more and more applied in parasitological research and diagnostic test development. In this paper, we focus on the history, advantages and disadvantages of MIA, and its application and perspective in the fields of parasitology research are also reviewed.

Du, X. L., et al. (2009). "Simultaneous detection of serum immunoglobulin G antibodies to Cryptosporidium parvum by multiplex microbead immunoassay using 3 recognized specific recombinant C. parvum antigens." Diagnostic Microbiology & Infectious Disease **65**(3): 271-278.

Cryptosporidiosis is a significant diarrheal disease in both humans and other mammals worldwide. In the present study, we established and validated a multiplex microbead immunoassay (MIA) for surveillance of Cryptosporidium parvum infections. In the multiplex MIA, 3 specific recombinant proteins, CP23, SA35, and SA40, were used as the capture antigens simultaneously. The antibody directed against CP23 is an index of historic infection, and those against SA35 and SA40 are indices of recent infection. The multiplex MIA yielded essentially identical results with that of monoplex MIA using these 3 recombinant proteins, and the reproducibility of the multiplex MIA results was high when standardized with a calibration curve. With multiplex MIA, we detected that the pediatric population showed a higher percentage of recent infections (seropositive rates of antibodies directed against CP23, SA35, and SA40 were 6.28%, 23.19%, and 22.71%, respectively, n = 207), whereas the adult population showed a higher percentage of historic infections (seropositive rates of antibodies directed against CP23, SA35, and SA40 were 24.40%, 11.48%, and 16.75%, respectively, n = 209).

Duan, H., et al. (2019). "Post-consumer packaging waste from express delivery in China." Resources, Conservation and Recycling **144**: 137-143.

Express delivery plays a vital role in modern economy, but also brings great concern on post-consumer packaging waste. This study is therefore designed to characterize the material flows and environmental implications of post-consumer packaging waste from express delivery in China. While express delivery packaging uses mainly recycled materials, post-consumer packaging wastes are only partially recycled in China. In addition, plastic packaging materials are mainly produced from recycled agricultural films and contain chemical residues from pesticide applications which may have significant health impacts on employees and consumers in the express delivery industry. Policy suggestions are provided for government, express delivery service providers, and consumers to mitigate environmental impacts of post-consumer packaging waste from China's booming express delivery industry. Duan, Z., et al. (2019). "Microplastics in Yellow River Delta wetland: Occurrence, characteristics, human influences, and marker." Environmental Pollution: 113232.

Microplastics (MPs) are widespread in the environment including coastal wetlands. The influence of different types and intensities of human activities on the occurrence of MPs in coastal wetlands is still unknown. The aim of this study was to investigate the distribution of MPs and the contribution of human activities in different areas of Yellow River Delta wetland. MPs were widely detected in different areas of the wetland even in the protection area with little human activities. Direct human activities resulted in more severe MPs contamination in the protection area than the tourism area. In the soil of different areas, the MPs abundances ranged from 136 to 2060 items/kg. The concentrations of polyethylene terephthalate (PET) ranged from 536 to 660mug/kg, and the concentrations of polycarbonate (PC) ranged from 83.9 to 196mug/kg. The MP abundances of the three areas had significant correlations with PET concentrations. These results indicate that the direct influence of human activities has much greater contribution than indirect influence. These results also suggest that PET concentration can be used as a potential marker of MPs contamination in wetland soils.

Duangchan, A. and C. Samart (2008). "Tertiary recycling of PVC-containing plastic waste by copyrolysis with cattle manure." Waste Management **28**(11): 2415-2421.

The corrosion from pyrolysis of PVC in plastic waste was reduced by copyrolysis of PVC with cattle manure. The optimization of pyrolysis conditions between PVC and cattle manure was studied via a statistical method, the Box-Behnken model. The pyrolysis reaction was operated in a tubular reactor. Heating rate, reaction temperature and the PVC:cattle manure ratio were optimized in the range of 1-5 degreeC/min, 250-450 degreeC and the ratio of 1:1-1:5, respectively. The suitable conditions which provided the highest HCl reduction efficiency were the lowest heating rate of 1 degreeC/min, the highest reaction temperature of 450 degreeC, and the PVC:cattle manure ratio of 1:5, with reliability of more than 90%. The copyrolysis of the mixture of PVC-containing plastic and cattle manure was operated at optimized conditions and the synergistic effect was studied on product yields. The presence of manure decreased the oil yield by about 17%. The distillation fractions of oil at various boiling points from both the presence and absence of manure were comparable. The BTX concentration decreased rapidly when manure was present and the chlorinated hydrocarbon was reduced by 45%. However, the octane number of the gasoline fraction was not affected by manure and was in the range of 99-100. © 2008 Elsevier Ltd. All rights reserved.

Dubaish, F. and G. Liebezeit (2013). "Suspended microplastics and black carbon particles in the Jade system, southern North Sea." Water, Air, and Soil Pollution **224 (2) (no pagination)**(1352).
Suspended microplastic and black carbon (BC) particles were determined in surface waters of the Jade system, southern North Sea, including freshwater sources. On average, 64 +/- 194 granular particles, 88 +/- 82 fibres and 30 +/- 41 BC particles/L were recorded. Maximum numbers reached 1,770/L for granules, 650/L for fibres and 330/L for black carbon particles. The distribution along a transect from the inner to the outer part of the Jade system indicates granular particles to be dominant in the inner part, while fibres occur more prominently in the outer part. The distribution of BC particles was more uniform. All freshwater sources including sewage treatment plant effluents discharged microplastics, while BC was encountered only at two of nine discharge points. © 2013 Springer Science+Business Media Dordrecht.

Dubbelboer, I. R., et al. (2018). "Porcine and Human In Vivo Simulations for Doxorubicin-Containing Formulations Used in Locoregional Hepatocellular Carcinoma Treatment." AAPS Journal **20**(6): 96.
It is important to be able to simulate and predict formulation effects on the pharmacokinetics of a drug in order to optimize effectivity in clinical practice and drug development. Two formulations containing doxorubicin are used in the treatment of hepatocellular carcinoma (HCC): a Lipiodol-based emulsion (LIPDOX) and a loadable microbead system (DEBDOX). Although equally effective, the formulations are vastly different, and little is known about the parameters affecting doxorubicin release in vivo. However, mathematical modeling can be used to predict doxorubicin release properties from these formulations and its in vivo pharmacokinetic (PK) profiles. A porcine semi-physiologically based pharmacokinetic (PBPK) model was scaled to a human physiologically based biopharmaceutical (PBBP) model that was altered to include HCC. DOX in vitro and in vivo release data from LIPDOX or DEBDOX were collected from the literature and combined with these in silico models. The simulated pharmacokinetic profiles were then compared with observed porcine and human HCC patient data. DOX pharmacokinetic profiles of LIPDOX-treated HCC patients were best predicted from release data sets acquired by in vitro methods that did not use a diffusion barrier. For the DEBDOX group, the best predictions were from the in vitro release method with a low ion concentration and a reduced loading dose. The in silico modeling combined with historical release data was effective in predicting in vivo plasma exposure. This can give useful insights into the release method properties necessary for correct in vivo predictions of pharmacokinetic profiles of HCC patients dosed with LIPDOX or DEBDOX.

Dubey, M. and J. R. Van Der Meer (2016). "Measuring microbial interactions in soil in high throughput."

Clinical Chemistry and Laboratory Medicine **54 (7)**: eA87.
Microbial ecosystem engineering approaches often rely on the introduction of one or more selected species into an existing microbial community. The success of introduced species to a large extent depends on the types of interactions that it is developing with other existing microbes, such as neutralism, commensalism, syntrophism or competition. Deciphering the rules governing microbial species' interactions is a strenuous task. Our project is focused on better understanding the principles of success of establishing pure cultures in complex microbial ecosystems such as contained within soil. Here we develop a high-throughput co-cultivation approach that might enable us to study the species' "interactome", the identification of favourable and non-favourable species combinations that decide on the survival of the inoculant in the community. We use agarose micro-beads as growth chambers to randomly combine soil community members with or without pure culture inoculants. Growth of co-cultured species members is followed by microscopy and enables a global overview of potentially positive effects of the inoculant on growth of the members in the soil on specific carbon substrates. In addition, the "interactome" study allows detecting possible species pairs, negative or positive, that can be recovered and identified in detail. The resulting knowledge not only provides ample data in designing functional synthetic communities but also construct new avenues for "synthetic ecology".

Dubey, S. K., et al. (2019). "Recent avenues in Novel Patient-Friendly Techniques for the Treatment of Diabetes." Current Drug Delivery **05**: 05.
BACKGROUND: Diabetes is one of the most common chronic metabolic disorder which affect the quality of human life worldwide. As per the WHO report, between 1980 to 2014, the number of diabetes patient increases from 108 million to 422 million, with a global prevalence rate of 8.5% per year. Diabetes is the prime reason behind various other diseases like kidney failure, stroke, heart disorders, glaucoma, etc. It is recognized as the seventh leading cause of death throughout the world. The available therapies are painful (insulin injections) and inconvenient due to higher dosing frequency. Thus, to find out a promising and convenient treatment, extensive investigations are carried out globally by combining novel carrier system (like microparticle, microneedle, nanocarrier, microbeads etc.) and delivery devices (insulin pump, stimuli-responsive device, inhalation system, bioadhesive patch, insulin pen etc.) for more precise diagnosis and painless or less invasive treatment of disease.
OBJECTIVE: The review article is made with an objective to compile information about various upcoming and existing modern technologies developed to provide greater patient compliance and reduce the undesirable side effect of the drug. These devices evade the necessity of daily insulin injection and offer a rapid onset of action, which sustained for a prolonged duration of time to achieve a better therapeutic effect.
CONCLUSION: Despite numerous advantages, various commercialized approaches like Afrezza (inhalation insulin) face failure in recent years. Such results call for more potential work to develop a promising system. The novel approaches range from the delivery of non-insulin blood glucose lowering agents to insulin-based therapy with minimal invasion are highly desirable.

Dubnyak, D., et al. (2017). "Short-term chimerism in T-helper cell subsets after allogeneic hematopoietic stem cell transplantation." Haematologica **102 (Supplement 2)**: 861.
Background: Despite the fact that almost all studies in transplant biology dedicate T-cells the chimerism in T-helper (Th) cells and its subsets such as T-regulatory (Treg) cells after allogeneic hematopoietic stem cell transplantation (allo-HSCT) has never been evaluated. Aim(s): To evaluate Th, Treg and bone marrow cell short-term chimerism in allo- HSCT patients. Method(s):

Between May 2015 and November 2016 there was 109 transplants in our center. The research included 24 patients with hematological malignancies (AML =14,ALL =7,MDS =2,CMML -1). The median age of patients was 33,5 (range 19 to 60) years old, female=16, male=8. Myeloablative conditioning regimen was used for 11 patients. The other 13 patients underwent reduced intensity conditioning regimen. Peripheral blood stem cells (PBSCs) as graft source was used in 9 patients, BM in 15 patients. 9 patients were transplanted from HLA-identical related donor ,15 - from unrelated matched. ?himerism was evaluated at +30, +60, and 90-day in blood and bone marrow. Peripheral blood mononuclear cells (PBMC) were isolated using standard protocol. Cells were sequentially incubated with CD4-biotin and anti-biotin microbeads (Milteney Biotec, Germany). Next pure fraction of Treg cells (CD4+CD25high) was obtained by positive selection with the use of anti-CD25 microbeads. DNA was isolated by AmpliSens DNA-sorbB nucleic acid extraction kit. Chimerism was assessed by the STR-PCR analysis (polymerase chain reaction with a panel of primers for loci of short tandem repeats). Result(s): For detailed result see Figure 1. 18 patients didn't have any signs of relapse, graft failure or acute graft-versus host disease at all observation time. In this group on day 30% of cells with donors genotype was - 97,17+/-0,75; on day 60 - 95,75+/-2,15; on day 90- 98,21+/-0,80. On day 30 T-helper - 87,51+/-3,12; on day Th 60-90,43+/-3,18; on day 90 Th - 93,71+/- 3,03. On day 30 T-regulatory - 77,36+/-4,50; on day 60Treg - 82,08+/- 5,94; on day 90Treg - 97,71+/- 1,18. Four patients were diagnosed with relapse at +4 and +6 months after allo-HSCT. Two patients were diagnosed with acute GVHD. (Figure presented) Summary/Conclusions: Impact of chimerism in different T-helper subsets still need further investigation. We will continue our research and further results will be reported later.

Duckett, P. E. and V. Repaci (2015). "Marine plastic pollution: using community science to address a global problem." Marine & Freshwater Research **66**(8): 665-673.

It was once thought oceans were so vast they could not be affected by humans, but unfortunately rapid globalisation now threatens marine biodiversity. The negative effects of marine debris were recognised in the 1970s, and more recently globally acknowledged in scientific literature. We revisited the Greater Sydney region in New South Wales Australia, to research whether plastic waste on coastal beaches has reduced in recent years. This was achieved by designing a community science project in collaboration with local schools and volunteers. We discovered that plastic debris differed between beaches and strata, but was similar to Australian beaches that were sampled over a decade ago. The high correlations we found between plastic debris and both the frequency of storm-water drains and local population sizes suggested that storm-water drains may be responsible for delivering plastic waste to coastal ecosystems, and the amount of plastic debris was proportional to the size of the surrounding population. Involving local communities has the potential to rapidly raise awareness about key conservation issues to large and broad demographic audiences. Ultimately, this may inspire public and political change. Additional keywords: conservation, consumerism, education, government.

Duddu, M. K. and G. Guntuku (2016). "Isolation, screening and characterization of antibiotic producing actinomycetes from kapuluppada plastic waste dumping yard, visakhapatnam." International Journal of Pharmacy and Pharmaceutical Sciences **8**(11): 221-229.

Objective: To isolate, screen and characterize antibiotic producing actinomycetes from Kapuluppada plastic waste dumping yard, Visakhapatnam. Method(s): A total of 12 soil samples were collected, serially diluted and spread on starch casein agar supplemented with Rifampicin and Cycloheximide for inhibition of bacteria and fungi, respectively. Cross-streak method was used to check the antagonistic activity of isolated actinomycetes against bacteria and fungi.

Crude extracts from submerged state fermentation were used for the production of antimicrobial compounds. Agar well diffusion method was used for antimicrobial activity of crude extracts against test organisms. The isolates were characterized by morphological, physiological and biochemical methods. Result(s): A total of 110 actinomycete isolates were isolated from plastic waste dumping yard. All isolates had shown antimicrobial activity against one or more tested bacteria/fungi. The crude extract of the isolates PD66 (12.2 mm), PD85 (11.5 mm) were most active against methicillin-resistant Staphylococcus aureus, PD4 (14.1 mm), PD66 (15.6 mm) were active against Pseudomonas aeruginosa, whereas the extracts of PD10 (19.2 mm), PD47 (19.8 mm), PD106 (19.1 mm) were active against Candida albicans, PD10 (14.6 mm), PD82 (15.7 mm) active against Saccharomyces cereviciae. The isolates had shown varying morphological, physiological and biochemical characteristics. Conclusion(s): The actinomycetes isolated from Kapuluppada plastic waste dumping yard were found to be most promising microorganisms for the production of antibacterial and antifungal antibiotics. Duemichen, E., et al. (2019). "Automated thermal extraction-desorption gas chromatography mass spectrometry: A multifunctional tool for comprehensive characterization of polymers and their degradation products." Journal of Chromatography. A **1592**: 133-142.

The TED-GC-MS analysis is a two-step method. A sample is first decomposed in a thermogravimetric analyzer (TGA) and the gaseous decomposition products are then trapped on a solid-phase adsorber. Subsequently, the solid-phase adsorber is analyzed with thermal desorption gas chromatography mass spectrometry (TDU-GC-MS). This method is ideally suited for the analysis of polymers and their degradation processes. Here, a new entirely automated system is introduced which enables high sample throughput and reproducible automated fractioned collection of decomposition products. The fractionated collection together with low temperatures reduces the risk of contamination, improves instrumental stability and minimizes maintenance efforts. Through variation of the two main parameters (purge gas flow and heating rate) it is shown how the extraction process can be optimized. By measuring the decomposition products of polyethylene it is demonstrated that compounds with masses of up to 434 Da can be detected. This is achieved despite the low temperature (~40 degreeC) of the solid-phase adsorber and the low thermal desorption temperature of 200 degreeC in the TDU unit. It is now shown that automated TED-GC-MS represents a new flexible multi-functional method for comprehensive polymer analyses. Comparable polymer characterization was previously only achievable through a combination of multiple independent analytical methods. This is demonstrated by three examples focused on practical challenges in materials analysis and identification: The first one is the analysis of wood plastic composites for which the decomposition processes of the polymer and the bio polymer (wood) could be clearly distinguished by fractionated collection using sequential adsorbers. Secondly, a fast quantitative application is shown by determining the weight concentrations of an unknown polyolefin blend through comparison with a reference material. Additionally, the determination of microplastic concentrations in environmental samples is becoming an increasingly important analytical necessity. It is demonstrated that with TED-GC-MS calibration curves showing good linearity for the most important precursors for microplastic, even complex matrix materials (suspended particulate matter) can be successfully analyzed.

Dufresne, J. and J. G. Marshall (2014). "The capture and characterization of the Fc-receptor complex from cultured macrophages." FEBS Journal **1)**: 211.

Cell surface receptors are of critical importance to biomedicine and the treatment of disease but are notoriously difficult to isolate and identify by classical approaches. Thus there is an urgent need to activate and capture receptor associated supramolecular complexes from the surface of live cells using liquid chromatography and tandem mass spectrometry (LC-ESI-MS/MS). The Fc gamma receptor (FCGR) is responsible for the engulfment of foreign particles and pathogens coated with Immunoglobulin G (IgG). The FCGR complex was captured from live human U937 and murine RAW 264.7 macrophages by presenting the cognate ligand (IgG) on micro chromatography beads. Many co-receptors, including innate immune receptors such as Fc-like receptors, scavenger receptors, toll-like receptors, Fc-like killer cell receptor, lectins, epidermal growth factor, interleukin and colony stimulating factor, chemokine, cytokines, histamine and other receptors that are known to modulate immunological response were observed to copurify alongside the Fc receptors on micro beads. As a second method, direct biotinylation of IgG provides for specific capture of the Biotin-IgG-FCGR complex on strepavidin beads, but the biotinylated receptor complex cannot be specifically separated from the contamination and background binding to the strepavidin resin. However, new affinity chromatography reagents such as NHS-SS-biotin may be cleaved with DTT to specifically release the FCGR complex. The monovalent versus aggregated FCGR complex was bound and activated by its IgG-S-S-biotin probe to activate and capture the receptor before collection over streptavidin followed by specific elution with the reducing agent DTT. After binding and activation of the cell surface receptor by its ligand, the cells were disrupted with a French press and the homogenate applied to a streptavidin agarose affinity column. After washing, the activated and assembled FCGR cell surface complex was eluted from the column with a reducing agent DTT, and digested with trypsin. The peptides were analyzed by LC-ESIMS/ MS using a linear ion trap (Thermo) where the peptides identification using the SEQUEST, MASCOT, OMSSA and X!TANDEM algorithms and quantified using R statistical analysis. We propose to define the role of a subset of the IgG-Fc co-receptors by phagocytosis assays and the measurement of phagocytosis and free radical production in the presence of specific siRNA or controls, mutant constructs and pharmacological agents. We also propose to quantify the assembly of the Fc-IgG receptor complex over time and compared to other innate immune receptors. The analysis of a cell surface receptor complex developed and tested on the model FCGR complex may be applied to a wide variety of receptors crucial in human infection, disease and pain.

Duis, K. and A. Coors (2016). "Microplastics in the aquatic and terrestrial environment: sources (with a specific focus on personal care products), fate and effects." Environmental Sciences Europe **28**(1): 2.
Due to the widespread use and durability of synthetic polymers, plastic debris occurs in the environment worldwide. In the present work, information on sources and fate of microplastic particles in the aquatic and terrestrial environment, and on their uptake and effects, mainly in aquatic organisms, is reviewed. Microplastics in the environment originate from a variety of sources. Quantitative information on the relevance of these sources is generally lacking, but first estimates indicate that abrasion and fragmentation of larger plastic items and materials containing synthetic polymers are likely to be most relevant. Microplastics are ingested and, mostly, excreted rapidly by numerous aquatic organisms. So far, there is no clear evidence of bioaccumulation or biomagnification. In laboratory studies, the ingestion of large amounts of microplastics mainly led to a lower food uptake and, consequently, reduced energy reserves and effects on other physiological functions. Based on the evaluated data, the lowest microplastic concentrations affecting marine organisms exposed via water are much higher than levels measured in marine water. In lugworms exposed via sediment, effects were observed at microplastic levels that were higher than those in subtidal sediments but in the same range as maximum levels in beach sediments. Hydrophobic contaminants are enriched on microplastics,

but the available experimental results and modelling approaches indicate that the transfer of sorbed pollutants by microplastics is not likely to contribute significantly to bioaccumulation of these pollutants. Prior to being able to comprehensively assess possible environmental risks caused by microplastics a number of knowledge gaps need to be filled. However, in view of the persistence of microplastics in the environment, the high concentrations measured at some environmental sites and the prospective of strongly increasing concentrations, the release of plastics into the environment should be reduced in a broad and global effort regardless of a proof of an environmental risk.

Dumas, H., et al. (1992). "Prilling process applied to collagen solutions." Drug Development and Industrial Pharmacy **18**(13): 1395-1409.

The present work concerns the preparation of microbeads of collagen by a prilling process. Collagen is one of the main components of vertebrate proteins, especially in such tissues as skin, tendons, placenta. Furthermore, it has some properties which makes it interesting to use as a biomaterial: biocompatibility, biodegradability, high tensile strength, hemostatic power, participation to the wound healing. The patented process which is developped in this paper combines two techniques: breaking of a capillary flow by prilling and; reticulation of collagen after oxydation with periodic acid. It uses neither organic solvents, nor variation of temperature and allows the production of microbeads which can be utilized for many different medical applications.

Dumichen, E., et al. (2015). "Analysis of polyethylene microplastics in environmental samples, using a thermal decomposition method." Water Research **85**: 451-457.

Small polymer particles with a diameter of less than 5 mm called microplastics find their way into the environment from polymer debris and industrial production. Therefore a method is needed to identify and quantify microplastics in various environmental samples to generate reliable concentration values. Such concentration values, i.e. quantitative results, are necessary for an assessment of microplastic in environmental media. This was achieved by thermal extraction in thermogravimetric analysis (TGA), connected to a solid-phase adsorber. These adsorbers were subsequently analysed by thermal desorption gas chromatography mass spectrometry (TDS-GC-MS). In comparison to other chromatographic methods, like pyrolyse gas chromatography mass spectrometry (Py-GC-MS), the relatively high sample masses in TGA (about 200 times higher than used in Py-GC-MS) analysed here enable the measurement of complex matrices that are not homogenous on a small scale. Through the characteristic decomposition products known for every kind of polymer it is possible to identify and even to quantify polymer particles in various matrices. Polyethylene (PE), one of the most important representatives for microplastics, was chosen as an example for identification and quantification.

Dumichen, E., et al. (2017). "Fast identification of microplastics in complex environmental samples by a thermal degradation method." Chemosphere **174**: 572-584.

In order to determine the relevance of microplastic particles in various environmental media, comprehensive investigations are needed. However, no analytical method exists for fast identification and quantification. At present, optical spectroscopy methods like IR and RAMAN imaging are used. Due to their time consuming procedures and uncertain extrapolation, reliable monitoring is difficult. For analyzing polymers Py-GC-MS is a standard method. However, due to a limited sample amount of about 0.5 mg it is not suited for analysis of complex sample mixtures like environmental samples. Therefore, we developed a new thermoanalytical method as a first

step for identifying microplastics in environmental samples. A sample amount of about 20 mg, which assures the homogeneity of the sample, is subjected to complete thermal decomposition. The specific degradation products of the respective polymer are adsorbed on a solid-phase adsorber and subsequently analyzed by thermal desorption gas chromatography mass spectrometry. For certain identification, the specific degradation products for the respective polymer were selected first. Afterwards real environmental samples from the aquatic (three different rivers) and the terrestrial (bio gas plant) systems were screened for microplastics. Mainly polypropylene (PP), polyethylene (PE) and polystyrene (PS) were identified for the samples from the bio gas plant and PE and PS from the rivers. However, this was only the first step and quantification measurements will follow.

Duncan, E. M., et al. (2019). "Diet-related selectivity of macroplastic ingestion in green turtles (Chelonia mydas) in the eastern Mediterranean." Scientific Reports **9**(1): 11581.

Understanding the drivers of key interactions between marine vertebrates and plastic pollution is now considered a research priority. Sea turtles are primarily visual predators, with the ability to discriminate according to colour and shape; therefore these factors play a role in feeding choices. Classification methodologies of ingested plastic currently do not record these variables, however here, refined protocols allow us to test the hypothesis that plastic is selectively ingested when it resembles the food items of green turtles (Chelonia mydas). Turtles in the eastern Mediterranean displayed strong diet-related selectivity towards certain types (sheet and threadlike), colours (black, clear and green) and shapes (linear items strongly preferred) of plastic when compared to the environmental baseline of plastic beach debris. There was a significant negative relationship between size of turtle (curved carapace length) and number/mass of plastic pieces ingested, which may be explained through naivety and/or ontogenetic shifts in diet. Further investigation in other species and sites are needed to more fully ascertain the role of selectivity in plastic ingestion in this marine vertebrate group.

Duncan, E. M., et al. (2019). "Microplastic ingestion ubiquitous in marine turtles." Global Change Biology **25**(2): 744-752.

Despite concerns regarding the environmental impacts of microplastics, knowledge of the incidence and levels of synthetic particles in large marine vertebrates is lacking. Here, we utilize an optimized enzymatic digestion methodology, previously developed for zooplankton, to explore whether synthetic particles could be isolated from marine turtle ingesta. We report the presence of synthetic particles in every turtle subjected to investigation (n=102) which included individuals from all seven species of marine turtle, sampled from three ocean basins (Atlantic [ATL]: n=30, four species; Mediterranean (MED): n=56, two species; Pacific (PAC): n=16, five species). Most particles (n=811) were fibres (ATL: 77.1% MED: 85.3% PAC: 64.8%) with blue and black being the dominant colours. In lesser quantities were fragments (ATL: 22.9%: MED: 14.7% PAC: 20.2%) and microbeads (4.8%; PAC only; to our knowledge the first isolation of microbeads from marine megavertebrates). Fourier transform infrared spectroscopy (FT-IR) of a subsample of particles (n=169) showed a range of synthetic materials such as elastomers (MED: 61.2%; PAC: 3.4%), thermoplastics (ATL: 36.8%: MED: 20.7% PAC: 27.7%) and synthetic regenerated cellulosic fibres (SRCF; ATL: 63.2%: MED: 5.8% PAC: 68.9%). Synthetic particles being isolated from species occupying different trophic levels suggest the possibility of multiple ingestion pathways. These include exposure from polluted seawater and sediments and/or additional trophic transfer from contaminated prey/forage items. We assess the likelihood that microplastic ingestion presents a significant conservation problem at current levels compared to other anthropogenic threats.

Dunlap, D. G., et al. (2018). "Use of magnetic activated cell sorting to identify immunoglobulin-bound bacteria in bronchoalveolar lavage fluid in individuals with HIV and COPD." American Journal of Respiratory and Critical Care Medicine. Conference: American Thoracic Society International Conference, ATS **197**(MeetingAbstracts).

Rationale: Greater than 70% of HIV+ outpatients manifest at least one lung function abnormality, with many developing COPD. However, the mechanisms are poorly understood. Alterations in the lung microbiome that occur in HIV may increase risk of COPD, but there are limited taxonomic differences in lung bacterial communities between HIV+ and HIV- individuals detected by 16S rRNA gene sequencing. Although bacterial communities may be similar, there may be differences in bacterial recognition by the host that contribute to lung dysfunction in HIV. Using magnetic activated cell sorting (MACS), immunoglobulin-bound bacteria can be sorted from bronchoalveolar lavage (BAL) fluid and analyzed using flow cytometry and 16S rRNA gene sequencing to elucidate the amount and type of Ig-bound bacteria in the lungs. Method(s): BAL fluid was obtained from individuals with and without HIV and with varying degrees of lung dysfunction. Fluid was stained with SYTO BC and IgG, IgA, or IgM PE, centrifuged, and supernatant removed. The pellet was suspended with buffer mixed with anti-PE micro beads, creating a magnetic label on Ig-bound bacteria. The fluid was then run through MACS columns composed of ferromagnetic spheres, embedded in a super magnet (MACS sorter). Unbound bacteria freely flowed through the column while immunoglobulin-bound material, including bacteria, were held in suspension within the column until being manually expelled and collected in separate tubes. The immunoglobulin-bound and unbound material was then analyzed using flow cytometry. Result(s): Four individuals (2 HIV+, 2 HIV-) were included in preliminary results. Half of the individuals were male with an average age of approximately 50 years. Both HIV+ individuals were taking antiretroviral therapy. HIV+ individuals tended to have a greater number of IgG-bound bacteria detected in BAL (Figure 1). The greatest number of IgG-bound bacteria were recovered from the individual with both COPD and HIV. Conclusion(s): We used magnetic activated cell sorting to identify immunoglobulin-bound bacteria in BAL samples. This technique enables determination of which bacteria are recognized by the host and provoke an adaptive immune response. Future 16S rRNA gene sequencing of Ig-bound and unbound bacteria promises to elucidate functional differences between microbial communities, allowing us to better define the impact of the lung microbiome in HIV and COPD. (Figure presented) .

Dunlap, D. G., et al. (2019). "HIV COPD: Exploring the role of host recognition and response to the lung microbiome in pulmonary disease." American Journal of Respiratory and Critical Care Medicine. Conference **199**(9).

Rationale: The lung microbiome in healthy, HIV+ individuals on appropriate anti-retroviral therapy (ART) is similar to that of HIV-individuals. However, the host's recognition and response to the lung microbiome via immunoglobulin binding in HIV infection has not been explored. Using a novel application of magnetic-activated cell sorting (MACS), IgG-bound bacteria from the lungs can be sorted from bronchoalveolar lavage (BAL) fluid and analyzed using flow cytometry and 16S rRNA gene sequencing. We have found that the lung bacterial community recognized by IgG is distinct when comparing HIV+ to HIV-individuals and hypothesize that IgG-bound bacteria provoke an inflammatory response, promoting lung disease. Method(s): Bronchoscopy with BAL was performed on individuals with and without HIV infection, with pulmonary function testing performed on all participants. Bacteria were suspended in bacterial DNA stain (SYTO BC) and IgG-PE, then incubated with anti-PE micro beads, creating a magnetic label on IgGbound bacteria. Running these samples through MACS columns embedded within a super magnet (MACS sorter), IgG-bound bacteria were magnetically pulled out of solution. IgG-bound and -unbound bacteria were analyzed using flow cytometry and 16S rRNA gene sequencing on the Illumina MiSeq platform. Bacteria from unsorted BAL samples were analyzed in parallel. BAL and serum cytokines were measured using Luminex assays, and differential cell counts were manually performed on BAL. Result(s): Sixty-five individuals (43 HIV+, 22 HIV-) were included in this study. The mean age of participants was 51 years and approximately 70% were male in both groups. The median CD4 count in the HIV+ group was over 700 cells/uL with 70% on ART. Among HIV+ individuals, 72% were ever smokers compared to 55% among HIV-participants. Beta diversity in the IgG+ fractions were significantly different between HIV+ and HIV-individuals ($p<0.002$) while no differences were seen between these groups in unsorted samples (Figure 1). Additionally, beta diversity in HIV+ individuals stratified by diffusing capacity (DLCO) percent predicted. Preliminary cytokine analysis in 35 individuals demonstrates increased IL-1 in BAL from HIV+ individuals ($p=0.02$). Conclusion(s): We report the first successful use of magneticactivated cell sorting to identify IgG-bound bacteria from the lungs, and found that the bacterial community being recognized and bound by IgG differs between HIV+ and HIV-individuals. Preliminary cytokine results demonstrated increased BAL IL-1 in HIV+ individuals. Additional cytokine analyses are needed to detail the immune response to IgG-bound bacteria and its relationship to lung function. (Figure Preseted).

Duong, V., et al. (2018). A model template green environment initiative for recycling plastic bottles with progressive entrepreneurship partnership. 2018 Portland International Conference on Management of Engineering and Technology, PICMET 2018, August 19, 2018 - August 23, 2018, Honolulu, HI, United states, Institute of Electrical and Electronics Engineers Inc.

Plastic has been widely adopted by the global industry as the most common and adaptable material for marketing their products. Current levels of plastic usage and disposal is one of the biggest environmental challenge that we have to deal with. Collecting and Recycling plastic is one of the most important actions currently used to meet this challenge, but it represents one of the most demanding areas in the plastics industry today. A major percentage of recycled plastic produced each year is used to manufacture disposable packaging items or other short-lived items that are discarded within a year or so. This clearly means that our current use of plastics is not sustainable. In addition, because of the durability of the polymers involved, large amounts of discarded end-of-life plastics are accumulating as debris in landfills and in natural habitats worldwide [1]. Energy efficient plastic recycling process involves a complex system of machines and new manufacturing practices. This paper discusses a promising environmental friendly solution for reducing pollution by recycling plastic bottles. The process of recovering waste plastic and reprocessing into useful products would be implemented in three stages: A) Set up and organize a system for collecting plastics used for water and soda bottles. b) Design and manufacture production line for automatically processing plastic bottles to make plastic ribbon/wire of various sizes. c) Use the plastic ribbon/wire to manufacture prototypes of useful artifacts and products like table, chair, roofing material, decorations, etc. The project has both economic and social value. On the economical side, this will save money by minimizing all expenditure for waste processing related to destroying the plastic waste; the second important contribution of the project is the significant impact on employment creation especially in rural areas; lastly, the recycled plastic is used to make new plastic products with reasonable price for low-income families. On the Social side, this will improve environmental conditions for life; reduce landfill waste; prevent disease-spreading due to recycling plastic; eliminate contamination from burning and melting plastic material and increase public awareness of environmental protection for benefit of humanity. A prototype of the project designed and

manufactured in Duy Tan University, Vietnam for cutting bottles into ribbon/wire and connecting them continuously is complete. We will present a pilot test result of our approach to use the plastic ribbon/wire to make new and useful products. A Progressive sustainable economic model of Entrepreneurship Partnership is presented for the developing economies. 2018 Portland International Conference on Management of Engineering and Technology, Inc. (PICMET).

Dupai, L., et al. (2019). "Empowerment of coastal communities through systems approach in the field of environmental health in Kendari city, Southeast Sulawesi Province, Indonesia." Indian Journal of Public Health Research and Development **10**(9): 741-745.

One of the health problems faced by coastal communities is community behavior in the management and utilization of environmental resources. Coastal area has problems like the limitations of environmental health facilities that cause the health status low. The study aimed to know the Coastal Community Empowerment with a environmental health systems approach of Kendari. The type of study was qualitative. The informants was 12 people. Data collection uses in-depth interviews and Focus Group Discussion. Results of the implementation program appeared in three dimensions: a) Development of local communities through cross training sectors: agriculture and food, fisheries, private institutions, finance lending institutions and academics; and empowering youth groups through social activities. Empowerment through health village was carried out with: environmental cleanliness, family education, clean and healthy behavior, increasing family income, hydroponic planting methods, and utilizing plastic waste. b) Judging from the aspect of social policy, there was already the KOTAKU program (city without slums). c) Social action: Initiation of Movement 1 house 1 hand-washing, family medicinal plants, mobilizing to cleanliness the house yard, waste transportation services, coordinating with the Government to provide environmental health education, made a healthy smoke-free village. Conclusion(s): Community empowerment in order to improve environmental health behaviors can be more effective if using all potential stakeholders, education and training, local community development, social action and social policy. Recommendation: needin for socialization, education and training for the community, advocacy and collaboration across sectors of government agencies, and continuous supervision. Duranceau, C. (2009). "PICKING UP SPEED." Recycling Today **47**(12): 38-43.

The article describes increasing use of recycled and sustainable virgin plastics in the U.S. automobile industry. It notes that the automotive applications of such materials cut costs and promote the protection of the environment by keeping plastic scraps from wasting in landfills and producing lighter vehicles that use less fuel. The plastics industry's initiatives to increase the use of recycled materials in vehicles and its end-of-life recycling efforts are also discussed.

Durrieu, L., et al. (2012). "IFN-alpha increases the cytotoxic effect of CIK cells on B-all." Journal of Immunotherapy **35 (1)**: 100-101.

Haematopoietic stem cell transplantation (HSCT) is required in about 20% to 30% of children with B-lineage acute lymphoblastic leukemia (B-ALL). Relapses after HSCT are usually refractory to further therapy and in these cases, the development of an optimized immunotherapeutic strategy would be of great clinical interest. In this setting, the Cytokine-Induced Killer (CIK) cells could represent an interesting tool for immunotherapy. Indeed, they were showed to be highly cytotoxic against many cancer types. Nevertheless, their cytotoxicity against ALL cells is not consistent. Therefore, we have investigated the possibility of combining adoptive immunotherapy with CIK cells and interferon alpha (IFNalpha), to optimise the cytotoxicity of CIK cells against B-ALL cells. CIK cells were differentiated from cord blood mononuclear cells or peripheral blood mononuclear cells for 21 days. At the end of the culture, there were around 45% CIK cells (CD3+CD56+). The other cells were 1% natural killer (NK) cells and 54% T cells. The bulk CIK (CIK cells, NK cells and T cells) showed a mild cytotoxic activity against B-ALL cell lines. However, when the bulk CIK was purified with CD56 human microbeads there was significant cytotoxic activity against B-ALL cell lines. In addition, we have showed that sorted CIK cells removed from NK and T cells, always showed a cytotoxic activity against B-ALL cells lines. Also, after pre-incubation of sorted CIK cells with IFNalpha overnight, we have observed an increase of cytotoxicity by more than 20% to 40%. CIK cells displayed a phosphorylation of STAT-1 after stimulation by IFNalpha. In addition, we have tested in vivo CIK cells in NOD/SCID/gammac-(NSG) mice injected with human B-ALL cell lines and we could show that CIK cells (Target on effector ratio of 1:80) could significantly delay mice mortality. Also, we showed that CIK cells treated by IFNalpha did not the induce of xeno-Graft-versus-Host Disease (GvHD) in NSG mice. In conclusion, we showed that CIK cells are cytotoxic against B-ALL when they are purified and also their effect is increased by the IFNalpha via STAT-1. Finally, the CIK cells have a GvL effect (graft versus leukemia) in the NOD/SCID/gammac- mouse model.

Duval, D. and H. L. MacLean (2007). "The role of product information in automotive plastics recycling: a financial and life cycle assessment." Journal of Cleaner Production **15**(11/12): 1158-1168.

Abstract: Over the last 30 years the use of light weight, inexpensive, and durable plastics in automobiles has nearly tripled on a per vehicle basis. Although this has created benefits such as increased fuel efficiency and associated lower CO2 emissions, the growing disposition of plastics from end-of-life vehicles has put increasing pressure on North American landfill capacity. Financial and life cycle assessment models were developed and applied to the current and proposed recycling business operations of AADCO Automotive Incorporated (AADCO), a leading Canadian automotive dismantling company. By applying both kinds of models, two key questions are addressed. First, how much is it expected to cost AADCO to participate in a start-up automotive plastics recycling network? and second, by estimating greenhouse gas emissions and energy requirements, is recycling automotive plastics actually better for the environment compared to manufacturing virgin plastic resin within the boundaries set forth in this case study? The present study concluded that the proposed recycling network would reduce greenhouse gas emissions and energy requirements by nearly 50% when compared to the current operations at AADCO (equating to a reduction of 1063tonnes of CO2(eq) and 18TJ, respectively). However, in spite of the environmental benefits, the magnitude of the added costs for AADCO to participate in the post-consumer automotive plastics recycling network resulted in an unprofitable value proposition for the company. Duvernay, M. T. and H. Hamm (2013). "Platelet microparticle production is regulated by stim1 dependent entry of extracellular CA²⁺ through orai1." Blood. Conference: 55th Annual Meeting of the American Society of Hematology, ASH **122**(21).

Microparticles are submicron lipid vesicles packed with protein and nucleic acid. They are found

in abundance circulating in the vasculature and can be generated from a number of cell types including endothelial cells, leukocytes, and platelets. The microparticles generated from platelets far out number those generated from other cell types and their incidence is correlated with a myriad of cardiovascular diseases. We recently demonstrated that stimulation of gel filtered human platelets through Protease activated receptor (PAR) 4 leads to the generation of 4-5 times more platelet microparticles (PMP) than PAR1 stimulation. Platelet microparticle (PMP) production was demonstrated to be downstream of a Rho kinase-dependent signaling pathway. Consistently, more myosinIIa phosphorylation was observed downstream of PAR4 stimulation. PMP generation was quantified by flow cytometry using polystyrene microbeads of standardized size for appropriate size gating, and CD41a (aIIb) and CD62p (P-selectin) staining for positive identification of platelet derived membranes. Submicron particles positive for both CD41a and CD62p were classified as true PMP. Recently, we have expanded these observations to platelet stimulation with thrombin, convulxin (a GPVI collagen receptor agonist), and dual PAR/collagen receptor stimulation. Thrombin and PAR4-activating peptide (AP) stimulation leads to equivalent levels of PMP production, confirming that PAR4 is the major thrombin receptor responsible for PMP generation, with PAR1 playing only a minor role. Collagen receptor stimulation with convulxin lead to a comparable level of PMP generation as thrombin stimulation. However, co-stimulation with convulxin and thrombin or convulxin and PAR1-AP or PAR4-AP lead to PMP production exceeding the sum of PMP by convulxin and PAR agonist alone by as much as 350%, suggesting a synergistic response. It is well documented that PMP generation does not occur in the absence of extracellular Ca²⁺. Recently published data collected with Orai1 knockout mice indicate that the majority of extracellular Ca²⁺ entry into the platelet is mediated by the plasma membrane Ca²⁺ channel Orai1. STIM1 is an ER calcium sensor that migrates near the cell surface upon depletion of intracellular Ca²⁺ stores to oligomerize and activate Orai1. In an attempt to further elucidate the signaling pathways responsible for PMP generation we treated platelets with the STIM1 inhibitor SKF 96365. Preincubation with SKF 96365 nearly abolished PMP production induced by PAR4-AP, thrombin, convulxin, or the combination of PAR and collagen receptor agonist. Scanning Electron Microscopy of PAR4-AP stimulated platelets in suspension revealed extended filipodia and bag-like structures protruding from the platelet core which correlated with the size of PMPs as analyzed by flow cytometry. Pretreatment with the SKF 96365 or exclusion of extracellular Ca²⁺ prevented the formation of the microparticle-like extensions and blunted filipodia extension. Finally, confocal analysis of Orai1 staining on platelets spread on a collagen matrix and co-stimulated with PAR4-AP revealed Orai1 throughout the plasma membrane with intense staining of the microparticle-like structures. These data suggest that PMP generation is nucleated by STIM1 dependent Orai1 Ca²⁺ entry. Current efforts are focused on elucidating the mechanism by which PAR and collagen receptor agonists differentially regulate STIM1 or Orai1 activity to mediate PMP generation.

Dwivedi, H., et al. (2013). "Fabrication and evaluation of colon targeted uricase containing microbeads for treatment of gout." Drug Delivery Letters **3**(1): 47-53.

Gout is a painful disease of joints generated because of the deposition of urate crystals within the joints. Uri-case is an enzyme capable of degrading less water soluble urate crystals into a compound allantoin, which is more water soluble and hence is easily excreted. Uricase being proteinaceous is degraded by the protein digestive enzymes of gastro intestinal tract (GIT) when administered orally. Colonic part of GIT lacks protein digestive enzymes and thus provides suitable conditions for the absorption of uricase. Colon consists of several microbial flora which secrete enzymes capable of degradation of alginates and pectin which are not digested by upper GI tract. Eudragit S-100 (pH sensitive polymer) coated alginate - pectinate microbeads were found to be effective for delivery of uricase directly to the colonic site. Sodium taurocholate, a bile salt, was found to be suitable for the effective absorption of uricase from colonic site into the systemic circulation. © 2012 Bentham Science Publishers.

Dykes, J. H., et al. (2010). "Effective CD3 T-cell depletion using the CliniMacs System to produce peripheral blood progenitor cell products for haploidentical transplantation in 23 children and adults: The updated Lund experience." Bone Marrow Transplantation **2)**: S325.

Background: Rigorous depletion of T-lymphocytes in the progenitor cell graft is an absolute prerequisite in haploidentical transplantation. In the current study, we investigated the performance of two CliniMACS direct T-cell depletion programs, the Depletion D2.1 program and the large-capacity program D3.1, which are attractive alternatives to standard stem cell enrichment procedures. Study design and methods: Peripheral blood progenitor cells were harvested from 23 human-leukocyte-antigen (HLA)- haploidentical donors. T-cells labelled with anti-CD3 coated beads were depleted with the CliniMACS device using either the Depletion 2.1 (n = 23) or the D3.1 (n = 13) program. If indicated, additional positive CD34-selections (n = 16) were performed. Twenty-three patients received T-cell depleted grafts after reduced-intensity conditioning, with a target cell dose of >= 5 x 10⁶ CD34 + cells and <= 1 x 10⁵ CD3 + cells per kilogram of recipient body weight. Result(s): The median log10 T-cell depletion rate was significantly better with the D2.1 compared to the D3.1 (log 3.6 vs. log 2.3, P < 0.05) and could be further improved by blocking of non-specific binding using 0.15% Gammagard immune-globulin (IgG) (log 4.5 and log 3.4, respectively) and surprisingly only to a remarkably lesser extend with 0.15% Kiovig IgG (log 3.8 and log 2.9, respectively). A negative impact of platelet contamination on T-cell depletion rate was observed. The D3.1 was superior to the D2.1 (P < 0.05) in median recovery of CD34 + cells (90% vs. 80%) and in median recovery of CD3-negative cells (87% vs. 75%). The median processing time/1010 total cells was 0.90 hours (D2.1) and 0.35 hours (D3.1) The transplanted grafts (directly T-cell depleted products +/- CD34 + selected cells) contained a median of 12,9 x 10⁶/ kg CD34 + , 0.90 x 10⁵/kg CD3 + , and 18,6 x 10⁶/kg CD56 +. Rapid engraftment was achieved in 22 patients. The incidence of acute Graft-versus-host disease was 22% (grade I/II) and 0% (grade III/IV). Conclusion(s): Our results indicate that non-specific binding of cells to anti-CD3 micro beads considerably impair depletion results. This effect can be overcome by blocking with a carefully selected IgG preparation. We, conclude that both, the D2.1 and the novel D3.1 program enable effective, time-saving large-scale T-cell depletion. Combining direct depletion techniques with standard CD34-selection facilitates the composition of grafts optimized to the specific requirements of the patients.

Dziubanek, G., et al. (2016). "Inhalation Exposure to Dioxins and dl-PCBs Depending on the Season in Upper Silesia, Poland: A Pilot Study." Central European Journal of Public Health **24**(2): 115-119.

AIM: The aim of this study was to investigate the seasonal fluctuation of PCDD/Fs and dl-PCBs levels in the ambient air of Upper Silesia in the aspect of human inhalation exposure as well as the estimation of health risk attributed to this exposure pathway to dioxins and dl-PCBs.

METHODS: In the study air samples were taken in five urban districts of Upper Silesia, Poland, where the houses are heated with coal. The same sampling points in summer and winter were analyzed for dioxins/furans and dl-PCBs. In addition, information was collected on awareness of the residents about the co-incineration of plastic waste and effects of this activity on human health.

RESULTS: The results show that the average daily exposure of residents of Upper Silesia to TCDD and

DLCs in the heating season was about 6.5.-fold higher than in summer. The risk assessment showed that expected excess of cancer cases per 1,000,000 people ranged from 4.5 to 13.2 in winter and from 0.9 to 2.1 in summer. The practice of mixing waste with coal for houses heating has been confirmed by investigated families, who do not associate it with the possibility of negative health effects.

CONCLUSIONS: Air pollution can be a significant source of dioxin and dl-PCB for people during the winter season, as a result of co-burning coal and waste containing plastics. The dose of dioxins inhaled through the respiratory pathway in winter can be associated with the higher cancer risk in the population of Upper Silesia.

Dzoganova, Z., et al. (2012). IMPACT ASSESSMENT OF MECHANICAL PROPERTIES OF DEGRADED PET BOTTLES IN SELECTED ENVIRONMENTAL DEGRADATION. Sofia, Surveying Geology & Mining Ecology Management (SGEM). **4:** 331-337.

Plastic bottles are one of the most custom packing materials in market. Plastic bottles are mainly made from polyethylenetereftalate, therefore they often are called like PET bottles. PET like basic plastic material is widely used for production fibers and foils because of its great abrasion resistance, chemical resistance, weather resistance, degradation and PET is dimensionally stable. Because of this properties PET is used like packing material of drinks in different shapes. PET bottles are consumer goods which are used only once and after that they are changed in waste. In environment, plastic waste is decomposed in many decades' years than is suitable to evaluate the degradation properties of PET bottles. For these experiments were selected two types of plastic bottles available in the Slovak market. Than from these bottles they were made some samples and they were taken into artificial environmental degradation of high and low temperature to simulate environmental conditions in summer and winter weather. After the exposition time the samples were taken out from environment degradation. To find out changed mechanical properties of PET bottles was made the tensile test where were defined the parameters like yield strength - aY, tensile strength - aM and relative elongation - eM. [PUBLICATION ABSTRACT]

Eagle, L., et al. (2016). "The role of social marketing, marine turtles and sustainable tourism in reducing plastic pollution." Marine Pollution Bulletin **107**(1): 324-332.

Environmental plastic pollution constitutes a significant hazard to marine turtles, human health and well-being. We describe a transdisciplinary approach to draw together findings from diverse disciplines in order to highlight key environmental pollution problems and their consequences, together with social marketing-based strategies to address the problems. The example of plastic pollution and impacts to marine turtles illustrates the severity of the problem. Wildlife tourism and sustainable tourism activity have not focussed on specific behaviours to change and have had minimal impact on subsequent human behaviour regarding environmental issues, indicating the need for new strategies. Social marketing principles offer promise, but there is a need to investigate the utility of various theoretical foundations to aid the design and implementation of interventions. We offer insight towards using sophisticated multi-method research to develop insights into behaviours and segmentation-based strategies, that can aid the identification of barriers to, and enablers of, sustained behaviour change.

Earley, M. C., et al. (2002). "Report from a workshop on multianalyte microsphere assays." Cytometry **50**(5): 239-242.

Multiplexed assays using fluorescent microspheres is an exciting technique that has been gaining popularity among researchers, particularly those in the public health field. Part of its

popularity is due to its flexibility, as both immunoassays and oligonucleotide hybridization assays can be developed on this platform. This report summarizes a workshop held by the Centers for Disease Control and Prevention that discussed issues surrounding these assays and the Luminex 100 xMAP instrument. Topics included instrumentation, assay design, sample matrix and volume, quality control, and development of commercial applications.

Echevarria, F. D., et al. (2016). "Interleukin-6: A Constitutive Modulator of Glycoprotein 130, Neuroinflammatory and Cell Survival Signaling in Retina." Journal of Clinical & Cellular Immunology **7**(4).

OBJECTIVE: The interleukin-6 (IL-6) family of cytokines and their signal transducer glycoprotein (gp130) are implicated in inflammatory and cell survival functions in glaucoma. There are several avenues for interdependent modulation of IL-6 family members and gp130 signaling. Here we investigated whether IL-6 modulates gp130 and related neuroinflammatory, cell survival and regulatory signaling in both healthy and glaucomatous retina.

METHODS: In naive and glaucomatous (Microbead Occlusion Model), wildtype (WT) and IL-6 knockout (IL-6-/-) mice, we examined gp130 protein expression and localization, using western blot and immunohistochemistry. Gene targets related to IL-6 and gp130 signaling and pertinent to neuroinflammation (TNFalpha, IL-1beta), cell health (Bax, Bcl-xl) and STAT3 regulation (Socs3) were quantified using qRTPCR.

RESULTS: In the naive retina, IL-6-/- retina contained significantly less gp130 compared to WT retina. This IL-6-related decrease in gp130 was accompanied by a reduction in mRNA expression of TNFalpha, Socs3 and Bax. After 4 weeks of microbead-induced ocular hypertension, both microbead- and saline-injected (control) eyes of IL-6-/- mice exhibited higher expression of TNFalpha, compared to WT mice. IL-1beta expression was also reduced specifically in IL-6-/- retina with microbead-induced glaucoma. While saline and microbead injection increased Bcl-xl and Socs3 mRNA in both WT and IL-6-/- mice, IL-6-/- deficiency led to smaller increases for both Bcl-xl and Socs3.

CONCLUSIONS: Our findings support a role for IL-6 in setting baseline parameters for neuroinflammatory, cell health and gp130 regulatory signaling that can impact the nature and magnitude of retinal responses to glaucoma-related stressors.

Eckert, E. M., et al. (2018). "Microplastics increase impact of treated wastewater on freshwater microbial community." Environmental Pollution **234**: 495-502.

Plastic pollution is a major global concern with several million microplastic particles entering every day freshwater ecosystems via wastewater discharge. Microplastic particles stimulate biofilm formation (plastisphere) throughout the water column and have the potential to affect microbial community structure if they accumulate in pelagic waters, especially enhancing the proliferation of biohazardous bacteria. To test this scenario, we simulated the inflow of treated wastewater into a temperate lake using a continuous culture system with a gradient of concentration of microplastic particles. We followed the effect of microplastics on the microbial community structure and on the occurrence of integrase 1 (int1), a marker associated with mobile genetic elements known as a proxy for anthropogenic effects on the spread of antimicrobial resistance genes. The abundance of int1 increased in the plastisphere with increasing microplastic particle concentration, but not in the water surrounding the microplastic particles. Likewise, the microbial community on microplastic was more similar to the original wastewater community with increasing microplastic concentrations. Our results show that microplastic particles indeed promote persistence of typical indicators of microbial anthropogenic pollution in natural waters, and substantiate that their removal from treated wastewater should be prioritised.

Eddy, T. D. (2019). "Climate change drowned out by plastic." Aquatic Conservation **29**(5): 848-848.

Edelstein, R. L., et al. (2000). "The BARC biosensor applied to the detection of biological warfare agents." Biosensors & Bioelectronics **14**(10-11): 805-813.

The Bead ARray Counter (BARC) is a multi-analyte biosensor that uses DNA hybridization, magnetic microbeads, and giant magnetoresistive (GMR) sensors to detect and identify biological warfare agents. The current prototype is a table-top instrument consisting of a microfabricated chip (solid substrate) with an array of GMR sensors, a chip carrier board with electronics for lock-in detection, a fluidics cell and cartridge, and an electromagnet. DNA probes are patterned onto the solid substrate chip directly above the GMR sensors, and sample analyte containing complementary DNA hybridizes with the probes on the surface. Labeled, micron-sized magnetic beads are then injected that specifically bind to the sample DNA. A magnetic field is applied, removing any beads that are not specifically bound to the surface. The beads remaining on the surface are detected by the GMR sensors, and the intensity and location of the signal indicate the concentration and identity of pathogens present in the sample. The current BARC chip contains a 64-element sensor array, however, with recent advances in magnetoresistive technology, chips with millions of these GMR sensors will soon be commercially available, allowing simultaneous detection of thousands of analytes. Because each GMR sensor is capable of detecting a single magnetic bead, in theory, the BARC biosensor should be able to detect the presence of a single analyte molecule.

Edo, C., et al. (2019). "Fate of microplastics in wastewater treatment plants and their environmental dispersion with effluent and sludge." Environmental Pollution **259**: 113837.

This work studied the occurrence of microplastics in primary and secondary effluents and mixed sludge of a WWTP as well as in processed heat-dried sludge marketed as soil amendment. Sampled microparticles were divided into fragments and fibres, the latter defined as those with cylindrical shape and length to diameter ratio >3. We showed the presence of 12 different anthropogenic polymers or groups of polymers with a predominance of polyethylene, polypropylene, polyester and acrylic fibres together with an important amount of manufactured natural fibres. The smaller sampled fraction, in the 25-104 mum range, was the largest in both primary and secondary effluents. Fibres displayed lower sizes than fragments and represented less than one third of the anthropogenic particles sampled in effluents but up to 84% of heat-dried sludge. The plant showed a high efficiency (>90%) in removing microplastics from wastewater. However, the amount of anthropogenic plastics debris in the 25 mum - 50 mm range still released with the effluent amounted to 12.8 +/- 6.3 particles/L, representing 300 million plastic debris per day and an approximate load of microplastics of 350 particles/m³ in the receiving Henares River. WWTP mixed sludge contained 183 +/- 84 particles/g while heat-dried sludge bore 165 +/- 37 particles/g. The sludge of the WWTP sampled in this work, would disseminate 8 x 10¹¹ plastic particles per year if improperly managed. The agricultural use of sludge as soil amendment in the area of Madrid could spread up to 10¹³ microplastic particles in agricultural soils per year.

Edson, E. C. and M. R. Patterson (2015). "MantaRay: A novel autonomous sampling instrument for in situ measurements of environmental microplastic particle concentrations." IEEE Conferences: 1-6.

Presented here is the initial hardware and software design of a prototype autonomous microplastic sampling instrument. Microplastics are defined as particles of plastic <5 mm greatest dimension. They are becoming pervasive in the world ocean due to anthropogenic pollution. The ocean has spatially variable concentrations of surface microplastics, so attempting to identify trends in global dispersal patterns is difficult and expensive using current research techniques. Understanding the global dispersion patterns and degradation rates of microplastics will help to uncover the associated human and ecosystem impacts. A novel low-cost oceanographic sensor has been developed that can determine the concentration of marine microplastics over large spatial areas. This sensor can remove plastic particulates from seawater and archive them for later analysis, determine microplastic concentrations for 28 discrete samples recording GPS position, and simultaneously measure salinity and water temperature. This sensor has been designed around the open-source Arduino platform, allowing for maximum implementation of additional sensors and systems in future prototypes. The MantaRay sensor can be implemented on a drifter, mooring, or Autonomous Underwater Vehicle to gather diverse data on the dispersion of microplastics. This sensor could drastically cut research costs associated with studying deep-sea microplastic concentrations and increase our understanding of plastic dispersion and degradation rates in marine ecosystems.

Edwards, R. (2000). "BAGS OF RUBBISH." Ecologist **30**(8): 52.

Reports on the growing problem of plastic waste in India. Estimated number of cows dying for eating discarded plastic bags; Reason behind the plastic waste problems facing the country in spite of its recycling efforts; Argument used by the Indian plastic industry to justify the status quo; Examples of legislation passed to address the problem.

Eerkes-Medrano, D., et al. (2015). "Microplastics in freshwater systems: a review of the emerging threats, identification of knowledge gaps and prioritisation of research needs." Water Research **75**: 63-82.

Plastic contamination is an increasing environmental problem in marine systems where it has spread globally to even the most remote habitats. Plastic pieces in smaller size scales, microplastics (particles <5 mm), have reached high densities (e.g., 100,000 items per m(3)) in waters and sediments, and are interacting with organisms and the environment in a variety of ways. Early investigations of freshwater systems suggest microplastic presence and interactions are equally as far reaching as are being observed in marine systems. Microplastics are being detected in freshwaters of Europe, North America, and Asia, and the first organismal studies are finding that freshwater fauna across a range of feeding guilds ingest microplastics. Drawing from the marine literature and these initial freshwater studies, we review the issue of microplastics in freshwater systems to summarise current understanding, identify knowledge gaps and suggest future research priorities. Evidence suggests that freshwater systems may share similarities to marine systems in the types of forces that transport microplastics (e.g. surface currents); the prevalence of microplastics (e.g. numerically abundant and ubiquitous); the approaches used for detection, identification and quantification (e.g. density separation, filtration, sieving and infrared spectroscopy); and the potential impacts (e.g. physical damage to organisms that ingest them, chemical transfer of toxicants). Differences between freshwater and marine systems include the closer proximity to point sources in freshwaters, the typically smaller sizes of freshwater systems, and spatial and temporal differences in the mixing/transport of particles by physical forces. These differences between marine and freshwater systems may lead to differences in the type of microplastics present. For example, rivers may show a predictable pattern in microplastic characteristics (size, shape, relative abundance) based on waste sources (e.g. household vs. industrial) adjacent to the river, and distance downstream from a point source. Given that the study of microplastics in freshwaters has only arisen in the last few years, we are still limited in our understanding of 1) their presence and distribution in the environment; 2) their transport pathways and factors that affect distributions; 3) methods for their accurate detection and quantification; 4) the extent and relevance of their impacts on aquatic life. We also do not know how microplastics might transfer from freshwater to terrestrial ecosystems, and we do not know if and how they may affect human health. This is concerning because human populations have a high dependency on freshwaters for drinking water and for food resources. Increasing the level of understanding in these areas is essential if we are to develop appropriate policy and management tools to address this emerging issue.

Ehlers, S. M. and J. A. Ellrich (2020). "First record of 'plasticrusts' and 'pyroplastic' from the Mediterranean Sea." Marine Pollution Bulletin **151 (no pagination)**(110845).

We report the presence of 'plasticrusts' and 'pyroplastic' from coastal habitats in Giglio island, Tyrrhenian Sea, Italy. These novel plastic debris types have only recently been described for the first time from Madeira island (NE Atlantic Ocean) and the United Kingdom, respectively. While 'plasticrusts' are generated by sea waves smashing plastic debris against intertidal rocks, 'pyroplastic' derives from (un)deliberately burnt plastic waste. Using Fourier-transform infrared (FTIR) spectroscopy, we identified the 'plasticrust' material as polyethylene (PE) and the 'pyroplastic' material as polyethylene terephthalate (PET). These polymers are widely used in everyday products and, therefore, contribute heavily to plastic pollution in aquatic and terrestrial environments worldwide. Furthermore, our field surveys suggest that 'plasticrust' abundance is related to wave-exposure and that the 'pyroplastic' derived from beverage bottles which we frequently found along the Giglio coast. Overall, our findings corroborate the notion that 'plasticrusts' and 'pyroplastic' are common debris types in marine coastal habitats. Copyright © 2019 Elsevier Ltd

Ehlers, S. M., et al. (2019). "Microplastics of different characteristics are incorporated into the larval cases of the freshwater caddisfly Lepidostoma basale." Aquatic Biology **28**: 67.

Plastic pollution is present in aquatic systems worldwide. While numerous studies have investigated microplastic interactions with marine organisms, microplastic effects on freshwater organisms, especially insects, have been rarely studied. Previous studies have mainly focused on dietary uptake of microplastics, but the presence of microplastics in animal constructions is largely unknown. To date, microplastics have only been observed in the tubes of a marine polychaete species. In freshwater systems, common caddisfly (Trichoptera) larvae build cases by using larval silk and mineral grains from benthic sediments, which are known microplastic sinks. Therefore, we examined caddisfly cases for microplastic presence. We collected caddisfly Lepidostoma basale cases in the field, disintegrated them using hydrogen peroxide, and determined microplastic polymer type through micro-Fourier-transform infrared spectroscopy. We found primary and secondary microplastics of different shapes, colors, sizes and chemical compositions (e.g. poly propylene, polyethylene, polyvinyl chloride). Thus, this is the first study to show that microplastics are present in the biological construction of a freshwater organism. Larval stages are usually more vulnerable than adult individuals, and microplastics can transport persistent organic pollutants and emit toxic leachates. In the caddisfly larval case, those substances are in close proximity to the sensitive larval body, which may be harmful for the larva and may eventually impede its development. We discuss the potential of caddisfly larval cases to act as microplastic bioindicators in freshwater habitats.

Einat, P. (2006). "Methodologies for high-throughput expression profiling of microRNAs." Methods in Molecular Biology **342**: 139-157.

MicroRNAs (miRNAs) have recently emerged as important regulators of gene expression controlling central biological processes. These small, approx 22-nucleotide (nt)-long RNA molecules induce translational suppression when they are imperfectly matched to their target messenger RNA (mRNA) or direct mRNA cleavage when perfectly, or nearly perfectly, matched to their target. Direct roles in developmental processes have been described in a variety of species, and involvement in human diseases, such as cancer and diabetes, has been implied. These studies highlight the need to obtain detailed expression profiles of miRNAs in tissues, during development, and in disease. Their small size and the existence of miRNA families of related sequences pose critical problems in approaching expression analysis of miRNAs, especially using high-throughput approaches. All methodologies presented here address the special requirements for the analysis of miRNA expression using a variety of platforms, including cloning, microarrays, and microbeads. The different variables, as well as the different approaches, used by various laboratories are detailed and general recommendations are provided. [References: 57]

Eitzen, L., et al. (2019). "The challenge in preparing particle suspensions for aquatic microplastic research." Environmental Research **168**: 490-495.

The occurrence of small particles consisting of organic polymers, so-called microplastic (MP), in aquatic environments attracts increasing interest in both public and science. Recent sampling campaigns in surface waters revealed substantial numbers of particles in the size range from a few micrometers to a few millimeters. In order to validate sample preparation, identification and quantification and to investigate the behavior of MP particles and potential toxic effects on organisms, defined MP model particles are needed. Many studies use spherical compounds that probably behave differently compared to irregularly shaped MP found in environmental samples. However, preparation and handling of MP particles are challenging tasks and have been systematically investigated in the present study. Polystyrene (PS) as a commonly found polymer with a density slightly above that of water was selected as polymer type for milling and fractionation studies. A cryogenic ball mill proved to be practical and effective to produce particles in the size range from 1 to 200micro m. The yield of small particles increased with increasing pre-cooling and milling durations. Depending on the concentration and the size, PS particles do not completely disperse in water and particles partly creep vertically up along glass walls. Stabilized MP suspensions without use of surfactants that might harm organisms are needed for toxicological studies. The stabilization of PS particle suspensions with ozone treatment reduced the wall effect and increased the number of dispersed PS particles but increased the dissolved organic carbon concentration and changed the size distribution of the particles.

Ekpunobi, U. E., et al. (2013). "Comparative study on the effect of density on water absorption of particle boards produced from Nipa palm fibres with HDPE wastes." Pertanika Journal of Science & Technology **21**(2): 499-506.

Nipa palm fibres were used in producing fibre boards with different mixtures of waste HDPE fibres. Density, swelling thickness and water absorption of the boards were determined and compared to know the combination that would yield the best quality. The relationship between the densities of boards produced and their ability to absorb water was also established. The significance of the results implies that the boards have special water resistant property, a feature that makes them suitable for use in areas of high humidity or occasional wetness. It is also noted that as more plastic waste is incorporated into Nipa fibres, the less density impacted on the particle boards and, hence, more water is absorbed.

Ekregbesi, P., et al. (2018). "Relationship between Anaemia, Haemolysis, Inflammation and Haem Oxygenase-1 at Admission with Sepsis: a pilot study." Scientific Reports **8**(1): 11198.

Upregulation of haem oxygenase-1 (HO-1), due to haemolysis and/or inflammation, can lead to impaired immune function. Anaemia is common among sepsis patients, but the consequences of sepsis-associated anaemia are poorly understood. Here, our objective was to determine the prevalence and extent of anaemia, haemolysis, inflammation, and HO-1 induction after early hospital admission. We hypothesised that inflammation- or infection-induced haemolysis contributes to sepsis-associated anaemia and that this will lead to expression of HO-1. In this study, plasma obtained from seventy adult patients within 12 hours of admission to intensive care due to sepsis were analysed for anaemia, haemolysis and inflammatory markers by ELISA and microbead array. The majority (82.6%) of patients were anaemic with evidence of haemolysis (raised haem, haptoglobin, haemopexin, and HO-1 concentrations). Interestingly, concentrations of both haemoglobin and IL-10 were moderately positively correlated with HO-1 concentration (Hb: $r = 0.32$, $p = 0.007$; IL-10 $r = 0.39$, $p = 0.0008$) whereas HO-1 concentration was weakly negatively correlated with haemopexin ($r = -0.23$, $p = 0.055$). Anaemia, while common, was not associated with HO-1 concentration. After adjusting for confounding, HO-1 induction appears to be associated primarily with IL-10 concentration rather than haemolysis. Disease severity at diagnosis was correlated with early plasma IL-10 ($r = 0.35$, $p = 0.003$) and HO-1 ($r = 0.24$, $p = 0.048$) concentrations. Notably, admission levels of haem, HO-1, and IL-10 were indicators of survival.

Ekstrom, S., et al. (2007). "Polymeric integrated selective enrichment target (ISET) for solid-phase-based sample preparation in MALDI-TOF MS." Journal of Mass Spectrometry **42**(11): 1445-1452.

A polymer microfabricated proteomic sample preparation and MALDI MS sample presentation device, the integrated selective enrichment target (ISET), comprising an array of perforated nanovials is reported. Each perforated nanovial can be filled with selective extraction media (microbeads) for purification and concentration of protein/peptides prior to matrix-assisted laser desorption/ionization mass spectrometry (MALDI MS). The main areas covered are the influence of the molding-process-induced surface roughness and how to address the lack of inherent conductivity in the polyetheretherketone (PEEK) material for optimal MALDI MS readout. Application of the disposable polymeric ISET devices for solid-phase extraction and phosphopeptide capture is also demonstrated.

El Essawy, N. A., et al. (2017). "Green synthesis of graphene from recycled PET bottle wastes for use in the adsorption of dyes in aqueous solution." Ecotoxicology & Environmental Safety **145**: 57-68.

Polyethyleneterephthalate (PET) is an important component of post-consumer plastic waste. This study focuses on the potential of utilizing "waste-treats-waste" by synthesis of graphene using PET bottle waste as a source material. The synthesized graphene is characterized by SEM, TEM, BET, Raman, TGA, and FT-IR. The adsorption of methylene blue (MB) and acid blue 25 (AB25) by graphene is studied and parameters such as contact time, adsorbent dosage were optimized. The Response Surface Methodology (RSM) is applied to investigate the effect of three variables (dye concentration, time and temperature) and their interaction on the removal efficiency. Adsorption kinetics and isotherm are followed a pseudo-second-order model and Langmuir and Freundlich isotherm models, respectively. Thermodynamic parameters demonstrated that adsorption of dye is spontaneous and endothermic in nature. The plastic waste can be used after transformation into valuable carbon-based nanomaterials for use in the adsorption of organic contaminants from aqueous solution.

El Haddad, L., et al. (2018). "Microencapsulation of a Staphylococcus phage for concentration and long-term storage." Food Microbiology **76**: 304-309.

In an effort to reduce food safety risks, virulent phages are investigated as antibacterial agents for the control of foodborne pathogens. The aim of this study was to evaluate microencapsulation (ME) as a tool to concentrate and store staphylococcal bacteriophages. As a proof of concept, phage Team1 belonging to the Myoviridae family was microencapsulated in alginate gel particles of 0.5mm (micro-beads) and 2mm (macro-beads) of diameter. Gel contraction occurred during the hardening period in the CaCl₂ solution, and the diameters of the initial alginate droplets shrunk by 16% (micro-beads) and 44% (micro-beads). As compared to the phage counts in the alginate solution, this contraction resulted in the increase of the phage titers, per g of alginate gel, by factors of 2 (micro-beads) and 6 (micro-beads). The encapsulation yield was highest in the macro-beads. Although phage Team1 was successfully frozen in beads, ME did not improve phage stability to freeze-drying. The addition of glycerol protected the microencapsulated phages during freezing but had no effect on free phage suspensions. Finally, ME improved storage stability at 4degreeC but had no impact on freezing or drying over three months of storage.

El Samaligy, M. and P. Rohdewald (1983). "Polyacrylamide microbeads, a sustained release drug delivery system." International Journal of Pharmaceutics **13**(1): 23-34.

Using tetracycline-HCl and theophylline as model drugs, polyacrylamide microbeads were prepared by w/o emulsion polymerization technique. Furthermore, drug-loaded polymer microbeads were prepared in the presence of different concentrations of gelatin, which were further cross-linked for different time intervals. The prepared microbeads were characterized through particle size analysis, electron microscopy, and in vitro dissolution. Relatively spherical free-flowing populations of microbeads were obtained. The presence of gelatin during the polymerization processes led to larger particles proportional to its concentration in the aqueous phase. The dried microbeads showed smooth pored or fissured surfaces. In aqueous media, they attained equilibrium hydration within 10 min, with 73.5% v/v water uptake forming spongy spheres. The products showed slower dissolution rates with higher gelatin concentrations and extended cross-linking.

El-Aassar, M. R., et al. (2014). "Microencapsulation of lectin anti-cancer agent and controlled release by alginate beads, biosafety approach." International Journal of Biological Macromolecules **69**: 88-94.

Hepatocellular carcinoma (HCC) is considered as one of the most aggressive cancer worldwide. In Egypt, the prevalence of HCC is increasing during last years. Recently, drug-loaded microparticles were used to improve the efficiency of various medical treatments. This study is designed to evaluate the anticancer potentialities of lectins against HCC while hinting to its safety usage. The aim is also extended to encapsulate lectins in alginate microbeads for oral drug delivery purposes. The extracted lectins showed anti-proliferative effect against HCC with a percentage of 60.76% by using its nontoxic dose with an up-regulation of P53 gene expression. Concerning the handling of lectin alginate microbeads for oral drug delivery, the prepared lectin alginate beads were ~100. mum in diameter. The efficiency of the microcapsules was checked by scanning electron microscopy, the SEM showed the change on the alginate beads surface revealing the successful lectin encapsulation. The release of lectins from the microbeads depended on a variety of factors as the microbeads forming carriers and the amount-encapsulated lectins. The Pisum sativum extracted lectins may be considered as a promising agent in controlling HCC and this solid dosage form could be suitable for oral administration complemented with/or without the standard HCC drugs. © 2014 Elsevier B.V.

Eldardiri, M., et al. (2009). "Comparative analysis of two types of Gelatin microcarrier beads for the culture of keratinocytes in vitro." Wound Repair and Regeneration **17 (4)**: A65.

The use of microcarriers for keratinocyte culture for skin replacement therapy has advantages including rapid cell expansion and the elimination of trypsinisation. In this study, we compared the behaviour of keratinocytes on two types of Gelatin-based microcarrier beads Cultispher-G and Cultispher-S in rotating and stirred culture. Isolated keratinocytes were cultured in Rheinwald and Green medium and either Cultispher-G or S in rotating tubes or in flasks on a magnetic stirrer. Keratinocyte attachment and proliferation was analysed at 4, 8, 12, 18, 24 and 30 days. MTT and Acridine orange staining were used for cell observation and Alamar Blue was used to quantitatively measure proliferation. Real-time PCR analysis was used to measure cytokeratin expression (K1, K10, K5, and K14) relative to GAPDH by keratinocytes grown in tissue culture flasks, on microcarrier beads in different conditions (+/- lethally irradiated 3T3 feeder cells). Cultispher-G and S supported keratinocyte culture in rotating tubes and cells were found to proliferate until d18 when a decrease was observed. Cultispher-G was used in stirred culture and staining demonstrated keratinocyte attachment and proliferation. Keratinocytes were found to proliferate with a slight decrease in proliferation after d12. There was no difference in the expression of cytokeratins K1/K10 which are markers for keratinocyte differentiation or K5/14, which are expressed by all keratinocytes, when grown on microcarrier beads (-3T3 cells) and compared with cells cultured on tissue culture plastic. Microcarrier beads allow easy retrieval and delivery of viable keratinocytes used as skin replacement therapy. Skin loss following full thickness burns, trauma, and chronic wounds remains a clinical challenge and the utilisation of keratinocytes in dynamic microbead culture may provide a substantial improvement to existing culture and delivery technologies.

Elert, A. M., et al. (2017). "Comparison of different methods for MP detection: What can we learn from them, and why asking the right question before measurements matters?" Environmental Pollution **231**(Pt 2): 1256-1264.

In recent years, an increasing trend towards investigating and monitoring the contamination of the environment by microplastics (MP) (plastic pieces < 5 mm) has been observed worldwide. Nonetheless, a reliable methodology that would facilitate and automate the monitoring of MP is still lacking. With the goal of selecting practical and standardized methods, and considering the challenges in microplastics detection, we present here a critical evaluation of two vibrational spectroscopies, Raman and Fourier transform infrared (FTIR) spectroscopy, and two extraction methods: thermal extraction desorption gas chromatography mass spectrometry (TED-GC-MS) and liquid extraction with subsequent size exclusion chromatography (SEC) using a soil with known contents of PE, PP, PS and PET as reference material. The obtained results were compared in terms of measurement time, technique handling, detection limits and requirements for sample preparation. The results showed that in designing and selecting the right methodology, the scientific question that determines what needs to be understood is significant, and should be considered carefully prior to analysis. Depending on whether the object of interest is quantification of the MP particles in the sample, or merely a quick estimate of sample contamination with plastics, the appropriate method must be selected. To obtain overall information about MP in environmental samples, the combination of several parallel approaches should be considered.

Elessawy, N. A., et al. (2020). "Ciprofloxacin removal using magnetic fullerene nanocomposite obtained from sustainable PET bottle wastes: Adsorption process optimization, kinetics, isotherm, regeneration

and recycling studies." Chemosphere **239 (no pagination)**(124728).

Numerous of pollutants threaten our planet, for instance plastic wastes causes a huge potential risk on the environment in addition to many of emergened pollutants as pharmaceutical residue in aquatic environments which affecting ecological balance and in-turn affecting human health. Accordingly, this research proposed an innovative facile, one-step synthesis of functionalized magnetic fullerene nanocomposite (FMFN) via catalytic thermal decomposition of sustainable poly (ethylene terephthalate) bottle wastes as feedstock and ferrocene as a catalyst and precursor of magnetite. Growth mechanism of FMFN was discussed and batch experiments were achieved to examine its adsorption efficiency in relation to Ciprofloxacin antibiotic. Different adsorption parameters including time, initial Ciprofloxacin concentration, and solution temperature were investigated and optimized using Response Surface Methodology (RSM) model. In addition, a study on the antibiotic adsorption process impact on the organisms of an ecosystem was conducted using E. coli DH5alpha, and results validated method's efficiency in overcoming problem of appearance of antibiotic-resistant microbes. Copyright © 2019 Elsevier Ltd

Elizalde-Velazquez, A., et al. (2020). "Translocation, trophic transfer, accumulation and depuration of polystyrene microplastics in Daphnia magna and Pimephales promelas." Environmental Pollution **259**: 113937.

In recent years, reports of plastic debris in the gastrointestinal (GI) tract of fish have been well documented in the scientific literature. This, in turn, increased concerns regarding human health exposure to microplastics through the consumption of contaminated fish. Most of the available research regarding microplastic toxicity has focused on marine organisms through direct feeding or waterborne exposures at the individual level. However, little is known about the trophic transfer of microplastics through the aquatic food chain. Freshwater zooplankton Daphnia magna (hereafter Daphnia), and the fathead minnow Pimephales promelas (FHM), are well-known model species used in standard toxicological studies and ecological risk assessments that provide a simple model for trophic transfer. The aim of this study was to assess the tissue translocation, trophic transfer, and depuration of two concentrations (20 and 2000-part ml⁻¹) of 6 mum polystyrene (PS) microplastics particles between Daphnia and FHM. Bioconcentration factors (BCF) and bioaccumulation factors (BAF) were determined. Fluorescent microscopy was used to determine the number of particles in the water media and within the organs of both species. Throughout the five days of exposure, PS particles were only found within the GI tract of both species. The BCF for Daphnia was 0.034 +/- 0.005 for the low concentration and 0.026 +/- 0.006 for the high concentration. The BAF for FHM was 0.094 +/- 0.037 for the low concentration and 0.205 +/- 0.051 for the high concentration. Between 72 and 96 h after exposure all microplastic particles were depurated from both species. The presence of food had a significant effect on the depuration of microplastic particles from Daphnia but not for FHM. Based on the low BCF and BAF values for both species, rapid depuration rates, and null translocation of microplastic particles to organs and tissues from the GI tract, there is a low probability that microplastics will bioconcentrate and bioaccumulate under environmental conditions.

Elkhalifa, M. Y., et al. (1992). "A flow cytometric method to detect anti-pyruvate dehydrogenase antibody in primary biliary cirrhosis." American Journal of Clinical Pathology **97**(2): 202-208.

Primary biliary cirrhosis (PBC) is an autoimmune disease characterized by the presence of anti-mitochondrial antibodies specifically directed against the M2 group of mitochondrial antigens. Recently, the E-1, the E-2, and protein X components of pyruvate dehydrogenase enzyme complex have been identified as the major antigens within the M2 group of autoantigens. An immunoassay using pyruvate dehydrogenase enzyme complex as a specific antigen for the diagnosis of PBC was developed. Pyruvate dehydrogenase enzyme complex was attached to polystyrene microbeads, incubated with sera from PBC patients (n = 18), normal controls (n = 50), or patients with other autoimmune diseases (n = 26), followed by incubation with a second fluorescein isothiocyanate conjugated goat anti-human immunoglobulin and then analyzed by flow cytometry. High numbers of fluorescence channels (mean, 1,693 +/- 846) were obtained for all PBC sera except for two patients. Compared to the conventional anti-mitochondrial antibody assay, the assay had a sensitivity rate of 94% and a specificity rate of 100%. The reactive antibodies are predominantly of the immunoglobulin G3 subclass. Their levels could be correlated with the histopathologic stages of PBC. These results were corroborated by immunoblotting. Sera from patients with later stages of PBC strongly reacted with pyruvate dehydrogenase enzyme complex components, E1 alpha, and protein X.

Elliott, J. E. and K. H. Elliott (2013). "Tracking Marine Pollution." Science **340**(6132): 556-558.

Visit a beach almost anywhere and you will see plastic waste floating in the water and heaped above the tide lines. That debris is both a source and an overt signal of the even more pervasive contamination of marine biota by persistent chemicals. Present at ultra-trace levels but often highly toxic, chemical pollutants can be challenging to measure and understand. As the most problematic compounds biomagnify in food chains, sampling of marine top predators yields a global picture of ocean pollution.

El-Mallawany, N. K., et al. (2010). "Global proteomic evaluation of the relationship between Epstein-Barr virus (EBV) and c-myc deregulation in endemic versus sporadic Burkitt lymphoma (BL)." Cancer Research. Conference: 101st Annual Meeting of the American Association for Cancer Research, AACR **70**(8 SUPPL. 1).

Endemic BL (eBL) is characteristically positive(100%) for EBV, contrasting with sporadic(sBL) BL(30% EBV+). eBL vs sBL have different breakpoint regions within c-myc. The different mechanisms of lymphomagenesis however, remain unknown. Global analysis of proteins expressed in the different subtypes may provide insights into biologic, pathogenetic, and molecular differences. Objective(s): To compare the proteomic expression profile and signal transduction pathways of EBV+ eBL with EBV+/- sBL and EBV+/- normal B-cells. Normal B-cells (EBV+/-) were isolated from leukopacks obtained from the NY Blood Center using Magnetic Cell Sorting CD20 MicroBeads (Miltenyi biotec, CA). Whole cell lysates obtained from EBV+ eBL Raji, EBV+ sBL NC37, EBV- sBL Ramos, and EBV+/- B-cells were digested and labeled with iTRAQ reagents. The peptides were resolved by 2D-LC technique. MS/MS spectra were acquired using an Orbitrap XL Tandem Mass Spectrometer (ThermoFisher). MS/MS data was searched using X! Tandem TPP software against human IPI database (v3.50) appended with decoy sequences. iTRAQ ratios of proteins (ProteinProphet probability of >0.9) were normalized and differentially expressed proteins were selected for further analysis. Over 400 proteins were identified; 827 binary differential protein expressions were established with a False Discovery Rate (FDR) of <0.4. Hierarchical clustering of the expression profiles grouped the 3 lymphoma cell lines and the 2 normal B-cell specimens. Specific cellular functions were implicated by differential protein expressions (with associated proteins in parentheses) including apoptotic signaling (AK2, C1QBP, DIABLO, PCNA, PPIF, SERPIN8&9, SET), viral pathogenesis (DDX3X, SYNCRIP, EIF5A), cell proliferation pathways and oncogenes (ANXA6, DDX5, DEK, GNB2L1, NME2, RAP1A&B, RIPK4, STMN1), c-myc expression regulation (ENO1, FUBP1), heat shock and ubiquitination (HSP90AB1, HSP90B1, HSPA5, UCHL1). There are several proteins with established links to malignancy

(RPL15, PSMA4, SLC3A2, TLX2, VIM) including TUBB2C, whose overexpression is found in pediatric BL and potential biomarkers for disease (IGHM, IGSF3, LDHA, LDHB, PPBP, LSP1, LYZ, DEFA1, DEFA3). We identified 41 proteins within the c-myc network, 21 of which are c-myc targets. Our results suggest that there are potentially different mechanisms driving cell proliferation and resistance to apoptosis in the different BL subtypes. Confirmatory studies will be required to establish the correlation between EBV, c-myc, and geographical subtype and how they may be involved in promoting lymphomagenesis. Ultimately, identification of proteins unique to the distinct disease subtypes will serve to establish tumor markers that may enable development of new diagnostic, prognostic, and therapeutic strategies.

Elmesmari, A., et al. (2014). "MIR-155 expression correlates with clinical disease activity and has effector function in rheumatoid arthritis." Arthritis and Rheumatology **10)**: S1069.

Background/Purpose: MicroRNAs are fine tuners of biological pathways that function via post-transcriptional regulation of target mRNA life span. MicroRNA 155 (miR155) is particularly implicated in Rheumatoid Arthritis (RA) pathology through regulation of synovial macrophage cytokine and chemokine production. Thus far miR155 expression across disease activity status has not been examined - to this end we have developed a novel assay of absolute copy number to facilitate such investigation. Method(s): Peripheral blood (PB) was obtained from healthy controls and RA patients who met the 2010 ACR/EULAR diagnostic criteria. CD14+ cells (monocytes) were isolated using micro-beads. The absolute copy numbers of miR-155 transcripts and housekeeping short RNA (U1) in peripheral blood (PB) and synovial fluid (SF) macrophages of RA and healthy controls were assessed using a novel qPCR methodology. Result(s): RA PB (n=24) and SF CD14+ monocytes (n=11) expressed higher copy numbers of miR-155 compared with healthy controls (n=22). As expected, RA SF macrophages exhibited the highest expression levels of miR-155 (75318.2/106 copies of RNU1A). In PB monocytes, miR-155 levels were higher when derived from patients with high or moderate disease activity (according to DAS28; $p < 0.05$) than those in remission or healthy controls. The copy number of miR-155 expression was significantly increased in anti-citrullinated protein antibody (ACPA) positive RA (n=17) compared with ACPA negative RA (n=7). The RA PB monocyte miR-155 copy number correlated positively and significantly with DAS28 as a continual variable. There was no correlation between observed increase in miR-155 copy number and patients' age, disease duration or medication. Conclusion(s): Our data demonstrate that miR-155 levels may reflect RA disease activity and could be a potential clinical disease activity biomarker for RA. Moreover our data suggest that circulating monocytes in RA patients exhibit an early activation signature, which is primed for subsequent cytokine release.

El-Mobaidh, A. M., et al. (2006). "Classification of in-flight catering wastes in Egypt air flights and its potential as energy source (chemical approach)." Waste Management **26**(6): 587-591.

Waste to energy conversion is based on the classification of waste. In-flight catering wastes resulting from Egypt Airlines economy class passengers were classified. The solid waste stream generated contains plastic, paper, left-over waste food and aluminum. The type of meal served varies according to the period of flight and so the quantity and content of the waste stream. It was found that the waste generation rate varied from 61.3 to 265 g according to the meal type. Breakfast snack meal generates the highest weight of waste which recorded an average of 265 g. Plastic waste generated varied from 39.6% to 64.6% by weight for the various types of meals served. A total amount of 725 tons were generated annually from organic waste (paper, plastic and food waste) among which a non combustible 39.4 tons of aluminum. The calorific value for each generated item is calculated and the total energy potential reached up to 14.3 TJ annually.

El-Sahrigy, S. A. F., et al. (2018). "The influence of interferon-beta supplemented human dendritic cells on BCG immunogenicity." Journal of Immunological Methods **457**: 15-21.

INTRODUCTION: Tuberculosis (TB) remains a huge worldwide burden, despite extensive vaccination coverage with the Bacillus Calmette-Guerin (BCG), the only vaccine available against this disease, indicating that BCG-driven immunity is inadequate to protect the human population against TB. This underscore the critical necessitate to develop an improved TB vaccine, based on a better understanding of host-pathogen interactions and immune responses during mycobacterial infection.

AIM OF THE WORK: To examine whether the exogenous addition of IFN-beta could improve dendritic cell (DC) response to Mycobacterium bovis (M. bovis) and to evaluate the effect induced by the infection of human DCs with M. bovis (with and without IFN-beta) and Mycobacterium tuberculosis (Mtb) on DC viability as well as to compare the ability of BCG and Mtb to provide DCs with a Th1-polarizing capacity through the assessment of the immunoregulatory cytokines interleukin (IL)-12, IL-10 and interferon-gamma (IFN-gamma).

METHODS: Immature DCs (iDCs) were generated in vitro using peripheral blood monocytes separated by anti-CD14-conjugated microbeads in the presence of granulocyte-macrophage-colony-stimulating factor (GM-CSF) and IL-4, cultured cells were analyzed using flow cytometry, then we tested DC viability after inoculation with M. bovis (with and without IFN-beta pretreatment) and Mtb using light microscopic examination and trypan blue exclusion method. Additionally, supernatants from infected-DCs cultures were analyzed for IFN-gamma, IL-12 and IL-10 by ELISA.

RESULTS: The viability of BCG-infected DCs was significantly higher than that of Mtb-infected DCs (61.55% vs 52.10%). BCG-infected DC produced significantly more IL-12 ($p=0.02$) and less IL-10 ($p=0.01$) compared with Mtb-infected cells. IFN-beta-pretreated BCG-infected DCs produced significantly larger amounts of IL-12 than did BCG-infected DCs ($p=0.03$) and Mtb-infected cells ($p<0.001$).

CONCLUSION: IFN-beta improves DC functions following BCG infection, thus assuming that IFN-beta could be used as a vaccine adjuvant.

Elsawy, M. A., et al. (2017). "Hydrolytic degradation of polylactic acid (PLA) and its composites." Renewable & Sustainable Energy Reviews **79**: 1346-1352.

Biodegradable polymers are seen as a potential solution to the environmental problems generated by plastic waste. In particular, the renewable aliphatic polyesters of poly(hydroxyacid)-type homopolymers and copolymers consisting of polylactic acid (PLA), poly(glycolic acid) (PGA), and poly(e -caprolactone) (PCL) constitute the most promising bioresorbable materials for applications in biomedical and consumer applications. Among those polymers, PLA has attracted particular attention as a substitute for conventional petroleum-based plastics. PLA is synthesized by the fermentation of renewable agricultural sources, including corn, cellulose, and other polysaccharides. Although some of its characteristics are disadvantageous (e.g., poor melt properties, mechanical brittleness, low heat resistance, and slow crystallization), there exist potential routes to resolve these shortcomings. These include copolymerization, blending, plasticization modification, or the addition of reinforcing phases (e.g., chitosan (Cs), cellulose, and starch). In this review, we discuss the degradation mechanisms of PLA and its modified form in the environment, current issues that hinder the achievement of good Cs/PLA combination, and ways to overcome some of these problems. Furthermore, our discussion is extended to cover the subjects of hydrolytic degradation and weathering effects with different Cs/PLA blends. [ABSTRACT FROM AUTHOR]

Eltemsah, Y. S. and T. Bohn (2019). "Acute and chronic effects of polystyrene microplastics on juvenile and adult Daphnia magna." Environmental Pollution **254**(Part A).

We investigate the distribution and effects of polystyrene microplastic (MP) particles in exposure experiments with the ecotoxicology model organism Daphnia magna. The aim was to investigate the short and long-term toxicity of MP at different concentrations. To achieve this goal, the effects of 6 micro m commercially available polystyrene beads on two different life-stages of D. magna: <24 h old juveniles and 9 days old adults was assessed. The following end points in test animals were measured: (1) survival, (2) growth, (3) individual and population fecundity, (4) age at maturation and (5) body size of newborn offspring. These response variables were followed in two acute and two chronic experiments. The acute experiments showed that MP is not acutely toxic to D. magna within 48 h, but cause added mortality within 120 h. The juveniles were about 50% more sensitive than the adults tested. In life-cycle experiments testing chronic exposure to MP, again, animals exposed as juveniles at relatively high concentrations, i.e. >30 micro g ml⁻¹ showed higher sensitivity. We observed slightly increased mortality, reduced growth and stimulation of early reproduction at the cost of later reproduction. Animals exposed after reaching adulthood did not show increased mortality and showed a stimulation response with higher reproductive rates than the control group. However, both the growth rate of mother animals and the body size of newborn declined with increasing dose of MP. We conclude that these effects indicate a role of MP in mechanical interaction/interference with the animal on the level of feeding (clogging filtering functions), digestion (gut filled with plastic particles), and/or other animal behavior. The study also illustrates how MP with slow break-down rates may accumulate in the environment and enter the food-chain as obstructing non-food particles in filter-feeding organisms.

Eltohamy, M., et al. (2011). "Electrosprayed tricalcium phosphate spherical microcups and antibiotic drug delivery." Materials Letters **65**(13): 2043-2046.

Here we prepared tricalcium phosphate (TCP) spherical cups of a few micrometers in size (average=2.74 mu m) by applying the electrospraying method. The sol-gel precursor containing calcium and phosphate (Ca/P=1.5) was mixed with Polyvinylpyrrolidone in ethanol at varying concentrations, and then sprayed under a controlled electrostatic field. The jets from the sol-gel solution changed from a complete fibrous mesh into a formation of microbeads connected with fibers and then further into a complete formation of microbeads as the solution viscosity became decreased. After the thermal treatment (800-1100A degree C), individual microbeads remained, to form the shape of a spherical cup and retained the phase of beta -TCP. The drug delivery potential of the TCP micro-cups, as assessed by using an antibiotic drug ampicillin, demonstrated a dose dependent loading capacity and almost a linear release profile over a day.

Ely, A., et al. (2009). "Copper and nitrophenol pollutants removal by Na-montmorillonite/alginate microcapsules." Journal of Hazardous Materials **171**(1-3): 405-409.

Abstract: The use of renewable bioresources allows the development of low cost adsorbents that are versatile. In the present paper, the affinity and the removal capacity of

montmorillonite/alginate microcapsules for a hydrophobic organic pollutant (4-nitrophenol) and an inorganic pollutant (copper) were evaluated. The physicochemical processes through sorption and kinetic experiments under different ratios of montmorillonite vs. alginate and initial contaminant concentrations were investigated. The total weight loss and diameter decrease during the drying process were 90–96% and 64%, respectively. A significant decrease in beads diameter, related to water elimination, has been observed during the first 24h. Structural modifications that occur during the drying process were evaluated using thermal analysis. From correlation coefficients, the second-order equation depicts properly the adsorption of copper by the microbeads adsorption capacity increases to saturation with time; 3 and 6h were needed to reach equilibrium on wet and dry mixed microcapsules. The pseudo-second order model properly depicts the adsorption process of 4-NP onto Na-mont and (Na-mont/SA) mixed microcapsules but failed to reproduce the data observed for the alginate beads. Isotherms data were fitted with good correlation using the Langmuir model; alginate and montmorillonite adsorption capacities (q m /wet beads) agree with those obtained by various studies. Enck, K., et al. (2017). "Development of a novel alginate based material for targeted intestinal delivery of therapeutic agents." Tissue Engineering - Part A **23 (Supplement 1)**: S18.

Alginate is a complex polysaccharide routinely used for various encapsulation purposes including oral drug delivery of therapeutic agents since it can immobilize and protect compounds from the harsh stomach acid. We have chemically modified alginate to enhance the bioavailability of orally-administered therapeutic substances through the generation of alginate microbeads resistant to low pH stomach conditions, but readily disintegrate in the more neutral pH of the small intestine. The alginate modification was achieved by oxidizing the vicinal diol in the alginate chain to an aldehyde, then coupling aminoethyl benzoic acid to the aldehyde. By uniquely combining both oxidizing and condensation chemistries, we have been able to more precisely control the degree of modification of alginate, which results in controlled levels of degradation of alginate hydrogel mi-crobeads under simulated gastrointestinal tract (GIT) regional pH conditions. Under these simulated GIT conditions, our in vitro experiments have shown that we can encapsulate specific compounds for oral drug delivery, protect them from low pH conditions and deliver them under neutral-basic pH conditions similar to those in the small intestine where nutrients are absorbed most effectively. Thus, the modification of alginate with aminoethyl benzoic acid would lead to enhanced bioavailability of therapeutic agents after release and absorption in the small intestine and as well as for targeted site delivery of certain substances such as probiotics.

Enders, K., et al. (2019). "Tracing microplastics in aquatic environments based on sediment analogies." Scientific Reports **9**(10).

Microplastics (MP) data collection from the aquatic environment is a challenging endeavour that sets apparent limitations to regional and global MP quantification. Expensive data collection causes small sample sizes and oftentimes existing data sets are compared without accounting for natural variability due to hydrodynamic processes governing the distribution of particles. In

Warnow estuarine sediments (Germany) we found significant correlations between high-density polymer size fractions (>=500 mm) and sediment grain size. Among potential predictor variables (source and environmental terms) sediment grain size was the critical proxy for MP abundance. The MP sediment relationship can be explained by the force necessary to start particle transport: at the same level of fluid motion, transported sediment grains and MP particles are offset in size by one to two orders of magnitude. Determining grain-size corrected MP abundances by fractionated granulometric normalisation is recommended as a basis for future MP projections and identification of sinks and sources.

Enders, K., et al. (2015). "Abundance, size and polymer composition of marine microplastics greater than or equal to 10 mu m in the Atlantic Ocean and their modelled vertical distribution." Marine Pollution Bulletin **100**(1): 70-81.

We studied abundance, size and polymer type of microplastic down to 10 mu m along a transect from the European Coast to the North Atlantic Subtropical Gyre (NASG) using an underway intake filtration technique and Raman micro-spectrometry. Concentrations ranged from 13 to 501itemsm-3. Highest concentrations were observed at the European coast, decreasing towards mid-Atlantic waters but elevated in the western NASG. We observed highest numbers among particles in the 10-20 mu m size fraction, whereas the total volume was highest in the 50-80 mu m range. Based on a numerical model size-dependent depth profiles of polyethylene microspheres in a range from 10-1000 mu m were calculated and show a strong dispersal throughout the surface mixed layer for sizes smaller than 200 mu m. From model and field study results we conclude that small microplastic is ubiquitously distributed over the ocean surface layer and has a lower residence time than larger plastic debris in this compartment.

Endo, S., et al. (2005). "Concentration of Polychlorinated Biphenyls (PCBs) in Beached Resin Pellets: Variability Among Individual Particles and Regional Differences." Marine Pollution Bulletin **50**(10): 1103.

Plastic resin pellets, which constitute one of the major components of plastic debris in the marine environment, contain PCBs, PAHs, and DDTs, among other contaminants, making their ingestion by marine organisms problematic. In this study, resin pellets were collected from a beach in Kasai Seaside Park, Tokyo, Japan, in July 2001 to assess the variation in PCB concentrations among pellets, and samples were also collected from 47 beaches in 2001 and 2002 to explore the regional variation in PCB concentrations. In 55 pellets from Kasai Seaside Park, PCB concentrations ranged from below the detection limit to 2300 ng/g, but only a small proportion of the pellets contained the bulk of the contaminant. Discolored and/or fouled polyethylene resin pellets had higher PCB concentrations than non-discolored pellets. Concentrations of PCBs in plastic resin pellets collected regionally also varied widely, with high PCB concentrations found most frequently in pellets from Tokyo Bay and its vicinity and Osaka Bay. The observed regional pattern of PCB concentrations in the pellets was consistent with that found in mussels.

Enfrin, M., et al. (2020). "Release of hazardous nanoplastic contaminants due to microplastics fragmentation under shear stress forces." Journal of Hazardous Materials **384**: 121393.

The presence of nanoplastics in water has become a major environmental concern in the last decade however the knowledge on the origin and formation of these emerging contaminants is lacking due to analytical challenges in detection and quantification techniques. The release of nanoplastics due to the fragmentation of microplastics extracted from a facial scrub and the resulting toxicity on aquatic species are reported here for the first time. The daily use of 4g of facial scrub could release up to 10¹¹ microplastics of 400nm in size per litre of wastewater from household drains. Turbulences created by mixing or pumping induced the fragmentation of microplastics into nanoplastics smaller than 10nm via a crack propagation and failure mechanism, increasing the number of particles in water by one order of magnitude. Compared to microplastics at a fixed concentration number of 6.8 x 10⁸ part./mL, the generated nanoplastics initiated the death of 54% more cells in zebrafish by passive ingestion via skin diffusion which therefore pose a real threat for aquatic living organisms. These results stress the need to reduce the release of nano/microplastics in the aquatic environment to prevent the contamination of all trophic levels.

Engelhard, H., et al. (2017). "Rotating magnetic beads for enhanced drug delivery: characterization of bead velocity, imaging, and adherence to cellular monolayers." Cancer Research. Conference: American Association for Cancer Research Annual Meeting **77**(13 Supplement 1).

Background: Superparamagnetic iron oxide nanoparticles (SPIONs) have been touted as promising vehicles for enhancing drug delivery for cancer, stroke, and other diseases. Unfortunately, successful clinical use has been hampered by the problem of scale, since the attractive force between iron particle and magnet is inversely proportional to at least the fourth power of the intervening distance. Utilization of magnetically-induced rotary traction (MIRT) offers a way to overcome this obstacle. Here, we present initial data from the use of a new two-part system consisting of: 1) a patented rotating magnet, and 2) magnetic microbeads (MBs), which have been optimized for MIRT. Method(s): MBs and the rotating magnet were provided by Pulse Therapeutics (St. Louis, MO). MBs consist of single-crystalline magnetite cores (~70 nm), which form aggregates in response to a magnetic field. Here, the field is generated by a neodymium-boron-iron permanent magnet, which is rapidly rotated causing MBs to counter-rotate (like meshed gears) at physiologic distances, and move by means of surface traction. Movement of MBs through PBS, DMEM with 5% serum, and 100% serum was measured 7.5 to 30 cm from the magnet. Suspensions of the particles were imaged at different concentrations by MRI and CT scan. 3 cancer cell lines (U87, E297, LKB1-KO), and normal vascular endothelial cells, were maintained using standard tissue culture technique. For adhesion studies, cells were grown in 6-well plates to confluence, treated with 10 uL MBs for 30 min., washed with PBS, imaged with standard light microscopy, digitized, then analyzed using Image J. Result(s): In our experiments, MBs moved readily through PBS, DMEM and serum at distances from 7.5 - 30 cm; with a maximum velocity at 22.5 cm (0.45 +/- 0.04 cm/sec, for serum). While MR imaging produced significant artifact as expected, MBs were clearly seen by CT scan. Adhesion of the MBs to the cancer cell lines was markedly higher than to the endothelial cells (10.9-12.0X) and to fixed cells, used as controls. Conclusion(s): MBs are easily rotated and moved at physiologic distances, even through 100% serum, by means of surface traction, and can be imaged by CT scan. Adhesion of MBs to cancer cells is significantly greater than to endothelial cells. These features show that the Pulse system is an extremely promising one, for use in magnetic drug targeting in the clinical setting.

Engler, R. E. (2012). "The Complex Interaction between Marine Debris and Toxic Chemicals in the Ocean." Environmental Science & Technology **46**(22): 12302-12315.

Marine debris, especially plastic debris, is widely recognized as a global environmental problem. There has been substantial research on the impacts of plastic marine debris, such as entanglement and ingestion. These impacts are largely due to the physical presence of plastic debris. In recent years there has been an increasing focus on the impacts of toxic chemicals as they relate to plastic debris. Some plastic debris acts as a source of toxic chemicals: substances that were added to the plastic during manufacturing leach from plastic debris. Plastic debris also

acts as a sink for toxic chemicals. Plastic sorbs persistent, bioaccumulative, and toxic substances (PBTs), such as polychlorinated biphenyls (PCBs) and dioxins, from the water or sediment. These PBTs may desorb when the plastic is ingested by any of a variety of marine species. This broad look at the current research suggests that while there is significant uncertainty and complexity in the kinetics and thermodynamics of the interaction, plastic debris appears to act as a vector transferring PBTs from the water to the food web, increasing risk throughout the marine food web, including humans. Because of the extremely long lifetime of plastic and PBTs in the ocean, prevention strategies are vital to minimizing these risks. [ABSTRACT FROM AUTHOR]

Entwistle, A., et al. (2018). "Fauna & Flora International expands strategy on marine plastics." Oryx **52**(4): 613-614.

Used in a wide range of consumer products, including rinse-off toiletries such as facial scrubs, shaving products and toothpastes, microbeads (microplastic particles) are known to pass through wastewater treatment and enter the sea, where their size makes them immediately available to filter feeders (Tanaka & Takada, 2016, Scientific Reports, 6, 34351). FFI recognizes the many threats plastic poses to marine life (including entanglement in abandoned fishing gear and the impact of ingestion of plastic pieces) and also has specific concerns about the potential for microplastic pollution to introduce hazardous substances into the marine food chain. [...]FFI also retains a strong focus on preventing direct sources of microplastic pollution (plastic particles reaching the ocean at sizes < 5 mm, such as microbeads, plastic pellets and microplastic fibres), given concerns about the potential for microplastics to introduce hazardous substances (either additives or sorbed chemicals) into the marine food chain.

Enyoh, C. E., et al. (2019). "Airborne microplastics: a review study on method for analysis, occurrence, movement and risks." Environmental Monitoring & Assessment **191**(11): 668.

Microplastics (of size < 5 mm) pollution in our environment is of current concern by researchers, public media and non-governmental organizations. Implications by their presence in aquatic and soil ecosystems have been well studied and documented, but less attention has been paid on airborne microplastics (MPs). Studies concerning airborne microplastics started from 2016 and only a few (n = 13) have been published to date. Although, studies may increase in the following years, since air is very important for human survival. Microplastics have been observed in atmospheric fallouts in indoor and outdoor environments using a sampling or vacuum pump, rain sampler, and/or particulate fallout collector. Identification and quantification have been carried out by visual, spectroscopic, and spectrometric techniques. Factors such as meteorological, climatic, and anthropogenic influence the distribution and movement of airborne MP. Human exposure may be through inhalation, dermal, and open meal during fallout, with their potential biopersistence and translocation. Ingestion may cause localized inflammation and cancer due to responses by the immune cells, especially in individuals with compromised metabolism and poor clearance mechanisms. Ecological risks involve possible contamination of the ecosystem through a dynamic relationship of MPs in soil, water, and air forming a MP contamination cycle. The present review aimed at providing a comprehensive overview of current knowledge or information regarding microplastics in air, identifying gap in knowledge, and giving suggestions for future research.

Eo, S., et al. (2018). "Abundance, composition, and distribution of microplastics larger than 20 µm in sand beaches of South Korea." Environmental Pollution **238**: 894-902.

To support microplastic management, the abundance, composition, and spatial distribution of microplastics on a national scale must be known. Hence, we studied the baseline level of microplastic pollution at 20 sandy beaches along the South Korean coast. All microplastic particles extracted from the sand samples were identified down to 20 µm in size using Fourier transform infrared spectroscopy. The abundances of large microplastics (L-MPs; 1–5 mm) and small microplastics (S-MPs; 0.02–1 mm) were in the range of 0–2088 n/m 2 and 1400–62800 n/m 2 , respectively. Maximum microplastic abundance was in the size range of 100–150 µm, and particles smaller than 300 µm accounted for 81% of the total abundance. Expanded polystyrene (EPS) accounted for 95% of L-MPs, whereas S-MPs were predominantly composed of polyethylene (49%) and polypropylene (38%). The spatial distribution of L-MPs, excluding EPS, was significantly related to population, precipitation, proximity to a river mouth and abundance of macroplastic debris on beach. However, there were no relationships between S-MPs and other environmental and source-related factors, except for macroplastic debris and L-MPs excluding EPS. These results imply that S-MPs are mainly produced on beaches by weathering, whereas L-MPs other than EPS are mainly introduced from land-based sources and are also partly produced on beaches. Eom, H. J., et al. (2018). "Potential detrimental effect of waterborne microplastics on differentiation and asexual reproduction of the jellyfish Sanderia malayensis." Toxicology and Environmental Health Sciences **10 (4)**: S43.

To examine potential detrimental effect of waterborne microplastics (MPs) on the development and asexual reproduction of the jellyfish Sanderia malayensis, different sizes of MPs (i.e. 1, 3, 6, and 10 mum) were exposed to the jellyfish under two different experimental conditions, direct and indirect exposures. Firstly, polyp and ephyra of S. malayensis were directly exposed to 200 mul/L of each size of MPs. As a result, the MPs were directly attached to the inside and outside of the polyp, which remained for up to 9 days, while MPs were observed to be attached only to the outside of ephyra. In addition, we observed that some MPs are transferred through body during strobilation. In the case of indirect exposure, the jellyfish were exposed through feeding with microplastic-fed brine shrimp. MPs movement in the inside of ephyra was observed compared to direct treatment. The MPs were remained until 6 days even without any food source. Finally, we observed that MPs treatment on polyps can affect next life cycle with differentiation.

Ercolini, D., et al. (2003). "Development of a fluorescence in situ hybridization method for cheese using a 16S rRNA probe." Journal of Microbiological Methods **52**(2): 267-271.

A 16S rRNA fluorescence in situ hybridization (FISH) method for cheese was developed to allow detection in situ of microorganisms within the dairy matrix. An embedding procedure using a plastic resin was applied to Stilton cheese, providing intact embedded cheese sections

withstanding the hybridization reaction. The use of a fluorescein-labelled 16S rRNA Domain Bacteria probe allowed observation of large colonies of microbial cells homogeneously distributed in the cheese matrix. FISH experiments performed on cheese suspensions provided images of the different microbial morphotypes occurring. The technique has great potential to study the spatial distribution of microbial populations in situ in foods, especially where the matrix is too fragile to allow manipulation of cryosections.

Erdem Yayayuruk, A., et al. (2019). "Polystyrene-divinyl benzene microspheres with amino methyl phosphonic acid functional hairy brushes for the sorption and speciation of chromium prior to inductively coupled plasma mass spectrometric determination." Mikrochimica Acta **186**(8): 571.

This article describes the synthesis and application of a novel sorbent for Cr(III) and Cr(VI) speciation prior to their quantitation by inductively coupled plasma mass spectrometry. The sorbent consists of polystyrene-divinyl benzene microbeads that were graft-coated with poly(oligo (ethylene glycol) methacrylate)-block-poly(glycidyl methacrylate). The particles were finally modified with phosphomethylated triethylene tetramine. The resulting microbeads are shown to be a viable sorbent for Cr(VI). The total concentration of chromium was determined after oxidation of Cr(III) to Cr(VI) with KMnO₄ using the novel sorbent. The Cr(III) amount was then calculated by subtracting the concentration of Cr(VI) from that of total chromium. The optimum conditions for batch type sorption were established. Under optimal conditions, the limit of detection and quantification are 0.015 mug L⁻¹ and 0.050 mug L⁻¹, respectively. The kinetics and isotherms of the sorption of Cr(VI) were investigated. Following desorption with 0.1 M hydroxylamine hydrochloride, the method was successfully applied to spiked real water samples and a certified reference material. Graphical abstract Schematic presentation of a method for the sorption and speciation of chromium using amino methyl phosphonic acid functional brushes on polystyrene-divinyl benzene microspheres.

Eriksen, M., et al. (2018). "Microplastic sampling with the AVANI trawl compared to two neuston trawls in the Bay of Bengal and South Pacific." Environmental Pollution **232**: 430-439.

Many typical neuston trawls can only be used during relatively calm sea states and slow tow speeds. During two expeditions to the Bay of Bengal and the eastern South Pacific we investigated whether the new, high-speed AVANI trawl (All-purpose Velocity Accelerated Net Instrument) collects similar amounts and types of microplastics as two established scientific trawl designs, the manta trawl and the DiSalvo neuston net. Using a 335 µm net, the AVANI trawl can collect microplastics from the sea surface at speeds up to 8 knots as it “skis” across the surface, whereas the manta and DiSalvo neuston trawls must be towed slowly in a less turbulent sea state and often represent shorter tow lengths. Generally, the AVANI trawl collected a greater numerical abundance and weight of plastic particles in most size classes and debris types than the manta trawl and DiSalvo neuston net, likely because these trawls only skim the surface layer while the AVANI trawl, moving vertically in a random fashion, collects a “deeper” sample, capturing the few plastics that float slightly lower in the water column. However, the samples did not differ enough that results were significantly affected, suggesting that studies done with these different trawls are comparable. The advantage of the AVANI trawl over traditional research trawls is that it allows for collection on vessels underway at high speeds and during long transits, allowing for a nearly continuous sampling effort over long distances. As local surface currents make sea surface abundance widely heterogeneous, widely spaced short-tow trawls, such as the manta and DiSalvo trawls, can catch or miss hotspots or meso-scale variability of microplastic accumulations, whereas the AVANI trawl, if utilized for back-to-back tows of intermediate distances (5–10 km), can bridge variable wind conditions and

debris concentrations potentially reducing variance and provide a greater resolution of spatial distribution. [ABSTRACT FROM AUTHOR]

Eriksen, M., et al. (2013). "Microplastic pollution in the surface waters of the Laurentian Great Lakes." Marine Pollution Bulletin **77**(1-2): 177-182.

Neuston samples were collected at 21 stations during an ~700 nautical mile (~1300 km) expedition in July 2012 in the Laurentian Great Lakes of the United States using a 333 mum mesh manta trawl and analyzed for plastic debris. Although the average abundance was approximately 43,000 microplastic particles/km2, station 20, downstream from two major cities, contained over 466,000 particles/km2, greater than all other stations combined. SEM analysis determined nearly 20% of particles less than 1 mm, which were initially identified as microplastic by visual observation, were aluminum silicate from coal ash. Many microplastic particles were multi-colored spheres, which were compared to, and are suspected to be, microbeads from consumer products containing microplastic particles of similar size, shape, texture and composition. The presence of microplastics and coal ash in these surface samples, which were most abundant where lake currents converge, are likely from nearby urban effluent and coal burning power plants.

Eriksson, C. and H. Burton (2003). "Origins and Biological Accumulation of Small Plastic Particles in Fur Seals from Macquarie Island." AMBIO - A Journal of the Human Environment **32**(6): 380.

One hundred and sixty four plastic particles (mean length 4.1 mm) recovered from the scats of fur seals (Arctocephalus spp.) on Macquarie Island were examined. Electron micrographs of 41 of the plastic particles showed that none could be identified as plastic pellet feedstock from their shapes. Commonly, such pellets are cylindrical and spherical. Instead, all the 164 plastic particles from the seal scats were angular particles of 7 colors (feedstock particles are normally opaque or white) and could be classified into 2 categories: i) fragmented along crystal lines and likely to be the result of UV breakdown; and ii) wom by abrasion (where striations were clearly visible) into irregular shapes with rounded corners. White, brown, green, yellow and blue were the most common colors. In composition, they came from 5 polymer groups; polyethylene 93%, polypropylene 4%, poly(1-Cl-1-butenylene) polychloroprene 2%, melamine-urea (phenol) (formaldehyde) resin 0.5%, and cellulose (rope fiber) 0.5%. The larger groups are buoyant with a specific gravity less than that of seawater. These small plastic particles are formed from the breakdown of larger particles (fragments). Their origin seems to be from the breakdown of user plastics washed ashore and ground down on cobbled beaches. Certainly most particles (70%) had attained their final form by active abrasion. It is hypothesized that the plastic particles were washed out to sea and then selected by size and consumed by individuals of a pelagic fish species, Electrona subaspera, who in turn were consumed by the fur seals. Thus, the particles were accumulated both by the fish and the seals in the usual process of their feeding. [ABSTRACT FROM AUTHOR]

Erkers, T., et al. (2018). "A proinflammatory invariant natural killer t cells phenotypic state associates with human graft-versus-host disease onset and response." Blood. Conference: 60th Annual Meeting of the American Society of Hematology, ASH **132**(Suppl. 1).

Human invariant natural killer T cells (iNKT) are a rare population of lymphocytes that bridges innate and adaptive immune functions. iNKt cells have different potent effector functions and subsets, but this heterogeneity is mostly understood by a superimposed framework of classic T cell markers. This may help explain contradictory studies of iNKt cells in diseases for which they are thought to play a pathogenic role. In this study, we present data suggesting new markers to understand human iNKt cell heterogeneity and function, as well as monitoring this in the clinical context of allogeneic stem cell transplantation (ASCT) and graft-versus-host disease (GVHD). In both preclinical murine models and in correlative clinical studies, iNKt cells are associated with less GVHD and better immune reconstitution following ASCT. We performed bulk whole transcriptome sequencing on iNKt cells from patients at day +30 after ASCT, some who developed and some who did not develop GVHD. Gene expression signatures of the iNKt cells from each individual are grouped based on a transcriptome library of reference cell types (CIBERSORT). Using this approach, we distinguished patients who will develop GVHD as predominately having an activated cytotoxic cell gene signature, whereas patients without GVHD had a CD4+ T cell gene signature within purified peripheral blood iNKt cells. Using two different high throughput single-cell RNA sequencing (sc-seq) platforms to determine differential gene expression on the single cell level, we first examined the gene expression signatures of primary human iNKt cells from healthy donors. Activation with CD3/28 microbeads of primary iNKt cells promoted two main differential transcriptional profiles in iNKt cells. One profile resembles conventional CD4+ T cells and associated Th2 cytokine profile (IL2, IL4), whereas the other profile has genes associated with cytotoxicity and inflammation (TNF, IFNG, GZMB). Confirmation by flow cytometry showed that while CD8 surface expression did not well differentiate the pro-inflammatory and cytotoxic subsets, but both CD94 and KLRG1 better associate with Th1 and cytotoxic responses. CD94+ iNKt are restricted to CD4-cells and KLRG1 expressed in both CD4+ and CD4-populations. By comparison, the analysis of sc-seq of normal healthy subjects and post-transplant patients with and without GVHD resulted in the identification of three major iNKt populations. The population most associated with GVHD showed expression of a pro-inflammatory profile enriched for CXCR4, CD94, HLADRB1/A1 and decreased KLRB1. Whereas, post-transplant patients with healthy GVHD-free and relapse free immune reconstitution showed a more T cell like profile but with increased expression of CXCR4, CD94, KLRB1 and decreased HLADRB1/A1. Using flow cytometry of ex vivo expanded iNKt cells, we found the expansion of CXCR4+HLA-DR+ that can be CD4+ or CD4-and that these cells produce high levels of the cytokine TNF-a, IFN-g and IL-4. Importantly, iNKt cells that are CXC4+HLA-DR+KLRB1^{low} make significantly less IL-4 and these are enriched in the GVHD setting. Using flow cytometry, we measured iNKt cell phenotypes in a pilot cohort of 48 individuals; 10 healthy controls, 10 patients with no complications or relapse after ASCt and 1 8 patients with GVHD of which 9 were steroid refractory. In addition, we evaluated 11 patients with new onset T frequency of the cytotoxic CD94+ iNKt cells were significantly increased in all patients following and in T1 D compared to healthy controls. patients with GVHD showed an increase in HLA-DR+CXCR4+KLRB1^{low} iNKt cells. Increases in the late activation marker HLA-DR distinguishe corticosteroid refractory (HLA-DR++) from steroid responsive

patients at the time of initial GVHD diagnosis. For patients who responded to steroids or further therapy, we found that a reduction in HLA-DR associated with treatment response. In a second 24 patient cohort, we found that the presence HLA-DR⁺CXCR4⁺CD161^{low} cells at day +30 was statistical y greater in patients who would go on to develop GVHD as compared as those who did not (student T test, p<0.01) To conclude, we have used different methods to discover and validate groups of iNKt cells with distinct functions, and the associated phenotype correlate with clinical inflammation both following ASCt and in T1D.

Erlandsen, S. L., et al. (1979). "Technical parameters of immunostaining of osmicated tissue in epoxy sections." Journal of Histochemistry and Cytochemistry **27**(9): 1286-1289.

The development of the labeled and unlabeled enzyme methods and their application at the light and electron microscopic level have led to the widespread use of postembedding staining techniques of a wide variety of antigens. An important step in the postembedding staining technique is the 'etching' or pretreatment of the plastic section with an agent to enhance the binding of specific primary antibody to antigen in the section. Sodium ethoxide (or alcoholic sodium hydroxide both of which physically dissolve polymerized epoxy resin, were initially used to facilitate tinctorial staining and later by Lange to enhance the imunofluorescence for glucagon in plastic sections of pancreatic islets. Hydrogen peroxide has been used to bleach osmium from plastic sections and to enhance staining for glycoproteins at the ultrastructural level, but was first used by Nakane in 1971 to enhance immunostaining at the ultrastructural level for growth hormone and prolactin in osmicated sections or rat pituitary. Using the unlabeled antibody enzyme method, Moriarty and Halmi and Erlandsen showed that intensity of immunostaining in the postembedding technique was enhanced if sections of aldehyde fixed tissue were briefly exposed to hydrogen peroxide before application of immunoreagents. The successful use of hydrogen peroxide and alcoholic sodium hydroxide in the enhancement of immunostaining has led to their widespread adoption as an essential step in post embedding staining despite the fact that there is relatively little information available as to what effect these agents may have on the plastic resin or on the stability and extraction of antigens from the tissue sections. In this report the effect of various types of etching or pretreatment agents on the surface topography of the plastic sections has been investigated and has been correlated with withg the immunostaining for lysozyme within rat Paneth cells and with the extraction of Na¹²⁵I by these agents from cured epoxy resin.

Erni-Cassola, G., et al. (2017). "Lost, but Found with Nile Red: A Novel Method for Detecting and Quantifying Small Microplastics (1 mm to 20 µm) in Environmental Samples." Environmental Science & Technology **51**(23): 13641.

Marine plastic debris is a global environmental problem. Surveys have shown that <5 mm plastic particles, known as microplastics, are significantly more abundant in surface seawater and on shorelines than larger plastic particles are. Nevertheless, quantification of microplastics in the environment is hampered by a lack of adequate high-throughput methods for distinguishing and quantifying smaller size fractions (<1 mm), and this has probably resulted in an underestimation of actual microplastic concentrations. Here we present a protocol that allows high-throughput detection and automated quantification of small microplastic particles (20-1000 µm) using the dye Nile red, fluorescence microscopy, and image analysis software. This protocol has proven to be highly effective in the quantification of small polyethylene, polypropylene, polystyrene, and nylon-6 particles, which frequently occur in the water column. Our preliminary results from sea surface tows show a power-law increase in small microplastics (i.e., <1 mm) with a decreasing particle size. Hence, our data help to resolve speculation about the "apparent" loss of this fraction from surface waters. We consider that this method presents a step change in the ability to detect small microplastics by substituting the subjectivity of human visual sorting with a sensitive and semiautomated procedure.

Erni-Cassola, G., et al. (2019). "Distribution of plastic polymer types in the marine environment; A meta-analysis." Journal of Hazardous Materials **369**: 691-698.

Despite growing plastic discharge into the environment, researchers have struggled to detect expected increases of marine plastic debris in sea surfaces, sparking discussions about "missing plastics" and final sinks, which are hypothesized to be coastal and deep-sea sediments. While it holds true that the highest concentrations of plastic particles are found in these locations (10³-10⁴ particles m⁻³ in sediments vs. 0.1-1 particles m⁻³ in the water column), our meta-analysis also highlights that in open oceans, microplastic polymer types segregated in the water column according to their density. Lower density polymers, such as polypropylene and polyethylene, dominated sea surface samples (25% and 42%, respectively) but decreased in abundance through the water column (3% and 2% in the deep-sea, respectively), whereas only denser polymers (i.e. polyesters and acrylics) were enriched with depth (5% in surface seawater vs. 77% in deep-sea locations). Our meta-analysis demonstrates that some of the most abundant and recalcitrant manufactured plastics are more persistent in the sea surface than previously anticipated and that further research is required to determine the ultimate fate of these polymers as current knowledge does not support the deep sea as the final sink for all polymer types. Ersoz, A., et al. (2004). "Ni(II) ion-imprinted solid-phase extraction and preconcentration in aqueous solutions by packed-bed columns." Analytica Chimica Acta **502**(1): 91-97.

Solid-phase extraction (SPE) columns packed with materials based on molecularly imprinted polymers (MIPs) were used to develop selective separation and preconcentration for Ni(II) ion from aqueous solutions. SPE is more rapid, simple and economical method than the traditional liquid-liquid extraction. MIPs were used as column sorbent to increase the grade of selectivity in SPE columns. In this study, we have developed a polymer obtained by imprinting with Ni(II) ion as a ion-imprinted SPE sorbent. For this purpose, NI(II)-methacryloylhistidinedihydrate (MAH/Ni(II)) complex monomer was synthesized and polymerized with cross-linking ethyleneglycoldimethacrylate to obtain [poly(EGDMA-MAH/Ni(II))]. Then, Ni(II) ions were removed from the polymer getting Ni(II) ion-imprinted sorbent. The MIP-SPE preconcentration procedure showed a linear calibration curve within concentration range from 0.3 to 25ng/ml and the detection limit was 0.3ng/ml (3s) for flame atomic absorption spectrometry (FAAS). Ni(II) ion-imprinted microbeads can be used several times without considerable loss of adsorption capacity. When the adsorption capacity of nickel imprinted microbeads were compared with non-imprinted microbeads, nickel imprinted microbeads have higher adsorption capacity. The K<inf>d</inf> (distribution coefficient) values for the Ni(II)-imprinted microbeads show increase in K<inf>d</inf> for Ni(II) with respect to both K<inf>d</inf> values of Zn(II), Cu(II)

and Co(II) ions and non-imprinted polymer. During that time K<inf>d</inf> decreases for Zn(II), Cu(II) and Co(II) ions and the k' (relative selectivity coefficient) values which are greater than 1 for imprinted microbeads of Ni(II)/Cu(II), Ni(II)/Zn(II) and Ni(II)/Co(II) are 57.3, 53.9, and 17.3, respectively. Determination of Ni(II) ion in sea water showed that the interfering matrix had been almost removed during preconcentration. The column was good enough for Ni determination in matrixes containing similar ionic radii ions such as Cu(II), Zn(II) and Co(II). © 2003 Elsevier B.V. All rights reserved.

Esbert, M., et al. (2017). "Spermatozoa with numerical chromosomal abnormalities are more prone to be retained by Annexin V-MACS columns." Andrology **5**(4): 807-813.

Colloidal super-paramagnetic microbeads conjugated with annexin V are effective for separating apoptotic spermatozoa by MACS as a result of the high affinity of annexin V for externalized PS molecules. The effectiveness of the procedure in reducing the percentage of sperm with fragmented DNA and abnormal morphology has also been reported. However, it is still unknown if it could decrease the percentage of aneuploid spermatozoa. The objective of our prospective study, performed on 16 males with abnormal FISH on spermatozoa, was to assess if MACS columns were useful tools to retain spermatozoa carrying chromosomal abnormalities in semen samples processed after density gradient centrifugation (DGC). The pellet obtained after DGC was subjected to MACS, and sperm FISH analyses were performed both in the eluded fraction and in the fraction retained in the column. The observed frequencies of disomy and nullisomy 13, 18, and 21, X and Y, as well as the diploidy rates in the MACS eluded fraction and the fraction retained in the MACS column were recorded. We observed that the frequencies of aneuploidies in the eluded fraction were lower than in the fraction retained in the MACS column (0.59% vs. 0.75%; $p = 0.010$). DGC determined a significant reduction in sperm concentration (z-ratio = 2.83; $p = 0.005$) and a significant increase in sperm progressive motility (z-ratio = -3.5; $p < 0.001$). MACS also led to a significant reduction in sperm concentration (z-ratio = 3.14; $p = 0.002$) and a significant increase in progressive motility (z-ratio = -2.59; $p = 0.01$) when compared with the post-DGC sample. Sperm concentration was similar in the two fractions generated by MACS (z-ratio = 0.63; $p = 0.52$), while progressive motility was significantly higher in the MACS eluded fraction (z-ratio = 2.42; $p = 0.02$). According to our results, MACS columns are able to selectively retain spermatozoa carrying chromosomal abnormalities. Furthermore, the performance of DGC and MACS on semen samples leads to an enrichment of progressive motility.

Esiukova, E. (2017). "Plastic pollution on the Baltic beaches of Kaliningrad region, Russia." Marine Pollution Bulletin **114**(2): 1072-1080.

Contamination of sandy beaches of the Baltic Sea in Kaliningrad region is evaluated on the base of surveys carried out from June 2015 to January 2016. Quantity of macro/meso/microplastic objects in the upper 2cm of the sandy sediments of the wrack zone at 13 sampling sites all along the Russian coast is reported. Occurrence of paraffin and amber pieces at the same sites is pointed out. Special attention is paid to microplastics (range 0.5-5mm): its content ranges between 1.3 and 36.3 items per kg dry sediment. The prevailing found type is foamed plastic. No sound differences in contamination are discovered between beaches with high and low anthropogenic load. Mean level of contamination is of the same order of magnitude as has been reported by other authors for the Baltic Sea beaches.

Esiukova, E., et al. (2020). "Data on microplastic contamination of the Baltic Sea bottom sediment samples in 2015-2016." Data in Brief **28**: 104887.

The contamination by microplastics particles (MPs, 0.2-5 mm) in bottom sediments of the Baltic

Sea is quantified. In total, 53 sediment samples were obtained in 8 cruises of research vessels in July-October 2015 and March-December 2016. The depths from 3 to 215 m in the Gotland, Gdansk, and Bornholm Basins are covered. Primary data is provided, along with exhaustive information on sampling dates and coordinates, depths, sampling methods, extracting procedures, control measures, detection techniques, and verification by mu-Raman spectroscopy. Number of pieces per kg dry weight is determined separately for fibres, films, and fragments. Distributions by size, plastic colour, and plastic type are presented. Modified NOAA method and mu-Raman spectroscopy were applied to obtain the data, thus they can be used for comparative analyses.

Eskandari, H. G. (2011). "Flow cytometric applications in general and it's role on organ transplantation. [Turkish, English]." Turkish Journal of Biochemistry. Conference: 23rd National Biochemistry Congress. Adana Turkey. Conference Publication: **36**(SPEC. ISS. 2).

A flow cytometer is an instrument that illuminates cells or other particles as they flow individually in front of a light source and then detects and correlates the signals from those cells that result from the illumination. The value of the technique lies in the ability to make measurements on large numbers of single cells within a short period of time. The heterogeneity of populations can be revealed and different subsets of cells identified and quantified. Selected cell populations can also be physically sorted for further study. Flow cytometry is finding increasing use in routine clinical laboratories for the diagnosis, prognosis and monitoring of disease. The immunophenotyping of patients with a haematological neoplasm is the most frequently used area of the tool. Flow cytometry has also been used in the transplantation laboratory for several years. The presence of recipient antibodies against antigens expressed on donor cells are a major risk factor for early rejection or graft loss. To overcome this problem crossmatching between donor cells and recipient serum is performing. The initial tecnique for crossmatching, complement-dependent cytotoxicity, is relatively insensitive. The flow cytometric crossmatch which was developed in 1982, is an important method to investigate donor specific HLA antibodies before transplantation. The test has the advantage of being more sensitive than the initial tecnique. Since the early 2000s, panel reactive antibodies have been investigated by flow cytometry. In this system micro beads coated with HLA antigens have been used to detect both the frequency and the specificity of HLA antibodies.

Eskin, D., et al. (2005). "Microhydrodynamic analysis of nanogrinding in stirred media mills." American Institute of Chemical Engineers. AIChE Journal **51**(5): 1346-1358.

The dynamics of the milling media in a turbulent flow is considered. The mean velocity of the milling beads is calculated on the assumption that the power spent on stirring is transferred into the energy of turbulent eddies. The energy spent on stirring dissipates as a result of media-liquid viscous friction, lubrication, and by inelastic collisions of the beads with each other. The maximum force at which the milling beads can compress particles between them is calculated by the Hertzian theory of elastic impact. The frequency of compressions for a single particle is evaluated by probabilistic analysis. A criterion of milling efficiency, based on calculating the energy spent on the plastic particle deformation, is proposed. A numerical study of the milling bead dynamics and their interactions with the particles in the mixing tank is performed. The numerical results are in qualitative agreement with the experimental data. Both the numerical and experimental analyses show that, from the perspective of hydrodynamics, an optimization of stirred media mills can be achieved by choosing the optimum size and concentration of the milling media. Esparza, M., et al. (2015). "PstS-1, the 38-kDa mycobacterium tuberculosis glycoprotein, is an adhesin, which binds the macrophage mannose receptor and promotes phagocytosis." Scandinavian Journal of Immunology **81**(1): 46-55.

Mycobacterium tuberculosis, the primary causative agent of tuberculosis, infects macrophages and transforms the hostile intracellular environment into a permissive niche. M. tuberculosis infects macrophages using a variety of microbial ligand/cell receptor systems. In this study, binding assays with biotin-labelled mycobacterial cell wall proteins revealed five Concanavalin A-reactive proteins that bind macrophages. Among these proteins, we identified PstS-1, a 38-kDa M. tuberculosis mannosylated glycolipoprotein, and characterized it as an adhesin. Inhibition assays with mannan and immunoprecipitation demonstrated that PstS-1 binds the mannose receptor. We purified PstS-1 to 95.9% purity using ion exchange chromatography. The presence of mannose in purified PstS-1 was demonstrated by Concanavalin A interaction, which was abolished in the presence of sodium m-periodate and α-D-mannosidase. Gas chromatography revealed that purified PstS-1 contained 1% of carbohydrates by weight, which was mainly mannose. Finally, we used fluorescent microbeads coated with purified PstS-1 in phagocytosis assays and discovered that microbead uptake was inhibited by the pre-incubation of cells with GlcNAc, mannan and α-methyl mannoside. The interaction of PstS-1 coated beads with the mannose receptor was confirmed by confocal colocalization studies that showed high Pearson and Manders's colocalization coefficients. Our findings contribute to a better understanding of the strategies M. tuberculosis uses to infect host cells, the critical first step in the pathogenesis of tuberculosis. © 2015 John Wiley & Sons Ltd.

Espinosa, C., et al. (2019). "Dietary administration of PVC and PE microplastics produces histological damage, oxidative stress and immunoregulation in European sea bass (Dicentrarchus labrax L.)." Fish & Shellfish Immunology **95**: 574-583.

Worldwide, plastic waste is increasingly being discharged into the oceans, where it breaks down into smaller particles. Of these particles, the ingestion of microplastics (MPs; particles smaller than 5mm) have been documented in some aquatic animals, including fish, whose health and welfare suffer as a consequence. However, their precise effects are not completely understood. To shed light on this issue, European sea bass (Dicentrarchus labrax L.) specimens were fed diets containing 0 (control), 100 or 500mg polyvinylchloride (PVC) or polyethylene (PE) MPs kg⁻¹ diet for three weeks, after which samples of liver, intestine, skin mucus and head kidney (HK) were obtained. A histological study of the liver and intestine revealed important alterations in the fish fed the MP diets, compared with control fish. At a functional level, PE-MPs, but not PVC-MPs, decreased the activity of antioxidant enzymes, suggesting a certain level of oxidative stress. As regards immunity, the intake of PVC-MPs increased the phagocytic and respiratory burst activities of HK leucocytes whilst the intake of PE-MPs increased skin mucus immunoglobulin M levels and the respiratory burst activity of leucocytes. The results suggest that the short-medium term intake of PVC- or PE-MPs by fish slightly depresses their immunity and produces oxidative stress. However, based on the histological alterations found, it seems that longer exposure times might lead to irreversible damage that could compromise fish health and welfare.

Espinosa, C., et al. (2018). "In vitro effects of virgin microplastics on fish head-kidney leucocyte activities." Environmental Pollution **235**: 30-38.

Microplastics are well-documented pollutants in the marine environment that result from production or fragmentation of larger plastic items. The knowledge about the direct effects of microplastics on immunity, including fish, is still very limited. We investigated the in vitro effects

of microplastics [polyvinylchloride (PVC) and polyethylene (PE)] on gilthead seabream (Sparus aurata) and European sea bass (Dicentrarchus labrax) head-kidney leucocytes (HKLs). After 1 and 24 h of exposure of HKLs with 0 (control), 1, 10 and 100 mg mL⁻¹ MPs in a rotatory system, cell viability, innate immune parameters (phagocytic, respiratory burst and peroxidase activities) and the expression of genes related to inflammation (il1b), oxidative stress (nrf2, prdx3), metabolism of xenobiotics (cyp1a1, mta) and cell apoptosis (casp3) were studied. Microplastics failed to affect the cell viability of HKLs. In addition, they provoke very few significant effects on the main cellular innate immune activities, as decrease on phagocytosis or increase in the respiratory burst of HKLs with the highest dose of microplastics tested. Furthermore, microplastics failed to affect the expression of the selected genes on sea bass or seabream, except the nrf2 which was up-regulated in seabream HKLs incubated with the highest doses. Present results seem to suggest that continue exposure of fish to PVC or PE microplastics could impair fish immune parameters probably due to the oxidative stress produced in the fish leucocytes.

Espulgar, W., et al. (2019). "Utility of Centrifugation-Controlled Convective (C3) Flow for Rapid On-chip ELISA." Scientific Reports **9**(1): 20150.

Miniaturizing the enzyme-linked immunosorbent assay (ELISA) protocols in microfluidics is sought after by researchers for a rapid, high throughput screening, on-site diagnosis, and ease in operation for detection and quantification of biomarkers. Herein, we report the use of the centrifugation-controlled convective (C3) flow as an alternative method in fluid flow control in a ring-structured channel for enhanced on-chip ELISA. A system that consists of a rotating heater stage and a microfluidic disk chip has been developed and demonstrated to detect IgA. The ring-structured channel was partially filled with microbeads (250 micro m in diameter) carrying the capture antibodies and the analyte solution was driven by thermal convection flow (50 micro L/min) to promote the reaction. The remaining part of the circular channel without microbeads served as the observation area to measure the absorbance value of the labeled protein. Currently, the system is capable of conducting four reactions in parallel and can be performed within 30 min at 300 G. A detection limit of 6.16 ng/mL using 24 micro L of target sample (IgA) was observed. By simply changing the capture antibodies, the system is expected to be versatile for other immunoassays.

Estahbanati, S. and N. L. Fahrenfeld (2016). "Influence of wastewater treatment plant discharges on microplastic concentrations in surface water." Chemosphere **162**: 277-284.

The abundance of microplastic particles in the marine environment is well documented, but less is known about microplastics in the freshwater environment. Wastewater treatment plants (WWTPs) may not effectively remove microplastics allowing for their release to the freshwater environment. To investigate concentration of microplastic in fresh water and the impact of WWTP effluent, samples were collected upstream and downstream of four major municipal WWTPs on the Raritan River, NJ. Microplastics were categorized into three quantitative categories (500-2000 mum, 250-500 mum, 125-250 mum), and one semi-quantitative category (63-125 mum). Then, microplastics were classified as primary (manufactured in small size) or secondary (derived from larger plastics) based on morphology. The concentration of microplastics in the 125-250 and 250-500 mum size categories significantly increased downstream of WWTP. The smaller size classes, often not quantified in microplastic studies, were in high relative abundance across sampling sites. While primary microplastics significantly increased downstream of WWTP, secondary microplastic was the dominant type in the quantitative size categories (66-88%). A moderate correlation between microplastic and

distance downstream was observed. These results have implications for understanding the fate and transport of microplastics in the freshwater environment.

Esther, C. R. (2015). "Of mucins, microbiome, and metabolome: Assessing the pathobiology of early Cf airways disease." Pediatric Pulmonology **41)**: 143.

Although airways from infants with cystic fibrosis (CF) appear anatomically normal at birth, lung disease can start very early in life. This disease develops in very heterogeneous fashion, progressing to bronchiectasis in less than a year in some regions of the lung but seemingly sparing other airways, and some individuals, entirely. Our group has hypothesized that abnormal hydration of mucins is the initiating defect in early CF airways disease, with heterogeneity arising from the fact that redundant (non-CFTR based) systems can normally maintain airway hydration but are vulnerable to localized exogenous insults that alter the airway milieu. Thus, we predict that early CF airway disease would be characterized by changes in airway mucins and aspects of the airway microenvironment (reflected in the metabolome and microbiome) that could alter redundant hydration pathways. We are testing these hypotheses through a collaborative effort between the Australian Respiratory Early Surveillance Team for CF (AREST CF) and the University of North Carolina at Chapel Hill (UNC). Preschool subjects in AREST CF undergo annual chest CT and bronchoscopy, and bronchoalveolar lavage fluid (BALF) samples are sent to UNC for analyses of mucins, metabolome, and microbiome. Heterogeneity is addressed through use of lobe specific lavages and chest CT scores. These collaborative studies have revealed that BALF obtained from lobes with CT evidence of structural lung disease have higher mucin concentrations than samples from lobes with minimal or no disease. In addition, immunohistochemistry studies suggest that mucins from children with CF exhibit a compact structure that differs from the more filamentous appearance of mucins from non-CF disease controls, and microbead rheology reveals the presence of highly concentrated mucin flakes in CF BALF. These structural changes to mucins likely exacerbate the airway dehydration phenotype. Early lung disease is also associated with changes in the airway microenvironment. Metabolomics studies have identified several altered pathways, including elevated extracellular adenosine metabolism and protease activity in early disease. Similar findings are observed with glutathione, indicating a role for oxidative stress. These pathways have been associated with airway neutrophils, consistent with inflammation occurring early in disease. The metabolites within these pathways can serve as biomarkers of structural lung disease and are predictive of future bronchiectasis. We have also observed changes in the microbiome associated with early disease. In preliminary studies, microbiota from CF airways appear to cluster into three general groups: environmental bacteria (that may reflect background signal), oral flora, and established pathogens. Not surprisingly, we find that pathogens are overrepresented in samples from lobes with bronchiectasis. More interestingly, oral flora are found at greater frequency in lobes with early disease (bronchial wall thickening), and we also detect higher concentrations of salivary amylase from these samples as well. In summary, our findings support the hypothesis that early CF lung disease is associated with changes in mucin concentration and structure as well as metabolomic biomarkers of inflammation and oxidative stress. The microbiome studies suggest the possibility that aspiration may serve as a trigger for early disease, though causation cannot necessarily be proven from these correlative studies. These findings provide new insights into early CF lung disease pathophysiology, and we are exploring methods such as biomarker detection in exhaled breath condensate (EBC) that could serve as less invasive methods to assess early disease.

Esther, C. R., et al. (2016). "Mucus dehydration as the initiating defect in early CF airways disease."

Pediatric Pulmonology **51 (Supplement 45)**: 223.

Background: While loss of CFTR-mediated airway hydration is hypothesized to be the initiating defect in CF airways disease, recent animal studies suggest that reduced bacterial killing and subsequent airway infection may precede changes in mucus hydration. To assess which factors are associated with the earliest stages of airways disease in humans, we measured mucin and metabolomic profiles of bronchoalveolar lavage fluid (BALF) relative to measures of infection, inflammation, and structural lung disease in preschool subjects enrolled in AREST CF. Method(s): Separate aliquots of BALF were obtained from the right middle lobe and lingula of 40 preschool subjects with CF (80 lobes) enrolled in AREST CF (age 3.5+/-2.0 years) and 14 non-CF disease controls (28 lobes) (age 3.2+/-1.8 years). Mucin concentrations were measured by refractometry, staining intensities of MUC5AC and MUC5B by immunohistochemistry, and rheological characteristics by microbead rheology. Findings were analyzed relative to BALF inflammatory markers, cultures, and metabolomic profiling in 24 subjects (48 lobes) as well as lobe-specific CT scores for bronchial wall thickening or bronchiectasis as markers of structural lung disease. Result(s): Airway mucus concentrations were higher in preschool subjects with CF relative to non-CF disease controls (Non-CF 99 [61-145] mug/mL vs. CF 182 [101-629] mug/mL, p<0.01), even in the subset without airway infection (58 [30-97] mug/mL vs. 155 [91-444] mug/mL, p<0.002). Mucus concentrations correlated with inflammatory markers including IL-8 (r=0.60, p<0.001) and % neutrophils (r=0.64, p<0.001) as well as metabolomic biomarkers of airway hypoxia (lactate r=0.69, p<0.001) and oxidative stress (oxidized glutathione r=0.57, p<0.001). Staining intensities of both MUC5AC (1.2 [0.6-1.7] vs. 4.6 [1.4-9.7], p<0.01) and MUC5B (4.2 [3.1- 7.7] vs. 13.0 [4.5-28], p<0.01) were elevated in CF, suggesting that mucins arose from both airway epithelia and glands. Mucus concentrations were most highly elevated in lobes with bronchial wall thickening as an early marker of disease (p<0.001 by ANOVA), and changes in structural lung disease scores were associated with altered mucus rheology. Conclusion(s): Airway mucus is elevated in preschool children with CF and associated with inflammatory markers, changes in the airway milieu, and early structural lung disease. These findings appeared independent of airways infection and are most consistent with airway mucus dehydration as the initiating defect in human CF airways disease. Thus, airway dehydration remains a high value target for therapeutic intervention in the youngest children with CF.

Esumi, K., et al. (1996). "Preparation of hollow carbon-microbeads from water-in-oil emulsion using amphiphilic carbonaceous material." Colloids and Surfaces A: Physicochemical and Engineering Aspects **108**(1): 113-116.

Carbon microbeads were prepared from water-in-oil emulsion using amphiphilic carbonaceous material and urea. With urea as a forming agent with a concentration 1-20 wt.%, hollow carbon-microbeads were obtained, and their particle size ranged between 2 and 15 mum. The true density of the hollow carbon-microbeads was changed, by varying the concentration of urea and the heat-treatment temperature. In particular, a pore size of about 50 A was predominantly produced under a certain condition. Carbon microbeads were prepared from water-in-oil emulsion using amphiphilic carbonaceous material and urea. With urea as a forming agent with a concentration 1-20 wt.%, hollow carbon-microbeads were obtained, and their particle size ranged between 2 and 15 mum. The true density of the hollow carbon-microbeads was changed, by varying the concentration of urea and the heat-treatment temperature. In particular, a pore size of about 50 angstrom was predominantly produced under a certain condition.

Esuvaranathan, K., et al. (2012). "Lactobacilli secreting a tumor antigen and IL15 activates neutrophils and dendritic cells and generates cytotoxic T lymphocytes against cancer cells." Cancer Research. Conference: 103rd Annual Meeting of the American Association for Cancer Research, AACR **72**(8 SUPPL. 1).

Introduction and Objective Lactobacillus rhamnosus GG (LGG) are lactic acid bacteria, which were found to be better than BCG at inducing cell death in human bladder cancer cell lines. This study compares both LGG and BCG in vivo in an orthopic model and further evaluates the potential of recombinant LGG to induce a directed anti-tumor response. Methods MB49-PSA (murine bladder cancer cells secreting human PSA) cells were implanted orthotopically in C57BL/6 mice and either LGG or BCG was instilled weekly for 6 weeks. Tumor cure rates were noted and an immnohistochemical examination was performed on the tumors. The human prostate specific antigen (PSA) PSA was cloned into pLP500-slpAp vector under the control of S-layer promoter of L. acidophilus. The murine IL-15 cDNA minus its termination codon was cloned upstream of the PSA protein sequence. Lactobacilli were transformed with the plasmids to generate LGG-IL15-PSA, LGG-PSA and LGG-S (pLP500-slpAp) respectively. PSA and IL15 secretion was 16-19 ng/2x109 CFU/ml. Bone marrow cells were isolated from the tibia and femur of 8-10 weeks old female C57BL/6 mice. Neutrophils were isolated by positive selection with anti-Ly6G microbead kit (Miltenyi Biotech, Germany). To generate DCs, bone marrow derived cells were cultured for 9 days in media with 40ng/ml of GM-CSF (BD Bioscience) which was replaced every other day. Neutrophils and DC were exposed to the recombinant LGG for 2h and used to stimulate T cells to generate CTL against the murine bladder cancer cell lines expressing PSA (MB49-PSA). Results LGG was as effective as BCG in the mice. Analysis of tumors after repeated weekly LGG instillations showed increased infiltration of neutrophils and macrophages into the tumor mass after therapy. In vitro, recombinant LGG activated neutrophils (elevated MHC class I expression) induced DC maturation (increased expression of CD86, CD80, CD40, MHC II and CD83), T cell proliferation and PSA specific cytotoxic T lymphocytes (CTL) activity. Activated DC were more efficient than activated neutrophils in inducing T cell IL2 and IFNalpha production. DC activated with LGG for 2 h or with LGG treated neutrophils were re-isolated and plated with naive T cells for 5 days to generate PSA specific T cells. Then PSA secreting or control MB49 cells were added to the wells. IL15 enhanced DC generation of CTL. Conclusions Intravesical instillation of LGG cured mice of tumors. LGG secreting tumor antigens and cytokines could be used to activate DC in vitro for DC therapy in patients or used as intravesical therapy.

Eswaramma, S. and K. S. Rao (2017). "Synthesis of dual responsive carbohydrate polymer based IPN microbeads for controlled release of anti-HIV drug." Carbohydrate Polymers **156**: 125-134.

The present study aims at preparation of dual responsive interpenetrating polymer network hydrogel microbeads from sodium alginate and functionally modified guar gum. Guar gum was modified by graft copolymerization using N-vinylcaprolactam, the maximum % grafting 123.2, obtained at different optimized conditions. The graft copolymer was blended with sodium alginate to form hydrogel microbeads by emulsion crosslinking method using glutaraldehyde as crosslinker. Zidovudine, an anti-HIV drug was encapsulated with 68% encapsulation efficiency. Fourier transform infrared spectroscopy, ¹H nuclear magnetic resonance spectroscopy, scanning electron microscopy, differential scanning calorimetry and X-ray diffraction studies justified the grafting reaction, structure, morphology and polymer-drug interactions, respectively. Swelling studies ascertained that microbeads were potentially sensitive to both pH and temperature. In vitro release studies were investigated in pH 1.2 and 7.4, the release time enhanced up to 34h in pH 7.4 at 37degreeC.

Evans, C. E., et al. (2015). "Pulmonary microvascular thrombosis enhances extravasation via myeloid hypoxia-inducible factors." Arteriosclerosis, Thrombosis, and Vascular Biology. Conference: American Heart Association's Arteriosclerosis, Thrombosis and Vascular Biology/Peripheral Vascular Disease **35**(SUPPL. 1).

Introduction: Mechanisms that regulate the positive association between thrombosis and metastasis are incompletely understood. It was hypothesised that thrombus formation stimulates a hypoxic response, which in turn promotes extravasation. The primary aim was to determine whether thrombosis of the pulmonary microvasculature (T<inf>pm</inf>) increases extravasation via myeloid (neutrophil and macrophage) hypoxia-inducible factor (HIF). Methods and Results: Tpm was induced in wild type mice via tail vein administration of polystyrene microbeads (15mum diameter, 1000/mouse). Tpm led to chronological increases in pulmonary HIF1alpha expression (P=0.01), HIF2alpha expression (P<0.01), neutrophil infiltration (P<0.05), and macrophage infiltration (P<0.05; 1-5days post-Tpm vs. non-thrombosed vehicle controls, n=8/group/time point); these increases were comparable with changes observed following vena cava thrombosis (assessed via image analysis of immunostained tissue throughout). In wild type mice with circulating Lewis lung cancer cells (LLCs, 1million/mouse i/v), Tpm led to increases in pulmonary fibrin deposition (P<0.0001), HIF1alpha expression (P<0.05), HIF2alpha expression (P<0.05), and LLC extravasation (P<0.0001; 14days post-LLCs vs. non-thrombosed controls, n=15/group). Using conditional HIFalpha knockout mice (vs. wild type littermates), it was shown that Tpm-induced increases in pulmonary fibrin deposition and LLC extravasation were dependent upon HIF1alpha or HIF2alpha in neutrophils and macrophages; myeloid HIFs were also responsible for Tpm-induced increases in pulmonary tumour proliferation and vascularisation (n=15/group). In human breast tumour microarrays (n=221), fibrin deposition was positively correlated with HIF2alpha expression (RS=0.22, P<0.001), while increases in HIF2alpha were associated with reductions in metastasis-free survival (HR=1.1, P<0.05). Conclusion(s): Thrombus formation in mouse pulmonary microvasculature enhances cancer cell extravasation via neutrophil- and macrophage-specific HIF1alpha or HIF2alpha. In human breast tumours, HIF2alpha is associated with increased fibrin deposition, and reduced survival. Pulmonary microvascular thrombosis can enhance cancer cell dissemination via myeloid cell-specific HIFs.

Evans, C. E., et al. (2017). "Modelling pulmonary microthrombosis coupled to metastasis: distinct effects of thrombogenesis on tumorigenesis." Biology Open **6**(5): 688-697.

Thrombosis can cause localized ischemia and tissue hypoxia, and both of these are linked to cancer metastasis. Vascular micro-occlusion can occur as a result of arrest of circulating tumour cells in small capillaries, giving rise to microthrombotic events that affect flow, creating localized hypoxic regions. To better understand the association between metastasis and thrombotic events, we generated an experimental strategy whereby we modelled the effect of microvascular occlusion in metastatic efficiency by using inert microbeads to obstruct lung microvasculature before, during and after intravenous tumour cell injection. We found that controlled induction of a specific number of these microthrombotic insults in the lungs caused an increase in expression of the hypoxia-inducible transcription factors (HIFs), a pro-angiogenic and pro-tumorigenic environment, as well as an increase in myeloid cell infiltration. Induction of pulmonary microthrombosis prior to introduction of tumour cells to the lungs had no effect on tumorigenic success, but thrombosis at the time of tumour cell seeding increased number and size of tumours in the lung, and this effect was strikingly more pronounced when the micro-occlusion occurred on the day following introduction of tumour cells. The tumorigenic effect of microbead treatment was seen even when thrombosis was induced five days after

tumour cell injection. We also found positive correlations between thrombotic factors and expression of HIF2alpha in human tumours. The model system described here demonstrates the importance of thrombotic insult in metastatic success and can be used to improve understanding of thrombosis-associated tumorigenesis and its treatment.

Evans, C. E., et al. (2015). "Microthrombosis enhances extravasation via myeloid hypoxia-inducible factors." Journal of Thoracic Oncology **2)**: S394-S395.

Background: Mechanisms that regulate the positive association between thrombosis and pulmonary metastasis are incompletely understood. It was hypothesised that thrombus formation stimulates a hypoxic response, which in turn promotes extravasation. The primary aim was to determine whether thrombosis of the pulmonary microvasculature (Tpm) increases extravasation via myeloid (neutrophil and macrophage) hypoxia-inducible factor (HIF). Method(s): Pulmonary microthrombosis was induced in wildtype and conditional HIFalpha knockout mice by administration of intravenous polystyrene microbeads (n=15/group). Murine lung cancer cell extravasation was quantified, and both murine pulmonary and human breast tumors (n=221) were characterised by immunostaining and image analysis. Result(s): Tpm was induced in wild type mice via tail vein administration of polystyrene microbeads (15mum diameter, 1000/mouse). Tpm led to chronological increases in pulmonary HIF1alpha expression (P=0.01), HIF2alpha expression (P<0.01), neutrophil infiltration (P<0.05), and macrophage infiltration (P<0.05; 1-5days post- Tpm vs. non-thrombosed vehicle controls, n=8/group/time point); these increases were comparable with changes observed following vena cava thrombosis (assessed via image analysis of immunostained tissue throughout). In wild type mice with circulating Lewis lung cancer cells (LLCs, 1million/mouse i/v), Tpm led to increases in pulmonary fibrin deposition (P<0.0001), HIF1alpha expression (P<0.05), HIF2alpha expression (P<0.05), and LLC extravasation (P<0.0001; 14days post-LLCs vs. non-thrombosed controls, n=15/group). Using conditional HIFalpha knockout mice (vs. wild type littermates), it was shown that Tpm- induced increases in pulmonary fibrin deposition and LLC extravasation were dependent upon HIF1alpha or HIF2alpha in neutrophils and macrophages; myeloid HIFs were also responsible for Tpm-induced increases in pulmonary tumour proliferation and vascularisation (n=15/ group). In human tumour samples (n=221), fibrin deposition was positively correlated with HIF2alpha expression (RS=0.22, P<0.001), while increases in HIF2alpha were associated with reductions in metastasis-free survival (P<0.05). Conclusion(s): Thrombus formation in mouse pulmonary microvasculature enhances cancer cell extravasation via neutrophiland macrophage-specific HIF1alpha or HIF2alpha. In human tumours, HIF2alpha is associated with increased fibrin deposition, and reduced survival. Pulmonary microvascular thrombosis can enhance cancer cell dissemination via myeloid cell-specific HIFs.

Evans, D. G., et al. (1979). "Purification and characterization of the CFA/I antigen of enterotoxigenic Escherichia coli." Infection & Immunity **25**(2): 738-748.

The fimbral colonization factor antigen CFA/I of enterotoxigenic Escherichia coli was purified and characterized. The initial purification step was release of these fimbriae from the bacterial cells by homogenization with a Waring blender. Common fimbriae and flagellar antigen were avoided by careful control of growth conditions and the use of a nonmotile (H-) mutant of the prototype strain H-10407 (O78:H11). The essential purification steps were membrane filtration (Millipore Corp.), ammonium sulfate fractionation, and negative diethylaminoethyl-Sephadex column chromatography. Yields were approximately 4.0 mg of CFA/I protein per g (wet weight) of bacteria. Purified CFA/I is a fimbrial molecule 7.0 nm in diameter and has an average molecular weight of 1.6 X 10(6), as determined by sedimentation equilibrium. CFA/I is a polymer of identical subunits of molecular weight 23,800 with an N-terminal valine, 37% hydrophobic amino acid residues, and 11 residues of proline per mol. The purified antigen retains its morphology, antigenicity, and biological activity. Purified antigen retains its morphology, antigenicity, and biological activity. Purified CFA/I exhibits mannose-resistant hemagglutination of human group A, bovine, and chicken erythrocytes, as do CFA/I-positive bacteria. This was demonstrated by sensitizing latex microbeads with the purified antigen since cell-free CFA/I fimbriae do not hemagglutinate erythrocytes. Thus, CFA/I detached from the bacteria are monovalent; however, purified CFA/I antigen retains an affinity for the epithelial cells of rabbit small intestine and blocks adhesion of CFA/I-positive bacteria. These results demonstrate that purified CFA/I is a good candidate for use in an oral vaccine for immunoprotection against diarrhea caused by CFA/I-positive enterotoxigenic E. coli.

Evariste, L., et al. (2019). "Gut microbiota of aquatic organisms: A key endpoint for ecotoxicological studies." Environmental Pollution **248**: 989-999.

Gut microbial communities constitute a compartment of crucial importance in regulation of homeostasis of multiple host physiological functions as well as in resistance towards environmental pollutants. Many chemical contaminants were shown to constitute a major threat for gut bacteria. Changes in gut microbiome could lead to alteration of host health. The access to high-throughput sequencing platforms permitted a great expansion of this discipline in human health while data from ecotoxicological studies are scarce and particularly those related to aquatic pollution. The main purpose of this review is to summarize recent body of literature providing data obtained from microbial community surveys using high-throughput 16S rRNA sequencing technology applied to aquatic ecotoxicity. Effects of pesticides, PCBs, PBDEs, heavy metals, nanoparticles, PPCPs, microplastics and endocrine disruptors on gut microbial communities are presented and discussed. We pointed out difficulties and limits provided by actual methodologies. We also proposed ways to improve understanding of links between changes in gut bacterial communities and host fitness loss, along with further applications for this emerging discipline.

Everaert, G., et al. (2018). "Risk assessment of microplastics in the ocean: Modelling approach and first conclusions." Environmental Pollution **242**(Pt B): 1930-1938.

We performed an environmental risk assessment for microplastics (<5mm) in the marine environment by estimating the order of magnitude of the past, present and future concentrations based on global plastic production data. In 2100, from 9.6 to 48.8 particles m⁻³ are predicted to float around in the ocean, which is a 50-fold increase compared to the present-day concentrations. From a meta-analysis with effect data available in literature, we derived a safe concentration of 6650 buoyant particles m⁻³ below which adverse effects are not likely to occur. Our risk assessment (excluding the potential role of microplastics as chemical vectors) suggests that on average, no direct effects of free-floating microplastics in the marine environment are to be expected up to the year 2100. Yet, even today, the safe concentration can be exceeded in sites that are heavily polluted with buoyant microplastics. In the marine benthic compartment between 32 and 144 particles kg⁻¹ dry sediment are predicted to be present in the beach deposition zone. Despite the scarcity of effect data, we expect adverse ecological effects along the coast as of the second half of the 21st century. From then ambient concentrations will start to outrange the safe concentration of sedimented microplastics (i.e. 540 particles kg⁻¹ sediment). Additional ecotoxicological research in which marine species are chronically exposed to realistic environmental microplastic concentration series are urgently needed to verify our findings.

Exley, M. A., et al. (2017). "Adoptive Transfer of Invariant NKT Cells as Immunotherapy for Advanced Melanoma: A Phase I Clinical Trial." Clinical Cancer Research **23**(14): 3510-3519.

Purpose: Invariant NKT cells (iNKT) are innate-like CD1d-restricted T cells with immunoregulatory activity in diseases including cancer. iNKT from advanced cancer patients can have reversible defects including IFNgamma production, and iNKT IFNgamma production may stratify for survival. Previous clinical trials using iNKT cell activating ligand alpha-galactosylceramide have shown clinical responses. Therefore, a phase I clinical trial was performed of autologous in vitro expanded iNKT cells in stage IIIB-IV melanoma.<b>Experimental

Fabbri, S., et al. (2016). "High-Velocity Microsprays Enhance Antimicrobial Activity in Streptococcus mutans Biofilms." Journal of Dental Research **95**(13): 1494-1500.

Streptococcus mutans in dental plaque biofilms play a role in caries development. The biofilm's complex structure enhances the resistance to antimicrobial agents by limiting the transport of active agents inside the biofilm. The authors assessed the ability of high-velocity water microsprays to enhance delivery of antimicrobials into 3-d-old S. mutans biofilms. Biofilms were exposed to a 90degree or 30degree impact, first using a 1-micro m tracer bead solution (10⁹ beads/mL) and, second, a 0.2% chlorhexidine (CHX) or 0.085% cetylpyridinium chloride (CPC) solution. For comparison, a 30-s diffusive transport and simulated mouthwash were also performed. Confocal microscopy was used to determine number and relative bead penetration depth into the biofilm. Assessment of antimicrobial penetration was determined by calculating the killing depth detected by live/dead viability staining. The authors first demonstrated that the microspray was able to deliver significantly more microbeads deeper in the biofilm compared with diffusion and mouthwashing exposures. Next, these experiments revealed that the microspray yielded better antimicrobial penetration evidenced by deeper killing inside the biofilm and a wider killing zone around the zone of clearance than diffusion alone. Interestingly the 30degree impact in the distal position delivered approximately 16 times more microbeads and yielded approximately 20% more bacteria killing (for both CHX and CPC) than the 90degree impact. These data suggest that high-velocity water microsprays can be used as an effective mechanism to deliver microparticles and antimicrobials inside S. mutans biofilms. High shear stresses generated at the biofilm-burst interface might have enhanced bead and antimicrobial delivery inside the remaining biofilm by combining forced advection into the biofilm matrix and physical restructuring of the biofilm itself. Further, the impact angle has potential to be optimized both for biofilm removal and active agents' delivery inside biofilm in those protected areas where some biofilm might remain.

Fackelmann, G. and S. Sommer (2019). "Microplastics and the gut microbiome: How chronically exposed species may suffer from gut dysbiosis." Marine Pollution Bulletin **143**: 193-203.

As small pieces of plastics known as microplastics pollute even the remotest parts of Earth, research currently focuses on unveiling how this pollution may affect biota. Despite increasing awareness, one potentially major consequence of chronic exposure to microplastics has been largely neglected: the impact of the disruption of the symbiosis between host and the natural community and abundance pattern of the gut microbiota. This so-called dysbiosis might be caused by the consumption of microplastics, associated mechanical disruption within the gastrointestinal tract, the ingestion of foreign and potentially pathogenic bacteria, as well as chemicals, which make-up or adhere to microplastics. Dysbiosis may interfere with the host immune system and trigger the onset of (chronic) diseases, promote pathogenic infections, and alter the gene capacity and expression of gut microbiota. We summarize how chronically exposed species may suffer from microplastics-induced gut dysbiosis, deteriorating host health, and highlight corresponding future directions of research.

Faggio, C., et al. (2018). "Mussel digestive gland as a model tissue for assessing xenobiotics: an overview." Science of the Total Environment **636**: 220-229.

Control strategies and routine biomonitoring programs are commonly performed worldwide using sentinel marine invertebrates, such as mussels of the genus Mytilus, for assessing the "health status" of the aquatic environment. Those species can accumulate and tolerate xenobiotics at levels higher than those being present into the aquatic environment, thus providing accurate and reliable biological endpoints (e.g. physiological, behavioral, cellular, biochemical and molecular indices) that can be measured in their tissues. Taking under consideration the significance of bivalves for assessing the environmental hazard of xenobiotics being present into the water medium, as well as the key role of digestive gland as a target-tissue for the compounds ingested in the organism, the present study aimed to summarize available data on the effects of different categories of xenobiotic compounds, previously characterized as a potential threat for the marine ecosystems. In this context, different types of pharmaceuticals and personal care products (PPCPs), biocides, microplastics (MPs) and nanoparticles (NPs), currently investigated in mussels' digestive gland, using a battery of experimental approaches and analytical methods, as well as stress indices evaluation, are briefly described and further discussed in order to elucidate not only the presence and the toxic mode of action of xenobiotics, but also the important role of the digestive gland as a reliable target-tissue for investigating the effects of xenobiotics at cellular, biochemical, and molecular levels.

Fahrenfeld, N. L., et al. (2019). "Source tracking microplastics in the freshwater environment." TrAC - Trends in Analytical Chemistry **112**: 248-254.

Plastics are a frequently observed component of marine debris and there is growing concern about microplastic (MP) ecotoxicity, and the impacts of additives, sorbed hazardous organic contaminants, heavy metals, and biofilm on MP surfaces. The relative importance of MP from different terrestrial and freshwater sources is poorly understood and limits our ability to develop best management practices. This review focuses on evidence and methods for source apportionment of MP in freshwater environments including the use of MP characteristics, mass balance techniques, and surface characteristics. Within-study data indicated some potential for differences in polymer identity and morphology for differentiating select sources, but clear cross-study patterns were lacking. Major challenges identified include technical challenges in accurately identifying polymers, multiple classification schemes for reported MP morphologies, lack of data for several terrestrial sources, poor understanding of differential fate/transport/weathering processes for MP and surface contaminants, and methodological difficulties simultaneously confirming polymers and surface contaminants. Faigel, D., et al. (2014). "Endoscopic ultrasonography-guided portal injection chemotherapy for hepatic metastases." Endoscopic Ultrasound **3**(Suppl 1): S1.

INTRODUCTION: We hypothesized that endoscopic ultrasonography-guided portal injection chemotherapy (EPIC) using irinotecan-loaded microbeads may achieve increased intrahepatic concentrations, while decreasing systemic exposure. This may achieve enhanced efficacy for the treatment of diffuse liver metastases, while decreasing systemic toxicities.

MATERIALS AND METHODS: In eight anesthetized 35 kg pigs, EPIC was performed transgastrically using

the linear-array echoendoscope and a 22 g fine-needle aspiration. In four animals, irinotecan (100 mg) loaded onto 75-150 micron liquid chromatography (LC) beads was injected. In four animals, saline was injected into the portal vein and unloaded irinotecan (100 mg) was injected into the jugular vein. Plasma (every 15 min), and at 1 h bone marrow, liver and skeletal muscle samples were obtained. Irinotecan and SN-38 (active metabolite) concentrations were assayed by LC/mass spectrometry.

RESULTS: The procedure was performed safely in all eight animals. Compared with systemic administration, EPIC resulted in almost twice the hepatic concentration of irinotecan (6242 vs. 3692 ng/g) and half the systemic concentrations in plasma (1092 vs. 2762 ng/mL), bone marrow (815 vs. 1703 ng/mL) and skeletal muscle (521 vs. 1058 ng/g). SN-38 levels were lower with EPIC (liver: 166 vs. 681 ng/g; plasma: 1.8 vs. 2.4 ng/mL; bone marrow: 0.9 vs. 1.4 ng/mL; muscle 4.6 vs. 9.2 ng/g). Liver histology showed the beads within small portal venules.

CONCLUSIONS: EPIC using irinotecan-loaded microbeads can enhance hepatic exposure to irinotecan, while decreasing systemic concentrations. SN-38 levels were lower with EPIC indicating that a substantial portion of the irinotecan was still loaded onto beads. The microbeads may act as a reservoir resulting in prolonged hepatic drug exposure.

Faigel, D. O., et al. (2016). "477 Safety and Toxicity of EUS-Guided Portal Injection Chemotherapy (EPIC) Using Drug-Eluting Microbeads...2016 DDW (Digestive Disease Week) ASGE (American Society for Gastrointestinal Endoscopy) Program and Abstracts 21 May 2016-24 May 2016, San Diego, California." Gastrointestinal Endoscopy **83**: AB150-AB150.

Faigel, D. O., et al. (2014). "Feasibility of eus-guided portal injection of chemotherapy (EPIC) using irinotecan-loaded microbeads for the treatment of hepatic metastases." Gastroenterology **1)**: S692-S693.

The liver is a common site of distant metastases. While solitary metastases may be treated with a variety of local options, for diffuse hepatic metastases the only current option is systemic chemotherapy. Drug-eluting microbeads have been used for transarterial chemoembolization of localized disease. Their use in the portal system has not been described. We hypothesized that EPIC using irinotecan loaded microbeads may achieve increased intrahepatic concentrations while decreasing systemic exposure. This may achieve enhanced efficacy for the treatment of diffuse liver metastases while decreasing systemic toxicities. Aim(s): Perform EPIC using irinotecan-loaded microbeads in the acute non-survival porcine model and compare hepatic, plasma, bone marrow and skeletal muscle levels to systemic administration of non-loaded irinotecan. Method(s): In 8 anesthetized 35kg pigs, the Olympus linear array echoendoscope was inserted perorally to the stomach. The portal vein was identified by location, appearance and pulse-wave Doppler signature. A standard 22g FNA needle (Cook Medical) was advanced transgastrically into the portal vein. In 4 animals, irinotecan (100 mg) loaded onto 75-150 micron LC beads (Biocompatibles) was injected. In 4 animals, saline was injected into the portal vein and unloaded irinotecan (100 mg) was injected systemically into the jugular vein. Plasma was collected at baseline and every 15 minutes for 1 hour. At 1 hour laparotomy was performed and liver and skeletal muscle samples obtained and frozen. Bone marrow aspirate was obtained at 1 hour from the right anterior tibia. Irinotecan and SN-38 (active metabolite) concentrations were determined using LC/MS at a reference laboratory (MicroConstants) and reported as ng/ml or ng/gm tissue. Result(s): Irinotecan and SN38 concentrations are shown in table 1. Compared to systemic administration, EPIC resulted in almost twice the hepatic concentration of irinotecan and half the systemic concentrations in plasma, bone marrow and skeletal muscle. SN38 levels were lower in all sites with EPIC. Liver histology showed the beads scattered within small portal venules in the liver. Conclusion(s): EPIC using irinotecan-loaded microbeads may enhance hepatic exposure to irinotecan while decreasing systemic concentrations. The SN38 levels were lower with EPIC indicating that a substantial portion of the irinotecan was still loaded onto beads at 1 hour and not yet converted to active metabolite. Thus, the microbeads may act as a reservoir resulting in prolonged hepatic drug exposure. EPIC holds promise as a novel therapy for patients with hepatic metastases. (Table Presented).

Faigel, D. O., et al. (2016). "EUS-guided portal injection chemotherapy for treatment of hepatic metastases: feasibility in the acute porcine model." Gastrointestinal Endoscopy **83**(2): 444-446.

Background and Aims Direct injection of chemotherapy into the portal vein for treatment of liver metastases may increase hepatic tissue levels while decreasing systemic levels and toxicities. We aimed to evaluate EUS-guided portal injection chemotherapy (EPIC) by using drug-eluting microbeads or nanoparticles and compare it with systemic injection. Methods We conducted a comparative feasibility trial in the acute porcine model (24 anesthetized pigs). Pigs were treated with irinotecan, doxorubicin, or albumin-bound paclitaxel nanoparticles (n = 8/group). Within each group, pigs were treated with EPIC or a systemic intravenous injection of drug and saline solution into the portal vein (n = 4/treatment). Irinotecan or doxorubicin were loaded onto microbeads for EPIC treatment only. We examined drug levels in tissue (1 hour) and plasma (15 minutes). Results EUS-guided access and injection was successful in all animals. EPIC with irinotecan-loaded microbeads showed nearly double the hepatic concentration compared with systemic injection (6242 vs 3692 ng/g) and almost half the systemic levels. EPIC with doxorubicin-loaded microbeads showed a 5-fold increase in hepatic levels (35,450 vs 6930 ng/g) and a 30-fold decrease in cardiac levels (153 vs 4805 ng/g) compared with systemic administration ($P < .05$ for both). EPIC with albumin-bound paclitaxel nanoparticles increased hepatic concentrations by 60% and decreased systemic levels by 24% to 32%. Conclusions EPIC holds promise as a new treatment for hepatic metastases.

Fairbank, N. J., Jr. (2009). Cytoskeletal stress alters airway smooth muscle cell structure and contractile function.

In the asthmatic lung, airway smooth muscle (ASM) constantly experiences characteristically-elevated internal contractile stress as well as external mechanical stress (MS) due to breathing, which may be elevated by symptoms. The ASM cytoskeleton is highly adaptable, responding dynamically to external MS and inflammatory mediators, leading to altered structure and function that may enhance airway narrowing in asthma. In this thesis, we developed methodology and software to apply a technique known as optical magnetic twisting cytometry to investigate the roles of external MS; internal MS, or tone; and inflammation - alone and in combination - on the functional response of the cytoskeleton. We applied external MS to cultured human bronchial ASM cells acutely (90 min.) by sinusoidal rotation of integrin-bound microbeads (4.5 km diameter) on cells that had been incubated with proinflammatory cytokine, interleukin-1b (IL-1b, 20 ng/mL), for 20 hr. As previously established, IL-1b incubation increased contractility and decreased relaxation induced by b-agonists, promoting hyperresponsiveness. We found this occurred via cytoskeletal stiffening of 34.2% associated with Rho activation, actin polymerization, and focal adhesion growth, all mediated by cyclooxygenase (COX)-2-dependent pathways. MS similarly induced cytoskeletal stiffening of 29.8% and focal adhesion growth, but this was independent of COX-2 and without increased contractility. Airway inflammation thus increased contractile function via stress-independent cytoskeletal remodeling. In another study, chronic (5 days) external and predominantly-uniaxial MS was applied to the basal surface of ASM cell cultures (5%, 0.3 Hz), during which tone was

either decreased by repeated addition of forskolin or increased by repeated addition of either carbachol or histamine, relative to sham. Cells aligned and baseline stiffness increased with strain, but decreased tone inhibited both effects (p<0.05). Importantly, strain reversed previously-reported inhibition of myosin light-chain kinase (MLCK) content by tone in unstrained cells. Strain and tone together increased both MLCK and myosin light-chain phosphorylation, leading to an increase in contractility of 176%. Along with increased contractile protein content and activity, observed strain-dependent changes in cytoskeletal organization contributed to the increase in contractility. Taken together, the presented data suggest that treatment with corticosteroids and bronchodilators may lead to improved airway function by a novel mechanism involving the reduction of cytoskeletal remodeling-induced increases in ASM contractility.

Fajardo, P., et al. (2014). Mitigation Of Pathogens And Marine Biotoxins Contamination In Shellfish. Southampton, W I T Press. **134:** 691-698.

The EU FP7 funded project \“Bio-engineered micro Encapsulation of Active agents Delivered to Shellfish (BEADS)” is focused on mitigating the impact of marine biotoxins (ASP/DSP), microbial contamination (bacteria/norovirus) and the parasitic protozoan Bonamia ostreae on shellfish aquaculture. Purpose: to develop probiotic diets and a microencapsulated delivery system in the digestive tract of shellfish to improve depuration. Feeding experiments were performed to identify the optimum size of alginate microcapsules, testing three different sizes and colours containing nondegradable fluorescent dye microbeads. Oysters and mussels were placed in tanks containing filtered seawater. Three sizes of microcapsules were mixed and shellfish were fed for 3 hours. Shellfish were removed during the feeding period at 0.5, 1, 2 and 3 hours and dissected. Any capsules remaining in the water and in the digestive organs of shellfish were extracted and measured using a fluoroskan analyzer. A higher concentration of the smaller capsules was found in the digestive gland, indicating that the smaller capsules were preferentially ingested. The ingestion increased during the three-hour period. Fluorescent beads of different colours embedded in alginate capsules were observed bound to the mucus string. Mussels were more efficient than oysters in incorporating alginate beads that were observed by light microscopy as intact in the digestive gland of mussels and oysters during feeding period. Broken alginate beads were found in faeces. During passage through the intestine, active agents embedded by alginate capsules are released into the digestive gland providing a useful tool to transport active agents.

Fakile, Y. F., et al. (2018). "Correlation of Treponemal Immunoassay Signal Strength Values with Reactivity of Confirmatory Treponemal Testing." Journal of Clinical Microbiology **56**(1): 01.

Automated treponemal immunoassays are used for syphilis screening with the reverse-sequence algorithm; discordant results (e.g., enzyme immunoassay [EIA] reactive and reactive plasma reagin [RPR] nonreactive) are resolved with a second treponemal test. We conducted a study to determine automated immunoassay signal strength values consistently correlating with reactive confirmatory treponemal testing. We conducted a cross-sectional analysis of four automated immunoassays (BioPlex 2200 microbead immunoassay [MBIA], Liaison chemiluminescence immunoassay [CIA], Advia-Centaur CIA, and Trep-Sure EIA) and three manual assays (Treponema pallidum particle agglutination [TP-PA], fluorescent treponemal antibody absorption [FTA-ABS] test, and Inno-LIA line immunoassay). We compared signal strength values of automated immunoassays and positive and negative agreement. Among 1,995 specimens, 908 (45.5%) were true positives (>=4/7 tests reactive) and 1,087 (54.5%) were true negatives (>=4/7 tests nonreactive). Positive agreement ranged from 86.1% (83.7 to 88.2%)

for FTA-ABS to 99.7% (99.0 to 99.9%) for Advia-Centaur CIA; negative agreement ranged from 86.3% (84.1 to 88.2%) for Trep-Sure EIA to 100% for TP-PA (99.6 to 100%). Increasing signal strength values correlated with increasing reactivity of confirmatory testing (P < 0.0001 for all automated immunoassays by Cochran-Armitage test for trend). All automated immunoassays had signal strength cutoffs corresponding to >=4/7 reactive treponemal tests. BioPlex MBIA and Liaison CIA had signal strength cutoffs correlating with >=99% and 100% TP-PA reactivity, respectively. The Advia-Centaur CIA and Trep-Sure EIA had signal strength cutoffs correlating with at least 95% TP-PA reactivity. All automated immunoassays had signal strength cutoffs correlating with at least 95% FTA-ABS reactivity. Assuming that a 95% level of confirmation is adequate, these signal strength values can be used in lieu of confirmatory testing with TP-PA and FTA-ABS.

Falahudin, D., et al. (2019). "The first occurrence, spatial distribution and characteristics of microplastic particles in sediments from Banten Bay, Indonesia." Science of the Total Environment **705**: 135304.

Microplastics (MPs) are recognized as an emerging issue worldwide, including Indonesia. Due to the limited of data available regarding MPs pollution in Indonesian waters, we investigated the occurrence, spatial distribution, characteristics, and potential ecological impacts of MPs in sediments from 25 stations in the Banten Bay, a shallow and semi enclosed bay located on the northwestern coast of Java, Indonesia. The bay has experienced very high population pressure due to increasing coastal development in the last decade. MPs were extracted by flotation methods, observed under a stereomicroscope, and identified by FTIR imaging. This study showed that MPs pollution is prevalent in the Banten Bay, where all sediments contained MPs with an average concentration of 267 +/- 98 particles/kg dw sediment. The most common shape, size, and polymer type were foam (38% of the observed MPs), size between 500 and 1000 mum (>50%), and extended polystyrene, respectively. The particles were found to be more highly distributed in the stations with fine sediment grain sizes and in locations near the river mouth of the island than in areas offshore, which suggests that the impact of the MPs currently in the sediments might be harmful to the benthic community and potentially increase the magnitude into the pelagic community. Moreover, the river effluent is suggested as a pathway for plastic pollution to the Banten Bay.

Falk-Andersson, J., et al. (2019). "Citizen science for better management: Lessons learned from three Norwegian beach litter data sets." Marine Pollution Bulletin **138**: 364-375.

Increased plastic consumption and poor waste management have resulted in litter representing an ever-increasing threat to the marine environment. To identify sources and evaluate mitigation measures, beach litter has been monitored. Using data from two citizen science protocols (CSPs) and OSPAR monitoring of Norwegian beaches, this study 1) identifies the most abundant litter types, 2) compares OSPAR to citizen science data, and 3) examines how to improve the management relevance of beach litter data. The dominant litter types were; food and drink- and fishery related items, and unidentifiable plastic pieces. Data from CSPs are consistent with OSPAR data in abundance and diversity, although few OSPAR beaches limit verification of CSP data. In contrast to OSPAR, the CSPs estimate the weight of the litter. CSPs lack important variables which could explain why some litter types are abundant in some particular areas. The latter could be improved by recording GPS positions.

Fallon, A. M., et al. (2008). "Procoagulant properties of flow fields in stenotic and expansive orifices." Annals of Biomedical Engineering **36**(1): 1-13.

In the United States, over 125,000 mechanical heart valves (MHVs) are implanted each year.

Flow through the MHV hinge can cause thromboemboli formation. The purpose of this study was to examine various orifice geometries representing the MHV hinge region and how these geometries may contribute to platelet activation and thrombin generation. We also characterized these flow fields with digital particle image velocimetry (DPIV). Citrated human blood at room temperature was forced through the orifices (400 and 800 microm ID) with a centrifugal bypass pump, continuously infusing calcium chloride to partially reverse the citrate anticoagulant. Blood samples were tested for the presence of thrombin-antithrombin complex (TAT) and platelet factor 4 (PF4). Velocity and shear stress were measured with DPIV using a blood analog fluid seeded with fluorescent microbeads. The results indicate that small changes in geometry, although they do not affect the bulk flow, change the coagulation propensity as blood flows through the orifices. A more abrupt geometry allows more stagnation to occur resulting in more thrombin generation. PF4 measurements indicated similar levels of platelet activation for all orifices. DPIV showed differences in the jets with respect to entrainment of stagnant fluid. These results help to pinpoint the important parameters that lead to flow stasis and subsequent thrombus formation.

Fan, W., et al. (2020). "On-bead enzyme-catalyzed signal amplification for the high-sensitive detection of disease biomarkers." Methods in Enzymology **630**: 179-197.

The high-sensitive and rapid detection of critical biomarkers, e.g., disease-related nucleic acids and proteins, is always desired. Compared with the routine homogenous detection strategies, the on-bead flow cytometry (FCM)-based assays have drawn a lot of interests owing to their unique advantages. On one hand, microbeads (MBs) are employed for the enrichment of fluorescent signals, allowing the size encoding for multiplexed detection of biomarkers. On the other hand, FCM enables the fast read-out of the total fluorescent signals enriched on the MBs and the decoding of MBs' size information. For an improved sensitivity and versatile application scenarios, the signal amplification on MBs is required. However, the enzyme-catalyzed on-bead reactions remain challenging owing to the critical reaction conditions on the MBs/solution interface. Toward the high-sensitive detection of target biomolecules in real-samples, a series of on-bead enzyme-catalyzed signal amplification strategies have been developed. After careful optimization of the reaction conditions, the proposed sensors are proven to have ultra-high sensitivities to fulfill the requirement of real-sample detection.

Fan, X., et al. (2019). "Identification of deregulated microRNAs in hepatic stellate cells from mice infected with Schistosoma japonicum." China Tropical Medicine **19**(4): 301-306.

Objective: To screen and validate differentially expressed microRNAs (miRNAs) in hepatic stellate cells (HSCs) from mice infected Schistosoma japonicum.

Fan, Y., et al. (2019). "Distribution, sedimentary record, and persistence of microplastics in the Pearl River catchment, China." Environmental Pollution **251**: 862-870.

Microplastics (MPs) in the environment have become an issue worldwide. However, data about MPs in freshwater systems are still limited so far. This study investigated sources, fate, and seasonal and spatial distribution of MPs in the main stream Pearl River and its tributaries, as well as in the Pearl River Estuary (PRE), China. MPs were widely detected in the river water, river bed sediment, and estuarine sediment, with abundances of 0.57+/-0.71 items L⁻¹, 685+/-342 items kg⁻¹ dry weight (dw), and 258+/-133 items kg⁻¹ dw, respectively. Sheet, fragmental, and fibrous polyethylene, polypropylene, and ethylene-propylene copolymers were predominant, suggesting that MPs in the Pearl River catchment be mainly derived from fragmentation of discarded plastic wastes. In addition,

municipal wastewater was also an important MPs source, especially for polyethylene terephthalate (PET) fibers. Polymers of higher density, such as PET and polyvinyl alcohol were relatively more abundant in the sediment than in the river water, especially in the estuarine sediment. Upward increase of the MP abundance was observed in the sedimentary core, probably indicating increasing release of plastic wastes due to growing production and uses of plastic products. On the other hand, percentage of finer MPs increased with increasing depth. The results revealed persistence and potential downward dispersion of the fine MPs. The MPs abundance was positively related with population density and gross domestic product, demonstrating impacts of human activities and economic development on the MPs contamination. Higher MPs abundance was detected in dry season than in wet season in the river water, suggesting dilution effect of precipitation. It's estimated that 15963 tons of MPs could be released annually into the PRE from the main stream Pearl River and its tributaries.

Fang, C., et al. (2019). "Comparison of microplastic contamination in fish and bivalves from two major cities in Fujian province, China and the implications for human health." Aquaculture **512**(734322).

There is a growing global concern about the negative effects of microplastics (MPs) in aquaculture and their consequences for human health. This is the first study to investigate the contamination status and human health risks of MPs in commercial fish and bivalves collected from fishery markets of two major cities in Fujian province of China and compare them both nationally and internationally. The MP abundances in the bivalves from both cities were found to be lower when compared nationally (Qingdao and Shanghai) as well as internationally to several European countries (Italy, UK, France and Belgium). The MP abundances in the fish from both cities were also lower than reported nationally (Shanghai), but higher when compared internationally (Indonesia, USA and Portugal). In general, a higher percentage of fish than of bivalves tested positive for MPs. Moreover, fish contained higher abundances of total MPs and higher percentages of fibers, polystyrene (PS), polyvinyl chloride (PVC), blue and longer MPs than bivalves. In contrast, bivalves possessed higher percentages of fragments, films and particles together with polyethylene terephthalate (PET), transparent and shorter MPs than fish. Regarding regional differences, seafood collected at Xiamen had relatively higher abundances of total MPs and higher percentages of PET, polyacrylonitrile (PAN), fragments, films and particles along with black, white and transparent MPs. Whereas seafood from Fuzhou contained higher percentages of other polymers, fibers, and blue MPs. Finally, the polymer risk indexes caused by MPs in seafood were calculated based on the chemical hazards of polymers. The outcome of the risk assessment indicated human health risks posed by MPs via seafood consumption from both cities is likely to be higher than those from Shanghai, UK and South Korea due to greater percentages of PAN contamination.

Fang, C., et al. (2018). "Microplastic contamination in benthic organisms from the Arctic and sub-Arctic regions." Chemosphere **209**: 298-306.

The seafloor is recognized as one of the major sinks for microplastics (MPs). However, to date there have been no studies reported the MP contamination in benthic organisms from the Arctic and sub-Arctic regions. Therefore, this study provided the first data on the abundances and characteristics of MPs in a total of 413 dominant benthic organisms representing 11 different species inhabiting in the shelf of Bering and Chukchi Seas. The mean abundances of MP uptake by the benthos from all sites ranged from 0.02 to 0.46 items g⁻¹ wet weight (ww) or 0.04-1.67 items individual⁻¹, which were lower values than those found in other regions worldwide. The highest value appeared at the northernmost site, implying that the sea ice and the cold current represent possible transport mediums. Interestingly, the predator A.

rubens ingested the maximum quantities of MPs, suggesting that the trophic transfer of MPs through benthic food webs may play a critical role. Fibers constituted the major type (87%) in each species, followed by film (13%). The colors of fibers were classified as red (46%) and transparent (41%), and the film was all gray. The predominant composition was polyamide (PA) (46%), followed by polyethylene (PE) (23%), polyester (PET) (18%) and cellophane (CP) (13%). The most common sizes of MPs concentrated in the interval from 0.10 to 1.50 mm, and the mean size was 1.45+or-0.13 mm. Further studies about the temporal trends and detrimental effects of MPs remain to be carried out in benthic organisms from the Arctic and sub-Arctic regions.

Fang, H., et al. (2018). "Detection of Nucleic Acids in Complex Samples via Magnetic Microbead-Assisted Catalyzed Hairpin Assembly and "DD-A" FRET." Analytical Chemistry **90**(12): 7164-7170.

Nucleic acids, as one kind of significant biomarker, have attracted tremendous attention and exhibited immense values in fundamental studies and clinical applications. In this work, we developed a fluorescent assay for detecting nucleic acids in complex samples based on magnetic microbead (MMB)-assisted catalyzed hairpin assembly (CHA) and a donor donor-acceptor fluorescence resonance energy transfer ("DD-A" FRET) signaling mechanism. Three types of DNA hairpin probes were employed in this system, including Capture, H1 (double FAM-labeled probe as FRET donor), and H2 (TAMRA-labeled probe as FRET acceptor). First, the Captures immobilized on MMBs bound to targets in complex samples, and the sequences in Captures that could trigger catalyzed hairpin assembly (CHA) were exposed. Then, target-enriched MMB complexes were separated and resuspended in the reaction buffer containing H1 and H2. As a result, numerous H1-H2 duplexes were formed during the CHA process, inducing an obvious FRET signal. In contrast, CHA could not be triggered, and the FRET signal was weak, while target was absent. With the aid of magnetic separation and "DD-A" FRET, errors from background interference were effectively eliminated. Importantly, this strategy realized amplified detection in buffer, with detection limits of microRNA as low as 34 pM. Furthermore, this method was successfully applied to detect microRNA-21 in serum and cell culture media. The results showed that our method has the potential for biomedical research and clinical application.

Fang, S., et al. (2019). "Adsorption behavior of three triazole fungicides on polystyrene microplastics." Science of the Total Environment **691**: 1119-1126.

Environmental pollution caused by microplastics (MPs) and pesticides has become a global challenge, and increasing evidence shows that MPs can adsorb organic pollutants which may affect their distribution and bioavailability. As widely used pesticides, triazole fungicides with potential environmental and human safety risks often coexist with MPs in the environment. Understanding the adsorption behavior is the basis of risk assessment of co-exposure of MPs and triazole fungicides. In this study, the adsorption behavior of three commonly used triazole fungicides on polystyrene (PS) was studied using adsorption test. The influences of PS particle size and environmental factors on adsorption capacity were evaluated, and the adsorption mechanisms were discussed.

Faraca, G. and T. Astrup (2019). "Plastic waste from recycling centres: Characterisation and evaluation of plastic recyclability." Waste Management **95**: 388-398.

While recycling has been recognised as the preferred plastic waste management solution, little is known about the detailed characteristics of plastic waste and how these may affect its recycling. In this study hard plastic, plastic film and PVC waste collected at three Danish recycling centres were sampled and characterised according to product applications, legislative

requirements (quality), expected product life time, polymer types and presence of potential impurities such as coloured plastics, non-plastic materials and multi-polymer products. The obtained information was applied for estimation of overall recycling potentials for selected archetype recycling process chains based on material flow analysis. In addition to providing detailed data for the composition of the plastic waste products, the results showed that impurities represented 28% (wet weight) of the plastic waste, and that about 75% of the plastic waste was characterised as Low Quality applications, indicating some legislative recovery restrictions. By accounting for the level/type of impurities, the overall recycling potential was found to be 52% for hard plastics, 59% for plastic films and 79% for PVC waste. The results showed that while varying according to polymer type, the recyclability of "High Quality" plastic waste was 12-35% higher than "Low Quality" applications. While actual results are representative of Danish conditions, the study demonstrates that detailed characteristics of plastic waste are needed to identify potential challenges to recycling and thereby potentially improving the design (and recovery efficiency) of recycling facilities.

Faraca, G., et al. (2019). "Environmental life cycle cost assessment: Recycling of hard plastic waste collected at Danish recycling centres." Resources, Conservation and Recycling **143**: 299-309.

Recycling of plastic waste is promoted by the European Union as an important step toward a circular economy. Recovered plastic waste is a complex and heterogeneous material, and the impurities and/or untargeted polymers associated to plastic waste may affect the recycling process and potentially decrease the intended benefits. An environmental and financial assessment was conducted on one tonne of hard plastic waste collected at Danish recycling centres. Three management scenarios were considered: two mechanical recycling (a simpler and a more advanced configuration, namely sMR and aMR) and a feedstock recycling (FR) scenario based on conversion through pyrolysis. Scenario aMR provided the largest savings in the highest number of impact categories (including global warming potential) and total costs; scenarios sMR and FR provided smaller savings (or even burdens), depending on the environmental impact category considered. A scenario analysis evaluating the type of energy provision, location of recycling facilities and the application of the recycled material confirmed the ranking of results with respect to global warming potential and total costs. A global sensitivity assessment of model data inputs demonstrated that three to nine parameters were typically sufficient to achieve more than 90% of total variance of the results; critical parameters were mainly related to sorting efficiencies, technical yields and market substitution factors. The study demonstrates that if high quality of the recycled plastic is achieved, both environmental savings and financial revenues are possible. Copyright © 2019 Elsevier B.V.

Fard, N. A., et al. (2016). "The Safety Property of beta-D-Mannuronic Acid (M2000) as a Novel Immunosuppressive Agent on Differentiation, Maturation and Function of Human Dendritic Cells." Current Drug Discovery Technologies **13**(3): 164-169.

The study's background and aim: In this investigation, the safety property of M2000 (beta-D-mannuronic acid) on differentiation, maturation and function of dendritic cells, was determined. beta-D-mannuronic acid, as a novel immunosuppressive and anti-inflammatory agent, has been tested in various experimental models. In addition, DC-based immunosuppressive drugs can suppress the progression of autoimmune diseases, although, their notable side effects in increasing the risk of infectious diseases and cancers should be considered.

MATERIALS AND METHODS: The effect of M2000 on differentiation, maturation and function of dendritic cells was examined. To investigate how M2000 affects human dendritic cells (DC) in a

defined inflammatory environment, human peripheral blood mononuclear cells (PBMC) were isolated from healthy blood and monocytes were purified using anti-CD14 microbeads. Monocytes were incubated with M2000 in two different doses (6 and 12 J.g/well) along with adding the granulocyte-macrophage colony-stimulating factor (GM-CSF) and interleukin-4 for inducing monocytes to immature DC and lipopolysaccharide for running DC maturation. The differentiation, maturation and function of dendritic cells were examined with flow cytometry and ELISA method.
RESULT: The results demonstrate that M2000 has no significant side on differentiation, maturation and function of dendritic cells in immature DC and mature DC process in vitro.
CONCLUSION: Our findings show that beta-D-mannuronic acid (m2000) as a safe agent had no adverse effect on differentiation, maturation and function of dendritic cells which might be recommended as a novel immunosuppressive agent with no or fewer side effects in increasing the risk of infectious diseases and cancers.

Farlow, S. J., et al. (2007). "Enhanced transduction of colonic cell lines in vitro and the inflamed colon in mice by viral vectors, derived from adeno-associated virus serotype 2, using virus-microbead conjugates bearing lectin." BMC Biotechnology **7 (no pagination)**(83).
Background: Virus-mediated delivery of therapeutic transgenes to the inflamed colon holds a great potential to serve as an effective therapeutic strategy for inflammatory bowel disease, since local, long-term expression of the encoded therapeutic proteins in the colorectal system is potentially achievable. Viral vectors, derived from adeno-associated virus (AAV), should be very useful for such therapeutic strategies, particularly because they can establish long-term expression of transgenes. However, few studies have been carried out to investigate the ability of AAV-based vectors to transduce the inflamed colon. Result(s): AAV, derived from adeno-associated virus serotype 2 (AAV2), showed a limited ability to transduce colonic cell lines in vitro when used in free form. No appreciable enhancement of the transduction efficiency was seen when AAV2 particles were attached stably to the surfaces of microbeads and delivered to target cells in the form of AAV2-microbead conjugates. However, the transduction efficiency of these colonic cell lines was enhanced substantially when a lectin, concanavalin A (Con A), was co-attached to the microbead surfaces, to which AAV2 particles had been conjugated. This considerable infectivity enhancement of AAV2-microbead conjugates by the co-attachment of Con A may be derived from the fact that Con A binds to alpha-D-mannosyl moieties that are commonly and abundantly present in cell-surface carbohydrate chains, allowing the conjugates to associate stably with target cells. Intracolonical administration of free AAV2 or AAV2-microbead conjugates without Con A into a mouse colitis model by enema showed very poor transduction of the colonic tissue. In contrast, the delivery of AAV2 in the form of AAV2-microbead conjugates bearing Con A resulted in efficient transduction of the inflamed colon. Conclusion(s): AAV2-microbead conjugates bearing Con A can serve as efficient gene transfer agents both for poorly permissive colonic cell lines in vitro and for the inflamed colon in a mouse colitis model. This efficient transduction system for the inflamed colon should be useful for the development of gene therapy strategies for inflammatory bowel disease. © 2007 Farlow et al; licensee BioMed Central Ltd.

Farmer, R. W., et al. (2011). "Hepatic arterial therapy as a bridge to ablation or transplant in the treatment of hepatocellular carcinoma." American Surgeon **77**(7): 868-873.
Hepatocellular carcinoma (HCC) is a challenging malignancy as a result of the advanced course at presentation. Recent interventional advances have improved treatment of lesions unamenable to resection using drug-eluting microbeads delivered into the hepatic circulation. We

hypothesize that the use of hepatic arterial therapy (HAT) will safely identify appropriate patients who can proceed to ablation and/or transplantation. We evaluated our open-label, multicenter, multinational, single-arm study including 240 patients with intermediate-staged HCC who received drugeluting beads and were not initial candidates for transplantation or resection. We reviewed the resulting clinical data to determine factors leading to possible ablation or transplant. Of 240 patients undergoing HAT, 14 (5.8%) received ablation or transplant. We compared those receiving ablation or transplant with those receiving only HAT. Groups were similar regarding sex, age, median number of tumors (one; range, 1 to 25), Child's score, tobacco and alcohol abuse, and treatment type. Patients who were downstaged were more likely to have: hepatitis-related tumors (76 to 66%, P = 0.02), distinct lesions on imaging (92 to 76%, P = 0.004), and less than 25 per cent parenchymal involvement (84 to 59%, P = 0.0001). These patients typically had one tumor frequently in the left lobe (58.8 vs 30.9%, P = 0.0001), accessible through segmental arteries (47 vs 17%, P = 0.001), with increased segmental branch occlusion (57 vs 39%, P = 0.02). HATshould be considered a potential bridging therapy to eventual ablation or transplant in the multimodal treatment of HCC.

Farrell, P. and K. Nelson (2013). "Trophic level transfer of microplastic: Mytilus edulis (L.) to Carcinus maenas (L.)." Environmental Pollution **177**: 1-3.

This study investigated the trophic transfer of microplastic from mussels to crabs. Mussels (Mytilus edulis) were exposed to 0.5 micro m fluorescent polystyrene microspheres, then fed to crabs (Carcinus maenas). Tissue samples were then taken at intervals up to 21 days. The number of microspheres in the haemolymph of the crabs was highest at 24 h (15 033 ml⁻¹+or-SE 3146), and was almost gone after 21 days (267 ml⁻¹+or-SE 120). The maximum amount of microspheres in the haemolymph was 0.04% of the amount to which the mussels were exposed. Microspheres were also found in the stomach, hepatopancreas, ovary and gills of the crabs, in decreasing numbers over the trial period. This study is the first to show 'natural' trophic transfer of microplastic, and its translocation to haemolymph and tissues of a crab. This has implications for the health of marine organisms, the wider food web and humans.

Farzana, J., et al. (2018). "A novel pooled-sample multiplex luminex assay for high-throughput measurement of relative telomere length." American Journal of Human Biology **30**(4).

ObjectivesRelative telomere length (RTL) is a potential biomarker of aging and risk for chronic disease. Previously, we developed a probe-based RTL assay on Luminex platform, where probes for Telomere (T) and reference gene (R) for a given DNA sample were tested in a single well. Here, we describe a method of pooling multiple samples in one well to increase the throughput and cost-effectiveness.MethodsWe used four different microbeads for the same T-probe and four different microbeads for the same R-probe. Each pair of probe sets were hybridized to DNA in separate plates and then pooled in a single plate for all the subsequent steps. We used DNA samples from 60 independent individuals and repeated in multiple batches to test the precision.ResultsThe precision was good to excellent with Intraclass correlation coefficient (ICC) of 0.908 (95% CI 0.856–0.942). More than 67% of the variation in the RTL could be explained by sample-to-sample variation; less than 0.1% variation was due to batch-to-batch variation and 0.3% variation was explained by bead-to-bead variation. We increased the throughput of RTL Luminex assay from 60 to 240 samples per run. The new assay was validated against the original Luminex assay without pooling (r = 0.79, P = 1.44 × 10−15). In an independent set of samples (n = 550), the new assay showed a negative correlation of RTL with age (r = −0.41), a result providing external validation for the method.ConclusionWe describe a novel high throughput pooled-sample multiplex Luminex assay for RTL with good to excellent precision suitable for large-scale studies.

Fasano, R. M., et al. (2010). "HLA alloantibody persistence and de novo production of HLA alloantibodies of donor origin following reduced intensity allogeneic hematopoietic stem cell transplantation." Blood. Conference: 52nd Annual Meeting of the American Society of Hematology, ASH **116**(21).

Background: Platelet refractoriness as a consequence of HLA alloimmunization complicates allogeneic hematopoietic stem cell transplantation (HSCT). Little is known regarding the affects of reduced intensity HSCT on the incidence and duration of HLA alloimmune-mediated platelet refractoriness following reduced intensity HSCT. Method(s): We retrospectively studied HLA alloimmunization in 16 patients with malignant and non-malignant hematological disorders, who underwent an allogeneic HSCT from an HLA matched relative using reduced intensity, non-myeloablative conditioning. All patients received a G-CSF mobilized, lymphocyte replete, peripheral blood stem cell (PBSC) allograft following cyclophosphamide (120 mg/kg) and fludarabine (125 mg/m2) based conditioning (+/- equine ATG 40 mg/kg x 4 days) with cyclosporine (CSA; beginning on day -4) and IV methotrexate (5 mg/m2 x 3 days) given as GVHD prophylaxis. Eight patients known to be HLA alloimmunized pre-transplant were compared to 8 control patients who were HLA alloantibody negative pre-transplant. Stored patients' serum samples from pre-transplant (day -30) and post-transplant intervals (days +30, +60, +100, +180, and >= 365) were analyzed for the presence of IgG antibodies to HLA class I antigens using a membrane-independent solid phase assay involving color-coded microbeads coated with HLA antigens and analysis with a flow analyzer (LABScan 100; One Lambda, Canoga Park, CA). Panel reactive antibody (PRA) and mean fluorescent intensity (MFI) were analyzed for all samples to measure HLA antibody strength and specificity, respectively. HLA alloantibodies were analyzed and compared with the degree of donor myeloid and T-cell engraftment measured on post-transplant blood samples by PCR of short tandem repeats (STRs). Result(s): Among the 8 alloimmunized patients who required HLA matched platelets pre-transplant, the median time until HLA antibodies disappeared was 100 days post HSCT. Remarkably, among these patients, 3/8 (37%) had HLA class I antibodies detectable for more than 100 days post-transplant including one patient who continued to show high level alloreactivity greater than 1 year after HSCT. Among the 8 control patients who tested negative for HLA alloantibodies pre-transplant, 3 acquired HLA alloantibodies after HSCT which were first detected at day +30 in all 3 cases. In 2 of the 3 cases, the donors for these patients were found to have pre-existing HLA antibodies of equivalent specificity to those found in the patient post-transplant suggesting patient acquisition of HLA antibodies was mediated by passenger donor lymphocytes that were transplanted in the allograft. Overall, HLA antibodies were detectable for more than 100 days after transplantation in 6/16 (37%) patients analyzed with 3/16 (18%) having alloantibodies detectable for more than 1 year post-transplant despite chimerism being 100% donor in myeloid and T cell lineages. Conclusion(s): Prolonged production of HLA alloantibodies leading to platelet refractoriness can occur following reduced intensity allogeneic HSCT and may persist even after full donor myeloid and T-cell chimerism have been achieved. Remarkably, we observed that transplantation of passenger donor lymphocytes can result in de novo HLA alloimmunization, complicating post-transplant transfusion management. Screening patients and their donors for HLA antibodies before HSCT would identify the majority of subjects at risk for alloimmune-mediated platelet refractoriness after transplantation. This new screening strategy would not only assist in transfusion support after allogeneic HSCT but could also play a role in the decision analysis for selecting optimal stem cell donors.

Fassihi, R. A., et al. (1994). "Potential use of magnesium stearate and talc as dissolution retardants in the development of controlled drug delivery systems." Pharmazeutische Industrie **56**(6): 579-583.

The potential role of magnesium stearate (MS) and talc as dissolution retardants in development of controlled drug delivery was investigated. It was found that when mixtures of brittle and plastic excipients were used in the formulation, MS up to a concentration of 6% w/w did not reduce the hardness significantly. Addition of 2% w/w talc to the formulation containing 2% w/w MS, however, increased the hardness by about 50% and reduced drug release by 50% over a 9 h dissolution study. No correlation existed between increase in hardness and decrease in drug release. Scanning electron micrographs showed that hydrophobic film formation around drug particles and bonding mechanisms were responsible for delay in drug release. Polymeric excipients which deform plastically were not coated significantly with either MS or talc, while brittle components were completely coated. It appears that stearates soften and spread under compression to provide a more coherent coverage and hydrophobicity, whereas talc remains at the surfaces of the particles, stabilizing bonding mechanisms. Plastic particles being uncoated undergo plastic deformation during compression and further add to the compact strength. Synergistic effects of MS and talc as dissolution retardants and stabilizers of bonding mechanism in a mixture of brittle and plastic materials is discussed.

Fatma Sabariah, A., et al. (2014). "Solid waste generation and composition at water villages in Sabah, Malaysia." Polish Journal of Environmental Studies **23**(5): 1475-1481.

Life in an estuary and at the beach are unique settlement patterns in the history of Malaysia. Sabah is well known for its water village settlements that are built on wooden pillars and which can be found along Sabah coastal water. However, a lot of problems have occurred at the Sabah water villages. Thus, the aim of this study is to measure the solid waste generation and composition in 150 households at select water villages in Sabah, Malaysia. The study was conducted at three major towns in Sabah, namely Kampung Tanjung Batu Laut, Tawau water village, Kampung Tanjung Aru, Kota Kinabalu water village and Kampung Sim-sim, Sandakan water village. Based on the results, the total waste generation is 1519.30 kg and the average solid waste generation rate per household is 0.29 kg/person/day. The main component of solid waste is food waste, which comprises 37% of the total waste generated, followed by plastic waste at 31%, paper waste 14.7%, glass 7.2%, and metal 6.3%. The remainder (3.8%) includes bulky waste, furniture, wood, etc. Although the solid waste generation rate is comparatively low, it will create a negative impact on the environment and public health if proper management of solid waste is not practiced.

Faure, F., et al. (2015). "Plastic pollution in Swiss surface waters: nature and concentrations, interaction with pollutants. (Special Issue: Microplastics in the environment.)." Environmental Chemistry **12**(5): 582-591.

Marine microplastic (<5 mm) water pollution has met growing public and scientific interest in the last few years. The situation in freshwater environments remains largely unknown, although it appears that they play an important role as part of the origin of marine pollution. Apart from the physical impacts on biota, chemical effects are to be expected as well, especially with smaller particles. This study aims at assessing plastic abundance in Lakes Geneva, Constance, Neuchatel, Maggiore, Zurich and Brienz, and identifying the nature of the particles, potential ingestion by birds and fishes, and the associated pollutants. Lake surface transects and a few rivers were sampled using a floating manta net, and beach sediments were analysed. Plastics were sorted by type (fragments, pellets, cosmetic beads, lines, fibres, films, foams) and composition (polypropylene, polyethylene, polystyrene, etc.); fish and water birds were dissected to assess their potential exposure, and analyses were conducted on the hydrophobic micropollutants adsorbed to the microplastics as well as some potentially toxic additives they contained. Evidence of this pollution is shown for all lakes, microplastics of all types and diverse composition having been found in all samples. Birds and fish are prone to microplastic ingestion, and all the tested chemicals (both adsorbed micropollutants and contained additives) were found above the detection limit, and often the quantification limit. The sources and their respective contribution need to be confirmed and quantified, and the ecotoxicological effects need further investigation. Other questions remain open, including the transport and fate of plastic particles in the environment.

Faure, F., et al. (2015). "An evaluation of surface micro- and mesoplastic pollution in pelagic ecosystems of the Western Mediterranean Sea." Environmental science and pollution research international **22**(16): 12190-12197.

This study examines the distribution, abundance and characteristics of surface micro- and mesoplastic debris in the Western Mediterranean Sea. 41 samples were collected in 2011 (summer) and 2012 (summer). Results, firstly, revealed that micro- (<5 mm) and mesoplastic debris were widely and uniformly distributed in this area with average concentrations of 130,000 parts/km 2 and 5700 parts/km2, respectively. Importantly, a strong correlation between micro- and mesoplastic concentrations was identified. Secondly, a classification based on the shape and appearance of microplastics indicated the predominant presence of fragments (73 %) followed by thin films (14 %). Thirdly, the average mass ratio of microplastic to dry organic matter has been measured at 0.5, revealing a significant presence of microplastics in comparison to plankton. Finally, a correction method was applied in order to correct wind mixing effect on microplastics' vertical distribution. This data allows for a comprehensive view, for the first time, of the spatial distribution and nature of plastic debris in the Western Mediterranean Sea.

Faussone, G. C. (2018). "Transportation fuel from plastic: Two cases of study." Waste Management **73**: 416-423.

Synthesis of liquid fuels from waste is a promising pathway for reducing the carbon footprint of transportation industry and optimizing waste management towards zero landfilling. The study of commercial plants that conduct pyrolysis of plastics from post-consumer recycled materials and directly mine from old landfills without any pre-treatment has revealed two cases that show the feasibility of manufacturing transportation fuels via these methods. Pyrolysis oil, consisting of almost 26% hydrocarbons within the gasoline range and almost 70% within the diesel range, is upgraded to transportation fuel in the existing refinery. A batch operating plant is able to deliver relatively good quality pyrolysis oil from post-consumer plastic waste, owing to the catalyst employed. Simple distillation was also evaluated as an alternative and cheaper upgrading process into transportation fuels, meeting EN590 diesel and ISO8217 marine fuel standards. Even though the two installations are outside the European Union, they represent good examples of the "circular economy" concept envisaged by the European Union via its ambitious "Circular Economy Package [1]", providing real world data for comparison with other experimental and lab results.

Fauziah, S. H., et al. (2015). "Plastic debris in the coastal environment: The invincible threat? Abundance of buried plastic debris on Malaysian beaches." Waste Management and Research **33**(9): 812-821.

Studies on marine debris have gained worldwide attention since many types of debris have found their way into the food chain of higher organisms. Thus, it is crucial that more focus is given to this area in order to curb contaminations in sea food. This study was conducted to quantify plastic debris buried in sand at selected beaches in Malaysia. Marine debris was identified according to size range and distribution, and this information was related to preventive actions to improve marine waste issues. For the purpose of this study, comparison of plastic waste abundance between a recreational beach and fish-landing beaches was also carried out, since the different beach types represent different activities that produce debris. Six beaches along the Malaysian coastline were selected for this study. The plastic types in this study were related to the functions of the beach. While recreational beaches have abundant quantities of plastic film, foamed plastic including polystyrene, and plastic fragment, fish-landing beaches accumulated line and foamed plastic. A total of 2542 pieces (265.30 g m⁻²) of small plastic debris were collected from all six beaches, with the highest number from Kuala Terengganu, at 879 items m⁻² on Seberang Takir Beach, followed by Batu Burok Beach with 780 items m⁻². Findings from studies of Malaysian beaches have provided a clearer understanding of the distribution of plastic debris. This demonstrates that commitments and actions, such as practices of the reduce, reuse, recycle (3R) approach, supporting public awareness programmes and beach clean-up activities, are essential in order to reduce and prevent plastic debris pollution. Copyright © The Author(s) 2015.

Fava, F., et al. (2014). "Investigation of polyvinylchloride biodegradation by microbial consortia enriched from digested sludges." New Biotechnology **1)**: S141-S142.

During last decades, production of synthetic plastics has increased dramatically to reach approximately 280 million tonnes in 2011. The accumulation of plastic waste in the environment is raising concerns about its effects both on human and the environment. In EU, about 40% of plastic waste is currently disposed of in landfills, where partially undergoes photodegradation, producing microplastics which can absorb toxins and toxic chemicals and together with plasticizers enter the marine environment and thus the food chain, where they exert toxic effects. Furthermore, colonization of plastics by sessile organisms may permit transport of alien species in the ocean environment and may threaten marine biodiversity. Therefore it is necessary to find new eco-friendly techniques for safe handling and degradation of plastic wastes. In this work, ten microbial communities enriched from waste plastics from digested sludges were screened for their capability of degrading non-pretreated films of polyvynil chloride (PVC) and polypropylene (PP). After six months of anaerobic incubation in the presence of the plastic films as main carbon source, growth of microbial community was recorded in all enriched consortia. Thermogravimetric analysis (TGA) performed on PP and PVC films showed biodegradation of only PVC plastic film by 5 communities. Further analyses, including ATR-FTIR and SEM analyses to analyze surface film modifications and GPC for the evaluation of the reduction of the polymer molecular weight on biodegraded PVC films are ongoing.

Favoino, E., et al. (2014). "Expression of the transcription factor forkhead box E3 (FOXE3) in monocytes from patients with systemic sclerosis and correlation with their serological profile." Annals of the Rheumatic Diseases. Conference: Annual European Congress of Rheumatology of the European League Against Rheumatism, EULAR **73**(SUPPL. 2).

Background The process of epithelial-mesenchymal transition (EMT) has been regarded in systemic sclerosis (SSc) as one of the possible mechanisms favouring tissue accumulation of monocyte-derived fibrocytes or myofibroblasts, which contribute to tissue fibrosis [1]. Forkhead box E3 (FOXE3) is a transcription factor involved in EMT of lens epithelial cells (LEC). Its expression progressively decreases with the migration of LEC from the anterior to the equatorial region. FOXE3 expression cessation marks initiation of fiber differentiation, suggesting that the

loss of FOXE3 expression favors a pro-fibrotic phenotype [2]. No data are available on mRNA FOXE3 expression in sites other than LEC Objectives In this study, we investigated the FOXE3 mRNA expression in unstimulated and TGF-beta- or IL-4-stimulated monocytes from SSc patients and healthy blood donors (HBD), to established whether i) FOXE3 is constitutively expressed in human monocytes; ii) FOXE3 expression can be modulated in vitro by cytokines involved in SSc profibrotic process; iii) there is any association between FOXE3 expression and a particular SSc serological profile Methods PBMC were isolated from heparinized peripheral blood of 9 patients with SSc (5 Scl70⁺; 4 Scl70⁻), and 3 HBD by Ficoll-Hypaque density gradient centrifugation. Monocytes (CD14⁺) were isolated by positive selection using microbeads. Cells (1x10⁶ cells/ml) were stimulated TGF-beta (10 ng/ml) and IL-4 (40 ng/ml) for 14 days. mRNA was extracted and semi-quantitative PCR was performed to assess FOXE3 expression. GM-CSF stimulation (50ng/ml) was used as positive control. The levels of FOXE3 mRNA were quantified by normalizing its expression against that of GAPDH. Expression was measured as mean relative expression level (MREL). Variation of expression was measured as mean fold change (MFC) Results Similar baseline levels of FOXE3 mRNA was observed in unstimulated CD14⁺ cells from SSc patients and HBD (MREL SSc=0.32; HBD=0.26). As expected, GM-CSF stimulation of CD14⁺ cells from SSc patients and HBD markedly up-regulated FOXE3 expression (SSc: MFC=3.24; HBD: MFC=1.84). TGF-beta and IL-4 behaved similarly to GM-CSF in enhancing FOXE3 expression in CD14⁺ cells from all HBD (MFC<inf>TGF-beta</inf>=1.35; MFCIL-4=1.59) and from 3 out 4 Scl70- patients (MFC<inf>TGF-beta</inf>=2.36; MFCIL-4=2.9), being the expression unchanged in the remaining Scl70- patient. By contrast, in the 4 Scl70⁺ patients, CD14⁺FOXE3 expression markedly decreased following these cytokines stimulation (MFC<inf>TGF-beta</inf>=0.28; MFCIL-4=0.31) Conclusions This is the first study to demonstrate FOXE3 mRNA expression in monocytes from HBD and SSc patients, and its differential expression following TGF-beta and IL-4 stimulation, correlating with the serological profile of SSc patients. The data suggest that the down-regulation of FOXE3 induced by TGF-beta and IL-4 may direct monocytes toward a more profibrotic phenotype in Scl70⁺ as compared to Scl70- patients. The relationship of this finding with the anti-FOXE3 antibodies recently detected in SSc sera [3], remains to be determined.

Favoino, E., et al. (2014). "Expression of the transcription factor forkhead box E3 (FOXE3) in peripheral blood mononuclear cells of patients with systemic sclerosis." Clinical and Experimental Rheumatology **81)**: S63.

Introduction. The process of epithelial (or endothelial)-mesenchymal transition (EMT) is at the basis of generation of renal and pulmonary fibrosis, and, in systemic sclerosis (SSc), has been regarded as one of the possible mechanism for accumulation of lymphocyte/monocyte-derived fibrocytes or myofibroblasts, which contribute to tissue fibrosis. Forkhead box E3 (FOXE3) is a transcription factor involved in EMT of lens epithelial cells (LEC). Its expression progressively decreases with the migration of LEC from the anterior to the equatorial region. FOXE3 expression cessation marks initiation of fiber differentiation. No data are available on FOXE3 expression in sites other than LEC. Therefore, in this study, we investigate FOXE3-expression in peripheral blood mononuclear cells (PBMC) of SSc patients, to eventually explore its potential role in the generation of lymphocyte/monocyte-derived fibrocytes or myofibroblasts, hence of tissue fibrosis. Material and Methods. PBMC were isolated from heparinized peripheral blood of 10 patients with SSc and 7 healthy blood donors (HBD) by Ficoll-Hypaque density gradient centrifugation. Lymphocyte subsets (CD2+, CD19+) and monocytes (CD14+) were isolated by positive selection using microbeads. CD2+ cells (5x105 cells/ml) were stimulated with TGF-beta

(1mug/ml) and IL-6 (10 ng/ml) for 7 days. Total RNA was extracted and semi-quantitative PCR was performed to assess FOXE3 gene expression. The levels of FOXE-3 mRNA were quantified by normalizing its expression against that of GAPDH. Expression was measured as mean relative expression level (MREL). Variation of expression was measured as mean fold change (MFC). Results. FOXE3 was expressed in CD2+, CD19+ and CD14+ cells from SSc patients and HBD. Specifically, expression level of SSc was similar to that of HBD in both CD19+ (MREL, SSc= 0.02; HBD= 0.08) and CD14+ (MREL SSc= 0.52; HBD=0.61) cells, while in CD2+ cells, the expression in HBD was higher (MREL=0.58) than in SSc patients (MRE 0.22). FOXE3 expression markedly increased following TGF-beta stimulation in CD2+ cells from all HBD (MFC=1.43) and 5 SSc patients (MFC 1.94), whereas it decreased in CD2+ cells from the remaining 5 SSc patients (MFC = 0.71). IL-6 stimulation had no significant effect on FOXE-3 expression in CD2+ cells from both SSc patients and HBD. Conclusion. This study has shown, for the first time, the FOXE3 expression in PBMC of SSc patients, and an heterogeneity in the expression level changes in SSc CD2+ cells following stimulation with TGF-beta but not IL-6. Whether this heterogeneity parallels that of clinical manifestations remains to be determined.

Fay, S. P., et al. (1991). "Real-time analysis of the assembly of ligand, receptor, and G protein by quantitative fluorescence flow cytometry." Biochemistry **30**(20): 5066-5075.

We describe a general approach for the quantitative analysis of the interaction among fluorescent peptide ligands (L), receptors (R), and G proteins (G) using fluorescence flow cytometry. The scheme depends upon the use of commercially available fluorescent microbeads as standards to calibrate the concentration of fluorescent peptides in solution and the receptor number on cells in suspension. We have characterized a family of fluoresceinated formyl peptides and analyzed both steady-state and dynamic aspects of ligand formyl peptide-receptor interactions in digitonin-permeabilized human neutrophils. Detailed receptor-binding studies were performed with the pentapeptide N-formyl-Met-Leu-Phe-Phe-Lys-fluorescein. Equilibrium studies showed that GTP [S] caused a loss of binding affinity of approximately two orders of magnitude, from approximately 0.04 nM (LRG) to approximately 3 nM (LR), respectively. Kinetic studies revealed that this change in affinity was principally due to an increase in the dissociation rate constants from approximately 1 x 10(-3) s-1 (LRG) to approximately 1 x 10(-1) s-1 (LR). In contrast, the association rate constants in the presence and absence of guanine nucleotide (approximately 3 x 10(7) s-1 M-1) were statistically indistinguishable and close to the diffusion limit. In the presence of guanine nucleotide (LR), the kinetic data were adequately fit by a single-step reversible-binding model. In the absence of guanine nucleotides, not all receptors have rapid access to G to form the LRG ternary complex. Mathematically, those R that have rapid access to G are either precoupled to R or the association of G with R is fast compared to the association of L with R. The physiological consequences of coupling heterogeneity are discussed.

Fazey, F. M. and P. G. Ryan (2016). "Biofouling on buoyant marine plastics: An experimental study into the effect of size on surface longevity." Environmental Pollution **210**: 354-360.

Recent estimates suggest that roughly 100 times more plastic litter enters the sea than is found floating at the sea surface, despite the buoyancy and durability of many plastic polymers. Biofouling by marine biota is one possible mechanism responsible for this discrepancy. Microplastics (<5 mm in diameter) are more scarce than larger size classes, which makes sense because fouling is a function of surface area whereas buoyancy is a function of volume; the smaller an object, the greater its relative surface area. We tested whether plastic items with high surface area to volume ratios sank more rapidly by submerging 15 different sizes of

polyethylene samples in False Bay, South Africa, for 12 weeks to determine the time required for samples to sink. All samples became sufficiently fouled to sink within the study period, but small samples lost buoyancy much faster than larger ones. There was a direct relationship between sample volume (buoyancy) and the time to attain a 50% probability of sinking, which ranged from 17 to 66 days of exposure. Our results provide the first estimates of the longevity of different sizes of plastic debris at the ocean surface. Further research is required to determine how fouling rates differ on free floating debris in different regions and in different types of marine environments. Such estimates could be used to improve model predictions of the distribution and abundance of floating plastic debris globally.

Fedrigo, M., et al. (2013). "HLA-DRB1 typing by micro-bead array assay identifies the origin of early lymphoproliferative disorder in a heart transplant recipient." American Journal of Transplantation **13**(3): 802-807.

We report the case of a 68-year-old woman who underwent heart transplantation for hypertrophic cardiomyopathy. Two months after the transplant she developed mild fever and dyspnea with a marked drop in left ventricle ejection fraction of 31%. Coronary angiography was negative for cardiac allograft vasculopathy. Endomyocardial biopsy revealed ischemic damage with no evidence of acute cellular rejection, antibody-mediated rejection or viral myocarditis. A neoplastic process was suspected even though full-body computerized tomography was negative for malignancy. The patient died 4 months after transplantation. The autopsy showed acute antero-septal myocardial infarction due to a nodular epicardial EBV-related posttransplant lymphoproliferative disorder (PTLD) infiltrating the left anterior descending coronary artery with occlusive neoplastic thrombosis. We highlight two major aspects of this case: (1) the unusual occurrence of early PTLD involving the cardiac allograft and causing a fatal outcome, (2) the application of an immunological technique for HLA-DRB1 typing to posttransplant paraffin-embedded autopsy material to identify the recipient origin of this early malignancy, thus excluding a possible donor-transmitted neoplasm. The authors report the application of HLA typing technique to identify neoplastic donor/recipient cell origin from a tumor mass infiltrating the coronary artery of a heart allograft. © 2013 The American Society of Transplantation and the American Society of Transplant Surgeons.

Fehniger, T. A., et al. (2014). "Preliminary results of a phase 1/2 clinical trial of CNDO-109-activated allogeneic natural killer cells in high risk acute myelogenous leukemia patients in first complete remission." Blood. Conference: 56th Annual Meeting of the American Society of Hematology, ASH **124**(21).

BACKGROUND We previously reported that resting human peripheral blood NK cells can be primed to kill NK-resistant tumor cells by co-incubation with a lysate of the leukemia cell line CTV-1. CNDO-109 is a clinical-grade CTV-1 lysate that primes NK cells ex-vivo to kill NK-resistant acute myeloid leukemia (AML) cells. CNDO-109-activated NK cells can be cryopreserved and remain primed when thawed. Incubation or treatment with IL-2 is not required. We report preliminary safety, outcome and NK chimerism data from an ongoing Phase 1/2 transitional clinical trial of CNDO-109-NK cells. METHODS A 3x3 dose escalation phase 1 trial was opened in 2013 for patients with AML in 1st CR with high-risk disease and no conventional treatment options. Patients were given preparative chemotherapy of cyclophosphamide and fludarabine on Study Days -6 to -2, followed on day 0 by a single dose of CNDO-109-activated NK cells at the following doses; cohort 1 = 3x10⁵, cohort 2 = 1x10⁶, cohort 3 = up to 3x10⁶ cells/kg recipient body weight. The MTD will set the dose for the transitional phase 2 trial. CNDO-109-NK cells were generated from a single apheresis collection from

HLA-haploidentical related donors. NK cells were isolated with anti-CD56 microbeads (CliniMACS, Miltenyi Biotec) and co-incubated with CNDO-109 lysate (Coronado Biosciences) overnight under cGMP conditions. After lysate removal cells were cryopreserved in dosed aliquots and released for infusion. Exogenous IL-2 was not used. Quality control testing of the final product included NK purity (>50%), viability (> 70%), potency, sterility, mycoplasma and endotoxin. Residual T cell contamination (<104 cells/kg patient body weight) was a lot release safety criterion. Patients were assessed for safety and efficacy whilst expansion, proliferation and persistence of donor NK cells were assayed by molecular-based chimerism techniques, and by flow cytometry, where informative markers were available. Pre- and post-treatment samples from cohort 3 patients are being tested for flow cytometric and molecular MRD (University of Washington - Walter, R.B.2013 and NextGene Sequencing). RESULTS Seven eligible patients have been enrolled. All products met lot release and contained activated NK cells as determined by killing of NK resistant Raji cells as well as increased expression of CD69 & CD25: No infusional toxicity, adverse events attributed to NK therapy, GvHD nor deaths have been reported. As expected, all patients experienced transient myelosuppression (approx. 2 weeks). 3 patients suffered early relapse post-treatment (2 in cohort 1, 1 in cohort 2; average time to relapse from CR1 for these 3 patients was 104 days). In 5 of 7 evaluable patients, persistence of donor activated NK cells was observed from Day +7 post-infusion (chimerism = 1%-84%) to as late as day +56 in one patient. Flow cytometric comparison of donor NK cells and patient NK cells in the same sample by selective gating on the mismatched HLA allele showed that circulating donor NK cells typically differed from recipient NK cell in higher expression of NKG2A (e.g. 63.5% vs 2.7%), CD57 (e.g. 80.5% vs 13.2%) and CD69 (e.g. 11.6% vs 2.52%) suggesting a more normal, mature and activated phenotype than the endogenous host NK population. Even after loss of circulating donor primed NK cells, 2 of the 3 patients tested showed persistence of low levels of activated autologous NK cells (~10-20% of circulating NK) exceeding the numbers circulating pre-CNDO-109 NK treatment, out to Day +56, suggesting that the therapy may induce endogenous NK activation to enhance the patients' innate immunity to AML. CONCLUSIONS This establishes proof of concept that CNDO-109-NK can persist transiently in patients with lasting microchimerism for > 1 month and can induce activation of endogenous NK cells in patients treated without cytokine administration. To date 4 of the 7 patients enrolled remain relapse free (max. = 410 days post CR1 date). These results highlight the potential of CNDO-109-NK cells in the treatment of

Fei, Y., et al. (2019). "Response of soil enzyme activities and bacterial communities to the accumulation of microplastics in an acid cropped soil." Science of the Total Environment: 135634.

The ecological stress of microplastics (MPs) contamination in agroecosystems raise worldwide concerns. However very few studies concentrated on the effects of MPs exposure on soil microbial community. The alterations of enzymatic activities and bacterial communities were assayed by spiking 1% and 5% (w/w) of polyethylene (PE) and polyvinyl chloride (PVC) MPs in an acid soil. The results showed that both PE and PVC addition inhibited fluorescein diacetate hydrolase activity and stimulated urease and acid phosphatase activities, and declined the richness and diversity of the bacterial communities. More severe effects were observed in the PE treated soils compared to the PVC treated soils generally. The relative abundances of families Burkholderiaceae increased significantly ($p < .05$) after MPs addition, suggesting the bacteria associated with nitrogen fixation stimulated by the MPs input. Meanwhile, significant ($p < .05$) decline of Sphingomonadaceae and Xanthobacteraceae after addition of 5% PVC and 1% PE MPs, respectively implied that MPs might inhibit the biodegradation of xenobiotics in the soil. Mover, the PICRUSt analysis demonstrated that membrane transporter was a sensitive

prediction functional gene of microplastics exposure in the soil. Future studies could be focused on the role of MPs on the regulation of nitrogen cycling and organic compounds degradation in soils.

Feil, A., et al. (2017). "Separate collection of plastic waste, better than technical sorting from municipal solid waste?" Waste Management & Research **35**(2): 172-180.

The politically preferred solution to fulfil legal recycling demands is often implementing separate collection systems. However, experience shows their limitations, particularly in urban centres with a high population density. In response to the European Union landfill directive, mechanical biological waste treatment plants have been installed all over Europe. This technology makes it possible to retrieve plastic waste from municipal solid waste. Operators of mechanical biological waste treatment plants, both in Germany and the Netherlands, have started to change their mechanical separation processes to additionally produce plastic pre-concentrates.

Fela, J. (2014). "Dutch lead EU in microbead ban." Frontiers in Ecology & the Environment **12**(10): 541-541.

The article offers information related to decision of the government of The Netherlands to completely ban the use of microplastics from cosmetics, announced by Dutch State Secretary for the Ministry of Infrastructure and the environment, Wilma Mansveld as of December 2014.

Feld, G. K., et al. (2011). "Particle formation and risk of embolization during transseptal catheterization: comparison of standard transseptal needles and a new radiofrequency transseptal needle." Journal of Interventional Cardiac Electrophysiology **30**(1): 31-36.

OBJECTIVE: Anecdotally, the Brockenbrough transseptal needle generates plastic particles through a process of skiving (shaving off particles), when advanced through the dilator and sheath. This study was performed to assess particle creation by the Brockenbrough needle during transseptal catheterization. We explore strategies that may reduce this phenomenon, including use of the Brockenbrough stylet and a radiofrequency transseptal needle.

METHOD: In vitro simulations of transseptal catheterization were performed using Brockenbrough transseptal needles and a new radiofrequency transseptal needle. Particles that were created during advancement of transseptal needles through the sheath and dilator were collected and analyzed. Particles in the visible range of 50 mum to 4 mm were identified using a light microscope, whereas particles in the sub-visible, yet clinically relevant range of 10 to 50 mum, were counted using a light obscuration method.

RESULTS: All simulated procedures using the Brockenbrough transseptal needles, with or without a stylet, generated visible particles. Simulated procedures with the radiofrequency transseptal needle generated no visible particles. A greater number of sub-visible particles were generated with the standard Brockenbrough transseptal needle (BKR-1) without stylet compared with the standard Brockenbrough needle (BRK-1) with stylet, the Brockenbrough extra sharp (BRK-1XS) needle with or without stylet, and the radiofrequency needle (NRG C1).

CONCLUSION: Clinically relevant particles, both visible and sub-visible, with the potential for causing embolic complications, are generated by the BRK-1 needle without stylet. Use of a stylet in the BRK-1 needle, or the BRK-1XS needle with or without stylet, appears to reduce the size and amount of particles created. The NRG C1 needle appears to eliminate visible particles and is comparable to the BRK-1 with stylet and the BRK-1XS with or without stylet in generation of sub-visible particles. Important steps can be taken to minimize the creation of particles during the advancement of the BRK-1 through the transseptal sheath and dilator.

Feldman, T. B., et al. (2015). "Changes in spectral properties and composition of lipofuscin fluorophores from human-retinal-pigment epithelium with age and pathology." Analytical and bioanalytical chemistry **407**(4): 1075-1088.

Issue Title: A different way of looking at vibrational hyperspectral data/Micellar extraction for the analysis of Alzheimer's disease brain proteome/Quantification of polyolefin microplastics in personal-care products/Removal of Triton X-100 by microdialysis Fundus autofluorescence mostly originates from bisretinoid fluorophores in lipofuscin granules, which accumulate in retinal-pigment-epithelium cells with age. The dynamics of accumulation, photo-oxidation, and photodegradation of bisretinoids during aging or in the presence of pathology have been insufficiently investigated. Changes in spectral properties and composition of human lipofuscin-granule fluorophores with age and pathology have now been investigated by a high-performance liquid chromatography method using spectrophotometric and fluorescent detectors connected in series. It was found that: (i) N-retinylidene-N-retinylethanolamine (A2E) fluorescence intensity is not predominant in the chloroform extract of human-cadaver-eye retinal pigment epithelium studied; bisretinoid photo-oxidation and photodegradation products have much higher fluorescent properties; (ii) the relative emission maximum in the fluorescence spectrum of suspended retinal-pigment-epithelium cells obtained from an individual human-cadaver eye without pathology is irrespective of donor age and falls within the range 575±15 nm; in two cadaver eyes with signs of age-related macular degeneration, emission maxima were shifted by 23-36 nm towards the shortwave region; and (iii) the ratio of bisretinoid photo-oxidation and photodegradation products to unoxidized bisretinoids in the chloroform extract of cadaver-eye retinal pigment epithelium increases with donor age, from 0.69±0.03 to 1.32±0.04. The differences in fluorescence properties between chloroform extracts obtained from cadaver eyes with and without signs of age-related macular degeneration could be used to increase the potential of fundus autofluorescence imaging as a noninvasive diagnostic method.

Feldmeyer, N., et al. (2009). "Arginine deficiency leads to impaired cofilin dephosphorylation and actin reorganization in activated human T lymphocytes." European Journal of Immunology **1)**: S159.

Objectives: The amino acid arginine is fundamentally involved in the regulation of the immune response during infection, inflammatory diseases and tumor growth. Arginine deficiency (e.g. due to the myeloid cell enzyme arginase) inhibits proliferation and effector functions of activated T lymphocytes. In this study we analysed intracellular mechanisms mediating T cell suppression in the absence of arginine. Method(s): In the absence or presence of arginine human T lymphocytes were stimulated with anti-CD3/anti-CD28-coupled microbeads or the Raji B cell line (as antigen presenting cells, APC) together with superantigen. T cell lysates were separated and comparatively analysed by 2D-gelelectrophoresis. Reproducibly overrepresented protein spots in the absence of arginine were sequenced by mass spectrometry and results were confirmed by Western Blot and various functional assays (proliferation assays, flow cytometry, ELISA, ImageStream Technology). Result(s): Our proteomic analysis revealed an impaired dephosphorylation of the actin-binding protein cofilin upon T cell activation in the absence of arginine. Normally, anti-CD3/anti-CD28-mediated T cell activation leads to dephosphorylation of cofilin and this plays an important role in the reorganization of the actin cytoskeleton, T cell proliferation and cytokine secretion of activated T cells. We show that the persistence of phospho-cofilin upon arginine withdrawal correlates with altered F-actin generation. While Calcium flux is unimpaired upon activation in arginine-deficient medium, cytokine synthesis is differentially regulated in human T lymphocytes. In contrast to impaired IFN-g secretion, T lymphocytes produce IL-2 irrespective of the extracellular arginine concentration. Finally, since the binding of cofilin to actin is important for immunological synapse formation we analysed the

accumulation of CD2 and CD3 in the evolving immunological synapse between T cell/APC conjugates. We demonstrate impairment of these crucial steps of immunological synapse formation in the context of arginine deficiency. Conclusion(s): Our data show for the first time an impairment of T lymphocyte actin reorganization and immunological synapse formation due to arginine deficiency. These findings clarify further the profound immune suppression in the context of chronic inflammation and cancer.

Felice, B. d., et al. (2019). "Polystyrene microplastics ingestion induced behavioral effects to the cladoceran Daphnia magna." Chemosphere **231**: 423-431.

Microplastic (micro Ps) contamination represents a dramatic environmental problem threatening both aquatic and terrestrial organisms. Although several studies have highlighted the presence of micro Ps in aquatic environments, the information regarding their toxicity towards organisms is still scant. Moreover, most of the ecotoxicological studies of micro Ps have focused on marine organisms, largely neglecting the effects on freshwater species. The present study aimed at exploring the effects caused by 21-days exposure to three concentrations (0.125, 1.25 and 12.5 micro g/mL) of two differently sized polystyrene microplastics (P micro Ps; 1 and 10 micro m) to the Cladoceran Daphnia magna. The ingestion/egestion capability of daphnids (<24 h) and adults, the changes in individual growth and behavior, in terms of changes in swimming activity, phototactic behavior and reproduction, were investigated. Both particles filled the digestive tract of daphnids and adults within 24 h of exposure at all the tested concentrations. Ingested P micro Ps remained in the digestive tract even after 96 h in a clean medium. For both particles, an overall increase in body size of adults was noted at the end of the exposure to the highest tested concentrations, accompanied by a significant increase in swimming activity, in terms of distance moved and swimming velocity, and by an alteration of the phototactic behavior. A significant increase in the mean number of offspring after the exposure to the highest P micro Ps concentrations of different size was recorded. Polystyrene micro Ps can affect behavioral traits of D. magna leading to potentially harmful consequences on population dynamics of this zooplanktonic species.

Fendall, L. S. and M. A. Sewell (2009). "Contributing to marine pollution by washing your face: microplastics in facial cleansers." Marine Pollution Bulletin **58**(8): 1225-1228.

Plastics pollution in the ocean is an area of growing concern, with research efforts focusing on both the macroplastic (>5mm) and microplastic (<5mm) fractions. In the 1990 s it was recognized that a minor source of microplastic pollution was derived from liquid hand-cleansers that would have been rarely used by the average consumer. In 2009, however, the average consumer is likely to be using microplastic-containing products on a daily basis, as the majority of facial cleansers now contain polyethylene microplastics which are not captured by wastewater plants and will enter the oceans. Four microplastic-containing facial cleansers available in New Zealand supermarkets were used to quantify the size of the polythelene fragments. Three-quarters of the brands had a modal size of <100 microns and could be immediately ingested by planktonic organisms at the base of the food chain. Over time the microplastics will be subject to UV-degradation and absorb hydrophobic materials such as PCBs, making them smaller and more toxic in the long-term. Marine scientists need to educate the public to the dangers of using products that pose an immediate and long-term threat to the health of the oceans and the food we eat.

Feng, C. and X. Q. Ma (2009). "The energy consumption and environmental impacts of a color TV set in China." Journal of Cleaner Production **17**(1): 13-25.

The present study analyses the different processes followed during color TV set production along with the energy consumption and the environment emissions in each stage. The purpose is to identify "hot-spots", i.e. parts of the life cycle important to the total environmental impact. The analysis is performed using life cycle assessment (LCA) methodology, which is a method used to identify and quantify in the environmental performance of a process or a product from "cradle to grave". LCA methodology provides a quantitative basis for assessing potential improvements in the environmental performance of a system throughout the life cycle. The system investigated includes the production of manufacturing materials, transport of manufacturing materials, color TV set manufacturing, transport of color TV sets, use of color TV sets, discarding color TV sets and partial plastic waste energy utilization. The environmental burdens that arise from color TV sets are mainly due to air emissions derived from fossil fuel utilization.

Feng, L. J., et al. (2018). "Role of extracellular polymeric substances in the acute inhibition of activated sludge by polystyrene nanoparticles." Environmental Pollution **238**: 859-865.

Microplastics and nanoplastics in aquatic systems have become a global concern because of their persistence and adverse consequences to ecosystems and potentially human health. Though wastewater treatment plants (WWTPs) are considered a potential source of microplastics in the environment, the role of extracellular polymeric substances (EPS) of activated sludge on the fate of nanoplastics is not clear. In this study, the role of EPS in the influence of polystyrene nanoparticles (PS-NPs) on the endogenous respiration of activated sludge was investigated for the first time. The results showed that the acute inhibition of activated sludge by PS-NPs was enhanced with increasing PS-NPs concentration. X-ray photoelectron spectroscopy (XPS) results indicate that the functional groups involved in the interactions between PS-NPs and EPS were carbonyl and amide groups and the side chains of lipids or amino acids. Furthermore, the Fourier transform infrared (FTIR) spectroscopy results show that the protein secondary structures in EPS were changed by PS-NPs and lead to the bioflocculation of activated sludge, which provides a better understanding on the fate of nanoplastics in WWTPs.

Feng, Y., et al. (2018). "Emerging investigator series: inhibition and recovery of anaerobic granular sludge performance in response to short-term polystyrene nanoparticle exposure." Environmental Science: Water Research & Technology **4**(12): 1902-1911.

Anaerobic treatment systems play an important role in treating nanoplastic-containing wastewater, such as textile dyeing wastewater. However, the influence of nanoplastics on anaerobic granular sludge (AGS), a key parameter determining the performance of anaerobic bioreactors, has not received sufficient attention. In this study, inhibition and recovery of AGS performances in response to short-term polystyrene (PS) nanoparticle exposure were investigated. Results showed that cationic PS nanoparticles (PS-NH₂) had higher inhibition capacity on methane production than anionic PS nanoparticles (PS-SO₃H). At the end of the first cycle, cumulative methane production was reduced by 22.98% and 17.47% by exposure to 20 micro g mL⁻¹ PS-NH₂ and 100 micro g mL⁻¹ PS-SO₃H, respectively. However, the system recovered in the second cycle of experiments. Volatile fatty acid (VFA) concentration had no obvious relationship to PS nanoparticle addition. Both functionalized PS nanoparticles could change the protein secondary structures of extracellular polymeric substances (EPS) and penetrate EPS matrix into AGS at specific concentration. The response of AGS was explored through bacterial and archaeal communities as well as the relative abundance of methanogenic functional genes. These results elucidated the complex interactions of AGS, EPS and PS-NPs, which will expand the knowledge on the stability of AGS under short-term exposure to nanoplastics.

Feng, Z., et al. (2019). "The accumulation of microplastics in fish from an important fish farm and mariculture area, Haizhou Bay, China." Science of the Total Environment **696**: 133948.

Marine fisheries and aquaculture can match growing demand for marine protein from an increasing population. However, the microplastics (MPs) in marine environments may pose a threat to human health through food chains by seafood consumption. The MPs have been found lodged in the digestive tracts and other tissues of various sea animals, nevertheless, little is known in regard to the accumulation of MPs in fish from major fish farms and mariculture areas, especially in non-digestive tissues of fishes. This study investigated the accumulation of MPs in six major wild fish species (including Thryssa kammalensis, Amblychaeturichthys hexanema, Odontamblyopus rubicundus, Cynoglossus semilaevis, Chaeturichthys stigmatias and Collichthys lucidus), both in digestive and non-digestive tissues, from an important fish farm and mariculture area, Haizhou Bay, China. All fishes had items that were identified as MPs. The highest abundance of MPs was 22.21+/-1.70items/individual or 11.19+/-1.28items/g in T. kammalensis, which is filter-feeding and usually inhabits in estuary. The lowest abundance of MPs was observed in C. semilaevis (13.54+/-2.09items/individual) and C. stigmatias (1.61+/-0.56items/g). The abundance of MPs exponentially increased with the decrease of MPs size. The MPs were dominated by fiber in shape, black or grey in colour and cellophane in composition. As to different tissues, the total number of MPs on skin (800) or in gills (746) was higher than that in gut (514). In terms of skin, the abundances of MPs in three species of scaleless fish with mucus (A. hexanema, C. stigmatias and O. rubicundus) were generally higher than other three fishes with scales (C. lucidus, C. semilaevis and T. kammalensis), implying the potential high risk of scaleless fish consumption for human health in Haizhou Bay. More in-depth studies need to focus on the scaleless fish through mucus adsorbing enormous MPs.

Ferguson, J. C. (1995). "The Structure and Mode of Function of the Water Vascular System of a Brittlestar, Ophioderma appressum." Biological Bulletin **188**(1): 98-110.

Unlike the asteroids, which have large madreporite structures, the ophiuroid Ophioderma appressum possesses only two small hidden madreporite pores. Experiments with labeled amino acids, fluorescent microbeads, and surgical obstruction show that small amounts of seawater do routinely enter these pores and become distributed throughout the water vascular system; but this uptake does not seem essential. The flagellated stone canal draws its fluid from the axial sinus, to which the pores connect through a tortuous ampulla. Thus, the stone canal mainly recirculates fluid from hyponeural (perihemal) passages. That perihemal fluid is augmented by seawater from the pores. As perihemal fluid moves towards the stone canal, it passes by or through the axial organ, where nutritive materials may be removed and passed into the hemal channels. Pressure generated by the stone canal forces flow out to the oral tube feet, polian vesicles, and, through valves, eventually to the arm tube feet. Inflation of the tube feet also might occur through osmotic mechanisms, but their activity was not impeded by raising the external osmotic level with dextran. Observations indicate that negative coelomic pressures must be generated during respiratory movements, and these could lead to sufficient body fluid production (by filtration) that the need for substantive madreporitic inflows would be alleviated.

Ferguson, K. (2010). "NOAA surveys plankton and plastic." Frontiers in Ecology & the Environment **8**(10): 511-511.

The article focuses on the plankton and plastic transect by the Fisheries Service researchers of U.S. National Oceanic and Atmospheric Administration (NOAA). It says that the funnel-shaped device called continuous plankton recorder was used in gathering plankton samples, while plastic wastes were taken in the North Pacific Ocean. It mentions that the survey will help in determining plankton communities' responses to environmental change and the effect of microplastic debris to planktons.

Fernandez, B. and M. Albentosa (2019). "Dynamic of small polyethylene microplastics (<=10 micro m) in mussel's tissues." Marine Pollution Bulletin **146**: 493-501.

MPs' uptake and tissue accumulation were investigated in mussel exposed to a single dose (2.85 mg ind⁻¹, 3 mg l⁻¹) of a heterogeneous mixture of irregularly shaped particles of HDPE (mainly <=10 micro m), followed by a 7 days depuration period. The results showed that mussels efficiently cleared MPs from water during exposure, and that MPs were accumulated in digestive gland and gills during depuration. In digestive gland, the amount and size of the MPs accumulated decreased with time, indicating a slower processing and elimination of small MPs than of larger ones. In gills, MPs' burdens increased with time, the MPs accumulated were the smallest ones, suggesting the translocation of small MPs from the digestive system to the gills. The hazardous potential of the smaller fraction of MPs (<=4 micro m) underlined that more focus should be directed towards the accumulation and effects of this fraction of MPs in the marine environment.

Fernández, B. and M. Albentosa (2019). "Dynamic of small polyethylene microplastics (≤10 μm) in mussel's tissues." Marine Pollution Bulletin **146**: 493.

MPs' uptake and tissue accumulation were investigated in mussel exposed to a single dose (2.85 mg ind−1, 3 mg l−1) of a heterogeneous mixture of irregularly shaped particles of HDPE (mainly ≤10 μm), followed by a 7 days depuration period. The results showed that mussels efficiently cleared MPs from water during exposure, and that MPs were accumulated in digestive gland and gills during depuration. In digestive gland, the amount and size of the MPs accumulated decreased with time, indicating a slower processing and elimination of small MPs than of larger ones. In gills, MPs' burdens increased with time, the MPs accumulated were the smallest ones, suggesting the translocation of small MPs from the digestive system to the gills. The hazardous potential of the smaller fraction of MPs (≤4 μm) underlined that more focus should be directed towards the accumulation and effects of this fraction of MPs in the marine environment.

Fernández, B. and M. Albentosa (2019). "Insights into the uptake, elimination and accumulation of microplastics in mussel." Environmental Pollution **249**: 321-329.

The majority of plastics present in the marine environment are microplastics (MPs, <5 mm). Suspension filter feeders are susceptible species to MPs ingestion. Once ingested MPs can be eliminated packed in fecal pellets, or they can be accumulated within tissues, and likely be transferred along the food web. The research on MPs is hampered by the difficulty on their quantification and the lack of standardized methodologies. Indeed, limited information exits about the capacity of marine organisms to ingest, accumulate and eliminate MPs. In this work we investigated the uptake, elimination and accumulation of MPs (irregularly shaped particles of high density polyethylene, ≤22 μm) in mussel. Mussels were exposed to two concentrations of MPs (2 and 4 mm3 l−1), and their uptake, elimination and accumulation in digestive gland was investigated. The results showed that the uptake of MPs increased at the high concentration tested, and that mussels cleared MPs at the same extent than a food item (microalgae) of similar size. Small MPs (2–4 μm) were less efficiently cleared than the larger ones. Large MPs

(>10 µm) were faster eliminated than the smaller ones. The global balance showed that after 6 days of depuration mussels eliminated ≈85% of the MPs cleared, and that ≈2–6% of the MPs cleared remained in the digestive gland, essentially those <6 µm. We recorded a long retention time for MPs, contrasting with the lower times assumed to be necessary to empty mussel's gut before quantifying MPs. Our study emphasized the gap of knowledge on the feeding behaviour of mussels in relation to MPs, and the necessity to investigate it in different marine species, and under different exposure scenarios. Image 1 • Mussels were exposed to microplastics (MPs, high density polyethylene, ≤ 22 µm). • Mussels cleared MPs with the same efficiency than a food item (microalgae) of similar size. • Around the 85% of the MPs cleared were eliminated after 6 days of depuration. • After 6 days of depuration the 2–6% of the MPs cleared remained in the digestive gland. • The MP particles tested showed a long retention time in mussel. This work contributes knowledge about the feeding behaviour of mussel towards microplastics by investigating their kinetics of uptake and elimination, and their retention in the digestive system. [ABSTRACT FROM AUTHOR]

Fernandez, L., et al. (2017). "NKG2D-car redirected CD45RA: Memory T cells target pediatric acute leukemia." Bone Marrow Transplantation **52 (Supplement 1)**: 470-471.

INTRODUCTION: Lymphoid and myeloid acute leukemia are the most frequent type of cancer and the most frequent cause of cancer related death in children. Relapse and refractory disease are the main clinical problems that current therapies are still unable to solve. One of the main NK cell activating receptors is NK cell group 2D (NKG2D). NKG2D receptor recognizes human MICA/ULBP1-6 ligands. These NKG2D ligands are expressed in leukemia cells and constitute suitable targets for immunotherapy. MATERIAL (OR PATIENTS) AND METHODS: The expression of NKG2D ligands was analyzed in Peripheral Blood Mononuclear Cells from 61 pediatric patients suffering from acute leukemia (21 Acute Myeloid Leukemia, 25 B cell Acute Lymphoid Leukemia and 15 T cell Acute Lymphoid Leukemia), as well as in 7 leukemia cell lines (K562, RS4-11, Jurkat, NALM-6, MOLT-3, REH and CEM), by flow cytometry using specific monoclonal antibodies directed against MICA, MICAB, ULBP-1, ULBP-2, ULBP-3 and ULBP-4, and by quantitative PCR using TaqMan probes. Peripheral blood mononuclear cells from healthy donors were labeled with CD45RA microbeads and depleted using AutoMACS device. The HL20i4r-MNDantiCD19bbz lentiviral vector was derived from the clinical vector CL20i4r-EF1a-hgcOPT27 but contained the extracellular domain of NKG2D, the hinge region of CD8a and the signaling domains of 4-1BB and CD3-z. The cassette was driven by MND promoter. Viral supernatant was produced by transient transfection of HEK293T cells with the vector genome plasmid and lentiviral packaging helper plasmids pCAGG-HIVgpco, pCAGG-VSVG and pCAG4-RTR2. Cytogenetic studies and array Comparative Genomic Hybridization were performed to analyze the genetic stability of lentiviral-transduced memory T cells. The in vitro cytotoxicity of CD45RA-T cells against leukemia cells, healthy PBMC and Mesenchymal Stem cells (MSC) was evaluated by performing conventional 4-hour europium-TDA release assays or by flow cytometry using CFSE and 7AAD labeling of target cells. RESULT(S): NKG2DL were heterogeneously expressed in leukemia primary cells and cell lines. For B cell ALL primary samples, we found expression of MICA/B, MICA and ULBP1 decreased in refractory disease compared to remission (p=0.01, p=0.03 and

p=0.02 respectively). Lentiviral transduction of NKG2D-4-1BB-CD3z markedly increased NKG2D surface expression in CD45RA-memory T cells, which became consistently more cytotoxic than untransduced cells against leukemia cells. Additionally, no chromosomal aberrations nor cytotoxic activity against healthy PBMC or Mesenchymal Stem cells was observed in NKG2D CAR expressing T cells. CONCLUSION(S): Our results demonstrate NKG2D-CAR redirected CD45RA-memory T cells target NKG2DL expressing leukemia cells in vitro and could be a promising and safe immunotherapeutic approach for acute leukemia patients.

Fernandez, L., et al. (2017). "CD45RA-memory T cells expressing an NKG2D-car target pediatric acute leukemia." Haematologica **102 (Supplement 2)**: 194.

Background: Lymphoid and myeloid acute leukemia are the most frequent type of cancer and the most frequent cause of cancer related death in children. Relapse and refractory disease are the main clinical problems that current therapies are still unable to solve. One of the main NK cell activating receptors is NK cell group 2D (NKG2D). NKG2D receptor recognizes human MICA, MICB and ULBP1-6 ligands. These NKG2D ligands (NKG2DL) are expressed in leukemia cells and constitute suitable targets for immunotherapy. Aim(s): The aim of thi study was to analyze the NKG2DL expression on pediatric acute leukemia cells and determine their susceptibility to an NKG2D CAR cell based immunotherapy. Method(s): The expression of NKG2DL was analyzed in Peripheral Blood Mononuclear Cells (PBMCs) from patients suffering from acute leukemia, as well as in leukemia cell lines, by flow cytometry (FCM) using specific monoclonal antibodies directed against MICA, MICAB, ULBP-1, ULBP-2, ULBP-3 and ULBP-4, and by quantitative PCR using TaqMan probes. PBMC from healthy donors were labeled with CD45RA microbeads and depleted using AutoMACS device. The HL20i4r-MNDantiCD19bbz lentiviral vector was derived from the clinical vector CL20i4r-EF1a-hgcOPT27 but contained the extracellular domain of NKG2D, the hinge region of CD8a and the signaling domains of 4-1BB and CD3-z. The cassette was driven by MND promoter. Viral supernatant was produced by transient transfection of HEK293T cells with the vector genome plasmid and lentiviral packaging helper plasmids pCAGG-HIVgpco, pCAGG-VSVG and pCAG4-RTR2. Cytogenetic studies and array Comparative Genomic Hybridization were performed to analyze the genetic stability of lentiviral-transduced memory T cells. The in vitro cytotoxicity of CD45RANKG2DCAR+ memory T cells against leukemia cells, healthy PBMC and Mesenchymal Stem cells (MSC) was evaluated by performing conventional 4-hour europium-TDA release assays or by FCM using CFSE and 7AAD labeling of target cells. Result(s): NKG2DL were heterogeneously expressed in leukemia primary cells and cell lines. For B cell ALL primary samples, we found expression of MICA/B, MICA and ULBP1 decreased in refractory disease compared to remission. Lentiviral transduction of NKG2D-4-1BB-CD3z increased NKG2D surface expression in CD45RA-memory T cells, which became consistently more cytotoxic than untransduced cells against leukemia cells. Additionally, no chromosomal aberrations nor cytotoxic activity against healthy PBMC or Mesenchymal Stem cells was observed in NKG2D CAR expressing T cells. Summary/Conclusions: Our results show NKG2D-CAR redirected CD45RAmemory T cells target NKG2DL expressing leukemia cells in vitro and could be a promising and safe immunotherapeutic approach for pediatric acute leukemia patients.

Fernandez Robledo, J. A., et al. (2019). "From the raw bar to the bench: Bivalves as models for human health." Developmental & Comparative Immunology **92**: 260-282.

Bivalves, from raw oysters to steamed clams, are popular choices among seafood lovers and once limited to the coastal areas. The rapid growth of the aquaculture industry and improvement in the preservation and transport of seafood have enabled them to be readily available anywhere in the world. Over the years, oysters, mussels, scallops, and clams have been the focus of research for improving the production, managing resources, and investigating basic biological and ecological questions. During this decade, an impressive amount of information using high-throughput genomic, transcriptomic and proteomic technologies has been produced in various classes of the Mollusca group, and it is anticipated that basic and applied research will significantly benefit from this resource. One aspect that is also taking momentum is the use of bivalves as a model system for human health. In this review, we highlight some of the aspects of the biology of bivalves that have direct implications in human health including the shell formation, stem cells and cell differentiation, the ability to fight opportunistic and specific pathogens in the absence of adaptive immunity, as source of alternative drugs, mucosal immunity and, microbiome turnover, toxicology, and cancer research. There is still a long way to go; however, the next time you order a dozen oysters at your favorite raw bar, think about a tasty model organism that will not only please your palate but also help unlock multiple aspects of molluscan biology and improve human health.

Fernandez-Repollet, E., et al. (1982). "In vivo effects of prostaglandin E<inf>2</inf> and arachidonic acid on phagocytosis of fluorescent methacrylate microbeads by rat peritoneal macrophages." Journal of Histochemistry and Cytochemistry **30**(5): 466-470.

Several studies have suggested that prostaglandin E<inf>2</inf> (PGE<inf>2</inf>) might influence the phagocytic activity of macrophage cells. The present study was designed to examine the in vivo effects of PGE<inf>2</inf>, the prostaglandin synthesis inhibitor meclofenamate, the prostaglandin precursor arachidonic acid, and the biologically inactive fatty acid 11,14,17-eicosatrienoic acid on phagocytosis by peritoneal macrophage cells in the rat. Following 3 days treatment with either agent, fluorescent methacrylate microbeads were injected intraperitoneally into all rats. Peritoneal exudates were harvested after administration of the microbeads and the percent phagocytosis determined in macrophage cells using a fluorescence-activated cell sorter (FACS II). The administration of PGE<inf>2</inf> was associated with a significant decrease in the percentage of peritoneal macrophages ingesting the fluorescent methacrylate microbeads. In contrast, treatment with arachidonic acid or 11,14,17-eicosatrienoic acid significantly enhanced the percentage of phagocytic macrophage cells. A significant increase in the number of macrophages undergoing phagocytosis of the methacrylate microbeads was also observed in rats treated with meclofenamate. This later observation, taken together with the inhibitory effect induced by PGE<inf>2</inf> on macrophage phagocytosis, points to a potential modulator role of PGE<inf>2</inf> on the phagocytic activity of macrophages. These data also suggest that arachidonic acid might influence macrophage phagocytosis by a mechanism independent of PGE<inf>2</inf>.

Ferrandiz, M., et al. (2017). "Development and characterization of bioactive alginate microcapsules with cedarwood essential oil." Flavour and Fragrance Journal **32**(3): 184-190.

In this work, sodium alginate microcapsules containing cedarwood essential oil (CWO) for uses in anti-acne tonic were prepared by ionic gelification of alginate with calcium chloride (CaCl₂) and subsequent addition of glutaraldehyde to improve the crosslinking degree. Alginate microcapsules with cedarwood essential oil were obtained in an encapsulator with a 600 micro m nozzle using different alginate concentrations (1, 3 and 4% w/v), and different compositions of the coagulation solution with CaCl₂ concentrations of 0.1, 0.25 and 0.5 M, and addition of glutaraldehyde at two concentrations: 12.5% and 50% (0.1 g L⁻¹ and 10 g L⁻¹, respectively). The effect of alginate concentration was followed by viscosimetry and the influence of the CaCl₂ concentration and

presence of glutaraldehyde on the microcapsules' shape as well as the total content on encapsulated cedarwood essential oil were evaluated by means of stereoscopic magnifying glass, scanning electron microscopy (SEM) and UV-vis spectrophotometry. Results show that proper shape formation is obtained for an alginate concentration of 3% w/v. With regard to the total encapsulated cedarwood oil, as the CaCl₂ concentration in the gelifying-coagulating solution increases the efficiency of the encapsulated oil. Best results in terms of micro-bead shape and total amount of encapsulated oil were obtained for a CaCl₂ concentration of 0.5 M without glutaraldehyde with a maximum encapsulation of 177.2 mg per gram of microcapsule.

Ferrante, M. C., et al. (2019). "PCB levels in adipose tissue of dogs from illegal dumping sites in Campania region (Italy)." Chemosphere **244**: 125478.

The aim of the study is to investigate the potential relationship between exposure to PCBs and cancer. In doing so we relied on a sample of dogs coming from a peculiar area of the Campania region (Italy), that has been suffering for illegal waste dumping and open air burning of plastic waste for many years. The latter determined the release of organic and inorganic pollutants, such as the PCBs. By comparing dogs with cancer and healthy dogs, we found much higher PCB concentrations in the former, with a significant difference (p < 0.05) for the non-indicator 10NDL-PCB and the DL-PCBs. A regression analysis, controlling for three potentially confounding factors, that are sex, age and weight, confirmed the higher 10NDL-PCB concentration in dogs with cancer. Hence, our evidence suggests a potential health hazard for animals and likewise people living in a risky area due to the presence of environmental organic pollutants.

Ferreira, G. V. B., et al. (2019). "Use of estuarine resources by top predator fishes. How do ecological patterns affect rates of contamination by microplastics?" Science of the Total Environment **655**: 292-304.

This study assessed the seasonal patterns of habitat utilization, feeding ecology and microplastic contamination in different ontogenetic phases of sympatric snooks (Centropomus undecimalis and C. mexicanus) inhabiting a tropical estuary. More than 50% of snooks, in all ontogenetic phases, ingested microplastics (1.5+or-0.1 and 1.4+or-0.1 particles ind⁻¹). Juveniles migrated to nursery grounds in the upper estuary, during the early dry (C. undecimalis 6.5+or-2.8 ind⁻¹) (p<0.01) and early rainy seasons (C. mexicanus 4.1+or-1.9 ind⁻¹). There, they fed mostly on invertebrates (Polychaeta) (p<0.01), and became contaminated by microplastics (C. undecimalis: 0.8+or-0.4 particles ind⁻¹; C. mexicanus: 1.7+or-0.5 particles ind⁻¹). Sub-adults of both species forage principally in the estuarine habitats after shifting their diet from invertebrates (shrimps) in the upper reaches (1806.4+or-1729.6 mg ind⁻¹) to pelagic fishes (R. bahiensis) in seaward habitats (2507.7+or-1758.4 mg ind⁻¹). During feeding continues the contamination by microplastics (3.1+or-0.8 part. ind⁻¹). Adults use the adjacent coastal as feeding and spawning grounds during the rainy season. In this phase, snooks are mostly piscivorous (R. bahiensis: up to 5303.8+or-3213.4 mg ind⁻¹), but also ingest penaeid shrimp as complementary item (up to 175.9+or-156.7). Microplastics contamination rates increased towards the adult phase, with maximum contamination coinciding with peaks of fish ingestion, suggesting trophic transfer of microplastics. The lower estuary and adjacent coastal zone were important contamination sites, especially during the rainy season (up to 3.1+or-0.8 part. ind⁻¹) (p<0.01), when fishery activities is intense and river basin runoff increases. Consequently, the availability of microplastics is higher during this time of year in the lower portion of the estuary. Snooks had similar prey preferences, but the use of different habitats

along the life cycle of each species avoids overlaps in estuarine use and minimizes competition.

Ferreira, G. V. B., et al. (2018). "High intake rates of microplastics in a Western Atlantic predatory fish, and insights of a direct fishery effect." Environmental Pollution **236**: 706-717.

Microplastic contamination was investigated in the gut contents of an economically important estuarine top predator, Cynoscion acoupa, according to spatiotemporal and ontogenetic use of a tropical estuary. Microplastic contamination was found in more than half of the analysed fish. Ingested microplastics were classified by type, colour and length with most of the particles consisting of filaments (<5 mm). Longer filaments were more frequently ingested in the upper estuary and smaller filaments in the lower estuary, as a result of differences in hydrodynamic forces and proximity to the probable input sources. The river is likely an important source of filaments to the estuary and filaments ingested in the upper estuary showed little sign of weathering, when compared with those from the lower estuary, which are subject to intense weathering and consequent break-up of particles to smaller sizes. Most filaments, of all colours, accumulated in adults of C. acoupa, which are more susceptible to contamination through both direct ingestion and trophic transference as they shift their feeding mode to piscivory. Moreover, the highest ingestion of filaments in adults occurred in the lower estuary, during the late rainy season, likely associated with the intense fishing activities in this habitat, which results in a greater input of filaments from fishing gear, which are mainly blue in colour. Overall, 44% of the ingested filaments were blue, 20% purple, 13% black, 10% red and 12% white. The next most common colour, the purple filaments, are most likely blue filaments whose colour has weathered to purple. Red filaments were proportionally more ingested in the lower estuary, indicating a coastal/oceanic source. White and black filaments were more commonly ingested in the inner estuary, suggesting that they have a riverine origin and/or were actively ingested by juveniles and sub-adults, which inhabit the inner estuary and have zooplankton as an important food resource. Environmental gradients and ecological interactions are responsible for the patterns of ingestion of the different colours and lengths of filaments by Cynoscion acoupa. Copyright © 2018 Elsevier Ltd

Ferreira, I., et al. (2019). "Nanoplastics and marine organisms: What has been studied?" Environmental Toxicology and Pharmacology **67**: 1-7.

Nowadays, there is an increased awareness on the threat that marine litter may pose to the marine environment. This review describes the major concerns related to plastic pollution, namely in terms of toxicity of different types and sizes of nanoplastics (particles smaller than 100 nm) to marine organisms, either producers or consumers. The available data show that nanoplastics may affect negatively organisms from different phyla with reported effects ranging from alterations in reproduction to lethality. Nevertheless, no information regarding marine vertebrates (e.g., fish) was found. Data show a high potential for bioaccumulation/biomagnification along marine food chains, since they can easily be retained inside organisms. The lack of standardized methodology for nanoplastics detection and the poor or inexistent legislation makes nanoplastics an environmental challenge. Copyright © 2019 Elsevier B.V.

Ferreira, P., et al. (2016). "Effects of multi-stressors on juveniles of the marine fish Pomatoschistus microps: gold nanoparticles, microplastics and temperature." Aquatic Toxicology **170**: 89-103.

Knowledge on multi-stressors effects required for environmental and human risk assessments is still limited. This study investigated the combined effects of gold nanoparticles (Au-NP), microplastics (MP) and temperature increase on Pomatoschistus microps, an important prey for

several higher level predators, including some species edible to humans. Four null hypotheses were tested: H0₁: P. microps juveniles do not take up Au-NP through the water; H0₂: Au-NP (ppb range) are not toxic to juveniles; H0₃: the presence of MP do not influence the effects of Au-NP on juveniles; H0₄: temperature increase (20-25 degrees C) does not change the effects of the tested chemicals on juveniles. Wild juveniles were acclimated to laboratory conditions. Then, they were exposed to Au-NP (~5 nm diameter) and MP (polyethylene spheres, 1-5 micro m diameter), alone and in mixture, at 20 degrees C and 25 degrees C, in semi-static conditions. After 96 h of exposure to Au-NP, fish had gold in their body (0.129-0.546 micro g/g w.w.) leading to H0₁ refusal. Exposure to Au-NP alone caused a predatory performance decrease (~-39%, p<0.05) leading to H0₂ refusal. MP did not change the Au-NP toxicity leading to H0₃ acceptance. Temperature rise significantly increased the concentration of gold in fish exposed to Au-NP (~2.3 fold), and interacted with chemical effects (e.g. glutathione S-transferases activity) leading to H0₄ refusal. Thus, the results of this study highlight the importance of further investigating the effects of multi-stressors on marine fish, particularly the effects of temperature on the uptake, biotransformation, elimination and effects of nanoparticles and microplastics, either alone or in mixture. This knowledge is most important to improve the basis for environmental and human risk assessments of these environmental contaminants of high concern.

Feuchtinger, T., et al. (2013). "Alternative donor stem cell transplantation in aplastic anemias and refractory cytopenias is save and feasible with T-and B-cell depleted haploidentical grafts." Blood. Conference: 55th Annual Meeting of the American Society of Hematology, ASH **122**(21).

Allogeneic stem cell transplantation is still the curative treatment option for the majority of patients with severe aplastic anemia and refractory cytopenias. However, a HLA-matched donor is not available for all patients. Alternative donor transplantation has been an experimental treatment option, limited by high rejection rates and transplant related mortality. We performed a prospective clinical trial to evaluate the safety and feasibility of haploidentical stem cell transplantation, since haploidentical family members are always available donors. We investigated a cohort of 10 pediatric patients with severe aplastic anemia or myelodysplatic syndrome transplanted (refractory cytopenia) with T-cell depleted grafts between 2004 and 2011. 7 patients had myelodyslastic syndrome with refractory cytopenia (MDS-RC), 3 had severe aplastic anemias (SAA) refractory to immunosuppresive treatment. 3 patients received a 2nd SCT after rejecting the graft from matched donors. Median age was 11.4 years. Standard conditioning regimen consisted of Fludarabin 3-4x40mg/m2, Thiotepa 1-3x5mg/kg, Melphalan 2x70mg/m2 (n=8) and serotherapy using OKT3 (n=5) and ATG (n=5). 8 patients received additional total lymphoid irradiation (TLI 7 Gy) to prevent graft rejection. In vitro graft manipulation was carried out by direct depletion using antiCD3/19 magnetic microbeads. A median number of 10.1x106 CD34+ progenitor cells and 27x103 T-cells/kg body weight (BW) were transfused. Pharmacological GvHD prophylaxis (graft vs. host disease) was carried out with Mycofenolate until day 60, if residual T-cells in the graft exceeded 25000/kg BW. Primary engraftment occurred in all patients Median time to reach 500/mul neutrophiles was 9 days (9-11). Independence from platelet substitution was reached after 13 days (8-16). Three patients rejected the graft later on. 6/10 patients had no signs of acute GvHD or GvHD grade I, 2 patients had GvHD grade II TRM at day +100 and after 1 year was 0% and 20%, respectively. Event free survival (EFS) at 3 years was 80%. Conclusions Haploidentical SCT with T-cell depleted grafts is a therapeutic option for refractory cytopenias and severe aplastic anemia after nonresponse to immunosuppressive treatment if no HLA-matched donor is available. Recovery of neutrophiles and platelets were fast and TRM was low, even if retransplantation was necessary. Since spontaneous outcome of these conditions are poor, alternative donor SCT is a realistic option for these patients.

Feuchtinger, T., et al. (2014). "HLA mismatched alternative donor SCT in aplastic anemias and refractory cytopenias is save and feasible using a reduced intensity conditioning and a T-and B-cell depleted graft but requires intensive immune ablation." Bone Marrow Transplantation **1)**: S384-S385.

Introduction: Allogeneic stem cell transplantation is still the curative treatment option of choice for the majority of patients with severe aplastic anemia and refractory cytopenias. However, a HLAmatched donor is not available for all patients. Alternative donor transplantation has been an experimental treatment option, limited by high rejection rates and transplant related mortality. Materials (or patients) and Methods: We performed a prospective clinical trial to evaluate the safety and feasibility of haploidentical stem cell transplantation, since haploidentical family members are always available donors. We investigated a cohort of 10 pediatric patients with severe aplastic anemia or myelodysplatic syndrome (refractory cytopenia) transplanted with T-cell depleted grafts between 2004 and 2011. Result(s): 7 patients had myelodyslastic syndrome with refractory cytopenia (MDS-RC), 3 had severe aplastic anemias (SAA) refractory to immunosuppressive treatment. 3 patients received a 2nd SCT after rejecting the graft from matched donors. Median age was 11.4 years. Standard conditioning regimen consisted of Fludarabin 3-4x40 mg/m², Thiotepa 1-3x5 mg/kg, Melphalan 2x70 mg/m² (n=8) and serotherapy using OKT3 (n=5) and ATG (n=5). 8 patients received additional total lymphoid irradiation (TLI 7 Gy) to prevent graft rejection. In vitro graft manipulation was carried out by direct depletion using antiCD3/19 magnetic microbeads. A median number of 10.1x106 CD34+ progenitor cells and 27x103 T-cells/kg body weight (BW) were transfused. Pharmacological GvHD prophylaxis (graft vs. host disease) was carried out with Mycophenolate until day 60, if residual T-cells in the graft exceeded 25000/kg BW. Primary engraftment occurred in all patients Median time to reach 500/mul neutrophiles was 9 days (9-11). Independence from platelet substitution was reached after 13 days (8-16). Three patients rejected the graft later on. 6/10 patients had no signs of acute GvHD or GvHD grade I, 2 patients had GvHD grade II. TRM at day +100 and after 1 year was 0% and 20%, respectively. After TLI no rejection was observed. Event free survival (EFS) at 3 years was 80%. Discussion(s): Haploidentical SCT with T-cell depleted grafts is a therapeutic option for refractory cytopenias and severe aplastic anemia after nonresponse to immunosuppressive treatment if no HLA-matched donor is available. Recovery of neutrophiles and platelets were fast and TRM was low, even if retransplantation was necessary. Since spontaneous outcome of these conditions are poor, alternative donor SCT is a realistic option for these patients.

Ficjan, A., et al. (2014). "Hypomethylation of interferon-regulated genes in invariant NKT cells from lupus patients." Journal fur Mineralstoffwechsel **21 (4)**: 140-141.

Purpose To characterize the DNA methylome of invariant natural killer T (iNKT) cells in patients suffering from systemic lupus erythematosus. Methods We performed a genome-wide DNA methylation study in 12 lupus patients and 12 age-matched healthy controls. Lupus patients fulfilling the ACR criteria were recruited consecutively; clinical data (including symptoms, laboratory findings, medication, and disease activity scores) and blood were collected at the same visit. Invariant NKT cells were separated from PBMCs at purities > 90 % (confirmed by flow cytometry using antibodies against CD3 and 6B11) using anti-iNKT Micro Beads (Miltenyi Biotec). DNA of iNKT cells was isolated using QIAamp DNA micro Kit (Qiagen). DNA methylation was quantified for > 485,000 methylation sites across the genome using the Illumina Infinium

HumanMethylation450 Bead chip array. Differentially methylated sites were defined as CG sites with an average level of at least 1.2-fold after adjusting for multiple testing (FDR < 5 %). Results Analysing the average level of DNA methylation of the whole genome revealed that iNKT cells of lupus patients exhibit globally hypermethylated DNA, with an average methylation level of 0.522 (CI: 0.5185-0.5245) in lupus patients and 0.515 (CI: 0.5119-0.5186) in controls (p = 0.014, Mann-Whitney-U Test). Te average methylation level of the whole genome does not correlate with disease activity measured by SLEDAI and ECLAM and is not influenced by immunosuppressive medication. We identified 19 differentially methylated CG sites between patients and controls in 12 genes, with the majority (14) being hypomethylated. Te entirety of hypomethylated genes is interferon-regulated. Significantly hypomethylated genes include IFI44L, MX1, and PLSCR1. We show consistent hypomethylation across multiple CG sites in the promoter region of IFI44L in iNKT cells. Regression analysis revealed correlation of the methylation level of cg00855901 (IFI44L) and ECLAM/SLEDAI (r2 = 0.334, B coefcient =-8.577), suggesting that hypomethylation of this position is associated with disease activity. To ensure differential methylation of the CG sites afliated to IFI44L between lupus patients and controls not being influenced by Chloroquin, Mycophenolate-mofetil (MMF), and prednisolon treatment, we performed a subset analysis in Chloroquin-, MMF-, and prednisolon-treated and non-treated patients. One out of the 4 differentially methylated CG loci of IFI44L (cg06872964) between lupus patients and controls was differentially methylated when comparing prednisolon-treated versus non-prednisolon-treated patients (Mann-Whitney-U Test; p = 0.026). Chloroquin and MMF treatment did not interfere with the methylation level of the differentially methylated CG loci of IFI44L (Kruskal-Wallis Test; Figure 9). Conclusion We identified DNA methylation changes in iNKT cells from lupus patients for the first time. In contrast to CD4 T cell DNA being hypomethylated in lupus patients, iNKT cells of lupus patients exhibit globally hypermethylated DNA. Consistent with resultsPurpose To characterize the DNA methylome of invariant natural killer T (iNKT) cells in patients suffering from systemic lupus erythematosus. Methods We performed a genome-wide DNA methylation study in 12 lupus patients and 12 age-matched healthy controls. Lupus patients fulfilling the ACR criteria were recruited consecutively; clinical data (including symptoms, laboratory findings, medication, and disease activity scores) and blood were collected at the same visit. Invariant NKT cells were separated from PBMCs at purities > 90 % (confirmed by flow cytometry using antibodies against CD3 and 6B11) using anti-iNKT Micro Beads (Miltenyi Biotec). DNA of iNKT cells was isolated using QIAamp DNA micro Kit (Qiagen). DNA methylation was quantified for > 485,000 methylation sites across the genome using the Illumina Infinium HumanMethylation450 Bead chip array. Differentially methylated sites were defined as CG sites with an average level of at least 1.2-fold after adjusting for multiple testing (FDR < 5 %) Results Analysing the average level of DNA methylation of the whole genome revealed that iNKT cells of lupus patients exhibit globally hypermethylated DNA, with an average methylation level of 0.522 (CI: 0.5185-0.5245) in lupus patients and 0.515 (CI: 0.5119-0.5186) in controls (p = 0.014, Mann-Whitney-U Test). Te average methylation level of the whole genome does not correlate with disease activity measured by SLEDAI and ECLAM and is not influenced by immunosuppressive medication. We identified 19 differentially methylated CG sites between patients and controls in 12 genes, with the majority (14) being hypomethylated. Te entirety of hypomethylated genes is interferon-regulated. Significantly hypomethylated genes include IFI44L, MX1, and PLSCR1. We show consistent hypomethylation across multiple CG sites in the promoter region of IFI44L in iNKT cells. Regression analysis revealed correlation of the methylation level of cg00855901 (IFI44L) and ECLAM/SLEDAI (r2 = 0.334, B coefcient =-8.577), suggesting that hypomethylation of this position is associated with disease activity. To ensure differential methylation of the CG sites

afliated to IFI44L between lupus patients and controls not being influenced by Chloroquin, Mycophenolate-mofetil (MMF), and prednisolon treatment, we performed a subset analysis in Chloroquin-, MMF-, and prednisolon-treated and non-treated patients. One out of the 4 differentially methylated CG loci of IFI44L (cg06872964) between lupus patients and controls was differentially methylated when comparing prednisolon-treated versus non-prednisolon-treated patients (Mann-Whitney-U Test; p = 0.026). Chloroquin and MMF treatment did not interfere with the methylation level of the differentially methylated CG loci of IFI44L (Kruskal-Wallis Test; Figure 9). Conclusion We identified DNA methylation changes in iNKT cells from lupus patients for the first time. In contrast to CD4 T cell DNA being hypomethylated in lupus patients, iNKT cells of lupus patients exhibit globally hypermethylated DNA. Consistent with results of previous genome-wide methylation studies on total CD4 T cells and naive CD4 T cells, we detected hypomethylation of interferonregulated genes in iNKT cells of lupus patients. To determine the functional consequences of the methylation changes, further experiments including gene expression analysis have to be performed.

Fickes, M. and E. Spinka (2004). "Diamonds in the Rough." Waste Age **35**(7): 20-20.

Presents information on a set of electronic recycling guidelines developed by the Stakeholder Dialogue which help recyclers extract plastic resin from electronic waste, published by the Institute of Scrap Recycling Industries Inc. in the U.S. in 2004. Aim of the guidelines; Categories identified in the guidelines; Recommendation goals. INSET: SUPPORTING THE PROCESS.

Fields, C., et al. (2012). "Isolation of Bowman-Birk-Inhibitor from soybean extracts using novel peptide probes and high gradient magnetic separation." Food Chemistry **134**(4): 1831-1838.

Soybean proteins offer exceptional promise in the area of cancer prevention and treatment. Specifically, Bowman-Birk Inhibitor (BBI) has the ability to suppress carcinogenesis in vivo, which has been attributed to BBI's inhibition of serine protease (trypsin and chymotrypsin) activity. The lack of molecular probes for the isolation of this protein has made it difficult to work with, limiting its progress as a significant candidate in the treatment of cancer. This study has successfully identified a set of novel synthetic peptides targeting the BBI, and has demonstrated the ability to bind BBI in vitro. One of those probes has been covalently immobilised on superparamagnetic microbeads to allow the isolation of BBI from soy whey mixtures in a single step. Our ultimate goal is the use of the described synthetic probe to facilitate the isolation of this potentially therapeutic protein for low cost, scalable analysis and production of BBI.

Figgener, C. (2018). "What I learnt pulling a straw out of a turtle's nose." Nature **563**(7730): 157.

(Roughly, they make up less than 0.03% of the more than 8 million tonnes of plastic waste, largely consumer trash and fishing nets, that makes its way to the ocean every year, mainly from middle-income countries.) I take care to explain that the straw is emblematic of unnecessary plastic items and how human activity harms oceans. When you're trying to preserve species effectively and have limited funds, you need to know which life stages have the highest chance of survival and whether there is enough suitable habitat left for a species to even sustain larger numbers. Thanks to my video, I have acquired a thicker skin and an eclectic set of skills ranging from copyright law, social-media marketing and unconventional ways of fundraising (I started a GoFundMe page for research).

Figueiredo, G. M. and T. M. P. Vianna (2018). "Suspended microplastics in a highly polluted bay: Abundance, size, and availability for mesozooplankton." Marine Pollution Bulletin **135**: 256-265.

Microplastic ingestion by mesozooplankton may be an important pathway for the microplastics

to enter the food web. To determine microplastic abundance in Guanabara Bay, samples were collected by neustonic haul with a 64-mum-net and oblique hauls using 64- and 200-mum nets. Microplastic size and abundance as well as copepod, fish-larvae, and chaetognath sizes, densities, and preferential prey sizes were determined. Microplastic abundance was higher in samples collected with fine nets (average 4.8 microplastics m⁻³, maximum 11 microplastics m⁻³) than in those collected with coarse net. Microplastic abundance in Guanabara Bay was higher than that in other marine ecosystems. Microplastics >100 mum were too large to be ingested by copepods. However, for fish larvae and chaetognaths, the abundance of microplastics, at the corresponding prey size range, were, respectively, ~9000- and 14,400-folds lower than the preferential copepod prey, in the same size range. Thus, in Guanabara Bay, microplastics were available, but too diluted to be frequently ingested by fish larvae and chaetognaths. Copyright © 2018 Elsevier Ltd

Fikarova, K., et al. (2019). "A flow-based platform hyphenated to on-line liquid chromatography for automatic leaching tests of chemical additives from microplastics into seawater." Journal of Chromatography. A **1602**: 160-167.

An automatic flow-based system as a front end to liquid chromatography (LC) for on-line dynamic leaching of microplastic materials (polyethylene of medium density and poly(vinyl chloride)) with incurred phthalates and bisphenol A is herein presented. The microplastic particles were packed in a metal column holder, through which seawater was pumped continuously by resorting to advanced flow methodology. Each milliliter of the leachable (bioaccessible) fraction of chemical additives was preconcentrated on-line using a 10mm-long octadecyl monolithic silica column placed in the sampling loop of the injection valve of a HPLC system that served concomitantly for analyte uptake and removal of the seawater matrix. After loading of the leachate fraction, the LC valve was switched to the inject position and the analytes were eluted and separated by a monolithic column (Onyx C18HD 100x4.6mm) using an optimized acetonitrile/water gradient with UV detection at 240nm. The automatic flow method including dynamic flow-through extraction, on-line sorptive preconcentration, and matrix clean-up was synchronized with the HPLC separation, which lasted ca. 9min. The only two currently available multi-component certified reference materials (CRM) of microplastics (CRM-PE002 and CRM-PVC001) were used for method development and validation. Out of the eight regulated phthalates contained in the two CRMs, only the 2 most polar species, namely, dimethyl phthalate and diethyl phthalate as well as bisphenol A, were leached significantly by the seawater in less than 2h, with bioaccessibility percentages of 51-100%. The leaching profiles were monitored and modeled with a first-order kinetic equation so as to determine the rate constants for desorption in a risk assessment scenario. Intermediate precision values of bioaccessibility data for three batches of CRMs were for the suite of targeted compounds <=22%. This work for the first time reports a fully automatic flow method with infinite sink capacity (i.e., using a surplus of extracting solution) for the target species able to mimic the leaching of additives from plastic debris across the water body in marine settings under worst-case extraction conditions.

Filgueiras, A. V., et al. (2019). "Microplastic distribution in surface sediments along the Spanish Mediterranean continental shelf." Environmental Science & Pollution Research **26**(21): 21264-21273.

Microplastics (MPs) are widely recognised as a contaminant of emerging concern in the marine environment. This work provides original data of the presence of MPs in coastal sediments along the Spanish Mediterranean continental shelf. Ten surface sediment samples were collected in order to document baseline microplastic distribution from Algeciras to Barcelona. Microplastics were extracted from bulk sediments by density separation. The number of microplastics per kilogramme of dry weight ranged from 45.9 +/- 23.9 MPs/kg d.w. observed at Palma de Mallorca to 280.3 +/- 164.9 MPs/kg d.w. noted at Malaga, with an average value of 113.2 +/- 88.9 MPs/kg d.w. The lower limit is defined by the pore filter size used (1.2 mum). For all analysed locations, the dominant microplastic type was fibres (82.9%), followed by fragments, and the main colours were transparent and blue. Microplastic size distribution was presented; in the case of fragments, 85% was lower than 0.5 mm, and in the case of fibres, the three studied intervals (0.5-1, 1-2, 2-5 mm) had similar distribution (35, 34 and 31%, respectively). Attending to all available data, no statistically significant relationship (Spearman's correlation) was found between microplastic average size and distance to the coast, the depth, density population and sediment grain size. Neither relationship was observed between these variables and microplastic concentration using the non-parametric Kruskal-Wallis H test. This study has confirmed the widespread distribution of MPs in surface sediments from the Spanish Mediterranean continental shelf, and these data are useful to define baselines for MPs in the Western Mediterranean region.

Finkelstein, S. D., et al. (1999). "Cold-temperature plastic resin embedding of liver for DNA- and RNA-based genotyping." Journal of Molecular Diagnostics **1**(1): 17-22.

The standard practice of tissue fixation in 10% formalin followed by embedding in paraffin wax preserves cellular morphology at the expense of availability and quality of DNA and RNA. The negative effect on cellular constituents results from a combination of extensive cross-linking and strand scission of DNA, RNA, and proteins induced by formaldehyde as well as RNA loss secondary to ubiquitous RNase activity and negative effects of high temperature exposure during paraffin melting, microscopic section collection, and tissue adherence to glass slides. An effective strategy to correlate cellular phenotype with molecular genotype involves microdissection of tissue sections based on specific histopathological features followed by genotyping of minute representative samples for specific underlying molecular alterations. Currently, this approach is limited to short-length polymerase chain reaction amplification (<250 bp) of DNA, due to the negative effects of standard tissue fixation and processing. To overcome this obstacle and permit both cellular morphology and nucleic acid content to be preserved to the fullest extent, we instituted a system of cold-temperature plastic resin embedding based on the use of the water-miscible methyl methacrylate polymer known as Immunobed (Polysciences, Warminster, PA). The system is simple, easy to adapt to clinical practice, and cost-effective. Immunobed tissue sections demonstrate a cellular appearance equivalent or even superior to that of standard tissue sections. Moreover, thin sectioning (0.5-1.0 microm thickness) renders ultrastructural evaluation feasible on plastic-embedded blocks. Tissue microdissection is readily performed, yielding high levels of long DNA and RNA for genomic and transcription-based correlative molecular analysis. We recommend the use of Immunobed or similar products for use in molecular anatomical pathology.

Finska, L. and J. G. Howden (2018). "Troubled waters – Where is the bridge? Confronting marine plastic pollution from international watercourses." Review of European Comparative & International Environmental Law **27**(3): 245-253.

A considerable volume of marine plastic pollution derives from watercourses, and many of the world's largest and most heavily polluted watercourses are international. In spite of the clear factual link between the utilization and protection of international watercourses and marine plastic pollution there is hardly any interaction between the legal sub-fields of international water law and marine environmental law. This lack of interaction also reflects the absence of a

global treaty, or even a shared global understanding, of the environmental threat from plastic pollution and the universal responsibility this generates also for landlocked States. This article investigates the possibilities for more integrated measures to prevent pollution of international watercourses and oceans, and argues that regimes within international water law and marine environmental law must cooperate to create awareness of the plastic pollution risk from watercourses and take steps to harmonize their legal rules and policies to contribute to the control and mitigation of marine plastic pollution. Regional coordination, such as improved cooperation between the regional seas organizations and river basin organizations, could provide a tool to better address transboundary sources of plastic. Potentially, such developments could be adopted to control marine plastic pollution from the most heavily polluted international watercourses. [ABSTRACT FROM AUTHOR]

Fiorio, R., et al. (2020). "Influence of Different Stabilization Systems and Multiple Ultraviolet A (UVA) Aging/Recycling Steps on Physicochemical, Mechanical, Colorimetric, and Thermal-Oxidative Properties of ABS." Materials **13**(1): 04.

Commercially mass-polymerized acrylonitrile-butadiene-styrene (ABS) polymers, pristine or modified by stabilization systems, have been injection molded and repeatedly exposed to ultravilolet A (UVA) radiation, mechanical recycling, and extra injection molding steps to study the impact of such treatments on the physicochemical, mechanical, colorimetric, and thermal-oxidative characteristics. The work focus on mimicking the effect of solar radiation behind a window glass as relevant during the lifetime of ABS polymers incorporated in electrical and electronic equipment, and interior automotive parts by using UVA technique. The accelerated aging promotes degradation and embrittlement of the surface exposed to radiation and causes physical aging, deteriorating mechanical properties, with an expressive reduction of impact strength (unnotched: up to 900%; notched: up to 250%) and strain at break (>1000%), as well as an increase in the yellowing index (e.g., 600%). UV-exposition promotes a slight increase in the tensile modulus (e.g., 10%). The addition of antioxidants (AOs) leads to a limited stabilization during the first UVA aging, although the proper AO formulation increases the thermal-oxidative resistance during all the cycles. Mechanical recycling promotes an increase in strain at break and unnotched impact strength alongside a slight decrease in tensile modulus, due to disruption of the brittle surface and elimination of the physical aging.

Firestone, G., et al. (2019). "Photothermally-driven thermo-oxidative degradation of low density polyethylene: heterogeneous heating plus a complex reaction leads to homogeneous chemistry." Nanotechnology **30**(47): 475706.

Photothermal heating from embedded nanoparticles, a process whereby visible light is converted into heat resulting in a high temperature in each particle's immediate vicinity, was utilized to degrade low density polyethylene (LDPE) via thermo-oxidation. The spatially-varying steady-state photothermal temperature field is a potential mechanism by which ambient light (e.g. sunlight) could be used to drive chemical reactions within solid materials and may result in a non-uniform pattern of products, an advantage or disadvantage depending on application. Novel approaches to control polymer degradation are of interest because of the goal of remediating plastic waste, including autonomous means to minimize its effect when unconfined in the environment. For thermoplastic auto-oxidation, heterogeneous degradation would likely enhance deleterious micro-fragmentation however, the multi-step, multi-site nature of the reaction mitigated the temperature non-uniformity. A photothermally-heated LDPE nanocomposite with silver nanoparticle and cobalt-stearate additives showed degradation, characterized by ultraviolet-visible and Fourier-transform infrared absorption spectroscopy, electron microscopy, and mechanical testing, nearly identical to that resulting from uniform conventional treatment at the same average temperature.

First, M. R. and L. A. Drake (2012). "Performance of the human "counting machine": evaluation of manual microscopy for enumerating plankton." Journal of Plankton Research **34**(12): 1028-1041.

In this study, live plankton (greater than or equal to 50 mu m in minimum dimension) in samples were counted by three analysts to determine counting rates, accuracy and precision of manual microscopy. Counting rates were compared with sample characteristics (e.g. concentration of dead organisms). In separate experiments, plankton proxies, spherical microbeads (49 and 150 mu m in diameters), were added to samples with varying degrees of debris loading, including samples from full-scale, replica ballast tanks. These analyses were used to test the hypothesis that as debris loading increases, counting rate increases and accuracy decreases. Highly concentrated samples and samples with high concentrations of dead plankton resulted in significantly slower counting rates. The recovery of 50- mu m microbeads was lowest (75%) in laboratory samples that contained the highest debris load. The recovery of 150- mu m microbeads was very high (>98%) in laboratory samples with and without debris. Field samples from the replica ballast tank were highly turbid, and microbead recoveries were low for both microbead sizes. Sample quality, therefore, will affect counting rates and accuracy and will limit the volume of the sample that can be analyzed within short-time windows available for counting live plankton samples.

First, M. R., et al. (2012). "Validation of a closed-housing filter skid for in-line sampling of aquatic organisms." Journal of Plankton Research **34**(4): 321-331.

A prototype shipboard filter skid (p1SFS) was designed and built to facilitate shipboard collection and concentration of greater than or equal to 50 mu m planktonic organisms from large volumes of water. The p1SFS consisted of two stainless steel filter housings, each containing a filter bag, arranged in parallel. Validation of the device examined the particle retention efficiency of filter bags (using inert polystyrene microbeads), the potential toxicity of filter skid materials and the capture efficiency of plankton collected with a filter skid versus a plankton net at two sample volumes (5 and 10 m super(3)). Microbead recovery in filter bags was >89 and 100% for microbeads of 50 and 150 mu m diameters, respectively. Exposure to the sealant used to close the filter bags' seams or stainless steel did not lead to mortality of two model zooplankton species. Overall, the concentration of greater than or equal to 50 mu m plankton in the p1SFS relative to concentrations in the plankton net (i.e. the capture efficiency, CE) was 108 +/- 66% (mean +/- 1 SD, n = 6). The p1SFS CE was higher in experiments with 5 m super(3) sample volume (147 +/- 74%; n = 3) relative to experiments with a 10 m super(3) sample volume (69 +/- 28%, n = 3), although the difference in CE between the sample volumes was not significant. Consequently, these experiments suggest this or similarly validated filter skids are appropriate for in-line sampling of plankton from relatively large volumes of water.

Fischer, D., et al. (2016). "Novel method to leukoreduce murine blood for transfusion: how to reduce animal usage." Transfusion **56**(1): 146-152.

BACKGROUND Basic research on the pathomechanisms of transfusion-related adverse events depends on murine transfusion models, in which leukoreduction (LR) is a prevalent standard. The commonly used neonatal LR filter (LRF) is associated with considerable animal numbers. A more efficient method would help support the guiding principles of "replacement, reduction, refinement" (3Rs). STUDY DESIGN AND METHODS Blood from C57BL/6 and C57BL/6-Tg(UBC-GFP)30Scha/J mice was leukoreduced using 1) a neonatal LRF, 2) a syringe LRF, or 3) CD45 microbeads. Product quality was assessed according to US Food and Drug Administration (FDA) standards. White blood cell numbers were analyzed by flow cytometry; hemoglobin concentrations and hematocrit were measured and in vivo posttransfusion recoveries were determined after 2 weeks of storage. RESULTS Using the neonatal filter, a LR of 99.56% was achieved with wastage of 12.4 mL in comparison to 99.68% and 1-mL hold-up volume with the syringe filter and 99.11±0.24% LR and 0.1-mL wastage using microbeads. All techniques achieved FDA quality standards, apart from posttransfusion recovery rate, which was only reached by the microbeads-based technique. CONCLUSION

Fischer, E. K., et al. (2016). "Microplastic pollution in lakes and lake shoreline sediments - A case study on Lake Bolsena and Lake Chiusi (central Italy)." Environmental Pollution **213**: 648-657.

Rivers and effluents have been identified as major pathways for microplastics of terrestrial sources. Moreover, lakes of different dimensions and even in remote locations contain microplastics in striking abundances. This study investigates concentrations of microplastic particles at two lakes in central Italy (Lake Bolsena, Lake Chiusi). A total number of six Manta Trawls have been carried out, two of them one day after heavy winds occurred on Lake Bolsena showing effects on particle distribution of fragments and fibers of varying size categories. Additionally, 36 sediment samples from lakeshores were analyzed for microplastic content. In the surface waters 2.68 to 3.36 particles/m³ (Lake Chiusi) and 0.82 to 4.42 particles/m³ (Lake Bolsena) were detected, respectively. Main differences between the lakes are attributed to lake characteristics such as surface and catchment area, depth and the presence of local wind patterns and tide range at Lake Bolsena. An event of heavy winds and moderate rainfall prior to one sampling led to an increase of concentrations at Lake Bolsena which is most probable related to lateral land-based and sewage effluent inputs. The abundances of microplastic particles in sediments vary from mean values of 112 (Lake Bolsena) to 234 particles/kg dry weight (Lake Chiusi). Lake Chiusi results reveal elevated fiber concentrations compared to those of Lake Bolsena what might be a result of higher organic content and a shift in grain size distribution towards the silt and clay fraction at the shallow and highly eutrophic Lake Chiusi. The distribution of particles along different beach levels revealed no significant differences. Copyright © 2016 Elsevier Ltd. All rights reserved.

Fischer, M. and B. M. Scholz-Böttcher (2019). "Microplastics analysis in environmental samples – recent pyrolysis-gas chromatography-mass spectrometry method improvements to increase the reliability of mass-related data (Electronic supplementary information (ESI) available. See DOI: 10.1039/c9ay00600a)." Analytical Methods **11**(18): 2489-2497.

Thermal methods are of increased relevance in the field of microplastics (MP) analysis. The presented method improvements emphasize the potential of pyrolysis gas-chromatography mass-spectrometry (Py-GCMS) methods for mass-related MP quantification in environmental samples. A previously established Curie-Point (CP)-pyrolyzer is compared to a micro furnace (MF) pyrolyzer of higher sample capacity. The two Py-GCMS systems are examined in terms of calibration aspects like dynamic range, linearity, process standard deviation and overall sensitivity. Here, MF-PyGCMS provided advantages. Depending on the samples and their residual organic matrix content, the related pyrolysis products may interact with relevant indicator ions of interesting polymers. This can hamper or even impede any calibration and quantification of MP in the given sample. An internal standard mixture added just before the pyrolysis process (ISTDpy) mimics these interactions to a certain extent. Based on selected peak ratios, ISTDpy offers a possible quantification option in those cases. The application in selected environmental samples (sea salt, surface water and muddy sediment) after adequate preconcentration illustrates the capability and sensitivity of MF-Py-GCMS for MP-quantification regarding the encountered concentrations (ppt–ppm).

Fischer, R. A., et al. (2019). "Impairment of Membrane Repolarization Accompanies Axon Transport Deficits in Glaucoma." Frontiers in Neuroscience **13**: 1139.

Glaucoma is a leading cause of blindness worldwide, resulting from degeneration of retinal ganglion cells (RGCs), which form the optic nerve. In glaucoma, axon transport deficits appear to precede structural degeneration of RGC axons. The period of time between the onset of axon transport deficits and the structural degeneration of RGC axons may represent a therapeutic window for the prevention of irreversible vision loss. However, it is unclear how deficits in axon transport relate to the electrophysiological capacity of RGCs to produce and maintain firing frequencies that encode visual stimuli. Here, we examined the electrophysiological signature of individual RGCs in glaucomatous retina with respect to axon transport facility. Utilizing the Microbead Occlusion Model of murine ocular hypertension, we performed electrophysiological recordings of RGCs with and without deficits in anterograde axon transport. We found that RGCs with deficits in axon transport have a reduced ability to maintain spiking frequency that arises from elongation of the repolarization phase of the action potential. This repolarization phenotype arises from reduced cation flux and K+ dyshomeostasis that accompanies pressure-induced decreases in Na/K-ATPase expression and activity. In vitro studies with purified RGCs indicate that elevated pressure induces early internalization of Na/K-ATPase that, when reversed, stabilizes cation flux and prevents K+ dyshomeostasis. Furthermore, pharmacological inhibition of the Na/K-ATPase is sufficient to replicate pressure-induced cation influx and repolarization phase phenotypes in healthy RGCs. These studies suggest that deficits in axon transport also likely reflect impaired electrophysiological function of RGCs. Our findings further identify a failure to maintain electrochemical gradients and cation dyshomeostasis as an early phenotype of glaucomatous pathology in RGCs that may have significant bearing on efforts to restore RGC health in diseased retina.

Fischer, R. A., et al. (2019). "Pressure-dependent modulation of inward-rectifying K⁺ channels: implications for cation homeostasis and K⁺ dynamics in glaucoma." American Journal of Physiology - Cell Physiology **317**(2): C375-C389.

Glaucoma is the leading cause of blindness worldwide, resulting from degeneration of retinal ganglion cells (RGCs), which form the optic nerve. Prior to structural degeneration, RGCs exhibit physiological deficits. Muller glia provide homeostatic regulation of ions that supports RGC physiology through a process called K⁺ siphoning. Recent studies suggest that several retinal conditions, including glaucoma, involve changes in the expression of K⁺ channels in Muller glia. To clarify whether glaucoma-related stressors directly alter expression and function of K⁺ channels in Muller glia, we examined changes in the expression of inwardly rectifying K⁺ (Kir) channels and two-pore domain (K2P) channels in response to elevated intraocular pressure (IOP) in vivo and in vitro in primary cultures of Muller glia exposed to elevated hydrostatic pressure. We then measured outcomes of cell health, cation homeostasis, and cation flux in Muller glia cultures. Transcriptome analysis

in a murine model of microbead-induced glaucoma revealed pressure-dependent downregulation of Kir and K2P channels in vivo. Changes in the expression and localization of Kir and K2P channels in response to elevated pressure were also found in Muller glia in vitro. Finally, we found that elevated pressure compromises the plasma membrane of Muller glia and induces cation dyshomeostasis that involves changes in ion flux through cation channels. Pressure-induced changes in cation flux precede both cation dyshomeostasis and membrane compromise. Our findings have implications for Muller glia responses to pressure-related conditions, i.e., glaucoma, and identify cation dyshomeostasis as a potential contributor to electrophysiological impairment observed in RGCs of glaucomatous retina.

Fisner, M., et al. (2017). "Colour spectrum and resin-type determine the concentration and composition of Polycyclic Aromatic Hydrocarbons (PAHs) in plastic pellets." Marine Pollution Bulletin **122**(1-2): 323-330.

This study assessed the concentration and composition of Polycyclic Aromatic Hydrocarbons (PAHs) in plastic pellets, collected from sandy beaches and considered different resin and colour tones.

Fisner, M., et al. (2013). "Polycyclic aromatic hydrocarbons (PAHs) in plastic pellets: Variability in the concentration and composition at different sediment depths in a sandy beach." Marine Pollution Bulletin **70**(1-2): 219-226.

Plastic pellets have the ability to adsorb organic pollutants such as PAHs. This study analyzed the variability in the concentration and composition of PAHs on plastic pellets sampled up to 1. m deep in the sediment of a sandy beach. The toxic potential of PAHs was analyzed, and the possible sources of contamination are discussed. The total PAHs varied, with the highest concentrations in the surface layer; the priority PAHs showed a different pattern. PAHs at greater depths did not reach toxicity levels above the PEL. The composition of PAHs differed between pellets from the shallower and from deeper sediment layers, and was suggested a mixture of sources. These results provided the first information on the depth distribution of PAHs in sandy beaches, associated with plastic pellets; and evidenced the potential environmental risk. Similarly to the abundance of pellets, the toxic potential is underestimated in surface samples. © 2013 Elsevier Ltd.

Flaxa, J., et al. (2015). "Methodological and clinical aspects of alloimmunization after granulocyte transfusion in patients undergoing allogeneic stem cell transplantation." Tissue Antigens **85**(2): 93-103.

In allogeneic hematopoietic stem cell transplantation (HSCT), granulocyte transfusions (GT) may be required in immunocompromised, neutropenic patients. In this context, alloimmunization against alloantigens may occur and affect HSCT outcome. Anti-human leukocyte antigen (HLA) and -MHC class I chain related antigens A (MICA) antibody response after the administration of GT in 29 patients undergoing allogeneic HSCT (n=27) encompassing 109 sera was investigated by multianalyte microbead assay before and up to 6month after HSCT. Anti-HLA class I and II antibodies emerged de novo in 11 (38%) and 4 (14%) patients, respectively. Similarly, preformed antibodies were observed in four cases (14%) for anti-HLA class I and also four patients for anti-HLA class II antibodies. Anti-MICA antibodies were observed in eight granulocyte recipients of which three patients developed anti-MICA antibodies after GT, whereas preformed antibodies were seen in five patients. The conversion to positivity for any of the investigated antibodies did not significantly affect overall survival or the incidence of GVHD. GT-associated alloantibody conversion observed did not significantly correlate with outcome. Thus, surveillance of anti-HLA antibodies in the course of GT in the context of HSCT may not be required routinely. The role of MICA antibodies in HSCT and GT, however, requires further study. Floren, H. P. and G. W. Shugart (2017). "Plastic in Cassin's Auklets (Ptychoramphus aleuticus) from the 2014 stranding on the Northeast Pacific Coast." Marine Pollution Bulletin **117**(1-2): 496-498.
Oceanic plastic debris found in the digestive tracts of seabirds includes industrial plastic pellets and post-consumer user plastics. We examined whether the amount and type of plastic ingested by Cassin's Auklets (Ptychoramphus aleuticus) is changing by surveying the stomach contents of 171 Cassin's Auklets stranded along the Washington and Oregon coasts in 2014. We found that 41.5% of the birds contained plastic in their ventriculi, similar to values from the North Subarctic Pacific reported in the 1980s. Industrial pellets were found in 22.8% of our samples, and accounted for 28.1% of all the plastic pieces found. Industrial pellets tended to be larger than pieces of user plastic and accounted for 40.2% of total plastic weight. These industrial pellets were significantly smaller than those found in other species, suggesting either that Cassin's Auklets selected smaller plastic particles or that plastic was retained in ventriculi and worn down. Florentinus-mefailoski, A., et al. (2015). "An enzyme-linked immuno-mass spectrometric assay with the substrate adenosine monophosphate." Analytical and bioanalytical chemistry **407**(4): 1119-1130.
Issue Title: A different way of looking at vibrational hyperspectral data/Micellar extraction for the analysis of Alzheimer's disease brain proteome/Quantification of polyolefin microplastics in personal-care products/Removal of Triton X-100 by microdialysis An enzyme-linked immuno-mass spectrometric assay (ELIMSA) with the specific detection probe streptavidin conjugated to alkaline phosphatase catalyzed the production of adenosine from the substrate adenosine monophosphate (AMP) for sensitive quantification of prostate-specific antigen (PSA) by mass spectrometry. Adenosine ionized efficiently and was measured to the femtomole range by dilution and direct analysis with micro-liquid chromatography, electrospray ionization, and mass spectrometry (LC-ESI-MS). The LC-ESI-MS assay for adenosine production was shown to be linear and accurate using internal ^sup 13^C^sup 15^N adenosine isotope dilution, internal ^sup 13^C^sup 15^N adenosine one-point calibration, and external adenosine standard curves with close agreement. The detection limits of LC-ESI-MS for alkaline phosphatase-streptavidin (AP-SA, 190,000 Da) was tested by injecting 0.1 [mu]l of a 1 pg/ml solution, i.e., 100 attograms or 526 yoctomole (5.26E-22) of the alkaline-phosphatase labeled probe on column (about 315 AP-SA molecules). The ELIMSA for PSA was linear and showed strong signals across the picogram per milliliter range and could robustly detect PSA from all of the prostatectomy patients and all of the female plasma samples that ranged as low as 70 pg/ml with strong signals well separated from the background and well within the limit of quantification of the AP-SA probe. The results of the ELIMSA assay for PSA are normal and homogenous when independently replicated with a fresh standard over multiple days, and intra and inter diem assay variation was less than 10 % of the mean. In a blind comparison, ELIMSA showed excellent agreement with, but was more sensitive than, the present gold standard commercial fluorescent ELISA, or ECL-based detection, of PSA from normal and prostatectomy samples, respectively.

Florentinus-Mefailoski, A. K. and J. G. Marshall (2013). "The CD36 scavenger receptor in the phagocytic engulfment of oxLDL particles in human U937 macrophages." FEBS Journal **1)**: 499.
Atherosclerosis is a leading cause of morbidity and mortality in developed countries. Atherosclerosis is an inflammatory disease in response to the buildup of fatty deposits within the intima of the walls of the artery. Macrophages become activated upon binding to oxidized

low density lipoprotein (oxLDL) deposited on the walls of the arteries resulting in the production of free radicals inducing oxidative stress, the formation of foam cells and atherosclerosis. CD36, a member of the class B scavenger receptor family, is known to play a key role in the uptake of ox- LDL by macrophages. In this study, U937 cells were treated with PMA to induce monocytic differentiation. Monocyte derived macrophages were stimulated with microbeads coated with ox- LDL or immunoglobulin (IgG) ligands to examine the oxLDL internalization pathway by mass spectrometry and confocal microscopy. Multiple peptides were correlated to CD36 like molecules in the oxLDL and IgG receptor complexes as determined by nano LC-ESI-MS/MS and confirmed by confocal microscopy and Western blots using anti CD36 IgA, IgM and IgG probes. Immunostaining with, versus without, detergent revealed that most of the CD36 signal was ectopic and thus associated with the exterior leaflet of the plasma membrane. Silencing RNA against CD36 inhibited the uptake of oxLDL beads by about 40% but did not inhibit IgG bead engulfment. Hence it may be possible to inhibit the phagocytic engulfment of oxLDL by macrophages without preventing bacterial clearance.

Flores, J. L., et al. (2007). "Flow-through optosensor combined with photochemically induced fluorescence for simultaneous determination of binary mixtures of sulfonamides in pharmaceuticals, milk and urine." Analytica Chimica Acta **600**(1-2): 164-171.

A sensitive and selective flow-through optosensor implemented with photochemically induced fluorescence (PIF) is proposed for the simultaneous determination of mixtures sulfamethoxazole/sulfanilamide and sulfathiazole/sulfanilamide. The resolution was accomplished by placing in the flow system a minicolumn filled with an appropriate solid support. Whereas one of the sulfonamides is not retained in the minicolumn and is determined by measuring its native fluorescence on the solid surface of the sensing microbeads in the detection area, the other one is retained and, after its elution, it is photochemically converted into a strongly fluorescent photoproduct which is transitorily retained on the sensing support in the flow cell and monitored. Linear calibration graphs were obtained over a concentration range of 2-3 orders of magnitude. The detection limits for the determination of sulfamethoxazole, sulfanilamide and sulfathiazole are 8.1, 2.9 and 5.7 ng mL(-1), respectively. The method was applied to pharmaceuticals, milk and human urine. The recovery of sulfamethoxazole from pharmaceuticals was 102.5% indicating no interference from trimethoprim which is not photochemically active. The recoveries for urine and milk samples fortified with sulfonamides at levels between 0.1 and 0.7 microgmL(-1) agreed within 95.0-107.5% of spiked levels.

Foekema, E. M., et al. (2013). "Plastic in North Sea Fish." Environmental Science & Technology **47**(15): 8818-8824.

To quantify the occurrence of ingested plastic in fish species caught at different geographical positions in the North Sea, and to test whether the fish condition is affected by ingestion of plastics, 1203 individual fish of seven common North Sea species were investigated: herring, gray gurnard, whiting, horse mackerel, haddock, atlantic mackerel, and cod. Plastic particles were found in 2.6% of the examined fish and in five of the seven species. No plastics were found in gray gurnard and mackerel. In most cases, only one particle was found per fish, ranging in size from 0.04 to 4.8 mm. Only particles larger than 0.2 mm, being the diameter of the sieve used, were considered for the data analyses, resulting in a median particle size of 0.8 mm. The frequency of fish with plastic was significantly higher (5.4%) in the southern North Sea, than in the northern North Sea above 55°N (1.2%). The highest frequency (>33%) was found in cod from the English Channel. In addition, small fibers were initially detected in most of the samples, but their abundance sharply decreased when working under special clean air conditions. Therefore, these fibers were considered to be artifacts related to air born contamination and were excluded from the analyses. No relationship was found between the condition factor (size–weight relationship) of the fish and the presence of ingested plastic particles. [ABSTRACT FROM AUTHOR]

Foerster, A., et al. (2008). "Detection and isolation of viable mouse IL-17-secreting T cells." Journal of visualized experiments : JoVE(22).

The MACS Cytokine Secretion Assay technology allows detection of secreted cytokines on the single cell level and sensitive isolation of viable cytokine-secreting cells. In order to label IL-17-secreting cells, a single cell suspension of mouse splenocytes is prepared and stimulated at 37 degrees C with PMA/ionomycin to induce cytokine secretion. To stop secretion cells are then placed on ice and are exposed to the IL-17 Catch Reagent a bi-specific antibody that binds to CD45 on the cell surface of leukocytes and to IL-17 as it is secreted and caught near the cell surface. Secretion is then re-started by increasing the temperature to 37 degrees C and IL-17 is trapped by the Catch Reagent. Secretion is then stopped again, by placing cells on ice. To detect the trapped IL-17, cells are incubated with a second IL-17-specific antibody conjugated to biotin and an Anti-Biotin-PE antibody. Cells can now be directly analyzed by flow cytometry or prepared for isolation and enrichment by subsequent labeling with Anti-PE conjugated MicroBeads.

Fogel, O., et al. (2018). "MicroRNAs dysregulation in monocytes and T CD4 lymphocytes from patients with axial spondyloarthritis." Annals of the Rheumatic Diseases **77 (Supplement 2)**: 625.

Background: MicroRNAs have been shown to play a crucial role during innate or adaptive immune response. Dysregulation of miRNAs has been described in several autoimmune or rheumatic diseases including rheumatoid arthritis, inflammatory bowel disease or psoriasis. In spondyloarthritis (SpA), only few studies on miR expression have been reported with highly diverse methodologies and involving small samples of patients. Objective(s): Because T CD4 lymphocytes and monocytes are important cells in SpA pathophysiology, we wanted to assess the miR expression profile in these two cell types sorted from axial SpA (AxSpA) patients. Method(s): Eighty one AxSpA patients were included in this study. Among these patients, 74 fulfilled the ASAS classification criteria (imaging arm) with sacro-iliitis on X-rays (n=56) or objective signs of inflammation on MRI (n=18). Two independent cohorts of 22 and 59 SpA patients were compared to 17 and 38 age and sexmatched controls. Both SpA patients and controls were recruited from October 2014 to July 2017 in the department of rheumatology at Cochin Hospital in Paris, France. All SpA patients had an active disease despite NSAIDs intake (mean BASDAI score of 49+/-19 and mean ASDAS score of 3+/-0.9), were free of any biologic treatment and were eligible for a TNF-blocker treatment. Seventy-seven percent were HLA-B27 positive. T lymphocytes and monocytes were isolated from PBMC by direct isolation with magnetic microbeads (CD4 +and CD14+). Threehundred seventy two miRs were screened by q-RT-PCR on the exploratory cohort and only MiRs showing a significant differential expression in the first cohort were analysed in the validation cohort. An unpaired T-test was used for comparison of miR expression level. Result(s): In the exploratory cohort, 51 (CD14+) and 70 miRs

(CD4+) were found to be differentially expressed between patients and controls. Among these, 15 miRs (in CD14+), and 12 miRs (in CD4+) were also found dysregulated in the validation cohort. These validated miRNAs were found to play a key role in physiological pathways such as NFkB or TGFbeta, Wnt signalling and monocyte differentiation that have been involved in the pathophysiology of the disease. Neither clinical subphenotypes nor biological parameters were associated with different profiles of miR expression after adjusting for multiple tests. We found a negative correlation between miR-146a-5p level and BASDAI (r=-0.28, p=0.011) and ASDAS (r=-0.38, p=5.9 10-4) in monocytes. Conclusion(s): We found a dysregulation of miR expression in monocytes and T CD4 lymphocytes from patients with axial spondyloarthritis, whose consequences could contribute to the pathophysiology of the disease and be of interest for therapeutic perspective. Moreover, identifying biomarkers with the potential of diagnostic signature should help the clinician in daily practice.

Fogel, O., et al. (2018). "Micrornas deregulation in monocytes and T CD4 lymphocytes from patients with axial spondyloarthritis." Arthritis and Rheumatology **70 (Supplement 9)**: 2304-2305.

Background/Purpose: MicroRNAs have been shown to play a crucial role during innate or adaptive immune response. Deregulation of miRNAs has been described in several autoimmune or rheumatic diseases including rheumatoid arthritis, inflammatory bowel disease or psoriasis. In spondyloarthritis (SpA), only few studies on miR expression have been reported with highly diverse methodologies and involving small samples of patients. Because T CD4 lymphocytes and monocytes are important cells in SpA pathophysiology, we wanted to assess the miR expression profile in these two cell types sorted from axial SpA (AxSpA) patients. Method(s): Eighty one AxSpA patients were included in this study. Among these patients, 74 fulfilled the ASAS classification criteria (imaging arm) with sacro-iliitis on X-rays (n=56) or objective signs of inflammation on MRI (n=18). Two independent cohorts of 22 and 59 SpA patients were compared to 17 and 38 age and sex-matched controls. Both SpA patients and controls were recruited from October 2014 to July 2017 in the department of rheumatology at Cochin Hospital in Paris, France. All SpA patients had an active disease despite NSAIDs intake (mean BASDAI score of 49 +/-19 and mean ASDAS score of 3 +/- 0.9), were free of any biologic treatment and were eligible for a TNF-blocker treatment. Seventy-seven percent were HLA-B27 positive. T lymphocytes and monocytes were isolated from PBMC by direct isolation with magnetic microbeads (CD4+ and CD14+). Three-hundred seventy two miRs were screened by q-RT-PCR on the exploratory cohort and only MiRs showing a significant differential expression in the first cohort were analyzed in the validation cohort. An unpaired T-test was used for comparison of miR expression level. Result(s): In the exploratory cohort, 51 (CD14+) and 70 miRs (CD4+) were found to be differentially expressed between patients and controls. Among these, 15 miRs (in CD14+), and 12 miRs (in CD4+) were also found deregulated in the validation cohort. These validated miRNAs were found to play a key role in physiological pathways such as NFkB or TGFbeta, Wnt signalling and monocyte differentiation that have been involved in the pathophysiology of the disease. Neither clinical subphenotypes nor biological parameters were associated with different profiles of miR expression after adjusting for multiple tests. We found a negative correlation between miR-146a-5p level and BASDAI (r=-0.28, p=0.011) and ASDAS (r=-0.38, p= 5.9 10-4) in monocytes. Conclusion(s): We found a deregulation of miR expression in monocytes and T CD4 lymphocytes from patients with axial spondyloarthritis, whose consequences could contribute to the pathophysiology of the disease and be of interest for therapeutic perspective. Moreover, identifying biomarkers with the potential of diagnostic signature should help the clinician in daily practice.

Foley, C. J., et al. (2018). "A meta-analysis of the effects of exposure to microplastics on fish and aquatic invertebrates." Science of the Total Environment **631**(632): 550-559.

Microplastics are present in aquatic ecosystems the world over and may influence the feeding, growth, reproduction, and survival of freshwater and marine biota; however, the extent and magnitude of potential effects of microplastics on aquatic organisms is poorly understood. In the current study, we conducted a meta-analysis of published literature to examine impacts of exposure to microplastics on consumption (and feeding), growth, reproduction, and survival of fish and aquatic invertebrates. While we did observe within-taxa negative effects for all four categories of responses, many of the effects summarized in our study were neutral, indicating that the effects of exposure to microplastics are highly variable across taxa. The most consistent effect was a reduction in consumption of natural prey when microplastics were present. For some taxa, negative effects on growth, reproduction and even survival were also evident. Organisms that serve as prey to larger predators, e.g., zooplankton, may be particularly susceptible to negative impacts of exposure to microplastic pollution, with potential for ramifications throughout the food web. Future work should focus on whether microplastics may be affecting aquatic organisms more subtly, e.g., by influencing exposure to contaminants and pathogens, or by acting at a molecular level.

Fomin, P., et al. (2017). "Optimized Time-Gated Fluorescence Spectroscopy for the Classification and Recycling of Fluorescently Labeled Plastics." Applied Spectroscopy **71**(5): 919-928.

For the production of high-quality parts from recycled plastics, a very high purity of the plastic waste to be recycled is mandatory. The incorporation of fluorescent tracers ("markers") into plastics during the manufacturing process helps overcome typical problems of non-tracer based optical classification methods. Despite the unique emission spectra of fluorescent markers, the classification becomes difficult when the host plastics exhibit (strong) autofluorescence that spectrally overlaps the marker fluorescence. Increasing the marker concentration is not an option from an economic perspective and might also adversely affect the properties of the plastics. A measurement approach that suppresses the autofluorescence in the acquired signal is time-gated fluorescence spectroscopy (TGFS). Unfortunately, TGFS is associated with a lower signal-to-noise (S/N) ratio, which results in larger classification errors. In order to optimize the S/N ratio we investigate and validate the best TGFS parameters-derived from a model for the fluorescence signal-for plastics labeled with four specifically designed fluorescent markers. In this study we also demonstrate the implementation of TGFS on a measurement and classification prototype system and determine its performance. Mean values for a sensitivity of [Formula: see text] = 99.93% and precision [Formula: see text] = 99.80% were achieved, proving that a highly reliable classification of plastics can be achieved in practice.

Fonseca M, M. A., et al. (2017). "The impact of microplastics on food safety: the case of fishery and aquaculture products." FAN FAO Aquaculture Newsletter **57**: 43-45.

The objective of the article was to determine the impact on human health of the presence of microplastics in fisheries and aquaculture conducted by the Fisheries and Aquaculture Department of FAO through an exposure assessment of plastic polymers, additives, and sorbed contaminants in mussels.

Fontana, S., et al. (2015). "Donor anti-HLA antibodies may not significantly increase the risk of transfusion reactions in recipients of apheresis platelet concentrates." Vox Sanguinis **1)**: 351.

Background: Donor antibodies against HLA antigens may induce TRALI, FNHTR or other transfusion reactions in recipients of blood components containing plasma. The prevalence of

HLA-antibodies in apheresis platelet (PLT) donors is high and varies depending on the detection test used. The clinical impact on patients of HLAantibodies detected in PLT apheresis donors, of the HLA-antibodies detection technique, and of the immunization history of donors, has not yet been assessed on a large transfusion data base. Aim(s): To explore the clinical risk of transfusion reactions in recipients of apheresis PLT concentrates collected from donors with HLA-antibodies detected by different laboratory tests in a broad donor and patient collective. Method(s): Retrospective cohort study on patients receiving PLT concentrates collected from donors previously tested for HLA-antibodies. HLA-antibodies were investigated by microbead single antigen essay (Luminex), ELISA (Lambda Antigen Tray), or a combination of GAT and GIFT. All consecutive patients of 2 large public hospitals transfused with PLT concentrates donated after HLA-antibody testing of the donor were included in the study. Transfusions and transfusion reactions were evaluated if sufficiently documented in the patient records. Transfusion reactions were classified on the basis of IHN standard definitions. The proportions of transfusion reactions were compared by chi-squared test in transfusions of PLT derived from donors with positive or negative HLA-antibody test, from male or female donors, and from females with or without history of pregnancy. Result(s): Out of 3'837 identified PLT concentrates, 2'976 transfusions were documented and 2'284 had charts evaluable for the occurrence of a transfusion reactions or not. The PLT concentrates were donated by 217 donors and transfused to 609 patients. The current results are summarized in Table 1. Donor, donation, and patient characteristics were roughly balanced between positive and negative HLA antibody results; further analyses aimed to identify confounding factors are ongoing. [TABLE PRESENTED] Conclusion(s): This first analyses exploring correlations between HLA antibodies and transfusion reactions in apheresis PLT concentrates doesn't indicate an increased risk due to donors with HLA antibodies, independently from the detection method, or to donors with immunization history (pregnancy). This conclusion may be limited to PLT in additive solution (<80% of the study products), is not applicable to HNAantibodies (no positive donors found in our study), and should be confirmed by the ongoing analysis of additional risk factors, which could bias the results. After the introduction of the mandatory pathogen reduction with amotosalen and UVA, Switzerland is increasing the proportion of buffy coat PLT, in which the antibodies are further diluted. Thus, further preventive measures reducing the risk of transfusion reactions after PLT transfusion in this setting may be not necessary.

Fontana, S., et al. (2010). "An evaluation of preventive measures to reduce the risk of TRALI after transfusion of single donor apheresis platelets in Switzerland." <u>Transfusion and Apheresis Science</u> **1)**: S13.

Background: TRALI is one of the most severe complications of blood transfusion. Exclusion of females from donation of fresh frozen plasma (FFP) has been implemented in several countries to reduce the risk of immunological TRALI. We compared different preventive measures in platelet (PLT) donors for their consequences on the supply of PLT concentrates in terms of loss of donors. Method(s): Assessment of gender, transfusion, pregnancy history, and leukocyte antibodies by different methods in apheresis PLT donors: granulocyte agglutination (GAT) and immunofluorescence test (GIFT), HLA antibodies by ELISA, and HLA antibodies by microbead flow analyzer (Luminex). Result(s): Out of our pool which includes 40% of female (F) donors, we analyzed 261 consecutive F and 118 control males (M). Ten percent of donors tested so far by GIFT and GAT were positive (17/170). Positive results by different methods of HLA class I and II antibody analysis (n, %; w/wo P = with/without pregnancies) (See Table). Conclusion(s): Assessment of pregnancy history may reduce the number of F donor excluded, but does not necessarily target all donors with leukocyte antibodies. Furthermore, the impact of a screening for antibodies depends largely on the technique used. Only taking into account this observation and further data showing which antibodies are clinical significant will allow the introduction of more efficient measures to prevent TRALI, without unnecessary loss of PLT donors. Table Presented.

Fonte, E., et al. (2016). "Temperature rise and microplastics interact with the toxicity of the antibiotic cefalexin to juveniles of the common goby (Pomatoschistus microps): post-exposure predatory behaviour, acetylcholinesterase activity and lipid peroxidation." Aquatic Toxicology **180**: 173-185.

The goal of this study was to investigate the toxicity of cefalexin to Pomatoschistus microps juveniles in relation to the presence of microplastics in the water and temperature rise. After acclimatization, groups of wild juveniles were exposed for 96 h to artificial salt water (control), microplastics alone (0.184 mg/l), cefalexin alone (1.3-10 mg/l) and in mixture with microplastics (cefalexin: 1.3-10 mg/l; microplastics: 0.184 mg/l) at 20 and 25 degrees C. Effect criteria were mortality, post-exposure predatory performance (PEPP), acetylcholinesterase activity (AChE) and lipid peroxidation levels (LPO). At 20 degrees C, concentrations of cefalexin alone >=5 mg/l significantly reduced PEPP (up to 56%; 96h-EC₅₀=8.4 mg/l), indicating toxicity of the antibiotic to juveniles after short-term exposure to water concentrations in the low ppm range. At 20 degrees C, fish exposed to microplastics alone did not have significant differences in any of the parameters tested relative to the control group but tended to have an inhibition of the PEPP (23%) and AChE (21%); at 25 degrees C, microplastics alone caused mortality (33%) and PEPP inhibition (28%). Thus, microplastics are toxic to P. microps juveniles. At 20 degrees C, under simultaneous exposure to cefalexin and microplastics, the PEPP was significantly reduced (at cefalexin concentrations >=1.25 mg/l). Moreover, at 25 degrees C, the toxicity curves of cefalexin (PEPP based), alone and in mixture with microplastics, were significantly different (p<0.05; 96h-EC₅₀ of 3.8 and 5.2 mg/l, respectively), and the integrated data analysis indicated significant interactions between the two substances for all biomarkers. Thus, the presence of microplastics in the water influenced the toxicity of cefalexin. The rise of water temperature (from 20 degrees C to 25 degrees C), increased the microplastics-induced mortality (from 8 to 33%), and the inhibitory effects of cefalexin on the PEPP (up to 70%). Significant differences (p<0.05) between the toxicity curves of cefalexin alone at distinct temperatures were found, with a lower 96h-EC₅₀ at 25 degrees C (3.8 mg/l) than at 20 degrees C (8.4 mg/l). Moreover, at 25 degrees C, increases of AChE activity (14%) and LPO (72%) in fish exposed to the mixture treatment containing the highest cefalexin concentration were found, and the integrated analysis of data indicated significant interactions between cefalexin and temperature for PEPP, and among all stressors for LPO. Thus, the temperature rise increased the toxicity of microplastics and of cefalexin, alone and in mixture with microplastics, to P. microps juveniles. These findings raise concern on the long-term exposure of wild populations to complex mixtures of pollutants, likely decreasing their fitness, and highlight the need of more research on the combined effects of widely used pharmaceuticals, microplastics and temperature increase on wild species to improve environmental and human risk assessments of chemicals and their safe use under a global warming scenario.

Fontes, G. C., et al. (2013). "Characterization of antibiotic-loaded alginate-OSA starch microbeads produced by ionotropic pregelation." BioMed Research International **2013**: 472626.

The aim of this study was to characterize the penicillin-loaded microbeads composed of alginate and octenyl succinic anhydride (OSA) starch prepared by ionotropic pregelation with calcium chloride and to evaluate their in vitro drug delivery profile. The beads were characterized by size, scanning electron microscopy (SEM), zeta potential, swelling behavior, and degree of erosion. Also, the possible interaction between penicillin and biopolymers was investigated by differential scanning calorimetry (DSC), powder X-ray diffraction (XRD), and Fourier transform infrared (FTIR) analysis. The SEM micrograph results indicated a homogeneous drug distribution in the matrix. Also, based on thermal analyses (TGA/DSC), interactions were detected between microbead components. Although FTIR spectra of penicillin-loaded microbeads did not reveal the formation of new chemical entities, they confirmed the chemical drug stability. XRD patterns showed that the incorporated crystalline structure of penicillin did not significantly alter the primarily amorphous polymeric network. In addition, the results confirmed a prolonged penicillin delivery system profile. These results imply that alginate and OSA starch beads can be used as a suitable controlled-release carrier for penicillin.

Ford, H. Z., et al. (2019). "Efferocytosis perpetuates substance accumulation inside macrophage populations." Proceedings of the Royal Society of London - Series B: Biological Sciences **286**(1904): 20190730.

In both cells and animals, cannibalism can transfer harmful substances from the consumed to the consumer. Macrophages are immune cells that consume their own dead via a process called cannibalistic efferocytosis. Macrophages that contain harmful substances are found at sites of chronic inflammation, yet the role of cannibalism in this context remains unexplored. Here we take mathematical and experimental approaches to study the relationship between cannibalistic efferocytosis and substance accumulation in macrophages. Through mathematical modelling, we deduce that substances which transfer between individuals through cannibalism will concentrate inside the population via a coalescence process. This prediction was confirmed for macrophage populations inside a closed system. We used image analysis of whole slide photomicrographs to measure both latex microbead and neutral lipid accumulation inside murine bone marrow-derived macrophages (10⁴-[Formula: see text]) following their stimulation into an inflammatory state ex vivo. While the total number of phagocytosed beads remained constant, cell death reduced cell numbers and efferocytosis concentrated the beads among the surviving macrophages. As lipids are also conserved during efferocytosis, these cells accumulated lipid derived from the membranes of dead and consumed macrophages (becoming macrophage foam cells). Consequently, enhanced macrophage cell death increased the rate and extent of foam cell formation. Our results demonstrate that cannibalistic efferocytosis perpetuates exogenous (e.g. beads) and endogenous (e.g. lipids) substance accumulation inside macrophage populations. As such, cannibalism has similar detrimental consequences in both cells and animals.

Ford, K. I. (2013). Applied Magnetic Forces Enhance Nanoparticle Based Gene Delivery and Characterize Intracellular Rheology and Transport.

Magnetically applied forces present the ability to manipulate paramagnetic nanoparticles for a wide variety of biomedical applications. In vivo gene delivery offers the promise of new ways to treat disease at a genetic level, but it unfortunately suffers from low efficiencies. Nanoparticles present a platform for non-viral gene therapy but delivery must be optimized to make them a viable option for treatment. This work describes how magnetic forces can be applied to paramagnetic nanoparticles to enhance the delivery of antisense oligonucleotides for correction of mRNA splicing errors. Applied oscillating forces can be used to stimulate certain endocytic pathways, which acts to more than double transfection efficiency. Once a nanoparticle enters the cell, it is surrounded by the complex intracellular environment. To understand the environment that the nanoparticle enters, intracellular rheology is probed with paramagnetic microbeads. A protocol for introducing 1 micron microbeads into cells is presented. By manipulation with 3-dimensional force microscopy, the mechanical features of the cell can be characterized. Additionally, the in vivo transport due to molecular motors is also characterized. Stall force on an intracellular 1 micron bead, caused by dynein motors, is determined. This represents the force exerted on a vesicle by the motors, as it is being transported towards the nucleus, the target of the oligonucleotide delivery.

Forde, E., et al. (2017). "AML blasts induce a senescent phenotype in the BM-MSC through the upregulation of P21." Haematologica **102 (Supplement 2)**: 359-360.

Background: Acute myeloid leukaemia (AML) is a heterogeneous clonal disorder that arises from the haematopoietic myeloid progenitor cells within the bone marrow microenvironment (BMM). Survival of patients with AML is presently poor; two-thirds of younger adults and 90% of older adults die of their disease. Even in patients who achieve remission with chemotherapy, relapse is common and occurs from minimal residual disease sequestered in protective niches in the BMM. Reciprocal interactions between that of the AML and bone marrow mesenchymal stromal cells (BM-MSC) are central to the survival and progression of the leukaemic blasts through micro-environmental promotion of quiescence in malignant cells as well as the activation of anti-apoptotic and pro-survival pathways. Aim(s): To investigate how BM-MSC are programmed by AML to generate a pro-tumoural environment. Method(s): Primary AML and BM-MSC were isolated from the pelvis of AML patients following informed consent and under approval from the UK National Research Ethics Service (LRCEref07/H0310/146). Low input RNASeq of 10 AML BM-MSC and 10 healthy BM-MSC (taken from the pelvis of patients undergoing elective hip replacement surgery) was performed following CD271 MicroBead selection. Primary AML blasts 1x10⁶ were co-cultured on confluent primary BM-MSC for 48 hours (h), 72h and 168h. Real-time PCR was used to verify the RNA sequencing data and Western Blot analysis to confirm protein expression. Lentivirus mediated knockdown was used to target gene expression in the BM-MSC. Senescence was assayed by beta-Galactosidase staining. Result(s): Results from the RNA sequencing carried out to compare 10 healthy and 10 AML BM-MSC show that 1125 genes were differentially expressed, with 924 down-regulated in AML derived BM-MSC and 201 up-regulated. From this analysis, we found that CDKN1A (p21) is up-regulated in BM-MSC from AML patients (7.406 logFC) compared to BM-MSC from patients with normal bone marrow. Further analysis of p21 mRNA expression confirmed an increase in AML BM-MSC compared to normal BM-MSC. In-vitro experimentation showed that p21 mRNA and protein expression is increased in BM-MSC when co-cultured with primary AML. Furthermore, we show that AML increased senescence beta-Galactosidase staining in BM-MSC and that p21 knockdown in BM-MSC reversed the senescent phenotype. Finally, primary AML cultured on p21 knockdown BM-MSC had reduced survival compared to control BM-MSC. Summary/Conclusions: We have identified that AML induces a senescent BM-MSC niche via the p21 mediated pathway which in turn promotes survival and proliferation of AML. Silencing of p21 within the BM-MSC reduces AML survival. In identifying this novel microenvironment feedback loop in AML we highlight a potential new target for future AML therapies.

Forrest, S. A., et al. (2019). "Citizen science sampling programs as a technique for monitoring microplastic pollution: results, lessons learned and recommendations for working with volunteers for monitoring plastic pollution in freshwater ecosystems." Environmental Monitoring & Assessment **191**(3): 172.

A citizen science microplastic monitoring method was developed to engage the public and quantify microplastic contamination at various sites along an approximately 550 km length of

the Ottawa River from Lake Temiskaming to Hawkesbury, Ontario, Canada. The volunteers filtered 100 L of river water through a 100-mum mesh at their desired location along the Ottawa River. All but one of the river samples (n = 43) contained microplastics, with the vast majority of microplastics identified as microfibers. Microplastic concentrations ranged from 0.02 to 0.41 microplastic pieces per litre. We noted numerous advantages in working with citizen scientists including actively engaging citizens in the research, ease of recruiting volunteers within the established Ottawa Riverkeeper network, and expanded spatial coverage at minimal additional costs. Despite these important advantages, there are some important considerations with citizen scientist sampling including the rare events where volunteers mislabelled sample sheets (e.g. labelling as control instead of river sample) and the relatively low volume of water (100 L) that the volunteers could easily sample using our methodology. Recommendations for future citizen science projects for freshwater microplastic research include utilising an established and engaged network, running both field and lab control samples (blanks) to obtain estimates of contamination with microplastic fibres, and increasing the amount of water filtered to obtain more reliable estimates of microplastic pollution in our freshwater ecosystems.

Forsmo, S. P. E., et al. (2008). "Studies on the influence of a flotation collector reagent on iron ore green pellet properties." Powder Technology **182**(3): 444-452.

The properties of iron ore green pellets with varying additions of a surface-active flotation collector reagent (Atrac) were studied by small-scale balling. The compression strength and plasticity were measured with a semi-automatic measuring device and the pressure curves were saved and subjected to further mathematical treatment. The green pellet breakage was also filmed with a high-speed camera. Adding Atrac to the pellet feed seriously damaged the quality of green pellets, even in small dosages. This is because an increasing amount of air bubbles became so strongly attached on the particle surfaces that they could not be removed during compaction by balling. The adsorption of air in green pellets was seen as an increase in porosity and a decrease in the filling degree (proportion of pores filled with water). Both the wet and dry compression strength decreased. The air bubbles behaved in wet green pellets like large, plastic particles and the plasticity increased beyond an acceptable level. Breakage started inside the green pellets, along the air bubbles, and generated multi-breakage patterns in wet as well as dry green pellets. Green pellet breakage to crumbs instead of a few distinct segments, promotes the generation of dust and fines and leads to lower bed permeability in the pelletizing machine. The results show that the decrease in iron ore green pellet wet strength in the presence of surface-active agents is not fully described by the so called Rumpf equation, where surface tension and contact angle are used as variables to describe the capillary forces. The green pellet breakage in the presence of air bubbles took place by crack propagation along pore structures rather than through the loss of the capillary forces. © 2007 Elsevier B.V. Fortin, S., et al. (2019). "Quantifying and identifying microplastics in the effluent of advanced wastewater treatment systems using Raman microspectroscopy." Marine Pollution Bulletin **149 (no pagination)**(110579).

Microplastics in wastewater treatment plant (WWTP) effluent have been identified and quantified, but few studies have examined the microplastics in advanced treatment systems. A new method for isolating, quantifying, and determining the polymer type of microplastics was developed that included chemical digestion coupled with Raman microspectroscopy to investigate microplastics in the effluent of reverse osmosis nanofiltration and activated carbon filtration systems. This method allows for the removal of organics and the quantification and identification of all microplastics present in the sample. A large number of microplastics, the

majority of which were smaller than 10 mum, were identified in the effluent of the advanced filtration systems with polyethylene the most common polymer identified. This study not only reports a new method for microplastic identification and quantification but also shows the importance of measuring the smallest fraction of microplastics, those smaller than 20 mum, which have previously been understudied. Fossi, M. C., et al. (2017). "Are whale sharks exposed to persistent organic pollutants and plastic pollution in the Gulf of California (Mexico)? First ecotoxicological investigation using skin biopsies. (Special Issue: Unraveling complexity: from molecules to ecosystems.)." Comparative Biochemistry and Physiology. C, Toxicology & Pharmacology **199**: 48-58.

The whale shark (Rhincodon typus) is an endangered species that may be exposed to micro- and macro-plastic ingestion as a result of their filter-feeding activity, particularly on the sea surface. In this pilot project we perform the first ecotoxicological investigation on whale sharks sampled in the Gulf of California exploring the potential interaction of this species with plastic debris (macro-, micro-plastics and related sorbed contaminants). Due to the difficulty in obtaining stranded specimens of this endangered species, an indirect approach, by skin biopsies was used for the evaluation of the whale shark ecotoxicological status. The levels of organochlorine compounds (PCBs, DDTs), polybrominated diphenyl ethers (PBDEs) plastic additives, and related biomarkers responses (CYP1A) were investigated for the first time in the whale shark. Twelve whale shark skin biopsy samples were collected in January 2014 in La Paz Bay (BCS, Mexico) and a preliminary investigation on microplastic concentration and polymer composition was also carried out in seawater samples from the same area. The average abundance pattern for the target contaminants was PCBs > DDTs > PBDEs > HCB. Mean concentration values of 8.42 ng/g w.w. were found for PCBs, 1.31 ng/g w.w. for DDTs, 0.29 ng/g w.w. for PBDEs and 0.19 ng/g w.w. for HCB. CYP1A-like protein was detected, for the first time, in whale shark skin samples. First data on the average density of microplastics in the superficial zooplankton/microplastic samples showed values ranging from 0.00 items/m³ to 0.14 items/m³. A focused PCA analysis was performed to evaluate a possible correlation among the size of the whale sharks, contaminants and CYP1A responses. Further ecotoxicological investigation on whale shark skin biopsies will be carried out for a worldwide ecotoxicological risk assessment of this endangered species.

Fossi, M. C., et al. (2014). "Large filter feeding marine organisms as indicators of microplastic in the pelagic environment: The case studies of the Mediterranean basking shark (Cetorhinus maximus) and fin whale (Balaenoptera physalus)." Marine Environmental Research **100**: 17-24.

The impact of microplastics (plastic fragments smaller than 5 mm) on large filter feeding marine organisms such as baleen whales and sharks are largely unknown. These species potentially are ingesting micro-litter by filter feeding activity. Here we present the case studies of the Mediterranean fin whale (Balaenoptera physalus) and basking shark (Cetorhinus maximus) exploring the toxicological effects of microplastics in these species measuring the levels of phthalates in both species. The results show higher concentration of MEHP in the muscle of basking shark in comparison to fin whale blubber. These species can be proposed as indicators of microplastics in the pelagic environment in the implementation of Descriptor 8 and 10 of the EU Marine Strategy Framework Directive (MSFD).

Fossi, M. C., et al. (2016). "Fin whales and microplastics: the Mediterranean Sea and the Sea of Cortez scenarios." Environmental Pollution **209**: 68-78.

The impact that microplastics have on baleen whales is a question that remains largely unexplored. This study examined the interaction between free-ranging fin whales (Balaenoptera physalus) and microplastics by comparing populations living in two semi-enclosed basins, the Mediterranean Sea and the Sea of Cortez (Gulf of California, Mexico). The results indicate that a considerable abundance of microplastics and plastic additives exists in the neustonic samples from Pelagos Sanctuary of the Mediterranean Sea, and that pelagic areas containing high densities of microplastics overlap with whale feeding grounds, suggesting that whales are exposed to microplastics during foraging; this was confirmed by the observation of a temporal increase in toxicological stress in whales. Given the abundance of microplastics in the Mediterranean environment, along with the high concentrations of Persistent Bioaccumulative and Toxic (PBT) chemicals, plastic additives and biomarker responses detected in the biopsies of Mediterranean whales as compared to those in whales inhabiting the Sea of Cortez, we believe that exposure to microplastics because of direct ingestion and consumption of contaminated prey poses a major threat to the health of fin whales in the Mediterranean Sea.

Fossi, M. C., et al. (2012). "Are baleen whales exposed to the threat of microplastics? A case study of the Mediterranean fin whale (Balaenoptera physalus)." Marine Pollution Bulletin **64**(11): 2374-2379.

Baleen whales are potentially exposed to micro-litter ingestion as a result of their filter-feeding activity. However, the impacts of microplastics on baleen whales are largely unknown. In this case study of the Mediterranean fin whale (Balaenoptera physalus), we explore the toxicological effects of microplastics on mysticetes. The study included the following three steps: (1) the collection/count of microplastics in the Pelagos Sanctuary (Mediterranean Sea), (2) the detection of phthalates in surface neustonic/planktonic samples, and (3) the detection of phthalates in stranded fin whales. A total of 56% of the surface neustonic/planktonic samples contained microplastic particles. The highest abundance of microplastics (9.63

items/m³) was found in the Portofino MPA (Ligurian Sea). High concentrations of phthalates (DEHP and MEHP) were detected in the neustonic/planktonic samples. The concentrations of MEHP found in the blubber of stranded fin whales suggested that phthalates could serve as a tracer of the intake of microplastics. The results of this study represent the first warning of this emerging threat to baleen whales.

Fossi, M. C., et al. (2018). "Bioindicators for monitoring marine litter ingestion and its impacts on Mediterranean biodiversity." Environmental Pollution **237**: 1023-1040.

The Mediterranean Sea has been described as one of the most affected areas by marine litter in the world. Although effects on organisms from marine plastic litter ingestion have been investigated in several oceanic areas, there is still a lack of information from the Mediterranean Sea. The main objectives of this paper are to review current knowledge on the impact of marine litter on Mediterranean biodiversity, to define selection criteria for choosing marine organisms suitable for use as bioindicator species, and to propose a methodological approach to assessing the harm related to marine litter ingestion in several Mediterranean habitats and sub-regions. A new integrated monitoring tool that would provide the information necessary to design and implement future mitigation actions in the Mediterranean basin is proposed. According to bibliographic research and statistical analysis on current knowledge of marine litter ingestion, the area of the Mediterranean most studied, in terms of number of species and papers in the Mediterranean Sea is the western sub-area as well as demersal (32.9%) and pelagic (27.7%) amongst habitats. Applying ecological and biological criteria to the most threatened species obtained by statistical analysis, bioindicator species for different habitats and monitoring scale were selected. A threefold approach, simultaneously measuring the presence and effects of plastic, can provide the actual harm and sub-lethal effects to organisms caused by marine litter ingestion. The research revealed gaps in knowledge, and this paper suggests measures to close the gap. This and the selection of appropriate bioindicator species would represent a step forward for marine litter risk assessment, and the implementation of future actions and mitigation measures for specific Mediterranean areas, habitats and species affected by marine litter ingestion. Selection of suitable bioindicators of marine litter ingestion and the simultaneous quantification of its presence and ecotoxicological effects is recommended in order to monitor the impact on Mediterranean fauna and habitats. Foster, S. (2008). "A materials world: PLASTICS." Materials Recycling Week **192**(9): 17-17.

The article discusses the opportunities and challenges faced by the waste plastic recycling industry in Great Britain. It highlights the significance of the government's backing to improve recycling facilities on streets, shopping center, transport hubs, theme parks and recreational centers. It states that recycling mixed plastics will set to be a key issue for the industry. It outlines the emergence of new facilities aiming to allow plastic bottles to be recycled back into plastic bottles. It emphasizes that a full supply chain approach will play an important role for the industry's progress.

Foster, S. (2012). "PLASTICS." Materials Recycling World **199**(22): 31-32.

The article discusses issues related to the collection of plastic waste in Great Britain and the market for recycled plastic products. It highlights the increase in domestic plastic packaging which led to high levels of recycling. It mentions the decrease in demand for plastic bottles from China and in the prices of HDPE and mixed bottles. The article explains the key requirements for any plastic collection scheme.

Fostier, K., et al. (2013). "Immunomodulatory drugs restore effector cell immune functions in myeloma patients with low disease burden after autologous stem cell transplantation." Blood. Conference: 55th Annual Meeting of the American Society of Hematology, ASH **122**(21).

The micro-environment in multiple myeloma (MM) is highly immunosuppressive with increased numbers of regulatory T cells (Tregs) and myeloid derived suppressor cells (MDSCs) favoring tumorcell survival and hampering immunotherapeutic strategies such as dendritic cell vaccination. Immunomodulatory drugs (IMiDs) are known to enhance T- and NK-cell function. In this study we evaluated the effects of low dose (0.5 microM) lenalidomide (Len) and pomalidomide (Pom) on the functionality of CD8+ and CD4+ T cells, MDSCs, Tregs and ex-vivo generated mononuclear derived dendritic cells (moDCs) obtained from MM patients after first autologous stem cell transplantation (ASCT). Peripheral blood mononuclear cell fractions were obtained by leukapheresis from 9 MM patients (age 29-62 years), in very good partial response (4/9) or complete response (5/9) after ASCT. The magnitude of cytokine release (mean +/- standard error of the mean, in ng/ml) by purified CD8+ T cells after 144 hours stimulation with anti-CD3/anti-CD28 coated microbeads was significantly increased after addition of Len and Pom to the culture medium, respectively : IFN-gamma (217.5 +/- 62.1 and 437.1 +/- 137.1** vs 66.4 +/- 21.0) , TNF-alpha (21.4 +/- 5.4 and 44.9 +/- 9.4*** vs 4.9 +/- 1.7) and IL-2 (5.3 +/- 2.7 and 12.7 +/- 6.6 vs 1.9 +/- 1.7 ng/ml) (** p< 0.01, *** p< 0.001). We also evaluated the number of different types of cytokines/chemokines on a per cell basis by intracellular flow cytometry staining for IFN-gamma, TNF-alpha, IL-2 and MIP-1beta and observed increased polyfunctionality of CD8+ and CD4+ T cells. After 72 h of stimulation with anti-CD3/CD28 microbeads the number of single, double, triple or quadruple functional CD8+ T cells increased from 5.96 %, 2.82 %, 0.1 %, 0 % (culture medium alone) to 9.68 %, 7.57 %, 0.41%, 0.03 % (Len) and 12.57 %, 8.96 %, 0.81 %, 0.03 % (Pom), respectively. A similar observation was made for CD4+ T cells. A significant percentage, median 5.7 % (4.0-7.2 %) of CD4+ CD25high CD127low (Tregs) was found in the CD4+ T cell population in 8 out of 9 patients, demonstrating the highly suppressive immune environment in myeloma patients even with low disease burden. Effector T cells (Teffs) were stimulated with anti-CD3/CD28 microbeads and cocultured at varying ratios with purified Tregs. After 144 h of coculture, Len and Pom reduced the suppressive effects of Tregs on Teffs proliferation and IFN-gamma and TNF-alpha production (see figure). A similar effect was observed for MDSC but did not reach statistical significance (data not shown). TriMix DCs (moDCs matured by electroporation with mRNA encoding TLR4, CD40L and CD70) and cytokine matured moDCs were cocultured with autologous CD4+ and CD8+ T cells and anti-CD3 microbeads. Adding IMiDs resulted in more polyfunctional CD4+ and CD8+ T cells with both types of DCs but effects were most pronounced with the TriMix variant. Our study shows that Len and Pom restore effector cell functions in myeloma patients with low tumor burden after ASCT. These findings provide a immunomechanistic explanation for IMiD-based maintenance therapy. They also offer a rationale to combine IMiD-based maintenance with immunotherapeutic approaches such as dendritic cell vaccination in this particular setting.

Foulon, V., et al. (2016). "Colonization of Polystyrene Microparticles by Vibrio crassostreae: Light and Electron Microscopic Investigation." Environmental Science & Technology **50**(20): 10988-10996.

Microplastics collected at sea harbor a high diversity of microorganisms, including some Vibrio genus members, raising questions about the role of microplastics as a novel ecological niche for potentially pathogenic microorganisms. In the present study, we investigated the adhesion dynamics of Vibrio crassostreae on polystyrene microparticles (micro-PS) using electronic and fluorescence microscopy techniques. Micro-PS were incubated with bacteria in different media

(Zobell culture medium and artificial seawater) with or without natural marine aggregates. The highest percentage of colonized particles (38-100%) was observed in Zobell culture medium, which may be related to nutrient availability for production of pili and exopolysaccharide adhesion structures. A longer bacterial attachment (6 days) was observed on irregular micro-PS compared to smooth particles (<10 h), but complete decolonization of all particles eventually occurred. The presence of natural marine agreggates around micro-PS led to substantial and perennial colonization featuring monospecific biofilms at the surface of the aggregates. These exploratory results suggest that V. crassostreae may be a secondary colonizer of micro-PS, requiring a multispecies community to form a durable adhesion phenotype. Temporal assessment of microbial colonization on microplastics at sea using imaging and omics approaches are further indicated to better understand the microplastics colonization dynamics and species assemblages. [ABSTRACT FROM AUTHOR]

Fragoulis, G. E., et al. (2009). "Immunological tolerance and autoimmunity: A1 Altered phagocytic activity in primary sjogren's syndrome: Similarity to lupus and association with extraglandular disease." Annals of the Rheumatic Diseases **1)**: A1.

Background and Objectives: The pathogenesis of systemic lupus erythematosus (SLE) has been thought to involve impaired clearance of apoptotic remnants, as suggested by altered uptake capacity of peripheral blood monocytes and granulocytes. In this study, we sought to assess the phagocytic capacity of peripheral blood monocytes and granulocytes of patients with primary Sjogren's syndrome (SS). For this purpose, we examined comparatively the uptake of fluorescent microbeads and of necrotic cellderived material in SS patients, SLE patients and healthy controls. Method(s): Patients studied included 29 with primary SS (American-European criteria 2002) and 13 with SLE (American College of Rheumatology criteria 1997). Healthy blood donors (HBD) matched for age and sex to the SS and SLE groups (HBD-1, n = 13and HBD-2, n = 13, respectively) were also studied in all assays. The phagocytosis capacity was assessed according to previously established methods (Gaipl et al, J Autoimmun 2007) using heparinised whole blood from individuals studied mixed with a commercially available preparation of fluorescent microbeads (MB-phagocytosis; Polysciences, size 1 mum, 25 SS and 13 SLE patients studied) or a preparation of propidium iodide-stained necrotic cell-derived material obtained from heat-treated normal peripheral blood mononuclear cells (SNEC-phagocytosis, 11 SS and 8 SLE patients studied). The ingestion of particles was assessed by flow cytometry and the phagocytosis index (PInd) was calculated as the product of the percentage of fluorescent cells by the mean fluorescence intensity. Result(s): In agreement with previous studies, SLE patients manifested significantly decreased capacity for MB-phagocytosis by granulocytes (median PInd 18, range 5-47), as well as by monocytes (median PInd 30, range 1-98), compared with HBD-2 (granulocytes: median PInd 53, range 42-110, p=0.002; monocytes: median PInd 108, range 90-182, p=0.0001). In SS patients, defective MB-phagocytosis involved only monocytes (median PInd 26, range 1-126), compared with HBD-1 (median PInd 113, range 70-191, p<0.0001). On the other hand, significantly increased SNEC-phagocytosis was observed in granulocytes (but not monocytes) in SLE (median PInd 419, range 270-1018), as well as in SS (median PInd 415, range 153-1487), compared with HBD-2 (median PInd 133, range 76-244, p<0.0001) and HBD-1 (median PInd 154, range 86-287, p=0.001), respectively. MB-phagocytosis by monocytes was significantly decreased in SS patients with extraglandular manifestations (median PInd 23, range 1-58) compared with SS patients without (median PInd 39, range 10-126, p=0.02). Conclusion(s): The peripheral blood phagocytes of SS patients appear to manifest altered capacity for the uptake of microbeads and SNEC, in a manner similar to SLE. Such disordered phagocytosis may play a role in the pathogenesis of SS.

Fragoulis, G. E., et al. (2009). "Evidence for defective phagocytic activity in primary sjogren's syndrome (ss) that is largely similar to lupus and is more pronounced in ss patients with extraglandular disease." European Journal of Immunology **1)**: S232.

Objectives: Altered phagocytic capacity has been shown to characterize systemic lupus erythematosus (SLE) that is thought to lead to impaired clearance of apoptotic remnants. Herein, we assessed comparatively the phagocytic capacity in the peripheral blood of SS and SLE patients and investigated the phagocytosis of apoptotic/necrotic cells in the salivary glands of SS patients. Method(s): Patients studied included 29 with primary SS (American-European criteria 2002) and 14 with SLE (ACR criteria 1997). Age- and sex-matched healthy blood donors to the SS and SLE groups (13 donors each) were also studied in all assays. The phagocytosis capacity (phagocytosis index) was assessed by flow cytometry, as previously (Gaipl et al, J Autoimmunity, 2007) using heparinized whole blood from individuals studied mixed with a commercially available preparation of fluorescent microbeads (MB-phagocytosis) or a preparation of propidium iodide-stained necrotic cell-derived material obtained from heat-treated normal PBMC (SNEC-phagocytosis). Salivary gland biopsies of patients with SS with and without MALT lymphoma (5 patients each) were also assessed by confocal microscopy for the presence of apoptotic/necrotic material (TUNEL assay) and the presence of macrophages (CD68-staining). Result(s): In agreement to previous studies, MB-phagocytosis was found significantly decreased in granulocytes and monocytes of SLE patients (both for P=0.0001). In SS patients, defective MB-phagocytosis involved only monocytes (P< 0.0001) and significantly correlated with the presence of extraglandular manifestations (P=0.02). Compared to controls, SNEC-phagocytosis was significantly increased in the granulocytes of SLE (P< 0.0001) and of SS (P=0.001). In the salivary gland biopsies of SS patients, the lymphoepithelial lesions and germinal center-like structures manifested significantly increased infiltrations by macrophages. These lesions were also characterized by notable accumulation of apoptotic/necrotic material that resided both inside and outside the phagocytes. These phenomena were significantly more intense in the salivary gland lesions that manifested malignant in-situ B-cell lymphoma. Conclusion(s): In a manner similar to SLE, SS patients appear to manifest altered phagocytic capacity. This may be associated with the observed accumulation of apoptotic/necrotic cells in the salivary glands that in turn, may participate in the chronic autoimmune reactions and/or the lymphoma-generating processes that characterize the disorder.

Francis, V., et al. (2012). "Characterization of linear low-density polyethylene/poly(vinyl alcohol) blends and their biodegradability by Vibrio sp. isolated from marine benthic environment." Journal of Applied Polymer Science **124**(1): 257-265.

Increasing amounts of plastic waste in the environment have become a problem of gigantic proportions. The case of linear low-density polyethylene (LLDPE) is especially significant as it is widely used for packaging and other applications. This synthetic polymer is normally not biodegradable until it is degraded into low molecular mass fragments that can be assimilated by microorganisms. Blends of nonbiodegradable polymers and biodegradable commercial polymers such as poly (vinyl alcohol) (PVA) can facilitate a reduction in the volume of plastic waste when

they undergo partial degradation. Further, the remaining fragments stand a greater chance of undergoing biodegradation in a much shorter span of time. In this investigation, LLDPE was blended with different proportions of PVA (5-30%) in a torque rheometer. Mechanical, thermal, and biodegradation studies were carried out on the blends. The biodegradability of LLDPE/PVA blends has been studied in two environments: (1) in a culture medium containing Vibrio sp. and (2) soil environment, both over a period of 15 weeks. Blends exposed to culture medium degraded more than that exposed to soil environment. Changes in various properties of LLDPE/PVA blends before and after degradation were monitored using Fourier transform infrared spectroscopy, a differential scanning calorimeter (DSC) for crystallinity, and scanning electron microscope (SEM) for surface morphology among other things. Percentage crystallinity decreased as the PVA content increased and biodegradation resulted in an increase of crystallinity in LLDPE/PVA blends. The results prove that partial biodegradation of the blends has occurred holding promise for an eventual biodegradable product. copyright 2011 Wiley Periodicals, Inc. J Appl Polym Sci, 2012

Franco, J., et al. (2019). "Incidence of plastic ingestion in seabirds from the Bay of Biscay (southwestern Europe)." Marine Pollution Bulletin **146**: 387-392.

Seabirds have been widely used to monitor marine debris by the analysis of plastic ingestion. With the aim of obtaining the first data on ingestion of plastics by different seabird species in the Bay of Biscay and evaluating their suitability as biomonitors of plastic pollution in this area, a total of 159 seabirds of fifteen species were analyzed. Plastics were found in 26 birds (16% of the individuals) of nine species (60% of the species). Frequency of occurrence of plastics varied between 0% (Razorbill) and 100% (species of the family Procellariidae). Considering several criteria to assess their suitability as biomonitors of plastic pollution (frequency of occurrence of plastic ingestion, species abundances and stranding occurrence in the Bay of Biscay), the Common Guillemot and the Atlantic Puffin seem the most promising candidates. This study provides the first data on plastic ingestion in seabirds of the Bay of Biscay.

Francois, A. and M. Himmelhaus (2009). "Optical sensors based on whispering gallery modes in fluorescent microbeads: size dependence and influence of substrate." Sensors **9**(9): 6836-6852.

Whispering gallery modes in surface-fixated fluorescent polystyrene microbeads are studied in view of their capability of sensing changes in the refractive index of the beads' environment by exposing them to water/glycerol mixtures of varying composition. The mode positions are analyzed by simultaneous fitting for mode number, bead radius, and environmental index. Down to a diameter of 8 mum, the sensor response follows the index of the bulk solution very well. For smaller bead sizes, some deviations occur, in particular for fluid indices not too different from that of water, which might be attributed to the presence of the substrate.

Francois, J. J., et al. (2015). "Mechanics of neutrophil migration in three-dimensional extra-cellular matrices." Molecular Biology of the Cell. Conference: Annual Meeting of the American Society for Cell Biology, ASCB **26**(25).

While much research has been dedicated to the identification of the cascade of specific biochemical processes involved in the recruitment of neutrophils, much less is known about the mechanical events driving their migration; in particular, how they generate the necessary traction forces to migrate across three-dimensional (3-D) extravascular spaces is unclear. In this study, we investigate the mechanics of 3- D neutrophil motility in collagen gels using a novel Elastographic 3D Force Microscopy (E3DFM) technique, which simultaneously determines the 3-D cellular forces and non-linear material properties of the extracellular environment. We used neutrophil-like differentiated human promyelocytic leukemia cells (dHL-60) as a model system. dHL-60 cells were embedded in collagen matrices of different porosities containing fluorescent micro-beads. The concentration of collagen was varied in order to fabricate collagen gels with different matrix porosities. Neutrophil motility was induced via the introduction of the neutrophil chemokine formyl-Methionyl-Leucyl-Phenylalanine (fMLP) in a custom build device. Both Confocal and Fluorescent microscopy techniques were used to image the movement of the embedded micro-beads as well as fluorescently labeled dHL-60 cells. Particle Image Velocimetry (PIV) and Finite Deformation Theory were used to compute displacement fields in the collagen matrices. Stress fields in the matrices were computed using a constitutive relationship with several material parameters. The over determined nature of the problem was used to estimate the aforementioned material parameters. We will present data showing that cell speed, morphological changes, and migratory patterns varied with differing matrix porosities. We will also provide data showing a clear relationship between the aforementioned migratory characteristics and computed displacement and stress fields around migrating neutrophils in these different collagen matrices. The results from our study show that neutrophils migrating in 3-D environments employ distinct mechanical mechanisms that depend on their environment's mechanical structure.

Franeker, J. and P. J. Bell (1988). "Plastic ingestion by petrels breeding in Antarctica." Marine Pollution Bulletin **19**(12): 672-674.

Plastic particles were found to be common pollutants in stomachs of Wilson's Storm Petrels and Cape Petrels breeding on the Antarctic continent. Highest incidence of plastics was found in chicks of Wilson's Storm Petrels that had died before fledging. Few or no plastics were found in Snow Petrels and Antarctic Petrels. Evidence suggests that most plastics originate from wintering areas outside the Antarctic, and that relatively few plastics are available in Antarctic waters. Possible hazards of plastic levels observed in Wilson's Storm Petrels are discussed.

Frank, R., et al. (2013). "Correlation of circulating donor-specific anti-HLA antibodies and presence of C4d in endomyocardial biopsy with heart allograft outcomes: A single-center, retrospective study." Journal of Heart and Lung Transplantation **32**(4): 410-417.

Background: Donor-specific antibodies (DSA) are associated with increased cardiac graft loss and cardiac vasculopathy (CAV). Detection of antibody-mediated rejection (AMR) relies on graft dysfunction, C4d immunofluorescence (IF) and DSA. Method(s): We retrospectively studied the relationship of DSA, endomyocardial biopsy (EMB) and C4d IF to cardiac transplant outcomes. DSA were evaluated against HLA Class I and II specificities, both pre- and post-transplant, using microbead-based assays. Result(s): Of 626 cardiac transplant patients, 109 with concurrent EMBs and C4d IF and DSA measurement were included in this study. In patients with and without DSA, CAV occurred in 31% and 13% and acute cellular rejection (ACR) in 100% and 84%, respectively. One hundred ten of 170 EMBs procured during episodes of graft dysfunction had concurrent DSA. In these patients, C4d IF correlated better with DSA to Class I or both Class I and II and less so in patients with DSA to Class II. Graft failure (GF) rates of 40%, 29% and 58% with average times to GF of 33, 77 and 48 months were seen in patients with DSA to Class I, II or both, respectively. Conclusion(s): Patients with DSA to Class I or to both Class I and II showed a correlation with C4d IF and had higher GF rates compared to patients with DSA to only Class II or no DSA; patients with DSA to Class II remained at risk for CAV. Episodes of ACR and CAV, but not AMR, appeared to be more frequently associated with graft dysfunction in patients with circulating DSA. © 2013 International Society for Heart and Lung Transplantation.

Franke, S., et al. (2015). "One-step assay for the quantification of T4 DNA ligase." Analytical and bioanalytical chemistry **407**(4): 1267-1271.

Issue Title: A different way of looking at vibrational hyperspectral data/Micellar extraction for the analysis of Alzheimer's disease brain proteome/Quantification of polyolefin microplastics in personal-care products/Removal of Triton X-100 by microdialysis As one of the most commonly used enzyme in molecular biology, the T4 DNA ligase presents an important tool for the manipulation of DNA. T4 DNA ligase activity measurements are based on the use of radioactivity or rather labor-intense procedures including gel-based analysis. We therefore established a homogeneous T4 DNA ligase assay utilizing a specifically designed fluorescein- and dark quencher-labeled DNA molecule. Upon ligation of both DNA molecules, a quenching occurs and the fluorescence intensity decreases with increasing ligase concentrations. The assay allows a sensitive and precise quantification (CV, 4.6-5.5 %) of T4 DNA ligase activities and showed a high specificity when tested against other ligases of related and different species. Most importantly, this T4 DNA ligase assay requires only one working and incubation step before measurement can take place at room temperature and may therefore offer an interesting alternative to existing, more laborious ligase assays.

Frankel, H. (1990). Automated sorting of post-consumer plastic waste. Proceedings of the ACS Division of Polymeric Materials: Science and Engineering, August 26, 1990 - August 31, 1990, Washington, DC, USA, Publ by ACS.

Almost all post-consumer plastic waste can be recycled (85% of plastic is thermoplastic) but it must be separated by type of polymer. Unfortunately, recycling is viewed and practiced as people hand-sorting municipal solid waste. This is totally unsatisfactory for handling the large volumes of material which must be recycled. This paper describes the development of an automatic recycling system which is capable of sorting post-consumer containers at a rate of over 200 bottles a minute. The purpose of the system is to reduce errors of sorting, reduce processing costs, and avoid the environmental and health concerns of handling post-consumer waste. In addition, future trends to increase the capacity and provide closer to source processing are also discussed.

Franzellitti, S., et al. (2019). "Microplastic exposure and effects in aquatic organisms: A physiological perspective." Environmental Toxicology & Pharmacology **68**: 37-51.

The impact of microplastics (MPs) on aquatic life, given their ubiquitous presence in the water compartment, represents a growing concern. Consistently, scientific knowledge is advancing rapidly, although evidence on actual adverse effects is still highly fragmented. This paper summarizes the recent literature on MP impacts on aquatic organisms in an attempt to link routes of uptake, possible alterations of physiological processes, and outcomes at different levels of biological organization. Animal feeding strategies and MP biodistribution is discussed, alongside with relevant effects at molecular, cellular, and systemic level. Pathways from animal exposure to apical physiological responses are examined to define the relevance of MPs for animal health, and to point out open questions and research gaps. Emphasis is given to emerging threats posed by leaching of plastic additives, many of which have endocrine disruption potential. The potential role of MPs as substrates for microorganism growth and vehicle for pathogen spreading is also addressed.

Franzellitti, S., et al. (2019). "The Multixenobiotic resistance system as a possible protective response triggered by microplastic ingestion in Mediterranean mussels (Mytilus galloprovincialis): Larvae and adult stages." Comparative biochemistry and physiology. Toxicology & pharmacology : CBP **219**: 50-58.

The emerging paradigm on plastic pollution in marine environments is that microsize particles (MPs) have far more subtle effects than bigger fragments, given their size range overlapping with that of particles ingested by filter-feeders. The impacts include gut blockage, altered feeding and energy allocation, with knock-on effects on widespread physiological processes. This study investigated whether ingestion of polystyrene MPs (PS-MPs) triggers protective processes in marine mussels. The Multixenobiotic resistance (MXR) system is a cytoprotective mechanism acting as an active barrier against harmful xenobiotics and a route of metabolite detoxification. Both larvae and adults were employed in laboratory experiments with different concentrations of 3-µm PS-MPs (larvae), and 3-µm and 45-µm PS-MPs (adults) matching size range of planktonic food through the mussel lifecycle. Embryos grown in the presence of 3-µm PS-MPs showed significant reduction of MXR activity and down-regulation of ABCB and ABCC transcripts encoding the two main MXR-related transporters P-glycoprotein and the Multidrug resistance-related protein, respectively. In adults, effects of PS-MPs were assessed in haemocytes and gills, which showed different modulation of MXR activity and ABCB/ABCC expression according to MP size (haemocyte and gills) or particle concentration (haemocyte). These data showed that modulation of MXR activity is part of a generalized response triggered by particle ingestion.

Frapin, L., et al. (2018). "Development of controlled release systems of biological factors for the regeneration of intervertebral disc." Osteoarthritis and Cartilage **26 (Supplement 1)**: S425.

Purpose: The degeneration of intervertebral disc (IVD), and notably of its central part the nucleus pulposus (NP), is responsible for 40% of chronic low back pain (LBP). Recent studies have reported the existence of endogenous regenerative cells in the IVD vicinity and within the IVD. These endogenous cells have been characterized as mesenchymal stem cell-like progenitors residing in specificniches. Inresponsetochemokines (stromal derived factor-1 (SDF-1)) these cells can be recruited and migrate to the site of injury and thus contribute to the endogenous repair process. In this context, the development of microbeads-based local delivery systems of factors involved in progenitors recruitment has recently been contemplated for IVD regenerative medicine. Because of their physicochemical and biological properties, microbeads of pullulans (PMBs) have long been investigated as drug carriers. In addition, we recently demonstrated that transforming growth factor-beta1 (TGF-beta1) and growth differentiation factor5 (GDF5) are potent stimulators of the differentiation ofmesenchymal stemcells(MSC) intoNP-like cells. In this context, the aim of this work was to develop an intradiscal pullulan microbeads-based delivery systemfor the controlled release of SDF-1, TGF-beta1 and GDF5. This drug delivery system would be able to sequentially contribute to 1) the recruitment and mobilization of resident progenitors, 2) the differentiation of themobilized progenitors and 3) the subsequent regeneration of NP. Method(s): Chemotaxis assays were performed to determine the in vitro cell migration. Human MSCs (1250 cells/ml) were incubated with or without SDF-1 (250 ng/ml) in Transwells for 4h, migratory cells were stained by crystal violet then quantified by spectrophotometry. In parallel, PMBs were prepared by a simultaneous crosslinking protocol coupled to a water-in-oil emulsification process. Freeze-dried PMBs were incubated with GDF-5 and TGF-beta1 separately (25 mg of PMBs at final concentration of 1, 2 and 4 mg/mL and in a final volume of 500 mL of PBS) for 24 h at 4degreeC under rotary stirring at 24 rpm. GDF-5 and TGF-beta1 release assays were performed in PBS at 37degreeC for 21 days and concentrations were measured by ELISA. Result(s): SDF-1 has improved the in vitro migration of hMSCs, increasing by more than twice the number of migratory cells. GDF-5 and TGF-beta1 were successfully adsorbed on PMBs with a 100% efficiency. Release experiments showed a burst release within the 1st h, at 604 ng/h and 50 ng/h for GDF-5 and TGF-beta1 respectively, then the

release rate decreased during 21 days with 0.6 ng/h and 0.15 ng/h during the last 7 days for GDF-5 and TGF-beta1, respectively. At day 21, GDF-5 was entirely released, whereas only 40% of TGF-beta1 was released. This different release profiles could be explained by the difference of molecular weight (13 kDa for GDF-5 and 25 kDa for TGF-beta1). Conclusion(s): We have confirmed that SDF-1 improved hMSCs in vitro migration, and that PMBs are suitable microcarriers for the loading and release of GDF-5 and TGFbeta-1. The loading and release capability of SDF- 1 by PMBs, as well as SDF-1 bioactivity after release will be analyzed, to obtain a fast and massive recruitment of resident progenitors in vivo. Then, we will study the action of GDF-5 and TGFbeta1 released from PMBs on in vitro NP differentiation, by using a 3D matrix model to mimic the NP microenvironment. Nucleopulpogenic differentiation will be evaluated by analysis of specific extracellular matrix production and gene expression markers. (Table Presented).

Fred, R. G., et al. (2011). "The human insulin mRNA is partly translated via a cap- and eIF4A-independent mechanism." Biochemical & Biophysical Research Communications **412**(4): 693-698.

The aim of this study was to investigate whether cap-independent insulin mRNA translation occurs in human pancreatic islets at basal conditions, during stimulation at a high glucose concentration and at conditions of nitrosative stress. We also aimed at correlating cap-independent insulin mRNA translation with binding of the IRES trans-acting factor polypyrimidine tract binding protein (PTB) to the 5'-UTR of insulin mRNA. For this purpose, human islets were incubated for 2h in the presence of low (1.67 mM) or high glucose (16.7 mM). Nitrosative stress was induced by addition of 1 mM DETA/NO and cap-dependent mRNA translation was inhibited with hippuristanol. Insulin biosynthesis rates were determined by radioactive labeling and immunoprecipitation. PTB affinity to insulin mRNA 5'-UTR was assessed by a magnetic micro bead pull-down procedure. We observed that in the presence of 1.67 mM glucose, approximately 70% of the insulin mRNA translation was inhibited by hippuristanol. Corresponding value from islets incubated at 16.7 mM glucose was 93%. DETA/NO treatment significantly decreased the translation of insulin by 85% in high glucose incubated islets, and by 50% at a low glucose concentration. The lowered insulin biosynthesis rates of DETA/NO-exposed islets were further suppressed by hippuristanol with 55% at 16.7 mM glucose but not at 1.67 mM glucose. Thus, hippuristanol-induced inhibition of insulin biosynthesis was less pronounced in DETA/NO-treated islets as compared to control islets. We observed also that PTB bound specifically to the insulin mRNA 5'-UTR in vitro, and that this binding corresponded well with rates of cap-independent insulin biosynthesis at the different conditions. In conclusion, our studies show that insulin biosynthesis is mainly cap-dependent at a high glucose concentration, but that the cap-independent biosynthesis of insulin can constitute as much as 40-100% of all insulin biosynthesis during conditions of nitrosative stress. These data suggest that the pancreatic beta-cell is able to uphold basal insulin synthesis at conditions of starvation and stress via a cap- and eIF4A-independent mechanism, possibly mediated by the binding of PTB to the 5'-UTR of the human insulin mRNA.

Fred-Ahmadu, O. H., et al. (2020). "Interaction of chemical contaminants with microplastics: Principles and perspectives." Science of the Total Environment **706**: 135978.

Scientific evidences abound of the occurrence of plastic pollution, from mega- to nano-sized plastics, in virtually all matrixes of the environment. Apart from the direct effects of plastics and microplastics pollution such as entanglement, inflammation of cells and gut blockage due to ingestion, plastics are also able to act as vectors of various chemical contaminants in the aquatic environment. This paper provides a review of the association of plastic additives with environmental microplastics, how the structure and composition of polymers influence sorption capacities and highlights some of the models that have been employed to interpret experimental data from recent sorption studies. The factors that influence the sorption of chemical contaminants such as the degree of crystallinity, surface weathering, and chemical properties of contaminants. and the implications of chemical sorption by plastics for the marine food web and human health are also discussed. It was however observed that most studies relied on pristine or artificially aged plastics rather than field plastic samples for studies on chemical sorption by plastics.

Free, C. M., et al. (2014). "High-levels of microplastic pollution in a large, remote, mountain lake." Marine Pollution Bulletin **85**(1): 156-163.

Despite the large and growing literature on microplastics in the ocean, little information exists on microplastics in freshwater systems. This study is the first to evaluate the abundance, distribution, and composition of pelagic microplastic pollution in a large, remote, mountain lake. We quantified pelagic microplastics and shoreline anthropogenic debris in Lake Hovsgol, Mongolia. With an average microplastic density of 20,264 particles km(-2), Lake Hovsgol is more heavily polluted with microplastics than the more developed Lakes Huron and Superior in the Laurentian Great Lakes. Fragments and films were the most abundant microplastic types; no plastic microbeads and few pellets were observed. Household plastics dominated the shoreline debris and were comprised largely of plastic bottles, fishing gear, and bags. Microplastic density decreased with distance from the southwestern shore, the most populated and accessible section of the park, and was distributed by the prevailing winds. These results demonstrate that without proper waste management, low-density populations can heavily pollute freshwater systems with consumer plastics.

Freeman, D. E., et al. (1992). "Comparison of the effects of intragastric infusion of equal volumes of water, dioctyl sodium sulfosuccinate, and magnesium sulfate on fecal composition and output in clinically normal horses." American Journal of Veterinary Research **53**(8): 1347-1353.

A Latin square design was used to compare the effects of laxatives and a corresponding volume of water on gastrointestinal tract function in 4 healthy Thoroughbred geldings. Horses were intragastrically infused with each of the following: dioctyl sodium sulfosuccinate (DSS; 50 mg/kg of body weight); magnesium sulfate (0.5 g/kg - low dosage); magnesium sulfate (1.0 g/kg - high dosage); and a equal volume of water (6 litre) given as a control infusion. From 5 to 33 hours after the high dosage of magnesium sulfate, faeces were slightly softer than usual in all horses. In 1 horse, DSS caused mild colic, hyperpnoea, and diarrhoea from 0.3 to 3 hours after administration. After all laxative treatments and the control infusion, faecal output, faecal water, number of defecations, and faecal water percentage were greater during the first 6 and 12 hours, compared with each subsequent 6-hour period. The high dosage of magnesium sulfate had greater effect on faecal output and faecal water than did the low dosage and control infusion. However, this effect preceded arrival of the liquid transit marker, polyethylene glycol, and magnesium at their highest concentrations in faeces by 12 to 18 hours. Compared with the control infusion, none of the laxative treatments affected excretion of polyethylene glycol and plastic particulate markers, nor did they increase water consumption. It was concluded that the response to intragastric infusions may involve reflex mechanisms in the gastrointestinal tract and that these responses could be used for treatment of colon impactions. Under conditions of this study, DSS was not a sufficiently effective laxative to outweigh the risk of toxic effects at recommended doses. Although DSS and the low dosage of magnesium sulfate may not provide a greater laxative effect than did an equal volume of water, the high dosage of magnesium sulfate should be more effective.

Frei, S., et al. (2019). "Occurence of microplastics in the hyporheic zone of rivers." Scientific Reports **9**(1): 15256.

Although recent studies indicate that fluvial systems can be accumulation areas for microplastics (MPs), the common perception still treats rivers and streams primarily as pure transport vectors for MPs. In this study we investigate the occurrence of MPs in a yet unnoticed but essential compartment of fluvial ecosystems - the hyporheic zone (HZ). Larger MP particles (500-5,000 micro m) were detected using attenuated total reflectance (ATR) - Fourier-transform infrared (FTIR) spectroscopy. Our analysis of MPs (500-5,000 micro m) in five freeze cores extracted for the Roter Main River sediments (Germany) showed that MPs were detectable down to a depth of 0.6 m below the streambed in low abundances (<<1 particle per kg dry weight). Additionally, one core was analyzed as an example for smaller MPs (20-500 micro m) with focal plane array (FPA)- based micro FTIR spectroscopy. Highest MP abundances (~30,000 particles per kg dry weight) were measured for pore scale particles (20-50 micro m). The detected high abundances indicate that the HZ can be a significant accumulation area for pore scale MPs (20-50 micro m), a size fraction that yet is not considered in literature. As the HZ is known as an important habitat for invertebrates representing the base of riverine food webs, aquatic food webs can potentially be threatened by the presence of MPs in the HZ. Hyporheic exchange is discussed as a potential mechanism leading to a transfer of pore scale MPs from surface flow into streambed sediments and as a potential vector for small MPs to enter the local aquifer. MPs in the HZ therefore may be a potential risk for drinking water supplies, particularly during drinking water production via river bank filtration.

Frentzel, S. (2017). "An assay to characterize the impact of cigarette smoke exposure on mucociliary clearance in-vitro." Toxicology Letters **280 (Supplement 1)**: S263.

Mucociliary clearance (MCC) constitutes a first-line defense mecha-nism to remove inhaled particles or pathogens from the respiratory tract. Impairment of MCC contributes or plays a causative role in the etiology of various respiratory diseases and is associated with an increased risk for pulmonary infections. Cigarette smoke (CS) has been reported to impact all functional elements required for an effective MCC. This includes the observation that respiratory epithelia of smokers show fewer cilia and with abnormal morphology. Smoking can lead to mucus hypersecretion or changes in the biophysical properties of mucus. CS may also influence the hydration of the periciliary surface liquid (PCL). While there are established tests to measure MCC (mucociliary transport) rates in humans (e.g. Saccharine transit test), standard in-vitro assays are lacking that can be used to characterize CS (whole smoke) effects. We have setup an assay to measure mucociliary transport rates in an in-vitro setting on nasal MucilAir^{TM} 3D-organotypic air-liquid interface cultures by determining velocities of polystyrene microbeads. We observed a dose-dependent decrease of bead transport rates upon exposure of MucilAir^{TM} to 3R4F Reference CS. Concomitant with a decreased transport, cilia beating, as determined at various post-exposure time points, was similarly impaired in the cultures. This assay is a useful addition to match clinical reports on CS effects on MCC in humans and may be used for comparative studies using potential modified risk tobacco products.

Frere, L., et al. (2018). "Microplastic bacterial communities in the Bay of Brest: Influence of polymer type and size." Environmental Pollution **242**(Pt A): 614-625.

Microplastics (<5mm) exhibit intrinsic features such as density, hydrophobic surface, or high

surface/volume ratio, that are known to promote microbial colonization and biofilm formation in marine ecosystems. Yet, a relatively low number of studies have investigated the nature of microplastic associated bacterial communities in coastal ecosystems and the potential factors influencing their composition and structure. Here, we characterized microplastics collected in the Bay of Brest by manual sorting followed by Raman spectroscopy and studied their associated bacterial assemblages using 16S amplicon high-throughput sequencing. Our methodology allowed discriminating polymer type (polyethylene, polypropylene and polystyrene) within small size ranges (0.3-1 vs. 1-2 vs. 2-5mm) of microplastics collected. Data showed high species richness and diversity on microplastics compared to surrounding seawater samples encompassing both free living and particle attached bacteria. Even though a high proportion of operational taxonomic units (OTU; 94+/-4%) was shared among all plastic polymers, polystyrene fragments exhibited distinct bacterial assemblages as compared to polyethylene and polypropylene samples. No effect of microplastic size was revealed regardless of polymer type, site and date of collection. The Vibrio genus was commonly detected in the microplastic fraction and specific PCR were performed to determine the presence of potentially pathogenic Vibrio strains (namely V. aestuarianus and the V. splendidus polyphyletic group). V. splendidus related species harboring putative oyster pathogens were detected on most microplastic pools (77%) emphasizing the need of further research to understand the role of microplastics on pathogen population transport and ultimate disease emergence.

Frere, L., et al. (2017). "Influence of environmental and anthropogenic factors on the composition, concentration and spatial distribution of microplastics: A case study of the Bay of Brest (Brittany, France)." Environmental Pollution **225**: 211-222.

The concentration and spatial distribution of microplastics in the Bay of Brest (Brittany, France) was investigated in two surveys. Surface water and sediment were sampled at nine locations in areas characterized by contrasting anthropic pressures, riverine influences or water mixing. Microplastics were categorized by their polymer type and size class. Microplastic contamination in surface water and sediment was dominated by polyethylene fragments (PE, 53-67%) followed by polypropylene (PP, 16-30%) and polystyrene (PS, 16-17%) microparticles. The presence of buoyant microplastics (PE, PP and PS) in sediment suggests the existence of physical and/or biological processes leading to vertical transfer of lightweight microplastics in the bay. In sediment (upper 5 cm), the percentage of particles identified by Raman micro-spectroscopy was lower (41%) than in surface water (79%) and may explain the apparent low concentration observed in this matrix (0.97 +/- 2.08 MP kg⁻¹ dry sediment). Mean microplastic concentration was 0.24 +/- 0.35 MP m⁻³ in surface water. We suggest that the observed spatial MP distribution is related to proximity to urbanized areas and to hydrodynamics in the bay. A particle dispersal model was used to study the influence of hydrodynamics on surface microplastic distribution. The outputs of the model showed the presence of a transitional convergence zone in the centre of the bay during flood tide, where floating debris coming from the northern and southern parts of the bay tends to accumulate before being expelled from the bay. Further modelling work and observations integrating (i) the complex vertical motion of microplastics, and (ii) their point sources is required to better understand the fate of microplastics in such a complex coastal ecosystem.

Frias, J. P., et al. (2016). "Microplastics in coastal sediments from Southern Portuguese shelf waters." Marine Environmental Research **114**: 24-30.

Microplastics are well-documented pollutants in the marine environment that result from fragmentation of larger plastic items. Due to their long chemical chains, they can remain in the environment for long periods of time. It is estimated that the vast majority (80%) of marine litter derives from land sources and that 70% will sink and remain at the bottom of the ocean. Microplastics that result from fragmentation of larger pieces of plastic are common to be found in beaches and in the water surface. The most common microplastics are pellets, fragments and fibres. This work provides original data of the presence of microplastics in coastal sediments from Southern Portuguese shelf waters, reporting on microplastic concentration and polymer types. Microplastic particles were found in nearly 56% of sediment samples, accounting a total of 31 particles in 27 samples. The vast majority were microfibers (25), identified as rayon fibres, and fragments (6) identified as polypropylene, through infrared spectroscopy (mu-FTIR). The concentration and polymer type data is consistent with other relevant studies and reports worldwide.

Frias, J. P. G. L., et al. (2014). "Evidence of microplastics in samples of zooplankton from Portuguese coastal waters." Marine Environmental Research **95**: 89-95.

Records of high concentrations of plastic and microplastic marine debris floating in the ocean have led to investigate the presence of microplastics in samples of zooplankton from Portuguese coastal waters. Zooplankton samples collected at four offshore sites, in surveys conducted between 2002 and 2008, with three different sampling methods, were used in this preliminary study. A total of 152 samples were processed and microplastics were identified in 93 of them, corresponding to 61% of the total. Costa Vicentina, followed by Lisboa, were the regions with higher microplastic concentrations (0.036 and 0.033 no. m⁻³) and abundances (0.07 and 0.06cm³m⁻³), respectively. Microplastic: zooplankton ratios were also higher in these two regions, which is probably related to the proximity of densely populated areas and inputs from the Tejo and Sado river estuaries. Microplastics polymers were identified using Micro Fourier Transformed Infrared Spectroscopy (mu-FTIR), as polyethylene (PE), polypropylene (PP) and polyacrylates (PA). The present work is the first report on the composition of microplastic particles collected with plankton nets in Portuguese coastal waters. Plankton surveys from regular monitoring campaigns conducted worldwide may be used to monitor plastic particles in the oceans and constitute an important and low cost tool to address marine litter within the scope of the Marine Strategy Framework Directive (2008/56/EC). © 2014 Elsevier Ltd.

Frias, J. P. G. L., et al. (2010). "Organic pollutants in microplastics from two beaches of the Portuguese coast." Marine Pollution Bulletin **60**(11): 1988-1992.

Microplastics pose a threat to coastal environments due to their capacity to adsorb persistent organic pollutants (POPs). These particles (less than 5. mm in size) are potentially dangerous to marine species due to magnification risk over the food chain. Samples were collected from two Portuguese beaches and sorted in four classes to relate the adsorption capacity of pollutants with color and age. Polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs) and DDTs were analysed on pellets through gas chromatography mass spectrometry (GC-MS), and types of plastic were identified using Fourier transformed infra-red spectroscopy (micro-FTIR). Microplastics were mostly polyethylene and polypropylene. Regarding sizes, some fibres ranged from 1 to 5mum in diameter and were 500mum in length. The majority of samples collected had sizes above 200mum. Black pellets, unlike aged pellets, had the highest concentrations of POPs except for PAHs in Fonte da Telha beach. PAHs with higher concentrations were pyrene, phenantrene, chrysene and fluoranthene. Higher concentrations of PCBs were found for congeners 18, 31, 138 and 187. Further investigation is necessary to understand the relationship between plastic degradation and adsorption for different pollutants. © 2010 Elsevier Ltd.

Fridlender, Z. G., et al. (2011). "Molecular characterization of tumor associated neutrophils from Non Small Cell Lung Cancer (NSCLC) and mesothelioma tumors." American Journal of Respiratory and Critical Care Medicine. Conference: American Thoracic Society International Conference, ATS **183**(1 MeetingAbstracts).

Rationale: We previously identified and preliminarily characterized two phenotypes of tumor-associated neutrophils (TAN) in murine models of non-small cell lung cancer (NSCLC) and mesothelioma, dependent on the presence or absence of active TGF-beta (Cancer Cell, 2009). In the current study, we further define the characteristics of these TAN using a microarray approach comparing naive bone-marrow neutrophils (BMN) to N1 ("anti-tumor") and N2 ("pro-tumor") TAN from mice bearing mesothelioma and NSCLC tumors. Method(s): Balb/C mice bearing large mesothelioma flank tumors were treated with SM16, a TGF-beta-R1 kinase inhibitor (N1-TAN) or left untreated (N2-TAN). Neutrophils were isolated from tumors using microbeads (CD11b) and flow cytometry (Ly6G). BMN were isolated from naive mice. mRNA from each subgroup was arrayed on Illumina chips. Enrichment pathways were identified using Genomica software. Selected results were validated by RT-PCR in these tumors and in tumors originating from an NSCLC cell line. Result(s):. Hierarchical clustering and PCA analysis showed that the three types of cells were clearly separated. Differences between N1- and N2-TAN were less prominent than between them and BMN. Many more genes were up-regulated than down-regulated in TAN compared to BMN, including pathways related to immune responses (e.g. Toll-like receptors), cytokine pathways (e.g. IL1beta and TNF), and a striking up-regulation of chemokines, including chemoattractants for T-cells (e.g. CXCL10), neutrophils (e.g. CXCL1), B-cells (CXCL13) and macrophages (e.g. CCL2). For several of these we found increased secretion to supernatant from TAN compared to BMN. Several pathways related to responses to stimuli were up-regulated in N1 versus N2 TAN, including the IL3 signaling pathway, CCR5, IRF-1, and some important anti-oxidants (e.g. GpX1). Up-regulated immune genes included TNF, Jak3, MapK14 and NF-kB-1alpha, and several antigen-processing and presentation genes, mostly by MHC-1. Macrophage chemoattractans (CCL2, CCL6 and CXCL10), as well as CXCL13, CCL8 and CCL3 were upregulated in N1-TAN, whereas the T-regulatory cell chemoattractant CCL17, was the only up-regulated in N2-TAN. In order to validate these results in humans, we are currently isolating and characterizing neutrophils from human NSCLC tumors. Conclusion(s): Our data demonstrate major differences between naive neutrophils and N1/N2-TAN in mesothelioma and NSCLC tumors, primarily in immune responses and chemotaxis. N1-TAN appear to make more macrophage chemoattractants and antigen processing and presentation genes. N2-TAN may attract Treg's with CCL17. The observation that differences between N1/N2-TAN are less prominent than between them and BMN, suggests that the change between N2 and N1 phenotypes is intra-tumoral and not d/t differential recruitment.

Friec, G. L., et al. (2011). "CD3/CD46-mediated generation of IL-10-secreting T cells is defective in rheumatoid arthritis." Annals of the Rheumatic Diseases **2)**: A48.

Background and objectives Control of effector T cell responses to foreign and self-antigens through interleukin (IL)-10-producing Th1 cells and adaptive IL-10+Tregs is vital for limiting immune pathology during infection and for preventing autoimmunity. However, the mechanisms that regulate their production remain incompletely understood. CD46 is the receptor for the C3b/C4b components of complement. The authors have previously demonstrated that activation of human CD4 T cells through the T-cell receptor and the complement regulator CD46 induces Tr1 like IL-10-producing Tregs. The authors set out to study factors that regulate the generation of IL-10 producing Tregs during normal immune homeostasis and to determine whether this pathway is defective in chronic inflammatory disease, such as rheumatoid arthritis. Materials and methods CD4 T lymphocytes were purified from PBMC of normal donors or PBMC and synovial fluid of rheumatoid arthritis (RA) and JIA patients using CD4 MicroBeads prior to activation with anti-CD3 and anti-CD46 mAb in the presence or absence of increasing concentrations of IL-2. After 36 h cytokine production was determined using the Th1/Th2 cytokine bead array. Cells were stained using the IFNgamma and IL-10 cytokine secretion assay kits in combination and IFNgamma⁺, IFNgamma ⁺/IL-10⁺ and IL-10⁺ cells isolated via cell sorting. Supernatants from cultures of these cells were then tested for their capacity to suppress proliferation of freshly purified T cells. Approval for this study was obtained from the Local Ethics Review Committee. Results IL-10-secreting T cells are derived from populations of differentiating Th1 effector T cells as they also secrete IFNgamma. The authors observed that the cytokine expression profile of CD3/CD46-activated T cells is heavily influenced by the amount of IL-2 present during activation. Thus, in the presence of low IL-2, CD3/CD46-activation induces strong IFNgamma-secretion and a proinflammatory effector phenotype. High IL-2 induces a 'switch' from IFNgamma⁺ T cells, via an IFNgamma⁺/ IL-10⁺ state, to an IL-10⁺ phenotype. CD46-induced IFNgamma⁺/ IL-10⁺ and IL-10⁺ cells are suppressive. By contrast, analysis of T cell populations from patients with inflammatory arthritis such as RA and JIA reveals that progression to the IL-10⁺ state is blocked even in the presence of high exogenous IL-2. In addition, CD3/CD46-activated T cells produce 20-30 times more IFN-gamma than IL-10. Conclusions CD46 activation during T cell response initiation supports IFNgamma secretion to combat infection while expansion of the effector response provides high IL-2 and the signal to switch to IL-10 production and resolution of the immune response. This regulatory switch appears to be defective in chronic inflammatory disease.

Friedlander, D. R., et al. (1994). "The neuronal chondroitin sulfate proteoglycan neurocan binds to the neural cell adhesion molecules Ng-CAM/L1/NILE and N-CAM, and inhibits neuronal adhesion and neurite outgrowth." Journal of Cell Biology **125**(3): 669-680.

We have previously shown that aggregation of microbeads coated with N-CAM and Ng-CAM is inhibited by incubation with soluble neurocan, a chondroitin sulfate proteoglycan of brain, suggesting that neurocan binds to these cell adhesion molecules (Grumet, M., A. Flaccus, and R. U. Margolis. 1993. J. Cell Biol. 120:815). To investigate these interactions more directly, we have tested binding of soluble ¹²⁵I-neurocan to microwells coated with different glycoproteins. Neurocan bound at high levels to Ng-CAM and N-CAM, but little or no binding was detected to myelin-associated glycoprotein, EGF receptor, fibronectin, laminin, and collagen IV. The binding to Ng-CAM and N- CAM was saturable and in each case Scatchard plots indicated a high affinity binding site with a dissociation constant of ~1 nM. Binding was significantly reduced after treatment of neurocan with chondroitinase, and free chondroitin sulfate inhibited binding of neurocan to Ng-CAM and N-CAM. These results indicate a role for chondroitin sulfate in this process, although the core glycoprotein also has binding activity. The COOH-terminal half of neurocan was shown to have binding properties essentially identical to those of the full-length proteoglycan. To study the potential biological functions of neurocan, its effects on neuronal adhesion and neurite growth were analyzed. When neurons were incubated on dishes coated with different combinations of neurocan and Ng-CAM, neuronal adhesion and neurite extension were inhibited. Experiments using anti-Ng-CAM antibodies as a substrate also indicate that neurocan has a direct inhibitory effect on neuronal adhesion and neurite growth.

Immunoperoxidase staining of tissue sections showed that neurocan, Ng-CAM, and N-CAM are all present at highest concentration in the molecular layer and fiber tracts of developing cerebellum. The overlapping localization in vivo, the molecular binding studies, and the striking effects on neuronal adhesion and neurite growth support the view that neurocan may modulate neuronal adhesion and neurite growth during development by binding to neural cell adhesion molecules.

Fries, E., et al. (2013). "Identification of polymer types and additives in marine microplastic particles using pyrolysis-GC/MS and scanning electron microscopy." Environmental Science. Processes & Impacts **15**(10): 1949-1956.

Any assessment of plastic contamination in the marine environment requires knowledge of the polymer type and the additive content of microplastics. Sequential pyrolysis-gas chromatography coupled to mass spectrometry (Pyr-GC/MS) was applied to simultaneously identify polymer types of microplastic particles and associated organic plastic additives (OPAs). In addition, a scanning electron microscope equipped with an energy-dispersive X-ray microanalyser was used to identify the inorganic plastic additives (IPAs) contained in these particles. A total of ten particles, which were optically identified as potentially being plastics, were extracted from two sediment samples collected from Norderney, a North Sea island, by density separation in sodium chloride. The weights of these blue, white and transparent fragments varied between 10 and 350 mug. Polymer types were identified by comparing the resulting pyrograms with those obtained from the pyrolysis of selected standard polymers. The particles consisted of polyethylene (PE), polypropylene, polystyrene, polyamide, chlorinated PE and chlorosulfonated PE. The polymers contained diethylhexyl phthalate, dibutyl phthalate, diethyl phthalate, diisobutyl phthalate, dimethyl phthalate, benzaldehyde and 2,4-di-tert-butylphenol. Sequential Py-GC/MS was found to be an appropriate tool for identifying marine microplastics for polymer types and OPAs. The IPAs identified were titanium dioxide nanoparticles (TiO2-NPs), barium, sulphur and zinc. When polymer-TiO2 composites are degraded in the marine environment, TiO2-NPs are probably released. Thus, marine microplastics may act as a TiO2-NP source, which has not yet been considered.

Fritzler, M. J. and M. L. Fritzler (2009). "Microbead-based technologies in diagnostic autoantibody detection." Expert Opinion on Medical Diagnostics **3**(1): 81-89.

BACKGROUND: There is a rapid proliferation of new technologies to identify a spectrum of autoantibodies in medical conditions that range from organ-specific autoimmune diseases to systemic rheumatic diseases. Although many laboratories have adopted high-throughput diagnostic platforms such as enzyme linked immunoassays (ELISA), other technologies such as microbead-based assays are emerging as an alternative diagnostic platform.

OBJECTIVE: To understand the performance and importance of bead based immunoassays in clinical diagnostics and therapeutics.

METHOD: Current literature was reviewed using the PubMed search engine combining keywords of immunoassay and Luminex, as well as a personal literature database. Included in the evaluation and commentary are bead-based assays such as addressable laser bead immunoassays and related magnetic bead assays.

CONCLUSIONS: Comparison with other conventional technologies has indicated that laser microbead immunoassays are reliable, accurate, cost-effective, highly sensitive and have rapid turn around time for results. While there are advantages to this diagnostic platform, there are challenges that must be addressed before wider acceptance or long-term use of this technology platform in the routine clinical diagnostic laboratory.

Fromant, A., et al. (2016). "Wide range of metallic and organic contaminants in various tissues of the Antarctic prion, a planktonophagous seabird from the Southern Ocean." Science of the Total Environment **544**: 754-764.
Trace elements (n = 14) and persistent organic pollutants (POPs, n = 30) were measured in blood, liver, kidney, muscle and feathers of 10 Antarctic prions (Pachyptila desolata) from Kerguelen Islands, southern Indian Ocean, in order to assess their concentrations, tissue distribution, and inter-tissue and inter-contaminant relationships. Liver, kidney and feathers presented the highest burdens of arsenic, cadmium and mercury, respectively. Concentrations of cadmium, copper, iron, and zinc correlated in liver and muscle, suggesting that uptake and pathways of metabolism and storage were similar for these elements. The major POPs were 4,4′-DDE, mirex, PCB-153 and PCB-138. The concentrations and tissue distribution patterns of environmental contaminants were overall in accordance with previous results in other seabirds. Conversely, some Antarctic prions showed surprisingly high concentrations of BDE-209. This compound has been rarely observed in seabirds before, and its presence in Antarctic prions could be due to the species feeding habits or to the ingestion of plastic debris. Overall, the study shows that relatively lower trophic level seabirds (zooplankton-eaters) breeding in the remote southern Indian Ocean are exposed to a wide range of environmental contaminants, in particular cadmium, selenium and some emerging-POPs, which merits further toxicological investigations. [ABSTRACT FROM AUTHOR]

Frommel, U., et al. (2013). "Adhesion of human and animal Escherichia coli strains in association with their virulence-associated genes and phylogenetic origins." Applied and environmental microbiology **79**(19): 5814-5829.
Intestinal colonization is influenced by the ability of the bacterium to inhabit a niche, which is based on the expression of colonization factors. Escherichia coli carries a broad range of virulence-associated genes (VAGs) which contribute to intestinal (inVAGs) and extraintestinal (exVAGs) infection. Moreover, initial evidence indicates that inVAGs and exVAGs support intestinal colonization. We developed new screening tools to genotypically and phenotypically characterize E. coli isolates originating in humans, domestic pigs, and 17 wild mammal and avian species. We analyzed 317 isolates for the occurrence of 44 VAGs using a novel multiplex PCR microbead assay (MPMA) and for adhesion to four epithelial cell lines using a new adhesion assay. We correlated data for the definition of new adhesion genes. inVAGs were identified only sporadically, particularly in roe deer (Capreolus capreolus) and the European hedgehog (Erinaceus europaeus). The prevalence of exVAGs depended on isolation from a specific host. Human uropathogenic E. coli isolates carried exVAGs with the highest prevalence, followed by badger (Meles meles) and roe deer isolates. Adhesion was found to be very diverse. Adhesion was specific to cells, host, and tissue, though it was also unspecific. Occurrence of the following VAGs was associated with a higher rate of adhesion to one or more cell lines: afa-dra, daaD, tsh, vat, ibeA, fyuA, mat, sfa-foc, malX, pic, irp2, and papC. In summary, we established new screening methods which enabled us to characterize large numbers of E. coli isolates. We defined reservoirs for potential pathogenic E. coli. We also identified a very broad range of

colonization strategies and defined potential new adhesion genes.

Frond, H. L., et al. (2019). "Estimating the Mass of Chemicals Associated with Ocean Plastic Pollution to Inform Mitigation Efforts." Integrated Environmental Assessment & Management **15**(4): 596-606.
Plastic pollution in the marine environment is well documented. What remains less recognized and understood are the chemicals associated with it. Plastics enter the ocean with unreacted monomers, oligomers, and additives, which can leach over time. Moreover, plastics sorb organic and inorganic chemicals from surrounding seawater, for example, polychlorinated biphenyls (PCBs) and metals. Thus, interception and cleanup of plastics reduces the amount of chemical contaminants entering or reentering the oceans and removes those already present. Here, we estimate 1) the mass of selected chemical additives entering the global oceans with common plastic debris items, and 2) the mass of sorbed chemicals (using PCBs as a case study) associated with microplastics in selected locations. We estimate the mass of additives that entered the oceans in 2015 as constituents of 7 common plastic debris items (bottles, bottle caps, expanded polystyrene (EPS) containers, cutlery, grocery bags, food wrappers, and straws or stirrers). We calculate that approximately 190 tonnes (t) of 20 chemical additives entered the oceans with these items in 2015. We also estimate the mass of PCBs associated with microplastics in 2 coastal (Hong Kong and Hawaii) and 2 open ocean (North Pacific and South Atlantic gyres) locations, as comparative case studies. We find that the mass of chemicals is related to the mass of plastics in a location, with greater mass of PCBs closer to the source (i.e., land), where there is more plastic per unit area compared to the open ocean. We estimate approximately 85 000 times more PCBs associated with plastics in an average 4.5-km stretch of beach in Hong Kong than from the same size transect in the North Pacific gyre. In conclusion, continuing efforts for plastic interception and cleanup on shorelines effectively reduces the amount of plastic-related chemicals entering and/or reentering the marine environment. Integr Environ Assess Manag 2019;15:596–606. © 2019 SETAC Key Points: Plastic debris is more than a physical presence; it is also associated with a mixture of chemicals that can be removed from the ocean with prevention and cleanup.We estimate that 87 000 t of plastic bottles, bottle caps, expanded polystyrene (EPS) food and drink containers, cutlery, grocery bags, straws or stirrers, and food wrappers entered the ocean in 2015; approximately 190 t of 20 chemical additives entered the oceans with these plastic items.The amount of sorbed chemicals per unit area is greater on shorelines where there is more concentrated plastic litter, with approximately 85 000 times more PCBs in Hong Kong than in the North Pacific gyre.Continuing efforts for plastic interception and cleanup on shorelines, where there are more plastics, effectively reduces the amount of plastic-related chemicals entering and/or reentering the marine environment. [ABSTRACT FROM AUTHOR]

Fry, D. M., et al. (1987). Ingestion of plastic debris by Laysan albatrosses and wedge-tailed shearwaters in the Hawaiian Islands.
Surveys of Laysan albatross (Diomedea immutabilis) and wedge-tailed shear-waters on (Puffinus pacificus) on Midway and Oahu Island, Hawaii, identified a high proportion of birds with plastic in the upper gastrointestinal tract. Fifty Laysan Albatross chicks were examined for

plastic items lodged within the upper digestive tract. Forty-five (90%) contained plastic, including 3 chicks having proventricular impactions or ulcerative lesions. Plastic items in 21 live albatross chicks weighed a mean of 35.7 g/ chick super(-1) (range 1-175 g). Two of four adult albatross examined contained plastic in the gut. Twelve of 20 adult Wedge-tailed Shearwaters (60%) contained plastic particles 2-4 mm in diameter. Chemical toxicity of plastic polymers, plasticizers and antioxidant additives is low, although many pigments are toxic and plastics may serve as vehicles for the adsorption of organochlorine pollutants from sea water, and the toxicity of plastics is unlikely to pose a significant hazard.

Frydkjær, C. K., et al. (2017). "Ingestion and Egestion of Microplastics by the Cladoceran <i>Daphnia magna</i>: Effects of Regular and Irregular Shaped Plastic and Sorbed Phenanthrene." Bulletin of environmental contamination and toxicology **99**(6): 655-661.

The presence of microplastics in aquatic ecosystems is of increasing global concern. This study investigated ingestion, egestion and acute effects of polyethylene microplastics in Daphnia magna. Fate of regular shaped microplastic beads (10–106 µm) were compared with irregular shaped microplastic fragments (10–75 µm). Daphnia magna ingested regular and irregular microplastic with uptake between 0.7 and 50 plastic particles/animal/day when exposed to microplastic concentrations of 0.0001–10 g/L. Egestion of irregular fragments was slower than that of microplastic beads. The EC50 for irregular microplastic was 0.065 g/L whereas microplastic beads were less inhibitory. The potential of microplastic to act as vector for hydrophobic pollutants was examined using [14C]phenanthrene as tracer. Polyethylene microplastic sorbed less [14C]phenanthrene compared to natural plankton organisms (bacteria, algae, yeast). As microplastics are much less abundant in most aquatic ecosystems compared to plankton organisms this suggests a limited role as vector for hydrophobic pollutants under current environmental conditions.

Frydkjaer, C. K., et al. (2017). "Ingestion and egestion of microplastics by the cladoceran Daphnia magna: effects of regular and irregular shaped plastic and sorbed phenanthrene." Bulletin of environmental contamination and toxicology **99**(6): 655-661.

The presence of microplastics in aquatic ecosystems is of increasing global concern. This study investigated ingestion, egestion and acute effects of polyethylene microplastics in Daphnia magna. Fate of regular shaped microplastic beads (10-106 micro m) were compared with irregular shaped microplastic fragments (10-75 micro m). Daphnia magna ingested regular and irregular microplastic with uptake between 0.7 and 50 plastic particles/animal/day when exposed to microplastic concentrations of 0.0001-10 g/L. Egestion of irregular fragments was slower than that of microplastic beads. The EC50 for irregular microplastic was 0.065 g/L whereas microplastic beads were less inhibitory. The potential of microplastic to act as vector for hydrophobic pollutants was examined using [¹⁴C]phenanthrene as tracer. Polyethylene microplastic sorbed less [¹⁴C]phenanthrene compared to natural plankton organisms (bacteria, algae, yeast). As microplastics are much less abundant in most aquatic ecosystems compared to plankton organisms this suggests a limited role as vector for hydrophobic pollutants under current environmental conditions.

Fu, D., et al. (2019). "Aged microplastics polyvinyl chloride interact with copper and cause oxidative stress towards microalgae Chlorella vulgaris." Aquatic Toxicology **216**: 105319.

Microplastics (MPs) could pose potential risks to microalgae, the primary producer of marine ecosystems. Currently, few studies focus on the interaction of aged MPs with other pollutants and their toxic effects to microalgae. Therefore, the present study aimed to investigate i) the

aging of microplastics polyvinyl chloride (mPVC) in simulated seawater and the changes in physical and chemical properties; ii) the effects of single mPVC (virgin and aged) and copper on microalgae Chlorella vulgaris; and iii) the interaction of aged mPVC and copper and the oxidative stress towards C. vulgaris. In this study, some wrinkles, rough and fractured surface textures can be observed on the aged mPVC, accompanying with increased hydroxyl groups and aromatic carbon-carbon double bond but decreased carbon hydrogen bond. It was found that single virgin or aged mPVC at low concentration (10mg/L) had significant inhibition on the growth of C. vulgaris but no inhibition at higher concentration (100, 1,000mg/L), which can be reasonably explained by the aggregation and precipitation of mPVC at high concentration. The aging of mPVC inhibited the growth of C. vulgaris with the maximum growth inhibition ratio (IR) of 35.26% as compared with that of virgin mPVC (IR=28.5%). However, the single copper could significantly inhibit the growth of C. vulgaris and the inhibitory effects increased with concentration (0.2, 0.5, 1.0mg/L). Furthermore, both the single aged mPVC (10mg/L) and copper (0.5mg/L) caused serious cell damage, although the concentration of superoxide dismutase (SOD) and the intracellular malonaldehyde (MDA) increased. In contrast to single treatment, the growth of C. vulgaris can be enhanced by the combined group with copper (0.5mg/L) and aged mPVC (10mg/L).

Fu, S. F., et al. (2018). "Exposure to polystyrene nanoplastic leads to inhibition of anaerobic digestion system." Science of the Total Environment **625**: 64-70.

In this study, impacts of nanoplastic on the pure and mixed anaerobic digestion systems were investigated.

Fu, Z., et al. (2006). "Flow-injection chemiluminescent immunoassay for alpha-fetoprotein based on epoxysilane modified glass microbeads." Journal of Immunological Methods **312**(1-2): 61-67.

A flow-injection chemiluminescent immunoassay system based on a novel transparent immunoaffinity reactor is proposed for the quantitation of alpha-fetoprotein. The reactor prepared with alpha-fetoprotein immobilized epoxysilane modified glass microbeads was used as an immunosensor for chemiluminescent detection. With a non-competitive immunoassay format, the proposed immunosensor system is a low cost, flexible and rapid assay for alpha-fetoprotein. After an off-line incubation of the analyte alpha-fetoprotein with horseradish peroxidase-labeled alpha-fetoprotein antibody as enzyme tracer, the mixture was injected into the reactor, which led to trapping of the free enzyme tracer by the reactor. The trapped enzyme tracer was detected by the p-iodophenol-luminol-H2O2 chemiluminescence system. Under optimal conditions, the decrease in chemiluminescence intensity was proportional to the alpha-fetoprotein concentration in the range of 5.0-100 ng/ml with a detection limit of 2.7 ng/ml at a signal/noise ratio of 3. The immunosensor system showed an acceptable reproducibility and stability. Clinical serum samples were assayed with this method and the results were in acceptable agreement with those obtained from immunoradiometric assay.

Fu, Z. and J. Wang (2019). "Current practices and future perspectives of microplastic pollution in freshwater ecosystems in China." Science of the Total Environment **691**: 697-712.

The pollution of marine and freshwater environments by plastic waste has attracted increasing public attention worldwide in recent years. China is the world's second largest economy and contributes the largest mass of mismanaged plastic waste. In this review, we collected accessible data on the abundance of microplastics in China's freshwater ecosystems, analyzing this pollutant in the samples of waters, sediments and biota. The results showed that microplastics are pervasive in surveyed freshwater environments, and a high abundance of microplastics was found in estuaries and inland waters located in populated urban areas. Moreover, many freshwater bivalve and fish have been found to uptake microplastics. Although similar sampling and laboratory processing methods were applied for microplastic research in different aquatic ecosystems, methods of investigation and units reported by different authors should be standardized. The characteristics of the detected microplastics showed that small size (<1 mm), fibers and transparency were the most common features in China's freshwater ecosystems and that PP and PE were the most common types of microplastics. The current situation of microplastic pollution in China is largely caused by inefficient administration and lack of applicable legislation and regulations. Therefore, we suggest that the Chinese government need to be more active in dealing with the plastic pollution issues, and increase education and publicity to promote people's awareness of environmental pollution caused by microplastics. Fuente-Cuesta, A., et al. (2012). "Biomass gasification chars for mercury capture from a simulated flue gas of coal combustion." Journal of Environmental Management **98**: 23-28.

The combustion of coal can result in trace elements, such as mercury, being released from power stations with potentially harmful effects for both human health and the environment. Research is ongoing to develop cost-effective and efficient control technologies for mercury removal from coal-fired power plants, the largest source of anthropogenic mercury emissions. A number of activated carbon sorbents have been demonstrated to be effective for mercury retention in coal combustion power plants. However, more economic alternatives need to be developed. Raw biomass gasification chars could serve as low-cost sorbents for capturing mercury since they are sub-products generated during a thermal conversion process. The aim of this study was to evaluate different biomass gasification chars as mercury sorbents in a simulated coal combustion flue gas. The results were compared with those obtained using a commercial activated carbon. Chars from a mixture of paper and plastic waste showed the highest retention capacity. It was found that not only a high carbon content and a well developed microporosity but also a high chlorine content and a high aluminium content improved the mercury retention capacity of biomass gasification chars. No relationship could be inferred between the surface oxygen functional groups and mercury retention in the char samples evaluated.

Fuentes Talavera, F. J., et al. (2007). "Effect of production variables on bending properties, water absorption and thickness swelling of bagasse/plastic composite boards." Industrial Crops and Products **26**(1): 1-7.

Composite boards of sugar cane bagasse particles and recycled high-density polyethylene were manufactured by means of a flat press process under laboratory conditions using a partial factorial experimental design (2^{K-1}) to determine the effects of the process variables press temperature, pressing time, bagasse/plastic content and pressure on bending properties, water absorption and thickness swelling. The sugar cane bagasse particles varied in size from 2 to 15 mm, the plastic particles from 1 to 3 mm. Nominal board dimensions and density were 300 mm x 300 mm x 5 mm and 0.75 g/cm³, respectively. The following process conditions were implemented: press temperature 140 and 160 degrees C, pressing time 6 and 12 min, bagasse/plastic content 40/60% and 60/40%, and pressure 3 and 6 MPa. Bending strength (MOR) and bending modulus of elasticity (MOE) increased proportionally with press temperature and pressing time. An increase of the bagasse content had a positive effect only on bending MOE. An increase in pressure had a negative effect on both bending strength and MOE. Water absorption and thickness swelling were reduced significantly by an increase in temperature and pressing time, whereas variation of pressure did not have any influence on these board properties.

Fueser, H., et al. (2019). "Ingestion of microplastics by nematodes depends on feeding strategy and buccal cavity size." Environmental Pollution **255**(Part 2).

Microplastics are hardly biodegradable and thus accumulate rather than decompose in the environment. Due to sedimentation processes, meiobenthic fauna is exposed to microplastics. Within the meiofauna, nematodes are a very abundant taxon and occupy an important position in benthic food webs by connecting lower and higher trophic levels. However, the key determinants of the uptake of microplastics by freshwater nematodes are still unknown. To investigate the bioaccessibility of microplastics for nematodes, we performed single- and multi-species ingestion experiments in which the ability of seven nematode species (six bacterial and one fungal feeder), diverse in their buccal cavity morphology (1.3-10.5 micro m), to ingest fluorescence-labelled polystyrene (PS) beads along with their natural diet was examined. Applied beads sizes (0.5, 1.0, 3.0 and 6.0 micro m), exposure time (4, 24 and 72 h) and concentration (3x10⁶ PS beads ml⁻¹ and 10⁷ PS beads ml⁻¹) were varied. Ingested beads were localized and quantified via fluorescence microscopy in the nematodes. In contrast to fungal-feeding nematode species with a stylet, bacterial-feeding species ingested 0.5- and 1.0- micro m PS beads with up to 249 and 255 beads after 24 h, respectively. Microplastics >=0.5 micro m could only be ingested and transported into the gastrointestinal tract, if the buccal cavities were considerably (>1.3 times) larger than the beads. At concentrations of 10⁷ PS beads ml⁻¹ ingestion rates were influenced by exposure time and PS bead concentration. In case of a known microplastic size distribution in the environment, predictions on the potential ingestion for nematode communities can be made based on the feeding type composition and the size of their buccal cavities.

Fugetsu, B., et al. (2004). "Encapsulation of multi-walled carbon nanotubes (MWCNTs) in Ba(2+)-alginate to form coated micro-beads and their application to the pre-concentration/elimination of dibenzo-p-dioxin, dibenzofuran, and biphenyl from contaminated water." Analyst **129**(7): 565-566.

We report preliminary data on the first use of multi-walled carbon nanotubes as adsorbents for the pre-concentration/elimination of dibenzo-p-dioxin, dibenzofuran and biphenyl from contaminated water.

Fujii, M., et al. (2012). "Smart recycling of organic solid wastes in an environmentally sustainable society." Resources, Conservation & Recycling **63**: 1-8.

Abstract: The organic fraction of municipal solid waste (MSW), such as plastics and paper, is commonly recycled in Japan, but a considerable room for improvement still remains. Energy intensive industries, such as steel, cement, paper, and power plants, have great capacities to accept waste plastics and paper to substitute their fossil resource consumption and to reduce carbon emissions. We propose a “smart recycling system” that utilizes existing industrial facilities that have high energy efficiency, for establishing a cost-effective and robust recycling system. The core of the smart recycling system is the smart recycling center (SRC) that establishes a new recycling pathway connecting spatially diffuse municipal sources to facilities in energy intensive industries. This paper discusses the design and function of an SRC and estimates the CO2 emissions and costs related to the operation and construction of the SRC. We also evaluated the cost effectiveness of the smart recycling system, taking into account sorted collection, incineration, processes in the SRC, and processes in industrial facilities. We estimated

that the system could result in a reduction of approximately 100kg of CO2 emissions per capita per year without a significant increase in cost. [Copyright &y& Elsevier]

Fujino, N., et al. (2011). "A new flow-cytometric method for isolating component cells individually from adult human distal lungs." American Journal of Respiratory and Critical Care Medicine. Conference: American Thoracic Society International Conference, ATS **183**(1 MeetingAbstracts).

RATIONALE: Constituent cells of the alveolar walls are approximately divided into three cell types: epithelial, mesenchymal and endothelial cells. These three cell-populations work together to maintain homeostasis and repair process of the lungs. Therefore, comprehensive analysis of the role of these cell populations in lung diseases is essential for better understanding of the pathophysiology and for discovering novel therapies. The aim of this study it to establish a new method for isolating each component cell from adult human distal lungs. METHODS We enzymatically digested human lung tissues obtained from thoracic surgery and prepared single cell suspensions. Hematopoietic cells were depleted with anti-CD45 antibody-coated microbeads. We sorted cell-populations by FACS based on staining pattern of the following antigens; EpCAM/E-cadherin (markers for epithelial cells), T1alpha (a marker for lymphatic endothelial and alveolar type I cells) and VE-cadherin (a marker for endothelial cells). Sorted cells were characterized by immunostaining, RT-PCR and subsequent culture. This study was approved by the Ethics Committee at Tohoku University School of Medicine and all subjects gave informed consent. RESULTS CD45-negative lung cells were divided into sub-populations based on the expression pattern of EpCAM, E-cadherin and T1alpha. The EpCAM/E-cadherin-highly positive subset without expression of T1alpha expressed surfactant protein-C (SP-C) but not Clara cell-specific protein (CCSP) or aquaporin 5 (AQP5), suggesting that alveolar type II cells were enriched in this subset. The other EpCAM/E-cadherin positive subset with no or low expression of T1alpha expressed CCSP and AQP5, but not SP-C, indicating that this EpCAM/E-cadherin-positive subset contained alveolar type I cells and bronchiolar epithelial cells including Clara cells. The T1alpha(hi) cells were thought to be lymphatic endothelial cells based on the positive expression of another lymphatic endothelial marker (VEGFR3). The EpCAM(-)/E-cadherin(-)/T1alpha subset was distinctively divided into a vascular endothelial population and a mesenchymal population based on the VE-cadherin expression. The VE-cadherin(+) cells expressed other vascular endothelial merkers (PECAM-1 and KDR), while the VE-cadherin(-) cells expressed markers for fibroblasts or pericytes, such as alpha-SMA. CONCLUSION This systematic approach facilitates comprehensive analysis of the lung component cells.

Fujino, Y., et al. (2013). "Art outcome of non-apoptotic spermatozoa selected by magnetic-activated cell sorting with annexin v-conjugated microbeads." Fertility and Sterility **1)**: S433.

OBJECTIVE: ART is a popular treatment but success rate remains still low. One of the reason may be the inclusion of sperm apoptosis. Magnetic activated cell sorting(MACS) with annexin-V microbeads recognizes externalized phosphatidylserine residues on the surface of apoptotic sperm. The aim of this study is to compare the outcome of ART using non-apoptotic sperm using with Annexin V-MACS and that of usual method. DESIGN: Clinical study. MATERIALS AND

METHODS: Twenty-three patients were received ovarian stimulation with clomiphene and hMG. Oocytes were retrieved at 32 hrs later after GnRHa spray. Motile sperm were selected by density- gradient centrifugation. One aliquot of sperm suspension was used for fertilization by usual method, the other aliquot by Annexin VMACS. Oocytes(N=64) in each case were divided into two, 34 oocytes were fertilized with the sperm by usual method (C) and 30 oocytes by Annexin V-MACS(VM). After fertilization and culture, one embryo was transferred in 14 cases(9:C, 5:VM). Another embryos were frozen with vitrification method. Fertilization, cleavage, growth rate and pregnancy rate were compared in two groups. Data were statically analyzed by c2test. RESULT(S): The mean concentration of sperm was 50.1x10[sup6]/ml and motility was 57% before the separation. After the separation, the mean concentration of sperm was 24.8x10[sup6]/ml and motility was 91% in "C", and that of 41.9x10[sup6]/ml and 92% in "VM", respectively. Fertilization rate was 88.2% and cleavage rate was 100% and blastocyst development rate was 36.7% in "C", and that was 90%, 85.2% and 33.3% in "VM", respectively. Pregnancy rate in transferred cases was 44.4%(C) and 40%(VM), respectively. There were no significant differences between two groups. CONCLUSION(S): The annexin V-MACS has the potential to benefit ART for the selection of apoptotic sperm. However, we cannot find any significant advantage in V-MACS procedure from this study. A larger scale prospective randomized study is required to evaluate the value of this technique.

Fujishiro, A., et al. (2015). "Vitamin K2 supports hematopoiesis through acting on bone marrow mesenchymal stromal/stem cells." Blood **126 (23)**: 1192.

[Background] Myelodysplastic syndrome is an intractable disorder characterized by ineffective hematopoiesis. Although allogeneic hematopoietic stem cell transplantation is the only curative therapy for eligible patients, hematopoiesis-supportive pharmacotherapy is practically important for transplant-ineligible patients to overcome transfusion dependency and infections. Vitamin K2 (VK2, menatetrenone) is a drug used to aim at improvement of hematopoiesis in MDS patients (Leukemia 14: 1156, 2000). However, the exact mechanism how VK2 improves hematopoiesis remains largely unknown. It was reported that VK2 induces MDS cells to undergo apoptosis (Leukemia 13: 1399, 1999). Here, we investigated our hypothesis that VK2 exerts its hematopoiesis-supportive effects through acting on mesenchymal stem/stromal cells (BM-MSCs) in the bone marrow microenvironment. [Methods] Normal bone marrow (BM) samples from healthy adult volunteers were purchased from AllCells (Emeryville, CA). BM-CD34⁺ cells were isolated from BM-mononuclear cells using anti-CD34 immunomagnetic microbeads (Miltenyi Biotec, Bergisch Gladbach, Germany). Human BM-MSCs were isolated according to our previously published methods (Stem Cells 32:2245, 2014). In co-culture experiments, BM-MSCs with or without VK2 treatment were seeded on a 24-well culture plate. BM-CD34⁺ cells were applied on the MSC-grown plate and co-cultured in SFEM (StemCell Technologies, Vancouver, Canada) supplemented with 100 ng/mL SCF, 100 ng/mL Flt-3 ligand, 50 ng/mL TPO and 20 ng/mL IL-3. After 10 days of co-culture, the number and surface marker expression of the expanded hematopoietic cells were examined by flow cytometric analysis. [Results] We first tested the direct effect of VK2 on BM-CD34⁺ cells. BM-CD34⁺ cells were treated with VK2 at various concentrations ranged from 0 muM to 10 muM for 24 hours and then cultured in SFEM in combinations with cytokines. Surprisingly, viable hematopoietic cells were hardly detected in the expansion culture of BM-CD34⁺ cells treated with 10 muM VK2. Even with 1 muM treatment, the number of CD45+ cells was decreased, as compared to that of expansion culture of untreated BM-CD34⁺ cells. The apoptosis analysis showed that the percentage of AnnexinV+ PI+ cells in the expanded hematopoietic cells is increased by VK2 treatment. We next examined the effect of VK2 on the hematopoiesis-supportive capability of BM-MSCs. BM-MSCs were pretreated with VK2 at various concentrations and then co-cultured with BM-CD34⁺ cells. The numbers of CD34⁺ cells and CD45+ cells were increased in a VK2 dose-dependent manner. These results demonstrated that VK2 shows different effects on distinct stem/progenitor cells: the induction of apoptosis in BM-CD34⁺ cells and the enhancement of hematopoiesis-supportive capability of BM-MSCs. We then investigated whether apoptosis-related cell death of BM-CD34⁺ cells by VK2 treatment is ameliorated in the presence of BM-MSCs. Both BM-CD34⁺ cells and BM-MSCs were treated with VK2 for 24 hours, and then co-cultured. The number of CD34⁺ cells was not decreased significantly in contrast to its severe decrease in single culture of VK2-treated BM-CD34⁺ cells. We further analyzed the effect of VK2 on BM-MSCs. Subpopulation analysis in co-culture of CD34⁺ cells with VK2-treated BM-MSCs showed that the expansion efficacy of CD34⁺CD38⁺ cells is higher in comparison to that of CD34⁺CD38- cells. In addition, the percentages of CD34-CD33+ cells and CD34-CD13+ cells were higher than those in co-cultures with untreated BM-MSCs. Therefore, VK2-treated BM-MSCs supported the expanded CD34⁺ cells to skew their phenotype toward myeloid lineage. The presence of a transwell in the co-culture system was unrelated to the expansion pattern of CD34⁺ cells, which suggested the involvement of soluble factors with respect to the underlining mechanism. We there ore compared the levels of hematopoiesis-supporting cytokine mRNA expression in VK2-treated and untreated BM-MSCs: VK2-treated BM-MSCs showed lower expression of CXCL12/SDF-1 mRNA and a trend toward higher expression of GM-CSF mRNA. [Summary] VK2 acted on BM-MSCs to support their ability to enhance expansion and myeloid differentiation of BM-CD34⁺ cells probably via altered GM-CSF and CXCL12/SDF-1 expression in MSCs. These findings may help to identify the mechanisms of therapeutic effects of VK2 in patients with MDS (Figure).

Fujiyama, T., et al. (2013). "Increased frequency of skin-infiltrating Th17 cells is associated with interstitial lung disease and hyperkeratotic eruptions in dermatomyositis patients." Journal of Investigative Dermatology **1)**: S35.

Dermatomyositis (DM) is an autoimmune disorder clinically characterized by skin eruptions, muscle weakness, autoantibodies, and occasional interstitial lung disease (ILD) and internal malignancy. Recently, DM has been reclassified into several subtypes according to the autoantibodies. ILD frequently occurs in the anti-aminoacyl-tRNA synthetase (ARS) antibody+ type and anti-CADM-140 antibody+ type. Meanwhile, the pathogenesis of skin eruptions in DM remains unfully elucidated. We sought to investigate the association of the eruptions with ILD, focusing on the skin-infiltrating T cells. Fourteen newly diagnosed DM patients were enrolled in this study, and skin biopsies were taken from markedly erythematous lesions. Eight patients had active ILD with elevated serum KL-6 levels (>=500 U/ml), while 6 had no detectable ILD with normal KL-6 levels (<500 U/ml). By immunofluorescence staining of the affected lesional skin, IL-17+ cells were observed in the majority of cases at various frequencies. We expanded skin-infiltrating T cells with IL-2 and anti-CD3/CD28 antibody-coated microbeads. T cells from DM patients with ILD produced significantly higher amounts of IL-17 in the culture supernatants than did those from DM patients without ILD (P=0.036). Flow cytometric analysis of the expanded T cells showed that they were positive for CD4 and CCR6, indicating Th17 cells. We found that this Th17 population was increased in skin-infiltrating cells from DM patients with ILD (mean, 1.9%) compared to those without ILD (mean, 0.2%). When the skin lesions were clinically divided into 4 grades in hyperkeratosis intensity, the patients with ILD exhibited significantly marked hyperkeratosis (top 2 grades, 7/8) and mimicked psoriasis as compared to those without ILD (2/7). Our study suggests that the frequency of skin-infiltrating Th17 cells and their cytokine production are increased in DM patients with ILD, and they preferentially manifest hyperkeratotic psoriasiform skin eruptions.

Fujiyama, T., et al. (2018). "Skin-infiltrating MDR1-expressing T cells are associated with therapeutic responsiveness to corticosteroids in severe cutaneous adverse reactions of drugs." Clinical and Translational Allergy. Conference: 8th Drug Hypersensitivity Meeting, DHM **8**(Supplement 3).

Background Systemic corticosteroid administration is the mainstay of therapeutic strategy for severe cutaneous adverse reactions (SCARs) of drugs. However, some cases are resistant to the treatment and occasionally need additional or alternative treatments to abrogate the inflammatory responses. It is believed that the type of eruptions, the severity of the inflammation and the clearance of the causative drugs are the main factors to influence on the responsiveness of corticosteroids. In addition to these factors, we hypothesized that there are some variations in the corticosteroid sensitivity of skin-infiltrating T cells, containing major effector cells concerned with drug eruptions. Multidrug resistance protein 1 (MDR1, CD243; also known as P-glycoprotein 1), capable of pumping many foreign substances out of the cells, is associated with corticosteroid resistance of T cells in certain diseases. Methods In this study, we investigated skin-infiltrating T cells from nine cases of drug eruption, including four cases of Stevens-Johnson syndrome or toxic epidermal necrolysis (SJS/TEN), four cases of drug-induced hypersensitivity syndrome or drug reaction with eosinophilia and systemic symptoms (DIHS/DRESS), and one case of fixed drug eruption (FDE). Skin-infiltrating T cells were expanded from skin biopsy specimen using IL-2 and anti-CD3/CD28 mAb-coated microbeads, and MDR1 gene and protein expressions were assessed by RT-PCR and flow cytometry, respectively. The function of MDR-1 was assessed by Rhodamine 123 efflux assay. Results In our preliminary study, we confirmed that the gene expression of MDR-1 was correlated with its function. The function of MDR-1 in T cells was not affected by the cultivation and stimulation process, while it was suppressed by cyclosporine A, an inhibitor of MDR-1. As assessed by cell survival assay, MDR-1+ cells were resistant to the in vitro treatment of corticosteroid. In all cases, both CD4+ and CD8+ T cells contained functional MDR-1+ T cells, and there was no significant difference in the frequency of MDR-1+ cells between SJS/TEN and DIHS/DRESS. However, the frequency of MDR-1+ tended to be higher in the patients who had previously received corticosteroid treatment. A case of FDE also showed a high frequency of MDR1+ T cells. MDR-1+ T cells produced IFNgamma in a SJS case, and both IFN-gamma and IL-4 in a DIHS case. Conclusion These results suggest that MDR-1+ cells contain T cells pathogenic for drug eruptions, and a medication history of previously used corticosteroids leads to a high frequency of MDR-1+ cells, resulting in the decreased sensitivity to corticosteroid treatment.

Fujiyama, T., et al. (2014). "Preferential infiltration of interleukin-4-producing CXCR4+ T cells in the lesional muscle but not skin of patients with dermatomyositis." Clinical & Experimental Immunology **177**(1): 110-120.

Dermatomyositis (DM) and polymyositis (PM) are collectively termed autoimmune myopathy. To investigate the difference between muscle- and skin-infiltrating T cells and to address their role for myopathy, we characterized T cells that were directly expanded from the tissues. Enrolled into this study were 25 patients with DM and three patients with PM. Muscle and skin biopsied specimens were immersed in cRPMI medium supplemented with interleukin (IL)-2 and anti-CD3/CD28 antibody-conjugated microbeads. The expanded cells were subjected to flow

cytometry to examine their phenotypes. We analysed the cytokine concentration in the culture supernatants from the expanded T cells and the frequencies of cytokine-bearing cells by intracellular staining. There was non-biased in-vitro expansion of tissue-infiltrating CD4(+) and CD8(+) T cells from the muscle and skin specimens. The majority of expanded T cells were chemokine receptor (CCR) type 7(-) CD45RO(+) effecter memory cells with various T cell receptor (TCR) Vbetas. The skin-derived but not muscle-derived T cells expressed cutaneous lymphocyte antigen (CLA) and CCR10 and secreted large amounts of IL-17A, suggesting that T helper type 17 (Th17) cells may have a crucial role in the development of skin lesions. Notably, the frequency of IL-4-producing chemokine (C-X-C motif) receptor (CXCR)4(+) Th2 cells was significantly higher in the muscle-derived cells and correlated inversely with the serum creatine phosphokinase (CPK) and lactate dehydrogenase (LDH) levels. stromal-derived factor (SDF)-1/CXCL12, a ligand for CXCR4, was expressed at a high level in the vascular endothelial cells between muscular fasciculi. Our study suggests that T cell populations in the muscle and skin are different, and the Th2 cell infiltrate in the muscle is associated with the low severity of myositis in DM.

Fujiyama, T., et al. (2013). "Tug-of-war between IFN-gamma-producing CD8 + T cells and IL-4-producing CD4 + T cells destines the severity of muscle injury in dermatomyositis." Journal of Dermatological Science **69 (2)**: e11.

Objective. Dermatomyositis (DM) is an autoimmune disorder characterized by inflammation of muscles and skin. Although it seems mediated by autoreactive lymphocytes, the mechanisms remain poorly understood. The aim of this study was to directly characterize pathogenic T-lymphocytes in their phenotype and function after expansion from skin and muscle lesions using the method that we have recently established. Methods. We expand T lymphocytes of skin and muscle biopsy specimens from 15 DM patients by the method that we have established using IL-2 and anti-CD3/CD28 Ab-coated microbeads, and investigated their phenotypes, T cell receptor (TCR) Vb usage, chemokine receptors and cytokine profiles. Results. Our observations demonstrated 1) the presence of type-1 and type-2 T cells in muscle lesions, 2) accumulation of antigen-reactive T cells comprising IL-4-producing CD4 + T cells and CD8 + T cells in muscle lesions and 3) negative correlation of the ratios of IL-4/IFN-gamma in the muscle-resident T cell cultures to muscle damage parameters, serum CPK and LDH. Conclusions. Our observations suggest that a tug of war between IFN-gamma-producing CD8 + T-lymphocytes that augment inflammation and IL-4-producing CD4 + T-lymphocytes that abrogate inflammation destines grade of muscle injury of DM.

Fujiyama, T., et al. (2019). "154 MDR1-expressing T cells accumulate in the resolved skin of psoriatic plaque after treatment with topical corticosteroid but not with anti-IL-17A mAb." Journal of Investigative Dermatology **139 (9 Supplement)**: S240.

Topical corticosteroid is a widely used for treatment of psoriasis. However, its long-term use may bring about resistance to the treatment. We have previously shown that multiple drug resistance 1 (MDR1)-expressing T cells infiltrate in the skin lesions of psoriasis, especially at the skin treated with a corticosteroid. Corticosteroids are a substrate of MDR1, and possible association of MDR1+ T cells and corticosteroid resistance has been documented in some diseases. Since MDR1+ T cells in psoriatic skin include a large number of IL-17A and IL-22-producing cells, they can be associated with corticosteroid resistance. In this study, we sought to clarify whether the blockade of IL-17A by Secukinumab affects MDR1 expression. We analyzed stocked T cells expanded by IL-2 and anti-CD3/CD28 mAb-coated microbeads from biopsy specimens taken from the skin of 7 patients treated with topical corticosteroid and from

the skin of 6 patients treated with Secukinumab. The function of MDR1 was investigated by Rh123 efflux assay. Rh123^{low} cells expressed ABCB1 gene, while Rh123^{hi} cells did not. In addition, verapamil, a specific inhibitor of MDR1 depressed the efflux of Rh123 at 94.0+/-2.3 percent, and thus, we considered Rh123^{low} cells as MDR1+ cells. In vitro treatment of a corticosteroid significantly increased the frequency of MDR1+ cells (P=0.02). The frequency of MDR1+ T cells was significantly higher in the corticosteroid-treated skin than in Secukinumab-treated patients' skin (P=0.01). Notably, this difference was more apparent in CD4+ T cells than in CD8+ T cells. Our results suggest that, unlike corticosteroid-treated skin, MDR1+ T cells do not accumulate in the skin of Secukinumab-treated patients. While anti-IL-17A mAb more strongly improves psoriasis than do topical corticosteroids, it renders remaining skin T cells susceptible to corticosteroid treatment. Copyright © 2019

Fujiyama, T., et al. (2018). "Skin-infiltrating Th17/Tc17 and Th1/Tc1cells are significantly decreased and IL-17+ CD103+ resident memory T cells partly remain after secukinumab treatment." Journal of Investigative Dermatology **138 (5 Supplement 1)**: S96.

IL-17-producing T cells are involved in the pathogenesis of psoriasis, and the blockade of IL- 17 by monoclonal antibodies dramatically improves the clinical symptoms of psoriasis. However, their effects on T cells in the patients skin is not fully investigated. To evaluate the alteration of skin-infiltrating T cells in response to the secukinumab, an IL-17A mAb therapy, we used our established method for ex vivo expansion of skin-infiltrating T cells from biopsied skin using IL-2 and anti-CD3/CD28 mAb-coated microbeads. Ten patients with psoriasis vulgaris were enrolled in this study. Four-mm punch skin biopsies were performed from lesional and non-lesional skin before treatment, 4 and 24 weeks after the treatment. The posttreatment biopsies were conducted from the skin where the first biopsy had been performed. In each time, a half of the biopsy specimens were used for T cell expansion and the other half was subjected to histology and immunostaining. After 2 weeks of expansion, the number of the cells and their cytokine profile were assessed using flow cytometry. We found that the numbers of total expanded T cells, and IFN-gamma and IL-17-producing CD4+ and CD8+ T cells from the lesional skin were significantly higher than those from non-lesional skin. These Th1/ Tc1 and Th17/Tc17 populations were decreased in the improved skin at 24 weeks after the therapy. The frequency of each cytokine-producing cells was not affected by the therapy. CD103+ resident memory T cells (TRM) were also expanded, and at 24 week-post-treatment, they contained a significantly higher frequency of IL-17-producing T cells than CD103- T cells. These results suggest that the blockade of IL-17 inhibits the local inflammatory loop of psoriasis by suppressing infiltration of IL-17-producing T cells, while a certain IL-17-producing TRM population remains in the skin even after the 24-week post-treatment.

Fuller, M., et al. (2011). "Screening patients referred to a metabolic clinic for lysosomal storage disorders." Journal of Medical Genetics **48**(6): 422-425.

Background: Lysosomal protein profiling is being developed as a high throughput method to screen populations for lysosomal storage disorders (LSD). Design(s): 1415 blood spots from patients referred to a metabolic clinic for LSD were screened using a single multiplex assay for 14 proteins in a dried blood spot. Results All patients with Pompe disease, metachromatic leukodystrophy, and mucopolysaccharidosis (MPS) type I, IIIA, IIIB and VI were identified by reduced lysosomal protein. Five samples were identified as possible pseudoarylsulfatase A deficiency; four were confirmed. One multiple sulfatase deficiency patient was identified with multiple reduced sulfatase proteins. There were 10 MPS II patients identified with reduced

iduronate 2-sulfatase, and one MPS II patient with iduronate 2-sulfatase in the unaffected range. For Fabry disease, 10 male patients were identified with reduced a-galactosidase and 2/6 female Fabry heterozygotes returned a-galactosidase concentrations in the male Fabry range. All 10 mucolipidosis II/III patients were identified with multiple raised proteins. For 79 blood spots with chitotriosidase >3.4 mg/l, a follow-up one-plex chitotriosidase assay enabled identification of all nine Gaucher patients. Conclusion(s): This study demonstrates the sensitivity and specificity of this technology to accurately identify 99% of LSD patients, with the exception of one MPS II false negative.

Fuller, S. and A. Gautam (2016). "A Procedure for Measuring Microplastics using Pressurized Fluid Extraction." Environmental Science & Technology **50**(11): 5774-5780.

A method based on pressurized fluid extraction (PFE) was developed for measuring microplastics in environmental samples. This method can address some limitations of the current microplastic methods and provide laboratories with a simple analytical method for quantifying common microplastics in a range of environmental samples. The method was initially developed by recovering 101% to 111% of spiked plastics on glass beads and was then applied to a composted municipal waste sample with spike recoveries ranging from 85% to 94%. The results from municipal waste samples and soil samples collected from an industrial area demonstrated that the method is a promising alternative for determining the concentration and identity of microplastics in environmental samples.

Fultz, K. (2019). UP AHEAD. Water Quality Products. Arlington Heights, Scranton Gillette Communications Inc. **24:** 10.

A proposed legislative or regulatory idea often takes more than one government session to gain the necessary traction and support to pass. During this time, provisions are amended and stakeholders lend expertise. In drinking water, the hot topics have been lead and per- and polyfl uoroalkyl substances (PFAS). Reviewing proposed legislation and regulations can provide some indication of drinking water concerns ahead. Beyond lead and PFAS concerns, proposed legislation considers other emerging contaminants including manganese, perchlorate, and microplastics.

Funane, T., et al. (2018). "Selective plane illumination microscopy (SPIM) with time-domain fluorescence lifetime imaging microscopy (FLIM) for volumetric measurement of cleared mouse brain samples." Review of Scientific Instruments **89**(5): 053705.

We have developed an imaging technique which combines selective plane illumination microscopy with time-domain fluorescence lifetime imaging microscopy (SPIM-FLIM) for three-dimensional volumetric imaging of cleared mouse brains with micro- to mesoscopic resolution. The main features of the microscope include a wavelength-adjustable pulsed laser source (Ti:sapphire) (near-infrared) laser, a BiBO frequency-doubling photonic crystal, a liquid chamber, an electrically focus-tunable lens, a cuvette based sample holder, and an air (dry) objective lens. The performance of the system was evaluated with a lifetime reference dye and micro-bead phantom measurements. Intensity and lifetime maps of three-dimensional human embryonic kidney (HEK) cell culture samples and cleared mouse brain samples expressing green fluorescent protein (GFP) (donor only) and green and red fluorescent protein [positive Forster (fluorescence) resonance energy transfer] were acquired. The results show that the SPIM-FLIM system can be used for sample sizes ranging from single cells to whole mouse organs and can serve as a powerful tool for medical and biological research.

Fung, Y. L. (2010). "Developments in the de tection of HNA and HLA antibodies." Vox Sanguinis **2)**: 9.

In the last decade there has been a resurgence of interest in neutrophil (PMN) reactive antibodies because antibodies to HNA- 1a, -1b, -2a and 3a have been associated with and implicated in TRALI events, which have been the top cause of transfusion related fatalities in the US (Holness, ABC Newletter 2007#12). Assays for detecting PMN antibodies include the granulocyte agglutination test (GAT), granulocyte immunofluorescence test (GIFT), and monoclonal antibody immobilisation of granulocyte antigen (MAIGA). However, because these assays are labour intensive and dependent on isolated viable PMNs, they are unsuitable for high throughput screening of blood donors to minimise the risk of TRALI. The use of solid phase assays for PMN antibodies may potentially address this problem, but published reports are scarce. Alternatively, transfected cells expressing HNA (Yasui et al. Transfusion 2007 & 2008) could potentially be a unlimited source of HNA for mass screening. In contrast, HLA antibodies which been associated in multiple TRALI events can easily be tested by high throughput and sensitive solid phase platforms. Briefly, soluble or recombinant HLA molecules are attached to solid phase media e.g. ELISA or microbeads, and bound antibodies are detected by changes in optical density (ELISA) or fluorescence detection (microbead). Studies indicate the following sensitivity; microbead assay > ELISA > antiglobulin-enhanced cytotoxicity based assay (Gebel et al. Transplantation 2000). Such sophisticated technology however appears to be over sensitive for screening donors for TRALI antibodies, as two studies show a disproportionately small number of detected HLA antibodies actually induce TRALI (Cooling et al. JAMA 2002, Toy et al. Transfusion 2004). This would suggest that the blanket application of antibody detection systems for different clinical applications (e.g. transplant in contrast to TRALI) is not always be suitable, and could unnecessarily reduce blood donor numbers. While we may be able to detect HNA and HLA antibodies, questions remain as to; Why do some antibodies (anti-HNA-3a, anti-HLA-A2) cause more severe reactions than others? Why does an antibody cause a reaction in one recipient and not another with the cognate antigen? Detailed studies of implicated antibodies may provide answers to these questions, as a study comparing anti-HNA-2a sera from ANN and TRALI cases demonstrated that although all 5 sera had the same specificity they had different titers, and variable serological and epitope preferences (Hassell et al. AABB 2009 abstract). In conclusion, even though HNA and HLA antibodies are implicated in both alloimmune neonatal neutropenia (ANN) and TRALI their underlying pathogenetic mechanisms are quite distinct. An effective antibody testing system for TRALI can only be developed by considering the underlying pathogenetic mechanisms.

Furlow, M. and S. L. Diamond (2011). "Interplay between membrane cholesterol and ethanol differentially regulates neutrophil tether mechanics and rolling dynamics." Biorheology **48**(1): 49-64.

Using microfluidic assays at a 100 s-1 wall shear rate, we examined the effects of ethanol on cholesterol-loaded neutrophils with respect to: (1) collision efficiency and membrane tethering to P-selectin-coated microbeads, (2) rolling on P-selectin-coated surfaces, and (3) primary and secondary interactions with neutrophils pre-adhered to intercellular adhesion molecule-1 (ICAM-1). Using methyl-beta-cyclodextrin:cholesterol complexes, membrane cholesterol was increased over control by 4.6-fold (no ethanol), 3.6-fold (0.3% ethanol pre-loading), and 1.6-fold (0.3% ethanol post-loading). These treatments did not alter CD11b expression; however, PSGL-1 and L-selectin were lowered by cholesterol enrichment (+/-ethanol). Cholesterol enrichment enhanced microbead collision efficiency, which was abrogated by ethanol. Ethanol had no effect on elevation of tethering fraction by cholesterol enrichment. Incubation of cholesterol-loaded neutrophils with ethanol resulted in significantly longer membrane tethers, due to tether lifetime enhancement. On P-selectin-coated surfaces, cholesterol-enriched neutrophils exposed

to ethanol rolled faster and with more variability than cholesterol-enriched neutrophils. Ethanol reduced homotypic collision efficiency of cholesterol-loaded neutrophils without effect on tethering fraction or secondary collision efficiency. Tether length during cholesterol-loaded neutrophil homotypic collisions was enhanced by ethanol, in part due to increased L-selectin/PSGL-1 bond tether lifetime. Overall, ethanol attenuated cholesterol-induced adhesion increases while increasing membrane fluidity as indicated by tether length.

Furness, R. W. (1985). "Ingestion of plastic particles by seabirds at Gough Island, South Atlantic Ocean." Environmental Pollution Series A: Ecological & Biological **38**(3): 261.

Furness, R. W. (1985). "Plastic particle pollution: Accumulation by procellariiform seabirds at Scottish colonies." Marine Pollution Bulletin **16**(3): 103-106.

Plastic particles were found in the gizzards of Leach's petrels, Manx shearwaters and fulmars from Scottish colonies, but were not found in 21 British storm petrels. Fulmars ingested larger particles than did Leach's petrels. The volume of plastic was equivalent to 59% of relaxed gizzard volume in most contaminated bird, but only equivocal statistical evidence for an influence of ingested plastic on body mass could be obtained.

Furst, A. (2007). "Thermal utilization of plastic waste material in the cement industry - potential impacts on the forest." Forstschutz Aktuell **38**: 26-28.

The production of cement is an energy-intensive process. Increasing production costs due to cost pressure from cheap cement imports have forced the cement industry to reduce production costs. Expensive fossil fuels have increasingly been replaced by alternative combustibles (e.g. plastic waste material) - cement works contribute therefore to a great extent to waste disposal. The authorities shall prescribe and enforce measures to be taken to control air pollution limit values. Strict intake control of the used alternative energy sources shall ensure that the levels of the relevant pollutants are maintained below the limit values. Adequate air pollution monitoring (e.g. local Biomonitoring grids) shall be used to effectively control the prescribed measures.

Furtado, R., et al. (2016). "White-faced storm-petrels Pelagodroma marina predated by gulls as biological monitors of plastic pollution in the pelagic subtropical Northeast Atlantic." Marine Pollution Bulletin **112**(1/2): 117-122.

Marine plastic pollution is rapidly growing and is a source of major concern. Seabirds often ingest plastic debris and are increasingly used as biological monitors of plastic pollution. However, virtually no studies have assessed plastics in seabirds in the deep subtropical North Atlantic. We investigated whether remains of white-faced storm-petrels (WFSP) present in gull pellets could be used for biomonitoring. We analysed 263 pellets and 79.0% of these contained plastic debris originating in the digestive tract of WFSP. Pellets with no bird prey did not contain plastics. Most debris were fragments (83.6%) with fewer plastic pellets (8.2%). Light-coloured plastics predominated (71.0%) and the most frequent polymer was HDPE (73.0%). Stable isotopes in toe-nails of WFSP containing many versus no plastics did not differ, indicating no individual specialisation leading to differential plastic ingestion. We suggest WFSP in pellets are highly suitable to monitor the little known pelagic subtropical Northeast Atlantic.

Gabbar, H. A., et al. (2017). "DC Thermal Plasma Design and Utilization for the Low Density Polyethylene to Diesel Oil Pyrolysis Reaction." Energies **10**(6).

Growing worldwide concerns regarding the environmental consequences of heavy dependence on fossil fuels, particularly climate change, are likely to constrain excessive use of fossil fuels in the near future. [...]plastic to oil pyrolysis could have a positive environmental impact by providing alternative fuels and reducing the carbon footprint of incineration [5]. [...]the steady increase in energy consumption coupled with environmental pollution promotes the evolution of alternative fuels such as plastic pyrolysis oil. Because of the increasing cost and decreasing space of landfills, traditional methods of plastic waste recycling such as landfilling and incineration cause irreversible environmental problems, including high NO2 and CO2 emissions [6]. The thermal plasma also accelerates reaction kinetics and improve thermal cracking and the emission enthalpy can be adjusted easily by electric power tuning [29]. [...]DC thermal plasma torches can act as a catalyst due to their excellent properties such as high energy density, high temperature range, and high chemical reactivity [30]. Oxidation and combustion is avoided and its occurrence can increase char by up to 40–55 wt. % [35]. Since the reaction residence time is longer than few seconds, a batch reactor or pressurized batch reactor is used.

Gabriel, A. and K. Menrad (2015). "Market acceptance and consumers' willingness-to-pay for plants in biodegradable pots." Acta Horticulturae.

In the last decades, society-driven topics like recycling and reduction of plastic waste increased efforts to utilize biodegradable materials. Up to now, a successful introduction of biodegradable flower pots on the German plant market has been hampered due to insufficient processing and marketing efforts. Although most plant buyers disclose high ecology-oriented attitudes, this does not result automatically in a higher willingness-to-pay for higher-priced biodegradable pots. In our study, 562 customers of six retail flower shops and garden centers in western and southern Germany were asked directly after buying certain potted plants (ornamentals, young vegetable plants, and herbs) offered in the shops - side-by-side in standard plastic and in biodegradable pots. Interviewers recorded the customers' choice in their shopping trolley and asked questions about the intention of the purchase, knowledge of biodegradable materials and characteristics of the buyer himself. The analysis exposes that the respondents showed both high interests in biodegradable pots and an increased willingness-to-pay additional price charges of 15-48% depending on the kind of potted plant. Especially for edible and vegetable plants the consumers showed an increased willingness-to-pay within the range of the additional costs of producing plants in biodegradable pots. Furthermore, the survey results revealed that quality and environmental aspects are higher-ranked product attributes than the price of biodegradable pots. An extended market potential can be created by combining these biodegradable pots with organically produced plants.

Gadush, M., et al. (2011). "The university of texas at Austin-protein and metabolite analysis facility." Journal of Biomolecular Techniques **1)**: S47.

The Protein and Metabolite Analysis Facility at the University of Texas at Austin is a joint effort of the College of Pharmacy, Center for Research on Environmental Disease (CRED), and the Institute for Cellular and Molecular Biology (ICMB). Services and collaborative research are offered for the detection, characterization and quantification of biomolecules. The Facility's goals are to provide sensitive protein identification and modification analyses, to provide custom peptide syntheses, to offer services for the identification and quantification of metabolites, nutrients and xenobiotics, to implement novel analytical methods, to improve the sensitivity of existing analyses, to provide consultation on the selection and implementation of analytical methods, to offer training in the usage and applications of the instrumentation, and to provide technical expertise in support of individual research goals. The ICMB portion of the Core contains an ABI Procise 492 cLC protein sequencer, a Protein Technologies Inc. Symphony

peptide synthesizer, two Bio-rad Duoflows and a GE Heathcare AKTA protein purification systems, two Beckman System Gold HPLC systems, a Berthold Technologies Mithras luminescence and fluorescence detector, an Invitrogen gel electrophoresis set-up, an Art Robbins Instruments Phoenix crystallography robot and a LC-MALDI-TOF/TOF (an ABI 4700 with a LC Packings Ultimate Nano-LC system with a Probot spotting robot). In the College of Pharmacy, the Core has an Applied Biosystems 4000 Q-trap LC MS/MS system with ESI, APCI and nanospray sources coupled with a Shimadzu LC-20AD HPLC system, ThermoFinnigan LCQ ion trap mass spectrometer with ESI, APCI and microspray interfaces combined with a Michrom Magic 2002 HPLC system, a ThermoFinnigan Trace MS GC-quadropole with EI positive, negative CI and selected ion monitoring (SIM), an ABI Voyager-DE Pro MALDI-TOF and a Bio-rad Bioplex 200 fluorescent microbead array system.

Gaggino, R., et al. (2014). Ecological roofing tiles made with rubber and plastic wastes. 1st Asia Pacific Rubber Conference 2013, APRC 2013, September 5, 2013 - September 6, 2013, Suratthani, Thailand, Trans Tech Publications Ltd.

The general objective of this research work was to contribute to the environmental decontamination. Its specific objective was to develop sustainable roofing tiles from the ecological, technical and economical points of view. These roofing tiles are made from recycled materials such as plastics from industry, and rubber from tires into disuse. In this way this technology contributes in the decontamination of the environment, since it uses waste materials that are buried in municipal land without any use, or accumulated and burned in landfills, causing pollution. The procedure used was the thermo-molding compaction. The available amounts of plastic waste are abundant. According to data provided in 2012 by the Ministry of Health and Environment of Argentina, Argentina produces 1,639 tons/year. The available amounts of rubber tires are also abundant. According to data provided in 2012 by the National Institute of Industrial Technology -INTI, Argentina generates more than 100,000 tons/year. Plastics and rubber are non bio-degradables materials, so nature can not absorb them as other waste. One purpose of this research work was to provide an alternative to other traditional building technologies that consume non-renewable resources, or produce negative environmental impact. The main technical advantages of these roofing tiles respect to other traditional such as ceramic or concrete tiles are their excellent resistance to hail and freezing, high flexural resistance, low specific weight, and low water absorption. (2014) Trans Tech Publications, Switzerland.

Gagne, F. (2017). "Toxicity and disruption of quorum sensing in Aliivibrio fisheri by environmental chemicals: Impacts of selected contaminants and microplastics." Journal of Xenobiotics **7**(1): 15-20.

The purpose of this study was to examine the effects of dissolved and particulate compounds on quorum sensing in the marine luminescent bacterium Aliivibrio fisheri. Bacteria were exposed to increasing concentrations of CuSO<inf>4</inf> (Cu²⁺), gadolinium chloride (Gd³⁺), 20-nm silver nanoparticles (nanoAg) and 1-3 mum microplastic polyethylene beads for 250 min. During this period, luminescence measurements were taken at 5-min intervals. Toxicity was first examined by measuring luminescence output at 5-min and 30-min incubation time. Based on the effective concentration that decreases luminescence by 20% (EC20), the compounds were toxic at the following concentrations in decreasing toxicity: Cu²⁺ (3.2 mg/L) < nanoAg (3.4 mg/L, reported) < Gd³⁺ (34 mg/L) < microplastics (2.6 g/L). The data revealed that luminescence changed non-linearly over time. In control bacteria, luminescence changed at eight specific major frequencies between 0.04 and 0.27 cycle/min after Fourier transformation of time-dependent luminescence data. The addition of dissolved Cu²⁺ and Gd³⁺ eliminated the amplitude changes at these frequencies in a concentration-dependent manner, indicating loss of quorum sensing between bacteria at concentrations below EC20. In the presence of nanoAg and microplastic beads, the decreases in amplitudes were modest but compressed the luminescence profiles, with shorter frequencies appearing at concentrations well below EC20. Thus, loss of communication between bacteria occurs at non-toxic concentrations. In addition, with exposure to a mixture of the above compounds at concentrations that do not produce effects for Gd³⁺, nanoAg and microplastics, Cu²⁺ toxicity was significantly enhanced, suggesting synergy. This study revealed for the first time that small microplastic particles and nanoparticles can disrupt quorum sensing in marine bacteria. Copyright © F. Gagne et al., 2017.

Gagné, F., et al. (2019). "Polystyrene nanoparticles induce anisotropic effects in subcellular fraction of the digestive system of freshwater mussels." Current Topics in Toxicology **15**: 43.

The release of nanoplastics (NP) from the weathering and degradation of plastics represents one of the major concerns for the environment given their pervasiveness in cells. A methodology for the detection of anisotropic changes induced by polystyrene NP is proposed using fluorescence polarization. The commercially available probe fluorescein octadecyl ester (FOE) has the property to interact in hydrophobic environments (phospholipids) which could be measured by fluorescence polarization spectroscopy. Although increasing the concentrations of 50 nm polystyrene NP in buffer alone did not change polarization, the addition of the subcellular fraction increased polarisation of the dye in a concentration-dependent manner. The assay was performed in mussels exposed to primary-treated effluents and revealed increased anisotropy of the subcellular fraction of the digestive gland suggesting NP-like effects. Although lipid contents were significantly correlated with fluorescence polarization ($r = 0.65$; $p < 0.001$), the increase in polarization was not entirely explained by changes in lipid droplets. In conclusion, polystyrene NP induces anisotropic effects at the subcellular fraction of the digestive gland as determined with the FOE probe. Mussels exposed to primary-treated effluents displayed NP-like anisotropic effects suggesting that these effluents contain NPs.

Gagne, F., et al. (2019). "Detection of polystyrene nanoplastics in biological samples based on the solvatochromic properties of Nile red: application in Hydra attenuata exposed to nanoplastics." Environmental Science & Pollution Research **26**(32): 33524-33531.

The release of nanoplastics (NP) from the weathering of microplastics is a major concern for the environment.

Gagné, F., et al. (2019). "Detection of polystyrene nanoplastics in biological samples based on the solvatochromic properties of Nile red: application in <i>Hydra attenuata</i> exposed to nanoplastics." Environmental science and pollution research international **26**(32): 33524-33531.

The release of nanoplastics (NP) from the weathering of microplastics is a major concern for the environment. Methods for the detection of NP in biological tissues are urgently needed because of their ability to penetrate not only in tissues but also in cells. A simple fluorescence-based methodology for the detection of polystyrene NP in biological tissues is proposed using the solvatochromic properties of Nile red. Although NPs alone increased somewhat Nile red fluorescence, a characteristic hypsochromic shift in the emission spectra was found when the dye and NP were incubated with subcellular tissue fraction. To explain this, the probe and NPs (50 and 100 nm) were prepared in the presence of increasing concentrations of two detergents (Tween-20, Triton X-100) as a proxy to phospholipids. The data revealed that both detergents readily increased fluorescence values when added to the NP and Nile red. The addition of NPs in tissue extracts blue-shifted further the emission spectra to 623 nm from the normal Nile red-lipid peak at 660 nm. The fluorescence intensity was proportional to the NP concentration. A methodology is thus proposed for the detection of NPs in laboratory-exposed organisms based on the solvatochromic properties of Nile red. The methodology was used to detect the presence of NP and changes in polar lipid contents in Hydra attenuata exposed to polystyrene NP.

Gago, J., et al. (2015). "First observation on neustonic plastics in waters off NW Spain (spring 2013 and 2014)." Marine Environmental Research **111**: 27-33.

This paper examines the presence and distribution of plastic particles in waters off the NW Spanish Atlantic coast. A pilot sampling program was initiated in 2013 to study the presence of plastic particles in surface waters. A total of 41 neuston samples were collected using a manta trawl fitted with a 333 mu m mesh (21 samples in 2013 and 20 samples in 2014). Several types of plastic particles were observed in 95% of the stations. A total of 1463 plastic microparticles (5 mm and <20 mm; MPS) were counted. Average concentrations recorded were 0.034 plus or minus 0.032 and 0.176 plus or minus 0.278 mps m-2 and 0.005 plus or minus 0.005 and 0.028 plus or minus 0.043 MPS m-2, respectively for 2013 and 2014. Results on this emerging topic are discussed as a preliminary step towards implementation of the Marine Strategy Framework Directive in the region. Harmonization of protocols for determination of plastic particles is urgently needed in order to compare results between regions and to ensure coherence in the implementation of the MSFD. This aspect is also important at a worldwide scale.

Gajendiran, A., et al. (2016). "Microbial degradation of low-density polyethylene (LDPE) by Aspergillus clavatus strain JASK1 isolated from landfill soil." 3 Biotech **6**(1): 52.

Polythene and plastic waste are found to accumulate in the environment, posing a major ecological threat. They are found to be considered non-degradable, once it enters the environment it has been found to remain there indefinitely. However, significant attention has been placed on biodegradable polymer, identification of microbes with degradative potential on plastic material. The aim of the present investigation was to biodegrade low-density polyethylene (LDPE) using potential fungi isolated from landfill soil. Based on 18S rRNA analyses the isolated strain was identified as Aspergillus clavatus. LDPE degradation by A. clavatus was monitored for 90 days of incubation in aqueous medium. The degradation was confirmed by changes in polyethylene weight, CO₂ evolution by Strum test, infrared spectra and morphological changes by SEM and AFM analysis.

Gajst, T., et al. (2016). "Sea surface microplastics in Slovenian part of the Northern Adriatic." Marine Pollution Bulletin **113**(1-2): 392-399.

Plastics are the most common material of marine litter and have become a global pollution concern. They are persistent in the environment where they gradually degrade into increasingly smaller particles-microplastics (MP). Our study presents results of sea-surface monitoring for MP in the Slovenian part of the Trieste Bay in the Northern Adriatic Sea. In 17 trawls conducted over a 20-month period we found a high average concentration of 406x10³MPparticles/km². Over 80% of the particles were identified as polyethylene. The significant variability of MP concentrations obtained on different sampling dates is explained by use of surface current maps and a recently developed Markov chain marine litter distribution model for the Adriatic Sea.

Galafassi, S., et al. (2019). "Plastic sources: A survey across scientific and grey literature for their inventory and relative contribution to microplastics pollution in natural environments, with an emphasis on surface water." Science of the Total Environment **693**: 133499.

Plastic debris are at present recognized as an emerging potential threat for natural environments, wildlife and humans. In the past years an increasing attention has been addressed to investigate the presence and concentration of plastic debris in the ecosystems, including surface waters. Scientific literature extensively describes the ingestion by aquatic fauna, the transfer into food webs and the potential action as a vector for toxic compounds or alien microorganisms. Although the scientific community addresses this issue with considerable effort, many questions remain open. In particular, new sources of microplastics have been recently recognized, possibly representing major environmental inputs compared to those previously considered. In addition to the already renowned sources such as the embrittlement of plastic litter and microbeads released from personal care products, microplastic can be released also by washing of synthetic clothes, abrasion of vehicles tyres and from the weathering of different kind of paints. This review tries to exhaustively enumerate all the possible sources of plastic litter that have been identified so far and to report quantitative assessments of their inputs on microplastics pollution to natural environments reported in scientific and grey literature, with an emphasis on surface waters.

Galambos, C., et al. (2013). "In utero embryonic intracardiac injection under biomicroscopy guidance: A cutting-edge technology to study embryonic lung development in vivo." Pediatric and Developmental Pathology **16 (2)**: 131.

Background: Approximately 14 per 10 000 live-born humans suffer from pulmonary hypoplasia (PH) often causing neonatal death. Although the pathomechanism of PH is poorly understood emerging data suggest a key role for pulmonary vessels and blood flow in regulating lung development. Therefore, there is a pressing need to utilize novel tools that permit in vivo manipulation of embryonic vasculature at early development stages. We aimed to develop a method that allows us to study the role of blood flow in lung development in vivo. Design(s): We devised a novel technique involving in utero fetal intracardiac injection under high-resolution ultrasound biomicroscopy-guidance (IHB) to identify perfused pulmonary vessels. We injected wild-type mouse embryos at early embryonic stage (E10.5-E12.5) using three different tracers; endothelial specific FITC-tomato lectin (FITC-TL), erythrocyte specific FITC-wheat germ lectin (FITC-WGL) and FITC-labeled microbeads (FBs). Intracardiac injection guaranteed that these tracers only highlight perfused vessels. We captured images of whole-mount fluorescent-labeled peripheral lung buds with confocal microscope and 3D reconstructions were performed by IMARIS software. We analyzed FITC-TL vs. PECAM labeled peripheral vasculature. Identification of FITC-WGL erythrocytes and FBs within peripheral vessels confirmed perfusion. Result(s): IHB provides direct vascular access to the developing mouse embryo at early time points; the technique is survivable and highly reproducible. Significant overlap was seen on merged PECAM and FITC-TL images of pulmonary vessels at all ages. FITC-WGL erythrocytes and FBs were present all throughout the lung vasculature including the developing peripheral microvessels around the growing lung buds. Conclusion(s): Our technique allows, for the first time, a performance of an embryonic ''pulmonary angiogram'' to show true embryonic blood flow in living, developing mouse lung. Our data suggest that most pulmonary vessels are perfused at a very early gestational age. This surprising finding led us to postulate that a blood perfused pulmonary vascular network is, in fact, necessary for proper lung growth and altered blood flow may play a role in the pathomechanism of PH. With this technique we are not only able to further study the role of embryonic pulmonary blood flow but we can also deliver a variety of agents directly to the embryo (bypassing the placental barrier) including genes, viruses, stem cells, and drugs to address the developmental pathobiology of the lung.

Galgani, F., et al. (2014). "Monitoring the impact of litter in large vertebrates in the Mediterranean Sea within the European Marine Strategy Framework Directive (MSFD): Constraints, specificities and recommendations." Marine Environmental Research **100**: 3-9.

In its decision (2010/477/EU) relating to the European Marine Strategy Framework Directive (MSFD, 2008/56/EC), the European Commission identified the following points as focuses for monitoring:. (i) 10.1.1: Trends in the amount, source and composition of litter washed ashore and/or deposited on coastlines,. (ii) 10.1.2: Trends in the amount and composition of litter in the water column and accumulation on the sea floor,. (iii) 10.1.3: Trends in the amount, distribution and composition of micro-particles (mainly microplastics), and. (iv) 10.2.1: Trends in the amount and composition of litter ingested by marine animals.Monitoring the impacts of litter will be considered further in 2014. At that time, the strategy will be discussed in the context of the Mediterranean Sea, providing information on constraints, protocols, existing harm and research needed to support monitoring efforts.The definition of targets and acceptable levels of harm must take all factors into account, whether entanglement, ingestion, the transport and release of pollutants, the transport of alien species and socio-economic impacts. It must also reflect on the practical deployment of "ingestion" measures (10.2.1). The analysis of existing data will reveal the potential and suitability of some higher trophic level organisms (fish, turtles, birds and mammals) for monitoring the adverse effects of litter. Sea turtles appear to be useful indicator species, but the definition of an ecological quality objective is still needed, as well as research on alternative potential indicator species. © 2014 Elsevier Ltd.

Galgani, F., et al. (2011). "Marine pollution: let us not forget beach sand." Environmental Sciences Europe **23**(40).

Background: Assessing the chemical or bacterial contamination in marine waters and sediments is a very common approach to evaluate marine pollution and associated risks. However, toxicity and organic pollution of beach sands have not yet been considered, except in adjacent waters. In the present study, the toxicity and the chemical contamination of natural beach sands collected 20 m from the shoreline at two sites located on the Mediterranean Sea (Marseille and La Marana, Corsica) were studied.

Gallagher, A., et al. (2016). "Microplastics in the Solent estuarine complex, UK: An initial assessment." Marine Pollution Bulletin **102**(2): 243-249.

Microplastics are known to be an increasing component found within both marine sediments and the water column. This study carried out an initial assessment of the levels of microplastics present within the Solent estuarine complex, focusing specifically on the water column. A plankton net trawl survey was carried out, with samples analysed using visual observation and Fourier Transform Infrared Spectroscopy (FT-IR). The study identified significant quantities of plastics, ranging in shape, with hot spots found at confluence points within the estuary. Though the FT-IR analysis was inconclusive, the nature of the samples indicates the effect of oceanographic conditions on the prevalent types of microplastics found, which in turn identifies key local sources such as wastewater treatment plants and the plastics industry as being the dominant inputs. Gallego, M. G., et al. (2016). "Gelatine-Based Antioxidant Packaging Containing Caesalpinia decapetala and Tara as a Coating for Ground Beef Patties." Antioxidants **5**(2): 31.

The development of antioxidant-active packaging has numerous advantages, such as the reduction of synthetic additives in food, the reduction of plastic waste and food protection against oxidation reactions. Different concentrations of extracts of the plants Caesalpinia decapetala (CD) and Caesalpinia spinosa "Tara" (CS) were incorporated into gelatine films as natural antioxidants. The physical, mechanical and antioxidant properties of these films were studied. Films containing plant extracts at a high concentration had lower tensile strength with higher elongation at break points, compared to the control film ($p < 0.05$). Films exhibited antioxidant activity in the oxygen radical absorbance capacity (ORAC) and Trolox equivalence antioxidant capacity (TEAC) assays when added at 0.2%. The application of gelatine film containing CD and CS was found to be effective in delaying lipid oxidation and deterioration of beef patty quality during storage. Therefore, the films prepared in this study offered an alternative edible coating for the preservation of fresh food.

Gallo, F., et al. (2018). "Marine litter plastics and microplastics and their toxic chemicals components: the need for urgent preventive measures." Environmental Sciences Europe **30**(1): 13.

Persistent plastics, with an estimated lifetime for degradation of hundreds of years in marine conditions, can break up into micro- and nanoplastics over shorter timescales, thus facilitating their uptake by marine biota throughout the food chain. These polymers may contain chemical additives and contaminants, including some known endocrine disruptors that may be harmful at extremely low concentrations for marine biota, thus posing potential risks to marine ecosystems, biodiversity and food availability. Although there is still need to carry out focused scientific research to fill the knowledge gaps about the impacts of plastic litter in the marine environment (Wagner et al. in Environ Sci Eur 26:9, 2014), the food chain and human health, existing scientific evidence and concerns are already sufficient to support actions by the scientific, industry, policy and civil society communities to curb the ongoing flow of plastics and the toxic chemicals they contain into the marine environment. Without immediate strong preventive measures, the environmental impacts and the economic costs are set only to become worse, even in the short term. Continued increases in plastic production and consumption, combined with wasteful uses, inefficient waste collection infrastructures and insufficient waste management facilities, especially in developing countries, mean that even achieving already established objectives for reductions in marine litter remains a huge challenge, and one unlikely to be met without a fundamental rethink of the ways in which we consume plastics. This document was prepared by a working group of Regional Centres of the Stockholm and Basel Conventions and related colleagues intended to be a background document for discussion in the 2017 Conference of the Parties (COP) of the Basel Convention on hazardous wastes and the Stockholm Convention on persistent organic pollutants (POPs). The COP finally approved that the issue of plastic waste could be dealt by its Regional Centres and consistently report their activities on the matter to next COP's meetings.

Galloway, T. S., et al. (2017). "Interactions of microplastic debris throughout the marine ecosystem." Nature Ecology & Evolution **1**(5): 116.

Marine microscopic plastic (microplastic) debris is a modern societal issue, illustrating the challenge of balancing the convenience of plastic in daily life with the prospect of causing ecological harm by careless disposal. Here we develop the concept of microplastic as a complex, dynamic mixture of polymers and additives, to which organic material and contaminants can successively bind to form an 'ecocorona', increasing the density and surface charge of particles and changing their bioavailability and toxicity. Chronic exposure to microplastic is rarely lethal, but can adversely affect individual animals, reducing feeding and depleting energy stores, with

knock-on effects for fecundity and growth. We explore the extent to which ecological processes could be impacted, including altered behaviours, bioturbation and impacts on carbon flux to the deep ocean. We discuss how microplastic compares with other anthropogenic pollutants in terms of ecological risk, and consider the role of science and society in tackling this global issue in the future.

Gambardella, C., et al. (2018). "Ecotoxicological effects of polystyrene microbeads in a battery of marine organisms belonging to different trophic levels." Marine Environmental Research **141**: 313-321.

The aim of this study was to detect ecotoxicological effects of 0.1mum polystyrene microbeads in marine organisms belonging to different trophic levels. MP build up, lethal and sub-lethal responses were investigated in the bacterium Vibrio anguillarum (culturability), in the green microalga Dunaliella tertiolecta (growth inhibition), in the rotifer Brachionus plicatilis (mortality and swimming speed alteration) and in the sea urchin Paracentrotus lividus (immobility and swimming speed alteration) exposed to a wide range of microplastic (MP) concentrations (from 0.001 to 10mgL⁻¹). Survival was not affected in all organisms up to 10mgL⁻¹, while algal growth inhibition, rotifer and sea urchin larvae swimming behaviour alterations were observed after exposure to MPs. Ingestion was only observed in rotifers and it was directly correlated with sub-lethal effects. These results account for the ecotoxicological risk associated to the polystyrene microbeads, which are able to affect different endpoints in primary producers and consumers (rotifers and sea urchins) since no effects were observed in decomposers. This study points out the importance of using a battery of marine organisms belonging to different trophic levels by studying acute toxicity of MPs at low and high contamination levels, and investigating sub-lethal responses. Further investigations aimed at studying the transfer of these materials through the web are particularly recommended.

Gambardella, C., et al. (2017). "Effects of polystyrene microbeads in marine planktonic crustaceans." Ecotoxicology and Environmental Safety **145**: 250-257.

Plastic debris accumulates in the marine environment, fragmenting into microplastics (MP), causing concern about their potential toxic effects when ingested by marine organisms. The aim of this study was to verify whether 0.1 micro m polystyrene beads are likely to trigger lethal and sub-lethal responses in marine planktonic crustaceans. MP build-up, mortality, swimming speed alteration and enzyme activity (cholinesterases, catalase) were investigated in the larval stages of Amphibalanus amphitrite barnacle and of Artemia franciscana brine shrimp exposed to a wide range of MP concentrations (from 0.001 to 10 mg L⁻¹) for 24 and 48 h. The results show that MP were accumulated in crustaceans, without affecting mortality. Swimming activity was significantly altered in crustaceans exposed to high MP concentrations (>1 mg L⁻¹) after 48 h. Enzyme activities were significantly affected in all organisms exposed to all the above MP concentrations, indicating that neurotoxic effects and oxidative stress were induced after MP treatment. These findings provide new insight into sub-lethal MP effects on marine crustaceans.

Gambardella, C., et al. (2019). "Microplastics do not affect standard ecotoxicological endpoints in marine unicellular organisms." Marine Pollution Bulletin **143**: 140-143.

In this study, the acute toxicity of microplastics (MPs) on unicellular organisms as marine decomposers and microalgae was assessed, by evaluating standards endpoints included in International Standard Organization (ISO) protocols. The bacteria Vibrio fischeri and the diatom Phaeodactylum tricornutum were exposed to different sizes (1-500mum) of polyethylene MPs in order to evaluate bioluminescence inhibition and microalgal growth. No acute toxicity was

found on bacteria or microalgae in an order of magnitude above environmentally relevant concentrations, suggesting that tested MPs did not affect the investigated biological processes. In conclusion, standard ecotoxicological endpoints are not sufficiently sensitive to assess the potential effects of MPs on decomposers and primary producers, conversely to nanoplastics. These findings highlight that the current approach for MP risk assessment in unicellular species should be revised, by providing alternative endpoints to be included in standardized protocols, able to monitor the fate and biological effects of MPs.

Gambino, G., et al. (2020). "Dynamics of interaction and effects of microplastics on planarian tissue regeneration and cellular homeostasis." Aquatic Toxicology **218**: 105354.

Increasing microplastics pollution of marine and terrestrial water is a concerning issue for ecosystems and human health. Nevertheless, the interaction of microplastics with freshwater biota is still a poorly explored field. In order to achieve information concerning the uptake, distribution and effect of microplastics in planarians, Dugesia japonica specimens have been fed with mixtures of food and differently shaped and sized plastic particles. Feeding activity and food intake were non-altered by the presence of high concentrations of different types of plastic particles. However, the persistence of microplastic within the planarian body was a function of size/shape, being small spheres (<10mum in diameter) and short fibers (14mum large and 5/6mum length) more persisting than larger spheres and longer fibers which were eliminated almost entirely by ejection in a few hours. Transmission electron microscopy analysis demonstrated that at least part of microplastics was phagocytized by the enterocytes. Chronic exposure to small plastic did not alter the regenerative ability but caused a significant reduction of the gut epithelium thickness and lipid content of enterocytes, together with the induction of apoptotic cell death, modulation of Djgata 4/5/6 expression and reduced growth rate. The ability of microplastic to perturb planarian homeostasis is concerning being them extremely resilient against mechanical and chemical insults and suggests possible harmful effects upon other more susceptible species in freshwater ecosystems.

Gamperl, H., et al. (2013). "Capture of tissue-factor-bearing microparticles with using annexin-V bound magnetic beads." Onkologie **7)**: 266.

A number of recent articles indicate that MPs are important regulators of cellular interactions under physiological and pathological conditions. They have been found in all body fluids and seem to play a regulative role in blood clotting, they enhance cell adhesiveness and increase cell aggregation. In addition, they mediate cell-to-cell communication by transferring cell surface receptors, mRNA, and miRNA from the cell of origin to target cells. MPs have also been found to be active in several diseases such as inflammation, sepsis and cancer where they may contribute to metastasis. They can be released by epithelial cells, thrombocytes and cancer cells and are composed of vesicles formed by double layer membrane and characteristically express tissue factor at the surface. Once exposed, the tissue factor instantly associates with FVII. This TF/FVIIa-complex is as well capable to initiate the extrinsic pathway of coagulation, as to activate PARs by its protease activity. There is an ongoing discussion if the composition of the emerging MP-complexes is decisive for their specific way of action. Thus both the quantitative detection and the possibility of investigating the composition of the microparticles are of high scientific interest. Here, we present a fast and specific method to isolate microparticles from body fluids, such as malignant effusion and plasma, using a sequence of centrifugation and capture by annexin-V magnetic MicroBeads. We proved the specificity and sensitivity by detecting the MPs in a modern flow-cytometer as defined by their size and the expression of tissue factor before and after annexin- V MicroBead capture. In addition, we show that the captured MPs are still functionally active by using a commercially available MP-activity assay. The captures MPs can then be used for further characterization.

Ganan-Calvo, A. M., et al. (2006). "Straightforward production of encoded microbeads by Flow Focusing: potential applications for biomolecule detection." International Journal of Pharmaceutics **324**(1): 19-26.
Fluorescently encoded polymeric microparticles are acquiring great importance in the development of simultaneous multianalyte screening assays. We have developed a very versatile and straightforward method for the production of dye-labeled microparticles with a very reproducible size distribution and freely-chosen and discernible fluorescent properties. Our method combines Flow Focusing technology with a solvent evaporation/extraction procedure in a single step, yielding spherical, non-aggregate and non-porous particles. We have designed a multi-coloured bead array which includes the possibility of modifying the surface properties of the microparticles, which offer excellent properties for covalent attachment of biomolecules such as peptides, oligonucleotides, proteins, etc. We also show the potential of the fluorescently labeled microspheres for the detection of biomolecule (peptides and oligonucelotides) interactions using flow cytometry.

Ganapa, T. S., et al. (2016). "Behavior of cells embedded in fibrin beads." Tissue Engineering - Part A **22 (Supplement 1)**: S138.
Researchers need better in vitro wound healing models to solve chronic wound issues. Current wound healing models utilize only one type of cell and the cells were coated outside of the microbeads. In addition, fabrication techniques involved heat and potentially harmful solvents. In this study, we have created a fibrin bead fabrication technique that does not require any harmful solvents or heat. Fibroblasts and keratinocytes are encapsulated within the fibrin microbeads so that researchers can track migration and proliferation of these cells in 2-D and 3-D in novel wound healing models for up to 1 week. Three different models for fibrin analysis were created and examined: fibrin beads containing cells of either keratinocytes or fibroblasts on a cell culture plate, beads on a layer of mixed fibrinogen and thrombin, and beads between two layers of fibrinogen and thrombin. The results for cell migration and proliferation showed that each cell behaves differently on certain surfaces. Fibroblasts and keratinocytes migrate and proliferate best on a plastic surface. Both cells migrate slowest inside a 3D fibrin construct because cells can migrate in all radial directions at random, resulting in overall slower movement. Fibrin beads create tunable microenvironments to sustain and optimize the performance of each cell type implanted into a wound-healing model. These microbeads can be implanted into a more realistic wound-healing model which will lead to greater understanding in the field as well as using cells for treatment by delivering cells in beads.

Gandara e Silva, P. P., et al. (2016). "Leachate from microplastics impairs larval development in brown mussels." Water Research **106**: 364-370.
Microplastic debris is a pervasive type of contaminant in marine ecosystems, being considered a major threat to marine biota. One of the problems of microplastics is that they can adsorb contaminants in extremely high concentrations. When released from the particle, these contaminants have the potential to cause toxic effects in the biota. So far, reports of toxic effects are mostly linked with the direct exposure of organisms through ingestion of contaminated microplastics. There is little information on the toxicity of leachates from microplastics to marine organisms. In this study, we conducted experiments to evaluate the toxicity of leachates from virgin and beached plastic pellets to embryo development of the brown mussel (Perna perna). We compared the efficiency of two test procedures, and evaluated

the toxicity of beached pellets collected in a coastal marine protected area. We observed that mussel embryo is sensitive to leachate from both virgin and beached pellets. However, the toxicity of the leachate from beached pellets was much higher than that of virgin pellets. We suggest contaminants adsorbed onto the surface of beached pellets were responsible for the high toxicity of leachate from beached pellets, while the toxicity of leachate from virgin pellets was mainly due to plastic additives. Our results suggest microplastic debris may be harmful even if ingestion is not the only or main pathway of interaction of marine organisms with contaminated plastic debris.

Gander, P. (2006). "Plastics packaging keeps options open." Materials Recycling Week **187**(23): 37-37.

The article focuses on how the range of polymers in use in plastic packaging is forcing the call for alternative recovery methods in recycling in Great Britain. It was stated that the plastics industry ha to come up with options to traditional recycling, in addition to energy-from-waste. Ministers are willing to consider incineration as an option which was discussed in the Department for Environment, Food and Rural Affairs' proposals for waste strategy review. It was hoped that the time may come when plastics recyclers try to expel green biodegradables.

Gandhi, J. K., et al. (2015). "Enhanced Viability of Endothelial Colony Forming Cells in Fibrin Microbeads for Sensor Vascularization." Sensors **15**(9): 23886-23902.

Enhanced vascularization at sensor interfaces can improve long-term function. Fibrin, a natural polymer, has shown promise as a biomaterial for sensor coating due to its ability to sustain endothelial cell growth and promote local vascularization. However, the culture of cells, particularly endothelial cells (EC), within 3D scaffolds for more than a few days is challenging due to rapid loss of EC viability. In this manuscript, a robust method for developing fibrin microbead scaffolds for long-term culture of encapsulated ECs is described. Fibrin microbeads are formed using sodium alginate as a structural template. The size, swelling and structural properties of the microbeads were varied with needle gauge and composition and concentration of the pre-gel solution. Endothelial colony-forming cells (ECFCs) were suspended in the fibrin beads and cultured within a perfusion bioreactor system. The perfusion bioreactor enhanced ECFCs viability and genome stability in fibrin beads relative to static culture. Perfusion bioreactors enable 3D culture of ECs within fibrin beads for potential application as a sensor coating.

Ganz, K. R., et al. (2015). "Enhancing the Detection of Giardia duodenalis Cysts in Foods by Inertial Microfluidic Separation." Applied & Environmental Microbiology **81**(12): 3925-3933.

The sensitivity and specificity of current Giardia cyst detection methods for foods are largely determined by the effectiveness of the elution, separation, and concentration methods used. The aim of these methods is to produce a final suspension with an adequate concentration of Giardia cysts for detection and a low concentration of interfering food debris. In the present study, a microfluidic device, which makes use of inertial separation, was designed and fabricated for the separation of Giardia cysts. A cyclical pumping platform and protocol was developed to concentrate 10-ml suspensions down to less than 1 ml. Tests involving Giardia duodenalis cysts and 1.90-mum microbeads in pure suspensions demonstrated the specificity of the microfluidic chip for cysts over smaller nonspecific particles. As the suspension cycled through the chip, a large number of beads were removed (70%) and the majority of the cysts were concentrated (82%). Subsequently, the microfluidic inertial separation chip was integrated into a method for the detection of G. duodenalis cysts from lettuce samples. The method greatly reduced the concentration of background debris in the final suspensions (10-fold reduction) in comparison to that obtained by a conventional method. The method also recovered an average of 68.4% of cysts from 25-g lettuce samples and had a limit of detection (LOD) of 38 cysts. While the recovery of cysts by inertial separation was slightly lower, and the LOD slightly higher, than with the conventional method, the sample analysis time was greatly reduced, as there were far fewer background food particles interfering with the detection of cysts by immunofluorescence microscopy.

Gao, B., et al. (2007). "Studies on preparing and adsorption property of grafting terpolymer microbeads of PEI-GMA/AM/MBA for bilirubin." Journal of Chromatography B: Analytical Technologies in the Biomedical & Life Sciences **853**(1-2): 62-69.

Crosslinking copolymer microbeads with a diameter range of 100-150 microm were synthesized by suspension copolymerization of glycidyl methacrylate (GMA), acrylamide (AM) and N,N'-methylene bisacrylamide (MBA). Subsequently, polyethyleneimine (PEI) was grafted on the surfaces of the terpolymer microbeads GMA/AM/MBA via the ring-opening reaction of the epoxy groups, and the grafting microbeads PEI-GMA/AM/MBA were prepared. In this paper, the adsorption property of the grafting microbeads for bilirubin was mainly investigated, and the effects of various factors, such as pH value, ionic strength and grafting degree of PEI on the surface of grafting microbeads and the adsorption capacity of the grafting microbeads for bilirubin were examined. The batch adsorption experiment results show that by right of the action of grafted polyamine macromolecules PEI, the grafting microbeads PEI-GMA/AM/MBA have quite strong adsorption ability for bilirubin; the isotherm adsorption conforms to Freundlich equation. The pH value of the medium affects the adsorption capacity greatly, As in the nearly neutral solutions with pH 6, the grafting microbeads have the strongest adsorption ability for bilirubin, whereas in acidic and basic solutions their adsorption ability is weak. The ionic strength hardly affects the adsorption ability of the grafting microbeads. The grafting degree of PEI on the surfaces of the grafting microbeads also has a great effect on the adsorption capacity, and higher the grafting degree of PEI on the surface of the microbead PEI-GMA/AM/MBA, the stronger is the adsorption ability of the microbeads.

Gao, F., et al. (2019). "Study on the capability and characteristics of heavy metals enriched on microplastics in marine environment." Marine Pollution Bulletin **144**: 61-67.

In this study we examined the adsorption characteristics of heavy metals on microplastic through laboratory test and field test. We demonstrated that polyvinyl chloride, polypropylene, polyethylene, polyamides and polyformaldehyde could adsorb lead, copper and cadmium in the simulating solution, and the heavy metals showed higher adsorbance on PVC and PP particles compared with PA, PE and POM. In the field experiment, the adsorption rate and concentration of heavy metals varied significantly among different plastic types and locations. The adsorbability of PP and PVC toward Pb and Mn was strongly correlated with the metal concentration in seawater. We also compared the adsorption quantity of PP to heavy metals and polycyclic aromatic hydrocarbons which resulted in an order of magnitude within one month. During the adsorption, the surface morphology of the microplastics which were washed and corroded by seawater underwent a rough-smooth-rough changing process, and different materials had great differences.

Gao, M., et al. (2019). "Effects of polyethylene microplastic on the phytotoxicity of di-n-butyl phthalate in lettuce (Lactuca sativa L. var. ramosa Hort)." Chemosphere **237**: 124482.

The increase in the proportion of microplastics in the environment has intensified the interest in phthalate and microplastic contamination in recent years. In this study, we investigated the response of photosynthetic parameters and the antioxidant system of lettuce to di-n-butyl phthalate (DBP) stress and exposure to various concentrations of microplastic polyethylene (MP) for different durations (14 d and 28 d). Lettuce growth, photosynthetic parameters, and chlorophyll content were reduced significantly after MP- and DBP-only treatments and after the combined (MP + DBP) treatments with both pollutants (P < 0.05), when compared with the control. Our findings indicated that the exposure to MP can inhibit growth, hinder photosynthesis, and interfere with the antioxidant defense system in lettuce. Specifically, compared with the DBP-only treatment group, in all MP + DBP treatment groups, the lettuce growth parameters (dry and fresh weights of the leaves and roots and the number of leaves) decreased (P<0.05). Moreover, the photosynthetic rate, stomatal conductance, transient transpiration rate, fluorescence parameters, chlorophyll content of leaves, and activity of Rubisco decreased, but the intercellular CO₂ concentration increased in all MP + DBP treatment groups. The reduction in photosynthesis was attributed to the limitation of non-porosity and inhibition of the photoelectron flow, and the increase in exogenous MP content aggravated the effect of DBP on photosynthesis in lettuce. Compared with the DBP-only group, in all MP + DBP treatment groups, the content of superoxide radicals and hydrogen peroxide in lettuce leaves and roots increased. Antioxidant levels increased with the increase in MP content, except in the 1.0 mg mL⁻¹ MP treatment after 14d. Although the antioxidant system exhibited certain protective effects in the latter treatment, the cell membranes were still damaged. The degree of damage to cells decreased with the growth of lettuce, but the damage to root tissue always remained higher than that of the leaves. In conclusion, exposure to exogenous MP exacerbated the damage to lettuce by DBP.

Gao, W., et al. (2008). "Rapid isothermal detection assay: a probe amplification method for the detection of nucleic acids." Diagnostic Microbiology & Infectious Disease **60**(2): 133-141.
Simple, accurate, and stable diagnostic tests are essential to control viral infectious diseases such as avian influenza virus. The current technologies are often inaccessible to people who need them, mainly because of the specialized equipment and the need for highly trained technologists. Here, we describe a rapid isothermal nucleic acid detection assay (RIDA) that can be used to detect both DNA and RNA targets. Using chemically modified probes, we designed a lateral-flow (LF) immunoassay that can be used in combination with RIDA for equipment-free nucleic acid target detection. RIDA is a "probe amplification" assay that uses the single-strand nicking activity of restriction nicking endonucleases to repeatedly cleave synthetic probes hybridizing to the same target sequences. In the RIDA-LF combined assay, chemically labeled probes are covalently conjugated to magnetic microbeads, which is propitious to separate cleaved probes from the reaction solution. The cleaved probes in the solution are then detected with an LF immunoassay. The real-time assay shows that RIDA is able to specifically detect target sequences in 5 to 15 min. The RIDA-LF combined assay can specifically detect nucleic acid targets without sophisticated equipment. In this report, our data suggest that RIDA is a flexible simple assay that could be applied for point-of-care detection. The modified-RIDA described in this report further extends the application of this technology.

Gao, W., et al. (2016). "Magnetic Driving Flowerlike Soft Platform: Biomimetic Fabrication and External Regulation." Acs Applied Materials & Interfaces **8**(22): 14182-14189.
Nature-inspired actuators that can be driven by various stimuli are an emerging application in mobile microrobotics and microfluidics. In this study, a soft and multiple-environment-adaptive robotic platform with ferromagnetic particles impregnated in silicon-based polymer is adopted to fabricate microrobots for minimally invasive locomotion and control interaction with their

environment. As an intelligent structure of platform, the change of its bending, deformation, and flapping displacement is rapid, reversible, and continuously controllable with sweeping and multicycle magnetic actuation. The bending angle of the soft platform (0.2 mm in thickness and 8.5 mm in length) can be deflected up to almost 90degree within 2.7 s. Experiments demonstrated that the flexible platform of human skin-like material in various shapes, that is, flowerlike shapes, can transport a cargo to targeted area in air and a variety of liquids. It indicates excellent magnetic-actuation ability and good controllability. The results may be helpful in developing a magnetic-driven carrying platform, which can be operated like a human finger to manipulate biological objects such as single cells, microbeads, or embryos. Especially, it is likely to be used in harsh chemical and physical circumstances.

Gao, X., et al. (2002). "Quantum-dot nanocrystals for ultrasensitive biological labeling and multicolor optical encoding." Journal of Biomedical Optics **7**(4): 532-537.
Semiconductor nanoparticles in the size range of 2-6 nm are of great current interest, not only because of their size-tunable properties but also because of their dimensional similarity with biological macromolecules (e.g., nucleic acids and proteins). This similarity could allow an integration of nanomaterials with biological molecules, which would have applications in medical diagnostics, targeted therapeutics, and high-throughput drug screening. Here we report new developments in preparing highly luminescent and biocompatible CdSe quantum dots (QDs), and in synthesizing QD-encoded micro- and nano-beads in the size range of 100 nm-10 microm. We show that the optical properties of ZnS-capped CdSe quantum dots are sensitive to environmental factors such as pH and divalent cations, leading to the potential use of quantum dots in molecular sensing. We also show that chemically modified proteins can be used to coat the surface of water-soluble QDs, to restore their fluorescence, and to provide functional groups for bioconjugation. For multiplexed optical encoding, we have prepared large microbeads with sizes similar to that of mammalian cells, and small nanobeads with sizes similar to that of viruses.

Gao, Y., et al. (2013). "Automating quantum dot barcode assays using microfluidics and magnetism for the development of a point-of-care device." Acs Applied Materials & Interfaces **5**(8): 2853-2860.
The impact of detecting multiple infectious diseases simultaneously at point-of-care with good sensitivity, specificity, and reproducibility would be enormous for containing the spread of diseases in both resource-limited and rich countries. Many barcoding technologies have been introduced for addressing this need as barcodes can be applied to detecting thousands of genetic and protein biomarkers simultaneously. However, the assay process is not automated and is tedious and requires skilled technicians. Barcoding technology is currently limited to use in resource-rich settings. Here we used magnetism and microfluidics technology to automate the multiple steps in a quantum dot barcode assay. The quantum dot-barcoded microbeads are sequentially (a) introduced into the chip, (b) magnetically moved to a stream containing target molecules, (c) moved back to the original stream containing secondary probes, (d) washed, and (e) finally aligned for detection. The assay requires 20 min, has a limit of detection of 1.2 nM, and can detect genetic targets for HIV, hepatitis B, and syphilis. This study provides a simple strategy to automate the entire barcode assay process and moves barcoding technologies one step closer to point-of-care applications.

Garaba, S. P., et al. (2018). "Sensing Ocean Plastics with an Airborne Hyperspectral Shortwave Infrared Imager." Environmental Science & Technology **52**(20): 11699-11707.
Here, we present a proof-of-concept on remote sensing of ocean plastics using airborne

shortwave infrared (SWIR) imagery. We captured red, green, and blue (RGB) and hyperspectral SWIR imagery with equipment mounted on a C-130 aircraft surveying the "Great Pacific Garbage Patch" at a height of 400 m and a speed of 140 knots. We recorded the position, size, color, and type (container, float, ghost net, rope, and unknown) of every plastic piece identified in the RGB mosaics. We then selected the top 30 largest items within each of our plastic type categories (0.6-6.8 m in length) to investigate SWIR spectral information obtained with a SASI-600 imager (950-2450 nm). Our analyses revealed unique SWIR spectral features common to plastics. The SWIR spectra obtained (N = 118 items) were quite similar both in magnitude and shape. Nonetheless, some spectral variability was observed, likely influenced by differences in the object optical properties, the level of water submersion, and an intervening atmosphere. Our simulations confirmed that the ~1215 and ~1732 nm absorption features have potential applications in detecting ocean plastics from spectral information. We explored the potential of SWIR remote sensing technology for detecting and quantifying ocean plastics, thus provide relevant information to those developing better monitoring solutions for ocean plastic pollution.

Garaba, S. P. and H. M. Dierssen (2018). "An airborne remote sensing case study of synthetic hydrocarbon detection using short wave infrared absorption features identified from marine-harvested macro- and microplastics." Remote Sensing of Environment **205**: 224.

The abundance and disiribuiion of plastic debris in natural waters is largely unknown due to limited comprehensive monitoring. Here, optical properties of dry and wet marine-harvested plastic debris were quantified to explore the feasibility of plastic debris optical remote sensing in the natural environment. We measured the spectral reflectance of microplastics (< 5 mm) from the North Atlantic Ocean, macroplastics (> 5 mm) washed ashore along the USA west coast and virgin plastic pellets over a wavelength range from 350 to 2500 nm. Compared to the spectral variability of multi-colored dry macroplastics, the measured dry marine-harvested microplastic reflectance spectra could be represented as a single bulk average spectrum with notable absorption features at -931. 1215, 1417 and 1732 nm. The wet marine-harvested microplastics had similar spectral features to the dry microplastics but the magnitude was lower over the measured spectrum. When spectrally matched to the reference library of typical dry virgin pellets, the mean dry marine-harvested microplastics reflectance had moderate similarities to low-density polyethylene, polyethylene terephthalate, polypropylene and polymethyl methacrylate. This composition was consistent with the subset sampled with the Fourier Transform Infrared (FTIR) spectrometer and what has been reported globally. The absorption features at 1215 and 1732 nm were observable through an intervening atmosphere and used to map the distributions of synthetic hydrocarbons at a landfill and on man-made structures from airborne visible-infrared imaging spectrometer (AV1RIS) imagery, indicating the potential to remotely sense dry washed ashore and land-origin plastics. These same absorption features were identifiable on wet marine-harvested microplastics, but the ability to conduct remote sensing of microplastics al the ocean surface layer will require more detailed radiative transfer analysis and development of high signal-to-noise sensors. The spectral measurements presented here provide a foundation for such advances towards remote detection of plastics from various platforms.

Garaba, S. P. and H. M. Dierssen (2020). "Hyperspectral ultraviolet to shortwave infrared characteristics of marine-harvested, washed-ashore and virgin plastics." Earth System Science Data **12**(1): 77-86.

Combating the imminent environmental problems associated with plastic litter requires a synergy of monitoring strategies, clean-up efforts, policymaking and interdisciplinary scientific research. Lately, remote sensing technologies have been evolving into a complementary monitoring strategy that might have future applications in the operational detection and tracking of plastic litter at repeated intervals covering wide geospatial areas. We therefore present a dataset of Lambertian-equivalent spectral reflectance measurements from the ultraviolet (UV, 350 nm) to shortwave infrared (SWIR, 2500 nm) of synthetic hydrocarbons (plastics). Spectral reflectance of wet and dry marine-harvested, washed-ashore, and virgin plastics was measured outdoors with a hyperspectral spectroradiometer. Samples were harvested from the major accumulation zones in the Atlantic and Pacific oceans, suggesting a near representation of plastic litter in global oceans. We determined a representative bulk average spectral reflectance for the dry marine-harvested microplastics dataset available at https://doi.org/10.21232/jyxq-1m66 (Garaba and Dierssen, 2019c). Similar absorption features were identified in the dry samples of washed-ashore plastics: dataset available at https://doi.org/10.21232/ex5j-0z25 (Garaba and Dierssen, 2019a). The virgin pellets samples consisted of 11 polymer types typically found in floating aquatic plastic litter: dataset available at https://doi.org/10.21232/C27H34 (Garaba and Dierssen, 2017). Magnitude and shape features of the spectral reflectance collected were also evaluated for two scenarios involving dry and wet marine-harvested microplastics: dataset available at https://doi.org/10.21232/r7gg-yv83 (Garaba and Dierssen, 2019b). Reflectance of wet marine-harvested microplastics was noted to be lower in magnitude but had similar spectral shape to that of dry marine-harvested microplastics. Diagnostic absorption features common in the marine-harvested microplastics and washed-ashore plastics were identified at ∼931, 1215, 1417 and 1732 nm. In addition, we include metrics for a subset of the marine-harvested microplastics related to particle morphology, including sphericity and roundness. These datasets are also expected to improve and expand the scientific evidence-based knowledge of optical characteristics of common plastics found in aquatic litter. Furthermore, these datasets have potential use in radiative transfer simulations exploring the effects of plastics on ocean colour remote sensing and developing algorithms applicable to remote detection of floating plastic litter.

Garces-Ordonez, O., et al. (2019). "Marine litter and microplastic pollution on mangrove soils of the Cienaga Grande de Santa Marta, Colombian Caribbean." Marine Pollution Bulletin **145**: 455-462.
Marine litter pollution has become a complex global problem, because of the negative ecological and socioeconomic impacts as well as the human health risks that it represents. In Colombia, mangroves are affected by inadequate solid waste management, which results in litter accumulation. Additionally, the information related to this problem is limited avoiding the development of prevention and reduction strategies. For the first time, pollution by marine litter and microplastics were evaluated in mangrove soils of the Cienaga Grande de Santa Marta, where 540+/-137 and 31+/-23 items/ha of marine litter were determined in mangroves near and away from populated centers respectively. Plastics represented between 73 and 96% of litter, and microplastic quantity oscillated between 31 and 2,863 items/kg finding the highest concentrations in mangroves near to the population. This study contributes to the knowledge of the marine litter problem in mangroves of the Colombian Caribbean, becoming a help for their conservation.

Garcés-Ordóñez, O., et al. (2019). "Marine litter and microplastic pollution on mangrove soils of the Ciénaga Grande de Santa Marta, Colombian Caribbean." Marine Pollution Bulletin **145**: 455.
Marine litter pollution has become a complex global problem, because of the negative ecological and socioeconomic impacts as well as the human health risks that it represents. In Colombia, mangroves are affected by inadequate solid waste management, which results in

litter accumulation. Additionally, the information related to this problem is limited avoiding the development of prevention and reduction strategies. For the first time, pollution by marine litter and microplastics were evaluated in mangrove soils of the Ciénaga Grande de Santa Marta, where 540 ± 137 and 31 ± 23 items/ha of marine litter were determined in mangroves near and away from populated centers respectively. Plastics represented between 73 and 96% of litter, and microplastic quantity oscillated between 31 and 2,863 items/kg finding the highest concentrations in mangroves near to the population. This study contributes to the knowledge of the marine litter problem in mangroves of the Colombian Caribbean, becoming a help for their conservation.

Garcia, T. M., et al. (2020). "Microplastics in subsurface waters of the western equatorial Atlantic (Brazil)." Marine Pollution Bulletin **150**: 110705.

We provide a baseline assessment of the density and types of microplastics in the western equatorial Atlantic. The highest microplastics density was found in coastal stations near urbanized sites, large tropical estuaries, and fishing grounds. With regard to microplastics composition, most of the identified particles were fibers/filaments, styrofoam, hard and soft plastic, paint, and glass/acrylic. Fibers/filaments were the most abundant (~80%) and occurred at all stations, in both types of mesh nets. Hard plastic particles were frequent (78%) only in the 120mum mesh net. The mean density recorded in the 120mum mesh net was about seven times greater than that in the 300mum mesh net, suggesting that the larger mesh size net did not lead to an accurate description of microplastics density in the pelagic environment or the degree of risk to which organisms are exposed.

García-altares, M., et al. (2015). "The novel ovatoxin-g and isobaric palytoxin (so far referred to as putative palytoxin) from Ostreopsis cf. ovata (NW Mediterranean Sea): structural insights by LC-high resolution MS^sup n." Analytical and bioanalytical chemistry **407**(4): 1191-1204.

Issue Title: A different way of looking at vibrational hyperspectral data/Micellar extraction for the analysis of Alzheimer's disease brain proteome/Quantification of polyolefin microplastics in personal-care products/Removal of Triton X-100 by microdialysis Blooms of the benthic dinoflagellate Ostreopsis cf. ovata are a concern in the Mediterranean Sea, since this species produces a wide range of palytoxin-like compounds listed among the most potent marine toxins. This study focused on two analogs of palytoxin found in cultures of six strains of O. cf. ovata isolated from the south of Catalonia (NW Mediterranean Sea). In addition to some already known ovatoxins, our strains produced two minor compounds, ovatoxin-g and the so far called putative palytoxin, whose structures had not been elucidated before. Insufficient quantity of these compounds impeded a full nuclear magnetic resonance (NMR)-based structural elucidation; thus, we studied their structure in crude algal extracts through liquid chromatography-electrospray ionization high-resolution mass spectrometry^sup n^ (LC-ESI-HRMS^sup n^) in positive ion mode. Under the used MS conditions, the molecules underwent fragmentation at many sites of their backbone and a large number of diagnostic fragment ions were identified. As a result, tentative structures were assigned to both ovatoxin-g and the putative palytoxin, the latter being identified as a palytoxin isomer and re-named as isobaric palytoxin.

Garcia-Garin, O., et al. (2019). "Boops boops as a bioindicator of microplastic pollution along the Spanish Catalan coast." Marine Pollution Bulletin **149**: 1.

Microplastic pollution is a growing cause of concern for the marine environment, particularly in the Mediterranean Sea, which is considered to be one of the most polluted seas worldwide. In

this study, the gastrointestinal tracts of 102 bogues (Boops boops), sampled from three areas off the Catalan coast (Spain) subject to different degrees of industrialization, were analysed to assess microplastic ingestion and thus estimate local levels of microplastic pollution. Microplastics were detected in 46% of samples analysed. As expected, the abundance and frequency of occurrence of ingested microplastics were higher off the most anthropized area of Barcelona. The majority of ingested microplastics were blue fragments ranging 0.1–0.5 mm, and the most common polymer type was polypropylene. The results of this study indicate the area off Barcelona as a possible area of concentration for microplastics, further supporting the use of B. boops as a bioindicator to assess microplastic pollution.

Garcia-Valverde, M. T., et al. (2018). "Lab-on-a-Valve Mesofluidic Platform for On-Chip Handling of Carbon-Coated Titanium Dioxide Nanotubes in a Disposable Microsolid Phase-Extraction Mode." Analytical Chemistry **90**(7): 4783-4791.

Mesofluidic lab-on-a-valve (LOV) platforms have been proven suitable to accommodate automatic micro-solid-phase extraction (muSPE) approaches with on-chip handling of micrometer-bead materials in a fully disposable mode to prevent sample cross-contamination and pressure-drop effects. The efficiency of the extraction process notably depends upon the sorptive capacity of the material because the sorbent mass is usually down to 10 mg in LOV devices. Nanomaterials, capitalizing upon their enhanced surface-to-volume ratio and diversity of potential chemical moieties, are appealing alternatives to microbead sorbents. However, the handling and confinement of nanomaterials in fluidic chip structures have been challenging to date. This is most likely a consequence of the aggregation tendency of a number of nanomaterials, including carbon-based sorbents, that leads to excessive back-pressure in flowing systems along with irreproducible bead loading. This paper addresses these challenges by ad hoc synthesis of hybrid nanomaterials, such as porous carbon-coated titanium dioxide nanotubes (TiO₂-NT@pC). Tailoring of the surface polarity of the carbon coating is proven to foster the dispersion of TiO₂-NT@pC in LOV settings while affording superior extraction capability of moderately nonpolar species from aqueous matrices. The determination of trace-level concentrations of butylparaben (BPB) and triclosan (TCS) in seawater samples is herein selected as a proof-of-concept of the exploitation of disposable nanomaterials in LOV. The mesofluidic platform accommodating muSPE features online hyphenation to liquid chromatography/tandem mass spectrometry (LC/MS/MS) for reliable determination of the target analytes with excellent limits of detection (0.5 and 0.6 ng/L for BPB and TCS, respectively) and intermediate precision (relative standard deviation <5.8%). For 5.0 mL of sample and 200 muL of eluent, enrichment factors of 23 and 14 with absolute extraction efficiencies of 90% +/- 14% and 58 +/- 8% for BPB and TCS, respectively, were obtained. The relative recovery values of 107% (BPB) and 97% (TCS) in seawater demonstrate the applicability of online LOV-LC/MS/MS using TiO₂-NT@pC for handling troublesome environmental samples.

Garcia-Xolalpa, H. L., et al. (2012). "Analysis of CD27/CD27L and CD30/CD30L in T lymphocytes exposed to dengue virus." Immunology **1)**: 634.

Purpose/Objective: To analyze if the co-stimulatory molecules CD27/ CD27L and CD30/CD30L are differentially expressed in T Lymphocytes exposed to dengue virus. Material(s) and Method(s): Peripheral blood mononuclear cells were obtained from Buffy coats from healthy donors by differential centrifugation over Fycoll-paqueTMPLUS. The T lymphocyte subpopulation was purified by anti-CD3-coated magnetic microbeads and these CD3+ T cell were assayed for the expression of CD27/CD27L and CD30/CD30L upon culture with: a)

Concanavalina A, b) dengue virus, c) dengue virus plus Concanavalina A and d) medium alone. After incubation for 36 h at 37degreeC in 5% CO_2, the expression of the co-stimulatory molecules was analyzed by flow cytometry. Result(s): The expression of CD27 and CD30 in Concanavalina A stimulation cells was twice as much as that of un-stimulated cells. Preincubation with dengue virus inhibited such a response, no significant differences were observed in the expression of CD27L/CD30L on T lymphocytes cultured under the same conditions. Conclusion(s): The CD27/CD27L and CD30/CD30L co-stimulatory molecules are related to the proliferation of T cells. Dengue virus seems to downregulate the expression of these co-stimulatory molecules, partially explaining the abnormal proliferation of T lymphocytes observed in vitro assays. Supported by SIP:20120911, and COFAA-IPN.

Gardon, T., et al. (2018). "Microplastics Affect Energy Balance and Gametogenesis in the Pearl Oyster Pinctada margaritifera." Environmental Science & Technology **52**(9): 5277.

Plastic pollution in the environment is increasing at global scale. Microplastics (MP) are derived from degradation of larger plastic items or directly produced in microparticles form (< 5 mm). Plastics, widely used in structures and equipment of pearl farming, are a source of pollution to the detriment of the lagoon ecosystem. To evaluate the impact of MP on the physiology of Pinctada margaritifera, a species of ecological and commercial interests, adult oysters were exposed to polystyrene microbeads (micro-PS of 6 and 10 µm) for 2 months. Three concentrations, 0.25, 2.5, and 25 µg L–1, and a control were tested. Ingestion and respiration rate and assimilation efficiency were monitored on a metabolic measurement system to determine the individual energy balance (Scope For Growth, SFG). Effects on reproduction were also assessed. The assimilation efficiency decreased significantly according to micro-PS concentration. The SFG was significantly impacted by a dose-dependent decrease from 0.25 µg L–1 ($p < 0.0001$), and a negative SFG was measured in oysters exposed to 25 µg L–1. Gonads may have provided the missing energy to maintain animals' metabolism through the production of metabolites derived from germ cells phagocytosis. This study shows that micro-PS significantly impact the assimilation efficiency and more broadly the energy balance of P. margaritifera, with negative repercussions on reproduction.

Garfall, A. L., et al. (2013). "Autologous agvhd associated with infusion of t-cells with engineered specificity for NY-ESO-1 and lage-1 following high-dose melphalan and asct in patients with multiple myeloma." Biology of Blood and Marrow Transplantation **1)**: S134.

Autologous stem cell transplantation (auto-SCT) is uncommonly associated with acute graft-versus-host disease (aGVHD)-like syndromes that are typically mild and self-limited; incidence is increased when auto-SCT is coupled with infusion of ex vivo expanded/costimulated Tcells. We describe here a gastrointestinal GVHD-like syndrome in multiple myeloma (MM) patients treated with auto-SCT and T-regulatory-cell (T<inf>reg</inf>)-depleted, autologous Tcells genetically modified to express a T-cell receptor with engineered specificity for a HLA-A*02-restricted epitope common to cancer-testis antigens NY-ESO-1 and LAGE-1. Subjects were HLA-A2+ and had high-risk MM with confirmed target expression. After initial therapy, T-cells were harvested via apheresis for transduction and culture with anti-CD3/-CD28-antibody-conjugated microbeads. Stem cells were then mobilized with cyclophosphamide +/- bortezomib. Subjects received melphalan 200 mg/m² on day -2 and >2 x 10⁶ CD34+ cells/kg on day 0. On day +2, autologous T-cells were infused (avg. 9x10⁹, range 7-10x10⁹; gene-modified avg. 33%, range 18-38%). Of the first 3 subjects treated, all developed persistent fever and grade 3-4 diarrhea beginning between days 2-7. Abdominal imaging was obtained in 2 subjects and demonstrated marked

wall thickening in the small and large bowel. Bowel biopsies from all subjects demonstrated aGVHD. The syndrome resolved spontaneously on day +37 in subject #1, but subjects #2 and #3 required immunosuppression with steroids. With recognition of this syndrome, prophylactic administration of oral budesonide and beclomethasone was implemented. The syndrome was then observed in only 1 of 7 subsequently treated subjects; in this subject, symptoms developed only after prophylactic budesonide was discontinued due to inability to administer the drug while the subject was ventilator-dependent with pneumonia. In subjects #2 and #3, bowel biopsy specimens were assayed by qPCR for the presence of the engineered cells, which were found to be present in all biopsy specimens from both subjects. Q-RT-PCR analysis of biopsy tissues showed absence of transcripts for both NY-ESO-1 and LAGE-1 antigens and accumulation. In conclusion, immunotherapy with Treg-depleted, NY-ESO-1/ LAGE-directed autologous T-cells after high-dose melphalan is associated with a steroid-responsive and preventable immune enteritis possibly mediated by infiltration of the GI tract by the engineered autologous T-cells.

Garg, R., et al. (2009). "Leishmania infantum amastigotes enhance HIV-1 production in cocultures of human dendritic cells and CD4 T cells by inducing secretion of IL-6 and TNF-alpha." PLoS Neglected Tropical Diseases [electronic resource] **3**(5): e441.

BACKGROUND: Visceral leishmaniasis has emerged as an important opportunistic disease among patients infected with HIV-1. Both HIV-1 and the protozoan parasite Leishmania can productively infect cells of the macrophage-dendritic cell lineage.

METHODOLOGY/PRINCIPAL FINDINGS: Here we demonstrate that Leishmania infantum amastigotes increase HIV-1 production when human primary dendritic cells (DCs) are cocultured together with autologous CD4(+) T cells. Interestingly, the promastigote form of the parasite does not modulate virus replication. Moreover, we report that amastigotes promote virus replication in both cell types. Our results indicate that this process is due to secretion of parasite-induced soluble factors by DCs. Luminex micro-beads array system analyses indicate that Leishmania infantum amastigotes induce a higher secretion of several cytokines (i.e. IL-1alpha, IL-2, IL-6, IL-10 and TNF-alpha) and chemokines (i.e. MIP-1alpha, MIP-1beta and RANTES) in these cells. Studies conducted with pentoxifylline and neutralizing antibodies revealed that the Leishmania-dependent augmentation in HIV-1 replication is due to a higher secretion of IL-6 and TNF-alpha.

CONCLUSIONS/SIGNIFICANCE: Altogether these findings suggest that the presence of Leishmania within DC/T-cell conjugates leads to an enhancement of virus production and demonstrate that HIV-1 and Leishmania can establish complex interactions in such a cellular microenvironment.

Garg, R., et al. (2009). "Leishmania infantum Amastigotes Enhance HIV-1 Production in Cocultures of Human Dendritic Cells and CD4 super(+) T Cells by Inducing Secretion of IL-6 and TNF-I." PLoS Neglected Tropical Diseases **3**(5): 1.

Background Visceral leishmaniasis has emerged as an important opportunistic disease among patients infected with HIV-1. Both HIV-1 and the protozoan parasite Leishmania can productively infect cells of the macrophage-dendritic cell lineage. Methodology/Principal Findings Here we demonstrate that Leishmania infantum amastigotes increase HIV-1 production when human primary dendritic cells (DCs) are cocultured together with autologous CD4 super(+) T cells. Interestingly, the promastigote form of the parasite does not modulate virus replication. Moreover, we report that amastigotes promote virus replication in both cell types. Our results indicate that this process is due to secretion of parasite-induced soluble factors by DCs. Luminex micro-beads array system analyses indicate that Leishmania infantum amastigotes induce a higher secretion of several cytokines (i.e. IL-1I-, IL-2, IL-6, IL-10 and TNF-I-) and chemokines (i.e. MIP-1I-, MIP-1I2 and RANTES) in these cells. Studies conducted with pentoxifylline and neutralizing antibodies revealed that the Leishmania-dependent augmentation in HIV-1 replication is due to a higher secretion of IL-6 and TNF-I-. Conclusions/Significance Altogether these findings suggest that the presence of Leishmania within DC/T-cell conjugates leads to an enhancement of virus production and demonstrate that HIV-1 and Leishmania can establish complex interactions in such a cellular microenvironment. Author Summary Visceral leishmaniasis (VL) is a potentially deadly parasitic disease afflicting millions worldwide. Although itself an important infectious illness, VL has also emerged as an opportunistic disease among patients infected with HIV-1. This is partly due to the increasing overlap between urban regions of high HIV-1 transmission and areas where Leishmania is endemic. Furthermore, VL increases the development and clinical progression of AIDS-related diseases. Conversely, HIV-1-infected individuals are at greater risk of developing VL or suffering relapse. Finally, HIV-1 and Leishmania can both productively infect cells of the macrophage-dendritic cell lineage, resulting in a cumulative deficiency of the immune response. We therefore studied the effect of Leishmania infantum on HIV-1 production when dendritic cells (DCs) are cocultured with autologous CD4 super(+) T cells. We show that amastigotes promote virus replication in both DCs and lymphocytes, due to a parasite-mediated production of soluble factors by DCs. Micro-beads array analyses indicate that Leishmania infantum amastigotes infection induces a higher secretion of several cytokines in these cells, and use of specific neutralizing antibodies revealed that the Leishmania-induced increase in HIV-1 replication is due to IL-6 and TNF-I-. These findings suggest that Leishmania's presence within DC/T-cell conjugates leads to an enhanced HIV-1 production.

Garlapati, D. (2019). "Comments on the paper "Marine microfiber pollution: A review on present status and future challenges"." Marine Pollution Bulletin **141**: 187.

Garley, M., et al. (2018). "Differences and similarities in the phenomenon of NETs formation in oral inflammation and in oral squamous cell carcinoma." Journal of Cancer **9**(11): 1958-1965.

Taking into account the previously reported relationship between inflammation and carcinogenesis, and the scant amount of data concerning the role of neutrophil extracellular traps (NETs) in carcinogenesis, we decided to study the process of extracellular trap formation in patients with inflammation as well as in patients with cancer occurring in the same location. For preliminary isolation of neutrophils (PMNs), we used PolymorphprepTM, then sorted with Microbeads. The cells were recorded in the incubation chamber with a BD Pathway 855 microscope system. Flow cytometric data (MPO+ neutrophils) were acquired on FACSCalibur flow cytometer. Amounts of cfDNA were determined by Abcam's Circulating DNA Quantification Kit. Neutrophils of patients with inflammation and of subjects with stage I/II oral squamous cell carcinoma (OSCC) produce increased amounts of NETs, while stage III/IV OSCC were comparable with the control group. In all of the studied groups of cells stimulation with LPS and rhIL-17 produced more NETs in relation to unstimulated cells. Neutrophil supernatant of inflammation patients and stage I/II cancer patients demonstrated the increased level of cfDNA, which decreased at stage III/IV. Patients with oral inflammations showed an increased rate of MPO+ neutrophils, which was lower than in stage I/II cancer patients and not significantly different than in Stage III/IV cancer patients and the control group. The direction of changes in NETs formation seems to be a new common element shared by inflammation and early stage cancer. Changes in the formation of NETs observed in patients with advanced cancer, other than an early phase or inflammation, indicate an alternative range of NETs involvement depending on different phases of this disease.

Garnham, G. W., et al. (1992). "Accumulation of cobalt, zinc and manganese by the estuarine green microalga Chlorella salina immobilized in alginate microbeads." Environmental Science and Technology **26**(9): 1764-1770.

This paper describes cobalt, zinc, and manganese accumulation by Chlorella salina immobilized in calcium alginate microbeads, investigated by use of the radioisotopes ⁶⁰Co, ⁵⁴Mn, and ⁶⁵Zn. A rapid biosorption of the metals to C. salina cell walls and the alginate matrix, which was independent of light, temperature, or the metabolic inhibitor CCCP, was followed by a slower energy-dependent phase of uptake. Under similar conditions, immobilized cells accumulated greater amounts of Co, Zn, or Mn than free cells due to an increased active phase of uptake. Accumulation was also dependent on cell density in the alginate beads, with a greater uptake of cobalt at the highest cell densities. Desorption of cobalt from loaded beads was increased by decreasing pH and increasing concentrations of the cations, probably due to exchange of cobalt bound to the cell wall/alginate matrix for H⁺ or cations.

Garnier, Y., et al. (2019). "Evaluation of microplastic ingestion by tropical fish from Moorea Island, French Polynesia." Marine Pollution Bulletin **140**: 165-170.

Microplastics are ubiquitous throughout the oceans, yet few studies have documented their occurrence in marine organisms associated with coral reefs. Four genera of adult fish were sampled (Myripristis spp., Siganus spp., Epinephelus merra and Cheilopogon simus) from different trophic guilds around the tropical island of Moorea, French Polynesia. Digestive tracts from 133 adult fish were surveyed and microplastics were found in 28 tracts (21%). Abundance of ingested microplastic pieces per individual fish varied from 1 to 3 pieces, with an average of 1.25 +/- 0.13 ingested microplastic pieces. Microplastics size ranged from 0.031 to 2.44 mm and 70% of microplastics did not exceed 0.3 mm in size. Overall, this study shows that the number and size of microplastic ingested per trophic groups are independent of trophic guild. Additional studies are needed to sample in other tropical regions in order to have a better assessment of microplastic occurrence in coral reefs. Copyright © 2019 Elsevier Ltd

Garrido, S., et al. (2019). "Effect of microplastics on the toxicity of chlorpyrifos to the microalgae Isochrysis galbana, clone t-ISO." Ecotoxicology & Environmental Safety **173**: 103-109.

It is highly likely that phytoplanktonic organisms will interact with MPs in the ocean, and consequently with the pollutants sorbed onto their surfaces. Microalgae play an essential role in maintaining the balance of the marine ecosystem due to the fact that they are a primary producer and the base of marine trophic chains. Therefore, their fitness represents an important index in the assessment of water quality. The objectives of this study were i) to assess the toxicity of MPs and the pesticide chlorpyrifos (CPF) to the microalgae, Isochrysis galbana, clone t-ISO and ii) to ascertain whether the presence of MPs affects the toxicity of CPF. Microalgae growth rate was selected as the endpoint and a commercial virgin PE micronized powder was chosen as a micro-plastic model, with mean size ranging from 2 to 6micro m, assayed until 25mgL⁻¹. CPF was tested at concentrations ranging from 0 to 4mgL⁻¹. A constant concentration of MPs (5mgL⁻¹) was loaded with increasing doses of CPF (0-3mgL⁻¹) with a 2h incubation period. Bioassays were performed at 20degreeC, in glass tubes of 50ml, with air and constant light and an exposure time of 72h. Cell counts were performed using a Coulter Counter Multisizer III and HPLC was used to quantify the partition of this pollutant among MPs and water. Although microalgae growth was not impacted by MPs,

growth was clearly affected by exposure to CPF from 2mgL⁻¹ and above, with a total growth inhibition at concentrations over 3mgL⁻¹. Subsequent to incubation, 80% of CPF was sorbed onto MP surfaces. Two different dose-response curves resulted from CPF bioassays depending on the presence of MP, with lower percentages of inhibition when CPF was presented through MP. Thus, the adsorption of CPF onto MP surfaces modulates the toxicity of CPF on I. galbana growth through a reduction in its toxicity, as CPF is adsorbed onto MP surfaces which are less bio-available to the algal cells.

Gasbarrino, K., et al. (2015). "Effects of statins on adiponectin receptor expression on circulating monocytes in hypertensive and dyslipidemic subjects." Arteriosclerosis, Thrombosis, and Vascular Biology. Conference: American Heart Association's Arteriosclerosis, Thrombosis and Vascular Biology/Peripheral Vascular Disease **35**(SUPPL. 1).

Introduction: Ample evidence exists in support of the anti-inflammatory and athero-protective properties of statins. AdipoR1 and AdipoR2 are receptors of adiponectin, which is an adipose tissue secreted protein with anti-inflammatory properties. Reduced AdipoR1/R2 expression is associated with hypertension, diabetes, and dyslipidemia. The aim of this ongoing study is to investigate whether statin treatment can affect the expression of AdipoR1/R2 on circulating monocytes in high-risk hypertensive and dyslipidemic subjects. Method(s): Subjects with hypertension and dyslipidemia were recruited from the Vascular Health Clinic at McGill University, Montreal. All subjects had clinical indication for statin therapy, were statin naive, and were prescribed low dose statin. After initiation of statin therapy, subjects were followed-up every 3-4 months for the length of one year. Blood samples were collected on the day of recruitment (baseline [pre-statins]) and at each follow-up (f/u) visit. Blood monocytes were isolated using a Magnetic Cell-Sorting technique with CD14+ Human Microbeads. RNA was isolated from monocytes to assess mRNA expression of AdipoR1/R2 using quantitative RT-PCR. Recruitment and f/u visits are ongoing. Result(s): A total of 13 subjects were recruited with 8 subjects having had at least one f/u visit. Baseline age of subjects (n=8) was 65.9 +/- 9.2 years, with 62.5% of subjects being men, and 37.5% diabetic. Statin significantly decreased total cholesterol (pre: 5.8+/-0.7 mmol/L, post: 4.1+/-0.5 mmol/L, P= 0.001) and LDL levels (3.9+/-0.6 mmol/L, 2.1+/-0.3 mmol/L, P<0.001). When assessing all f/u combined, AdipoR1 and AdipoR2 mRNA expression on circulating monocytes was increased post-statin therapy by 1.37 and 1.41-fold, respectively, when compared to baseline levels, with a significant difference found in AdipoR2 (P=0.05). Furthermore, a trend for progressive increase in AdipoR1/R2 mRNA expression was detected across all f/u. Conclusion(s): Statin treatment in hypertensive and dyslipidemic subjects led to increased AdipoR1/R2 mRNA expression on circulating monocytes, which illustrates a novel mechanism through which statins may exert its anti-inflammatory effects and protect against cardiovascular diseases.

Gasbarrino, K., et al. (2015). "Monocyte profiling of adiponectin receptors may be a potential systemic marker of plaque instability in subjects with carotid atherosclerotic disease." Canadian Journal of Cardiology **1)**: S281-S282.

BACKGROUND: Current guidelines for stroke prevention in patients with carotid atherosclerotic plaques, recommend carotid endarterectomy (CEA), based only on the degree of carotid artery stenosis. However, stenosis alone is an incomplete feature of stroke risk. Thus, understanding the mechanisms that contribute to plaque instability may lead to accurate patient risk stratification. Adipose tissue is a source of adipokines, such as adiponectin, that can mediate the crosstalk between adipose tissue and the vascular wall. Adiponectin possesses anti-inflammatory and vasculoprotective properties. Through its effects on receptors, AdipoR1 and AdipoR2, it may have the potential to protect against plaque development. Decreased circulating adiponectin levels (specifically its high molecular weight [HMW] isoform) and a lower abundance of AdipoR1/R2 on monocytes are associated with type 2 diabetes and coronary artery disease in humans. The aim of this study is to investigate HMW adiponectin levels and AdipoR1/R2 expression on monocytes, as potential systemic markers of plaque instability. METHOD(S): Consecutive patients scheduled for CEA were recruited from vascular clinics at the MUHC. Carotid plaque specimens and pre-operative blood samples were obtained. Vascular pathologists categorized the instability of the plaques according to gold-standard histological classifications. HMW adiponectin levels were measured using ELISA. Blood monocytes were isolated using a Magnetic Cell-Sorting technique with CD14+ Human Microbeads. RNA was isolated from monocytes to assess mRNA expression of AdipoR1/ R2 via quantitative RT-PCR. RESULT(S): All specimens were graded as either stable (n=20) or unstable plaques (n=18). Significant differences were found in HMW adiponectin levels between patients with stable versus unstable plaques (4.17 [3.02-9.84] mg/ml and 2.33 [1.23-5.66] mug/ml, respectively; p=0.028), while AdipoR2 mRNA expression on total monocytes was inversely associated with greater plaque instability (p=0.039). Logistic regression analyses demonstrated that AdipoR2 expression on monocytes can significantly predict the odds of having an unstable plaque versus a stable plaque. For age- and sexadjusted model, plaques were 3.3 times more likely to be unstable with each unit decrease in AdipoR2 gene expression, while further adjustments for BMI, increased the odds of having an unstable plaque by a factor of 4.2 (OR=4.15; 95% CI=1.13-15.32); p=0.033). CONCLUSION(S): HMW adiponectin and AdipoR2 mRNA expression on monocytes may act as important markers to discriminate between subjects with stable and unstable plaques. Recruitment of CEA patients for this study is ongoing.

Gaspar, K., et al. (2010). "Frequency and function of CD4⁺CD25⁺FOXP3⁺ regulatory T cells in atopic dermatitis." Journal of Investigative Dermatology **2)**: S40.

Atopic dermatitis (AD) is a chronic inflammatory skin disease resulted partly of type I and type IV hypersensitivity reactions triggered by T helper 2 (Th2) cells. The explanations behind the Th2 dominance in the disease are still controversial. We addressed the question whether the Th2 cell domination is associated with a reduction and/or functional impairment of CD4⁺CD25⁺FOXP3⁺ regulatory T cells (Treg) essential for the maintenance of Th1- Th2 balance. Peripheral blood of AD patients with severe clinical symptoms and extremely high serum IgE levels (>2000 U/ml) were investigated. Flow cytometry was utilised to determine the percentage of CD4⁺CD25^{bright}FOXP3⁺ Tregs and CLA⁺CD4⁺CD25^{bright}FOXP3⁺ Tregs in the samples of AD patients and healthy controls. For detection of suppressor activity of CD4⁺CD25⁺ Tregs, they were cocultured with CD4⁺CD25- effector T cells, and for T cell stimulation, anti-CD3/CD28 microbeads were applied alone or with Staphylococcus Enterotoxin B (SEB). The proliferation of the cells was measured by EZ4U colorimetric cell proliferation assay. Significantly increased number of CD4⁺CD25^{bright}FOXP3⁺ Tregs and also of CLA⁺ CD4⁺CD25^{bright}FOXP3⁺ Tregs were found in the peripheral blood of AD patients compared to healthy individuals. The degree of suppressor activity of CD4⁺CD25⁺ regulatory T cells were decreased in both anti-CD3/CD28 and SEB stimulated subgroups compared to control. Our data suggest coincidently with the literature that the pathogenesis of AD cannot be explained with the absence of CD4⁺CD25⁺FOXP3⁺ Treg cells, moreover the number of these cells is increased in the peripheral blood. At the same time the function of Tregs may be impaired.

Gaspari, J., et al. (2013). "EDTA-treatment to remove inhibitory effect of serum substances without increasing negative control bead MFI in micro-bead assays." Human Immunology **1)**: 62.

Aim: To study an effect of ethylenediaminetetraacetic acid (EDTA) on negative control (NC) bead mean fluorescence intensity (MFI) in Luminex micro-bead assays. Background(s): Inhibitory substances can mask HLA antibody specificity detection. Dithiothreitol (DTT) was reported to be effective for reducing interference from inhibitory substances (Kosmoliaptsis V, Transplantation 2009). However, we often observe an increase in the NC bead MFI with DTT treatment as reported (Zachary AA, Hum Immunol 2009). EDTA was also reported to be effective in reducing interference from inhibitory substances (Schnaidt M, Transplantation 2011). Method(s): Except for the pre-treatment of serum, One Lamba LABScreen Phenotype (PRA) and Single Antigen (SAB) reagents are used according to manufacturer instructions. Ten serum samples were selected that exhibited high NC bead MFI (>1000) with DTT-treatment (5mM at 37C for 30 minutes) in PRA beads (N=7) or SAB (N=3), requiring adsorption by Adsorb Out beads (One Lambda). NC bead MFI and specificity assignment of untreated, EDTA-treated (final concentration of 5mM; 20uL of 0.05M EDTA added to 180uL serum), and DTT-treated serum samples were compared. Result(s): NC bead MFI showed no significant difference between untreated and EDTA-treated serum (r=0.999), indicating that EDTA-treatment does not increase NC bead MFI. NC bead MFI was >1000 in 3/10 untreated serums, 3/10 EDTA-treated serums, and 10/10 DTT-treated serums. The NC bead MFI was successfully reduced after treatment with Adsorb Out in the 3 EDTA-treated serums. Specificity assignment and antibody strength between EDTA-treated and DTT-treated serum was consistent in all samples tested. Conclusion(s): EDTA is an effective treatment to remove interference from inhibitory substances without increasing NC bead MFI.

Gasperi, J., et al. (2014). "Assessment of floating plastic debris in surface water along the Seine River." Environmental Pollution **195**: 163-166.

This study is intended to examine the quality and quantity of floating plastic debris in the River Seine through use of an extensive regional network of floating debris-retention booms; it is one of the first attempts to provide reliable information on such debris at a large regional scale. Plastic debris represented between 0.8% and 5.1% of total debris collected by weight. A significant proportion consisted of food wrappers/containers and plastic cutlery, probably originating from voluntary or involuntary dumping, urban discharges and surface runoff. Most plastic items are made of polypropylene, polyethylene and, to a lesser extent, polyethylene terephthalate. By extrapolation, some 27 tons of floating plastic debris are intercepted annually by this network; corresponding to 2.3 g per Parisian inhabitant per year. Such data could serve to provide a first evaluation of floating plastic inputs conveyed by rivers. [ABSTRACT FROM AUTHOR]

Gassel, M. and C. M. Rochman (2019). "The complex issue of chemicals and microplastic pollution: a case study in North Pacific lanternfish." Environmental Pollution **248**: 1000-1009.

Marine plastic debris, including microplastics (<5 mm in size), comprises a suite of chemical ingredients and sorbed chemical contaminants. Thus, microplastics are a potential, and debated, source of anthropogenic chemicals for bioaccumulation and biomagnification. Several studies have investigated the role of microplastics as a vector of contaminants to marine organisms via modeling exercises, laboratory experiments, and field studies. Here, we examined relationships among chemical contaminants and microplastics in lanternfish (family Myctophidae), an important link in marine food webs, from the North Pacific Ocean as a case study from the field. We compared the body burden of several chemical groups (bisphenol A [BPA], nonylphenol [4-NP], octylphenol [4n-OP], alkylphenol ethoxylates [APEs], pesticides, polychlorinated biphenyls [PCBs], and polybrominated diphenyl ethers [PBDEs]) in fish caught within and outside the North Pacific Subtropical Gyre where plastic is known to accumulate. We also tested whether there was a relationship between chemical concentrations in fish and plastic density at each sampling location. Mean concentrations of common plastic constituents (BPA, 4-NP, 4n-OP, APEs, and total PBDEs) were comparable between myctophids collected within and outside the North Pacific Gyre. Pesticides were higher in lanternfish caught outside the gyre and were associated with lower plastic density. Total PCBs were also higher in fish outside the gyre. In contrast, lower chlorinated PCB congeners were higher in fish residing in the accumulation zone and were correlated with higher plastic density. This finding is consistent with other studies demonstrating an association between lower chlorinated PCBs and plastics in biota and suggests that microplastic may be a transport mechanism for some chemicals in nature.

Gatidou, G., et al. (2019). "Review on the occurrence and fate of microplastics in Sewage Treatment Plants." Journal of Hazardous Materials **367**: 504-512.

Microplastics are plastic fragments lower than 5 mm that are detected in the environment causing various effects on organisms. Several research articles have recognized Sewage Treatment Plants as important sources of polyethylene and polypropylene beads, polyester, polyamide and other types of microplastics. For their determination, techniques such as visual identification using microscope, Fourier-transform infrared and RAMAN spectroscopy are used, while chemical oxidation, enzymatic maceration and density separation are applied as pretreatment methods for the removal of the inorganic and organic content. Microplastics' concentrations range up to 3160 particles L⁻¹, 125 particles L⁻¹ and 170.9 x 10³ particles Kg⁻¹ TS dw in raw, treated wastewater and sludge, respectively. Their removal during wastewater treatment ranges between 72% and 99.4%; the main processes that contribute to their removal are primary and secondary treatment, while the effect of tertiary treatment depends on the applied technology. Entrapment in suspended solids and accumulation to sludge are the major mechanisms governing their fate. A standardized protocol for samples' collection and pretreatment as well as microplastics' isolation and characterization is needed; future reseach should investigate the possible chemical and physical changes of microplastics during treatment, and their role as carriers for the transfer of emerging micropollutants. Gattani, Y. S. (2010). "Floating multiparticulate drug delivery systems: An overview." International Journal of Pharma and Bio Sciences **1 (2) (no pagination)**(6).

In recent scientific and technological advancement have been made in the research and development of rate controlled oral drug delivery systems overcoming physiological adversities, such as short gastric residence times (GRT) and unpredictable gastric emptying times (GET).

Furthermore, absorption windows in the proximal gut can limit the bioavailability of orally administered compounds and can be a major obstacle to the development of controlled release formulations for important drugs. Methods to increase the residence of drug formulations at or above the absorption window are discussed in this review¹. Several approaches are currently utilized in the prolongation of the GRT, including floating drug delivery system (FDDS), also known as hydro dynamically balanced systems (HBS), swelling and expanding systems, modified shape systems and high density system. In this review, the current status of floating multiparticulate drug delivery systems including hollow microspheres (micro balloons), low density floating micro pellets and floating micro beads (acrylic resin based), microcapsules etc, their evaluation parameter, advantages, application, limitation and future potential for oral control drug delivery are discussed.

Gattas-Asfura, K., et al. (2014). "Covalent layer-by-layer assembly of hyperbranched polymers on alginate microcapsulesto impart stability and permselectivity." Journal of Materials Chemistry B **2**(46): 8208-8219.

The microencapsulation of cells has shown promise as a therapeutic vehicle for the treatment of a wide variety of diseases. While alginate microcapsules provide an ideal cell encapsulation material, polycations coatings are commonly employed to enhance stability and impart permselectivity. In this study, functionalized hyperbranched alginate and dendrimer polymers were used to generate discreet nanoscale coatings onto alginate microbeads via covalent layer-by-layer assembly. The bioorthogonal Staudinger ligation scheme was used to chemoselectively crosslink azide functionalized hyperbranched alginate (alginate-hN₃) to methyl-2-diphenylphosphino-terephthalate (MDT) linked PAMAM dendrimer (PAMAM-MDT). Covalent layer-by-layer deposition of PAMAM-MDT/alginate-hN₃ coatings onto alginate microbeads resulted in highly stable coatings, even after the inner alginate gel was liquefied to form microcapsules. The permselectivity of the coated microcapsules could be manipulated via the charge density of the PAMAM, the number of layers deposited, and the length of the functional arms. The cytocompatibility of the resulting PAMAM-MDT/alginate-hN₃ coating was evaluated using a beta cell line, with no significant detrimental response observed. The biocompatibility of the coatings in vivo was also found comparable to uncoated alginate beads. The remarkable stability and versatile nature of these coatings provides an appealing option for bioencapsulation and the release of therapeutic agents.

Gauquie, J., et al. (2015). "A qualitative screening and quantitative measurement of organic contaminants on different types of marine plastic debris." Chemosphere **138**: 348-356.

Chemical compounds present on plastic were characterised on different types of plastic litter and beached pellets, using a general GC–MS screening method. A variety of plastic related compounds, such as building blocks, antioxidants, additives and degradation products, were identified next to diverse environmental pollutants and biofilm compounds. A validated method for the analysis of PAHs and PCBs on beached pellets at the Belgian Coast, showed concentrations of ∑ 16 EPA-PAHs of 1076–3007 ng g −1 plastic, while the concentrations of ∑ 7 OSPAR-PCBs ranged from 31 to 236 ng g −1 plastic. The wide variety of plastic compounds retrieved in the general screening showed the importance of plastic as a potential source of contaminants and their degradation products. [ABSTRACT FROM AUTHOR]

Gavini, V., et al. (2014). "Formulation & in-vitro evaluation of wax incorporated floating beads of silymarin." International Journal of PharmTech Research **6**(6): 1824-1832.

Among modified-release oral dosage form increasing interest has currently turned to systems designed to achieve prolonged residence at the site of drug delivery. Among different controlled release systems microbeads offer prolonged residence time and controlled release in stomach. Silymarin (SLM) is an effective hepatoprotective drug used in therapeutic practice today. However, its absorption is in stomach and needs to be retained in the same for prolonged period. So Silymarin is suitable candidate to develop into wax incorporated alginate beads. The objective of this study was to formulate and evaluate wax incorporated alginate microbeads loaded with Silymarin. The alginate microbeads of Silymarin with variable concentrations of waxes (White bees wax & Carnauba wax) were prepared by Melt Extrusion-Ionotropic gellation method. The prepared microbeads were characterized for their pre-formulation and post formulation parameters. Compatibility studies proved that there was no interaction between Silymarin and waxes used. Silymarin beads were roughly spherical in nature, which was confirmed by Scanning electron microscopy. Silymarin beads with normal frequency distribution were obtained. A maximum of 94.75% drug entrapment efficiency was obtained. The in-vitro performance of Silymarin beads showed controlled release up to 12 hrs depending on the wax concentration. Finally it can be concluded that the formulated sodium alginate gel beads with white bees wax were more feasible and effective than carnauba wax beads in encapsulating SLM and thereby increasing the effectiveness of the drug. Gawai, K. J. and D. S. Ramteke (2017). "Characterisation of municipal solid waste of household and Sukali dumping depot of Amravati city." Asian Journal of Environmental Science **12**(2): 107-113.

Increasing population and urbanization created various problems among which solid waste management is the one. It arouses the problem of public health and environmental deterioration. Lifestyle of unconcern people is the root cause of this problem. Proper characterization of municipal solid waste is the first fundamental step for the planning of municipal waste management services. Based on composition/characterization of waste, appropriate waste processing technologies can be selected and implemented. Characterisation of the solid waste at the duping site shows the presence of high percentage of organic matter (24%) and inert material (25%) in the waste. Characterisation of the solid waste of the household samples shows high percentage of organic waste (55%) and low inert material (8.37%). Thus, it indicates that the proper on site (household level) segregation of different components of the waste viz., organic waste, plastic waste, metals, glass, paper, can reclaim the resources and better use it. It can be concluded that the way we manage will decide how well prepared we are for the better future.

Gayathri, J., et al. (2018). "Acute sensitivity of three Cladoceran species to different types of microplastics in combination with thermal stress." Environmental Pollution **239**: 733-740.

Microplastics (<5 mm, MP) are ubiquitously distributed in the environment, causing increasing concern regarding their potential toxicity to organisms. To date, most research has focussed on the impacts of MPs on marine and estuarine organisms, with fewer studies focussing on the effects of microplastics on freshwater ecosystems, especially under different environmental

conditions. In the present study, the sensitivity of two temperate Cladoceran species, Daphnia magna and Daphnia pulex, and a smaller tropical species Ceriodaphnia dubia, to primary microplastics (PMP) and secondary (weathered) microplastics (SMP) was assessed. A prolonged acute toxicity assay (up to 72 or 96 h) was performed at 18 degrees , 22 degrees , and 26 degrees C, to determine the influence of temperature as an additional stressor and survival data were analysed using toxicokinetic-toxicodynamic (TK-TD) model. Acute sensitivity of D. magna and D. pulex to both PMP and SMP increased sharply with temperature, whereas that of C. dubia remained relatively stable across temperatures. C. dubia was the most sensitive species at 18 degrees C, followed by D. pulex and D. magna, which were of comparable sensitivity. However, this ranking was reversed at 26 degrees C as could be seen from the No Effect Concentration (NEC) estimates of the TK-TD model. In addition, SMP and PMP had a similar effect on D. magna and D. pulex, but PMP was more toxic to C. dubia. Effects on survival were strongly time-dependent and became substantially more severe after the standard 48 h test period. Our results indicate that sensitivity to microplastics may differ between species for different types of microplastics, and could be drastically influenced by temperature albeit at high exposure concentrations.

Gayathri, J., et al. (2019). "Reproductive toxicity of primary and secondary microplastics to three cladocerans during chronic exposure." Environmental Pollution **249**: 638-646.

Microplastics (<5 mm) are distributed ubiquitously in natural environments. The majority of microplastics in aquatic environments are shown to have rough surfaces due to various weathering processes (secondary microplastics; SMP), while laboratory studies predominantly utilise pristine microplastics (primary microplastics; PMP). Here we present the results from a study comparing the chronic effects of pristine PMP and artificially weathered SMP to three different Cladoceran species (Daphnia magna, Daphnia pulex, Ceriodaphnia dubia). We assessed the impact of PMP and SMP on reproductive output using various measured parameters, including time of first brood, size of first brood, size of first three broods, cumulative number of neonates, total number of broods and terminal length of test animals. Our results show that reproductive output of all species declined in a dose-dependent manner. The No Observed Effect Concentration (NOEC) was less than the lowest tested concentration (10² p/mL) for at least one measured endpoint for all species and both PMP and SMP. Further, it was inferred that species sensitivity varied inversely with body size for most endpoints, resulting in C. dubia being the most sensitive species; and D. magna being the least sensitive species under study. In addition, PMP appeared to have greater toxic potential as compared to SMP. This study is the first to directly compare the chronic toxicity of both pristine and weathered microplastic particles on three freshwater toxicological model organisms. Our results indicate that sensitivity in reproduction and growth to microplastics may differ between species and type of microplastic exposed; highlighting the importance of using multiple species and structural types of particles.

Gazzola, M. V., et al. (2012). "Haploidentical TCR-alpha/beta and CD19-depleted hematopoietic stem cell transplantation in a case of scid." Journal of Clinical Immunology **1)**: S161-S162.

Introduction: Severe combined immunodeficiency (SCID) is a primary immunodeficiency (PID) with incidence < 1:100.000 newborns, characterized by early onset, failure to thrive, diarrhea, infections. Neonatal screenings are not implemented in our country. Treatment of choice is urgent hematopoietic stem cell transplantation (HSCT). Objective(s): We report the haplo-HSCT of a SCIDRAG1 baby with pneumonia by P.jiroveci. Method(s): 4-month-old female, weight 6.3kg, height 60cm (50degree percentile). Previously two perforated otitis, oral Candidiasis,

bronchopneumonia. Admitted to ICU for respiratory failure (P.jiroveci pneumonia, Rotavirus gastroenteritis), requiring assisted ventilation. CBC: lymphocytopenia (700 lymphocytes/mm3). Result(s): Immunophenotype: 8% CD3+CD4+CD8- (CD45RA+CD45RO-) T-cells ; 0% CD8+; 0% CD19+; 91% CD16/56+ ; negative CD25, CD38, HLA-DR. Molecular analysis identified RAG1 mutation, supporting SCID T-B-NK+ diagnosis. HSCT: haploidentical from father. TCRalphabeta-CD19- depletion with biotinylated anti-alphabeta antibody, anti-biotin antibody+magnetic microbeads, CliniMACS system, was highly effective (TCRalphabeta 5 log; CD19 3,2 log). Graft composition: 32.8x106/kg CD34+, 21.6x106/kg TCRgammadelta. Conditioning regimen: Treosulfan, Fludarabine, rabbit antilymphocyte serum. No subsequent immunosuppression. PMN-platelets engraftment: day +17 and +15 respectively. Progressive clinical and radiological improvement, independence from mechanical ventilation on day +14. Donor chimerism 100% (day+14). At day +100, CBC is stable at 700 lymphocytes/mm3. Immunophenotype: 2% CD3 (1% CD4, 1% CD8), 82% CD19, 13% CD16/56+. Chimerism 87% Donor (CD19 100%, CD3 99% ; CD16/56+ 84%). The baby is well at home, without infections. No signs of GvHD. Conclusion(s): TCRalphabeta-CD19-depleted TCRgammadelta-enriched haplo-HSCT seems useful in SCID cases with severe active infections, allowing early partial immune reconstitution and recovery from infections without GvHD. Longer follow-up is needed to assess outcome.

Gbewonyo, K. and D. I. Wang (1983). "Confining mycelial growth to porous microbeads: a novel technique to alter the morphology of non-newtonian mycelial cultures." Biotechnology & Bioengineering **25**(4): 967-983.

In an effort to alter the filamentous morphology of Penicillium chrysogenum cells, a technique was developed to confine the growth of the mycelia to porous celite beads. The pore matrix of these beads was found to be very effective for entrapping mycelial cells and spores. The entrapped spores were used to initiate the fermentations in shake flask cultures. Significant increases in final cell densities were obtained in the confined cell cultures reaching up to 60 g/L cells. This is nearly double the cell concentration attainable in free cell cultures grown in the absence of beads. Cell loadings up to 0.55 g cells per bead were obtained in the confined cell cultures. In the later stages of the fermentations, the specific oxygen uptake rates in the confined cell cultures were found to decrease with respect to free cell cultures.

Gbewonyo, K. and D. I. C. Wang (1983). "Enhancing gas-liquid mass transfer rates in non-Newtonian fermentations by confining mycelial growth to microbeads in a bubble column." Biotechnology and Bioengineering **25**(12): 2873-2887.

The performance of a penicillin fermentation was assessed in a laboratory-scale bubble column fermentor, with mycelial growth confined to the pore matrix of celite beads. Final cell densities of 29 g/L and penicillin titres of 5.5 g/L were obtained in the confined cell cultures. In comparison, cultures of free mycelial cells grown in the absence of beads experienced dissolved oxygen limitations in the bubble column, giving only 17 g/L final cell concentrations with equally low penicillin titres of 2 g/L. The better performance of the confined cell cultures was attributed to enhanced gas liquid mass transfer rates, with mass transfer coefficients (k sub(L)a) two to three times higher than those determined in the free cell cultures. Furthermore, the confined cell cultures showed more efficient utilization of power input for mass transfer, providing up to 50% reduction in energy requirements for aeration.

Ge, J., et al. (2017). "Expression and antiviral function of TLR7 in chronic hepatitis B patients and its up-regulation by PEG-IFN-alpha-2a therapy." Hepatology International **11 (1 Supplement 1)**: S21.

Background: Therapeutic strategy to activate host innate immunity, like toll-like receptor 7 (TLR7) agonist, had a great potential for the treatment of chronic hepatitis B (CHB). Here we investigated the expression of TLR7 in CHB patients with or without Peg-IFN-alpha-2a therapy and explored the mechanism contributing its antiviral function in vitro. Method(s): PBMC samples were collected from 31 healthy controls (HC) and 80 CHB patients; including 25 HBeAg-positive CHB patients received Peg-IFN-alpha-2a therapy. TLR7 expression in PBMC cells and liver tissues were evaluated using realtime RT-PCR and microarray analysis, respectively. HepG2.2.15 cells were incubated with conditioned media (CM) from PBMC treated with the TLR7- ligand imiquimod. HBV replication was analyzed by Southern blot and the antiviral cytokines production was examined by ELISA and antibody neutralization assay. CD19 + B cells were sorted by MicroBeads and were stimulated with imiquimod in the presence of IFN-alpha or not. B cells proliferation, activation, cytokines and antibody production were determined by FACS and ELISPOT analysis. Result(s): TLR7 expression in PBMC and liver tissue was significant higher in CHB patients than HC ($p = 0.003$) and had a positive correlation with ALT levels ($p<0.001$, $r = 0.333$). To examine the TLR7-mediated antiviral effect in vitro, exposure of HepG2.2.15 cells to the CM form HC or CHB PBMC strongly inhibited HBV replication and antigen expression, largely depend on the production of IFN-alpha. Interesting, more pronounced inhibition of HBV replication and induction of IFN-alpha were observed in CM from CHB, as compared to HC. Further, longitudinal analysis revealed that TLR7 levels in PBMC were steadily increased during 48 weeks of Peg-IFN-alpha-2a therapy and its expression at 24 weeks of treatment were much higher in group with off-treatment complete response (HBeAg seroconversion and HBV DNA<200 IU/ml for at least 6 months after the end of therapy, $n = 7$) than non-off treatment complete responders group ($n = 18$, $p = 0.006$). Consistently, peg-IFN-alpha-2a or recombinant IFN-alpha treatment were able to upregulate TLR7 expression in CD19 + B cells. Moreover, IFN-alpha was able to work synergistically with imiquimod to augment HBcAg specific B cells proliferation (CFSE staining), activation (CD69, CD80, CD86), cytokines (TNF-alpha, IL-6, IFN-gamma) and antibody (IgM, IgG) production. Conclusion(s): Our results suggested that TLR7 exerted its inhibitory effect on HBV replication by IFN-alpha secretion, while its expression and antiviral effect were enhanced in CHB patients. Moreover, TLR7 expression was up-regulated by Peg-IFN-alpha-2a therapy and its lig and could work synergistically with IFN-alpha to enhance B cells function, implying the application of sequential therapeutic strategy with Peg- IFN-alpha-2a and TLR7-ligand in CHB patients.

Ge, J., et al. (2017). "Expression signature of MicroRNA-155 in chronic hepatitis B patients and it regulates interferon-gamma production in natural killer cells." Hepatology International **11 (1 Supplement 1)**: S286.

Background: MicroRNAs (miRNA) can be detected in the serum and peripheral blood mononuclear cells (PBMCs) and have been reported to be differently regulated in a variety of liver diseases. miR-155 had been identified as a key modulator of cellular functions in both innate and adaptive immunity. The aim of this study was to clarify the relationship between the expression of miR-155 and clinical outcome in patients with Chronic Hepatitis B (CHB). Method(s): A total of 21 healthy controls (HC) and 120 patients with chronic HBV infection, including 41 telbivudine based therapy and 24 peg-IFN-alpha-2a treated CHB patients, were enrolled in this study. miR- 155 expression in PBMC and serum samples were evaluated by realtime RT-PCR, respectively. CD56+NK cells were sorted by MicroBeads and were electronically transfected with miR-155 mimic. Cytokines production and gene expression in NK cells were determined by FCAS Flow assay and realtime RT-PCR. Result(s): miR-155 expression in PBMC (CHB vs HC, $p = 0.560$; CHB vs IT, $p<0.001$) and serum samples (CHB vs HC, $p = 0.757$; CHB vs IT, p = 0.013) from CHB patients with abnormal ALT levels was comparable to HC, but higher than immunotolerant carriers and inactive carriers. There was a positive correlation between miR-155 expression and ALT levels in CHB patients (p = 0.002, r = 0.495). Accompanied with the reduction of ALT levels, miR-155 expression in PBMC was gradually decreased during telbivudine or peg-IFN-alpha- 2a therapy. Interestingly, telbivudine-treated patients achieved HBeAg seroconversion at week 52 exhibited higher miR-155 expression levels at baseline than non-responders (p = 0.007). Furthermore, we found that miR-155 (p = 0.002) and IFN-gamma expression (p = 0.015) in NK cells was significantly down-regulated in CHB compared with HC. Inversely, SCOS1, a target of miR-155, was up-regulated in NK cells of CHB. Finally, reconstitution of miR- 155 in NK cells from CHB patients led to a decrease in SCOS1 expression (p = 0.008) and an increase in IFN-gamma production (p = 0.001). Conclusion(s): Our study established the correlations between miR-155 expression and liver inflammation or treatment outcome during HBV infection and antiviral therapy. The in vitro data suggested that miR- 155 down-regulation in NK cells of CHB impaired IFN-gamma production by targeting SOCS1, which may contribute to immune defects and immunopathogenesis during chronic HBV infection.

Gebert, A., et al. (2004). "Antigen Transport into Peyer's Patches: Increased Uptake by Constant Numbers of M Cells." American Journal of Pathology **164**(1): 65-72.

Membranous (M) cells are specialized epithelial cells of the Peyer's patches that sample antigens from the gut lumen, thereby enabling the host to respond immunologically. Recent studies suggest that this transport can be up-regulated within hours by de novo formation of M cells from enterocytes. To test this hypothesis, we used an in vivo model and induced the transcytosis of tracers in Peyer's patches by application of Streptococcus pneumoniae R36a into the gut lumen. Using cell-type-specific markers, we quantified M cells in the Peyer's patch domes, lymphocytes associated with M cells, and the transport rate for experimentally applied microbeads after 3 hours of exposure to R36a. The transport of latex microbeads was significantly increased by +131% in the R36a-treated patches as compared to buffer controls (P < 0.001). While in controls, each M cell was associated with 2.05 +/- 0.64 lymphocytes, a significant increase (+55.1%; P < 0.001) was determined in the R36a-treated patches. However, no statistical difference was detected in the percentage of M cells in the dome epithelia (46.0 +/- 4.6% versus 45.5 +/- 3.8%). It is concluded that bacteria-induced up-regulation of particle transport in Peyer's patch domes is due to an increased transport rate of the M cells, but not to a de novo formation of M cells. The data support the hypothesis that M cells represent a separate cell lineage that does not derive from enterocytes on the domes.

Gebhardt, C. and S. Forster (2018). "Size-selective feeding of Arenicola marina promotes long-term burial of microplastic particles in marine sediments." Environmental Pollution **242**(Part B): 1777-1786.

Despite of their ubiquitous distribution in marine sediments, the role of benthic fauna in microplastic transport at the sea floor has received little attention yet. The present study investigated the influence of bioturbation activity of the polychaete Arenicola marina on microplastic transport and burial in marine sediments. Sediment ingestion was assessed in a long term mesocosm experiment with exposure times ranging from 106 to 240 days, using three particle tracers with different particle diameters (microplastic: 500 and 1000 micro m, respectively; luminophores: 130 micro m). Sediment grain size distributions were assessed after experiment termination in all feeding layers at 8-12 cm depth to determine the influence of size-selective feeding of A. marina on median grain size and microplastic retention. Burial of microplastic occurred in all mesocosms up to a depth of 20 cm and was strongly dependent on individual sediment feeding rates. For low bioturbation conditions, both microplastic and luminophore concentrations exhibited an exponential decrease with increasing sediment depth, indicating particle burial via feeding funnel transport. Particle concentrations remained high in the uppermost 4 cm of the sediment. At high bioturbation rates, no microplastic particles remained in near-surface sediment layers, but a distinct accumulation of microplastic was observed in the feeding layer, suggesting the discrimination of plastic particles during feeding. In contrast, luminophores displayed a similar accumulation, but additionally showed uniform distributions above feeding layers, indicating ingestion and defecation by polychaetes. In accordance with these findings, an overall coarsening of median grain sizes was observed in all feeding layers, indicating the retention of large microplastic due to size-selective feeding. These findings demonstrate the ability of the conveyor belt-feeding polychaete A. marina to promote unidirectional transports of microplastic >=500 micro m and the potential for the long-term retention of these particles in marine sediments.

Gehui, W., et al. (2012). "Molecular Distribution and Stable Carbon Isotopic Composition of Dicarboxylic Acids, Ketocarboxylic Acids, and α-Dicarbonyls in Size-Resolved Atmospheric Particles From Xi'an City, China." Environmental Science & Technology **46**(9): 4783-4791.

Size-resolved airborne particles (9-stages) in urban Xi'an, China, during summer and winter were measured for molecular distributions and stable carbon isotopic compositions of dicarboxylic acids, ketocarboxylic acids, and α-dicarbonyls. To our best knowledge, we report for the first time the size-resolved differences in stable carbon isotopic compositions of diacids and related compounds in continental organic aerosols. High ambient concentrations of terephthalic (tPh, 379 ± 200 ng m-3) and glyoxylic acids (ωC2, 235 ± 134 ng m-3) in Xi'an aerosols during winter compared to those in other Chinese cities suggest significant emissions from plastic waste burning and coal combustions. Most of the target compounds are enriched in the fine mode (<2.1 µm) in both seasons peaking at 0.7-2.1 µm. However, summertime concentrations of malonic (C3), succinic (C4), azelaic (C9), phthalic (Ph), pyruvic (Pyr), 4-oxobutanoic (ωC4), and 9-oxononanoic (ωC9) acids, and glyoxal (Gly) in the coarse mode (>2.1 µm) are comparable to and even higher than those in the fine mode (<2.1 µm). Stable carbon isotopic compositions of the major organics are higher in winter than in summer, except oxalic acid (C2), ωC4, and Ph. δ13C of C2 showed a clear difference in sizes during summer, with higher values in fine mode (ranging from -22.8‰ to -21.9‰) and lower values in coarse mode (-27.1‰ to -23.6‰). The lower δ13C of C2 in coarse particles indicate that coarse mode of the compound originates from evaporation from fine mode and subsequent condensation/adsorption onto pre-existing coarse particles. Positive linear correlations of C2, sulfate and ωC2 and their δ13C values suggest that ωC2 is a key intermediate, which is formed in aqueous-phase via photooxidation of precursors (e.g., Gly and Pyr), followed by a further oxidation to produce C2. [ABSTRACT FROM AUTHOR]

Geilfus, N. X., et al. (2019). "Distribution and impacts of microplastic incorporation within sea ice." Marine Pollution Bulletin **145**: 463-473.

Microplastics (plastic particles <5mm) are an emerging concern in Arctic sea ice with measured concentrations orders of magnitude higher than in surface seawater. However, incorporation of microplastics into sea ice, and their impact on sea ice properties, is unknown. We added

microplastic particles in a microcosm experiment to determine microplastic distributions and effects on sea ice properties. Microplastic additions did not affect sea ice growth, but high concentrations of microplastics at the ice surface resulted in high ice salinity and changes in sea ice albedo. Field studies in the Gulf of Bothnia (Baltic Sea) showed sea ice concentration of microplastics from 8 to 41 particles per liter of melted ice, wich were much lower than those found to impact sea ice properties in the microcosm experiments. However, should microplastic concentrations increase, microplastic incorporation in sea ice may impact sea ice albedo.

Geissler, M., et al. (2011). "Air stream-mediated vortex agitation of microlitre entities on a fluidic chip." Lab on a Chip **11**(10): 1717-1720.

The method presented in this paper uses air flux to induce spiral motion in small-scale (e.g., microlitre) fluid entities in an efficient, technologically convenient manner. The set-up entails a manifold that modulates the air flux and projects it onto a liquid-containing reservoir. The flow behaviour of the liquid phase has been visualized through the dissolution of rhodamine B crystallites and the motion of fluorescent microbeads. In addition, the method proved effective to restoring a suspension of spherical particles upon sedimentation, promoting displacement and capture of the beads within a microfluidic system.

Gemmell, C. H. (1997). "A flow cytometric immunoassay to quantify adsorption of complement activation products (iC3b, C3d, SC5b-9) on artificial surfaces." Journal of Biomedical Materials Research **37**(4): 474-480.

Crosslinked agarose microspheres and various polystyrene microspheres were analyzed for complement components after incubation with serum at 37 degrees C for times up to 2 h. Quantification involved direct flow cytometric analysis of the beads after the bound complement proteins were indirectly fluorescently tagged by use of a monoclonal antibody against a complement protein: C5b-9, iC3b, C3d, C4d, Bb, C3a, and C1q. Calibration with fluorescein microbead standards demonstrated that the membrane attack complex (SC5b-9) was surface bound on all surfaces and that the surface concentration gradually increased to levels as high as 0.5 micrograms/cm2. Further, the surface bound represented a substantial percentage of the total generated. The iC3b level on polystyrene beads rapidly reached 0.09 micrograms/cm2 and the C3d levels were an order of magnitude less. On agarose beads the iC3b levels continually rose to 0.17 micrograms/cm2 and, as before, the C3d levels were substantially lower. The surface concentration of C4d and Bb on both surfaces were significant but less than 1.0 ng/cm2. There was minimal evidence of C3a and C1q adsorption for any surface. Use of amino-polystyrene beads moderately reduced the level of bound iC3b, C3d, and SC5b-9, whereas carboxylated beads reduced the levels by almost a factor of two. The appreciable amounts of iC3b and SC5b-9 consistently noted on the artificial surfaces tested in this paper suggests that for these two activation products in vitro analysis of material induced complement activation should also include surface analysis.

Genc, A. N., et al. (2020). "Modeling transport of microplastics in enclosed coastal waters: A case study in the Fethiye Inner Bay." Marine Pollution Bulletin **150 (no pagination)**(110747).

In this study, transport and possible accumulation of microplastic marine litter in enclosed coastal waters are modeled numerically. The model is applied to the Fethiye Inner Bay, located in Fethiye-Gocek Specially Protected Area. In modeling studies, three dimensional coastal hydrodynamics, transport and water quality numerical model HYDROTAM-3D was used. The current climate was prepared by modeling long-term circulation patterns due to wind, wave and density stratifications. Following the hydrodynamic studies, the advection and diffusion of 3 mm size polystyrene particles by the coastal currents in the surface waters of Fethiye Inner Bay were simulated. The coastal regions where the microplastic pollution will be concentrated and transported were determined by the modeling scenarios. It has been found that microplastic accumulation is expected in the southwest and east coastal waters of the Fethiye Inner Bay. The results of the model will contribute to the databases for sustainable protection of the marine environments. Copyright © 2019 Elsevier Ltd

Geng, T., et al. (2014). "Single-cell forensic short tandem repeat typing within microfluidic droplets." Analytical Chemistry **86**(1): 703-712.

A short tandem repeat (STR) typing method is developed for forensic identification of individual cells. In our strategy, monodisperse 1.5 nL agarose-in-oil droplets are produced with a high frequency using a microfluidic droplet generator. Statistically dilute single cells, along with primer-functionalized microbeads, are randomly compartmentalized in the droplets. Massively parallel single-cell droplet polymerase chain reaction (PCR) is performed to transfer replicas of desired STR targets from the single-cell genomic DNA onto the coencapsulated microbeads. These DNA-conjugated beads are subsequently harvested and reamplified under statistically dilute conditions for conventional capillary electrophoresis (CE) STR fragment size analysis. The 9-plex STR profiles of single cells from both pure and mixed populations of GM09947 and GM09948 human lymphoid cells show that all alleles are correctly called and allelic drop-in/drop-out is not observed. The cell mixture study exhibits a good linear relationship between the observed and input cell ratios in the range of 1:1 to 10:1. Additionally, the STR profile of GM09947 cells could be deduced even in the presence of a high concentration of cell-free contaminating 9948 genomic DNA. Our method will be valuable for the STR analysis of samples containing mixtures of cells/DNA from multiple contributors and for low-concentration samples.

Gennip, S. J. V., et al. (2019). "In search for the sources of plastic marine litter that contaminates the Easter Island Ecoregion." Scientific Reports **9**(1): 19662.

Subtropical gyres are the oceanic regions where plastic litter accumulates over long timescales, exposing surrounding oceanic islands to plastic contamination, with potentially severe consequences on marine life. Islands' exposure to such contaminants, littered over long distances in marine or terrestrial habitats, is due to the ocean currents that can transport plastic over long ranges. Here, this issue is addressed for the Easter Island ecoregion (EIE). High-resolution ocean circulation models are used with a Lagrangian particle-tracking tool to identify the connectivity patterns of the EIE with industrial fishing areas and coastline regions of the Pacific basin. Connectivity patterns for "virtual" particles either floating (such as buoyant macroplastics) or neutrally-buoyant (smaller microplastics) are investigated. We find that the South American shoreline between 20degreeS and 40degreeS, and the fishing zone within international waters off Peru (20degreeS, 80degreeW) are associated with the highest probability for debris to reach the EIE, with transit times under 2 years. These regions coincide with the most-densely populated coastal region of Chile and the most-intensely fished region in the South Pacific. The findings offer potential for mitigating plastic contamination reaching the EIE through better upstream waste management.

Gent, M. R., et al. (2009). "Recycling of plastic waste by density separation: prospects for optimization." Waste Management & Research **27**(2): 175-187.

A review of existing industrial processing and results of alternative processing investigations for separating solid mixtures and specifically recycling plastic waste by density separation is presented. Media density separation is shown to be fundamental for separation and/or pre-concentration in the recycling of plastics. The current use of static media processes limits the capacity and size of material that can be treated commercially. Investigations have shown that the hydroscopic properties of plastics can be reduced to improve such separations. This indicates that an alternative processing method is required to increase the commercial recovery of recyclable plastics. Cylindroconical and cylindrical cyclone-type media separators, such as those used for processing coal, are reviewed and suggested as a potential substitute. Both have superior production capacities and are able to process a larger range in particle sizes treated. A summary of results of investigations with cyclone media devices for recycling plastics is presented.

Gentile, R., et al. (2012). "Human gallbladder is a highly available source of stem cells with multiple endodermic mature fates potentiality." Digestive and Liver Disease **2)**: S66.

Background and aim: Biliary tree stem/progenitor cells (BTSCs) have been identified in human extrahepatic bile ducts and are able to generate in vitro and in vivo mature cells of the hepato-biliary and pancreatic endocrine lineages. The aims have been to investigate in normal and pathological gallbladders: i) the presence and location of BTSCs and ii) the possibility to isolate, culture and differentiate BTSCs. Material(s) and Method(s): Gallbladders were obtained from organ donors and from laparoscopic surgery for symptomatic cholelithiasias. Tissues or isolated cells were characterized by flow-cytometry, histology, immunohistochemistry (IH), immunofluorescence for stem/progenitor and mature cells markers. Ep- CAM+ cells were immunoselected by magnetic microbeads and were plated onto plastic in Kubota's Medium for self-replication and successively transferred to distinct differentiation media. In vivo studies were conducted in an experimental model of liver fibrogenesis (carbon tetrachloride administered to SCID mice twice a week for7 weeks). Result(s): The in situ IH demonstrated that, in normal and pathological gallbladders, the surface epithelium contained cells with the phenotype of BTSCs. Tissue digestion resulted in the isolation of15+/-3.7 and13.3+/-3.6 million viable cells from normal (N=5) and pathological gallbladder (N=5), respectively. Flow-cytometry demonstrated that, before immunoselection, cell population was constituted by an average of44.7% and26.9% EpCAM+ cells from normal and pathological gallbladders, respectively. In vitro, in Kubota's Medium, single EpCAM sorted cells showed a clonogenic capacity maintaining an endodermal-like phenotype for more than a month. When transferred into differentiation conditions, EpCAM+ cells differentiated to distinct fates resulting in cords of albumin-secreting hepatocytes, branching ducts of secretin receptor+ cholangiocytes or functional pancreatic islets. In vivo, EpCAM+ cells injected into fibrotic livers of SCID mice resulted in repopulation of mice livers by human albumin-producing hepatocytes. Conclusion(s): Normal and pathological gallbladders contain easily isolable cells with the phenotype and the biological properties of BTSCs. Thus, gallbladders constitute a highly available candidate source for regenerative medicine of liver and diabetes.

George, M. and T. E. Abraham (2006). "Polyionic hydrocolloids for the intestinal delivery of protein drugs: Alginate and chitosan - a review." Journal of Controlled Release **114**(1): 1-14.

The protein pharmaceutical market is rapidly growing, since it is gaining support from the recombinant DNA technology. To deliver these drugs via the oral route, the most preferred route, is the toughest challenge. In the design of oral delivery of peptide or protein drugs, pH sensitive hydrogels like alginate and chitosan have attracted increasing attention, since most of the synthetic polymers are immunogenic and the incorporation of proteins in to these polymers require harsh environment which may denature and inactivate the desired protein. Alginate is a

water-soluble linear polysaccharide composed of alternating blocks of 1-4 linked alpha-l-guluronic and beta-d-mannuronic acid residues where as chitosan is a co polymer of d-glucosamine and N-acetyl glucosamine. The incorporation of protein into these two matrices can be done under relatively mild environment and hence the chances of protein denaturation are minimal. The limitations of these polymers, like drug leaching during preparation can be overcome by different techniques which increase their encapsulation efficiency. Alginate, being an anionic polymer with carboxyl end groups, is a good mucoadhesive agent. The pore size of alginate gel microbeads has been shown to be between 5 and 200 nm and coated beads and microspheres are found to be better oral delivery vehicles. Cross-linked alginate has more capacity to retain the entrapped drugs and mixing of alginate with other polymers such as neutral gums, pectin, chitosan, and eudragit have been found to solve the problem of drug leaching. Chitosan has only limited ability for controlling the release of encapsulated compound due to its hydrophilic nature and easy solubility in acidic medium. By simple covalent modifications of the polymer, its physicochemical properties can be changed and can be made suitable for the peroral drug delivery purpose. Ionic interactions between positively charged amino groups in chitosan and the negatively charged mucus gel layer make it mucoadhesive. The favourable properties like biocompatibility, biodegradability, pH sensitiveness, mucoadhesiveness, etc. has enabled these polymers to become the choice of the pharmacologists as oral delivery matrices for proteins.

Gerber, P. F., et al. (2014). "Comparison of commercial enzyme-linked immunosorbent assays and fluorescent microbead immunoassays for detection of antibodies against porcine reproductive and respiratory syndrome virus in boars." Journal of Virological Methods **197**: 63-66.

The objective of this study was to compare the ability of two commercial enzyme-linked immunosorbent assays (ELISAs) and an in-house fluorescent microbead immunoassay (FMIA) to detect IgG antibodies against porcine reproductive and respiratory syndrome virus (PRRSV) types 1 and 2 in serum and oral fluids from boars infected experimentally. Samples from uninfected control pigs and PRRSV-negative field samples were also used. Serum samples were tested by ELISAs (IDEXX Se, HIPRA Se) and an in-house FMIA-Se for detection of PRRSV types 1 and 2. Oral fluids were tested by ELISAs (IDEXX-SO, IDEXX-OF, HIPRA-OF) for detection of PRRSV types 1 and 2. Among the sera, IDEXX-Se and HIPRA-Se had similar sensitivity and specificity ($p > 0.05$); however, IDEXX-Se detected positive animals earlier than HIPRA-Se ($p < 0.05$). FMIA-Se had the highest false-positive rates in known negative field samples (1/205 for IDEXX-Se, 5/205 for HIPRA-Se, and 37/205 for FMIA-Se; $p < 0.01$). Serum and oral fluid samples had similar detection rates and antibody kinetics using the IDEXX tests. There was a higher detection rate in serum than oral fluid using the HIPRA assays. In this study, the nucleocapsid protein utilized as antigen in the FMIAs yielded a low specificity. IDEXX-Se had the earliest detection and similar sensitivity and specificity to the HIPRA-Se.

Gerber, P. F., et al. (2015). "Subclinical avian hepatitis E virus infection in layer flocks in the United States." Veterinary Journal **206**(3): 304-311.

The objective of this study was to determine patterns of avian HEV infection in naturally infected chicken farms. A total of 310 serum samples and 62 pooled fecal samples were collected from 62 chicken flocks on seven commercial in-line egg farms in the Midwestern United States and tested for avian HEV circulation. Serum samples were tested for the presence of anti-avian HEV IgY antibodies by a fluorescent microbead immunoassay (FMIA) which was developed for this study. The FMIA was validated using archived samples of chickens with known exposure (n=96) and compared to the results obtained with an enzyme-linked immunosorbent assay (ELISA) based on the same capture antigen. There was an overall substantial agreement between the two assays (kappa =0.63) with earlier detection of positive chickens by the FMIA (P=0.04). On the seven farms investigated, the overall prevalence of anti-avian HEV IgY antibodies in serum samples from commercial chickens was 44.8% (20-82% per farm). Fecal samples were tested for avian HEV RNA by a nested reverse-transcriptase PCR. The overall detection rate of avian HEV RNA in fecal samples was 62.9% (0-100% per farm). Sequencing analyses of partial helicase and capsid genes showed that different avian HEV genotype 2 strains were circulating within a farm. However, no correlation was found between avian HEV RNA detection and egg production, egg weight or mortality. In conclusion, avian HEV infection is widespread among clinically healthy laying hens in the United States.

Gerdes, Z., et al. (2019). "Microplastic-mediated transport of PCBs? A depuration study with Daphnia magna." PLoS ONE **14**(2).

The role of microplastic (MP) as a carrier of persistent organic pollutants (POPs) to aquatic organisms has been a topic of debate. However, the reverse POP transport can occur if relative contaminant concentrations are higher in the organism than in the microplastic. We evaluated the effect of microplastic on the PCB removal in planktonic animals by exposing the cladoceran Daphnia magna with a high body burden of polychlorinated biphenyls (PCB 18, 40, 128 and 209) to a mixture of microplastic and algae; daphnids exposed to only algae served as the control. As the endpoints, we used PCB body burden, growth, fecundity and elemental composition (%C and %N) of the daphnids. In the daphnids fed with microplastic, PCB 209 was removed more efficiently, while there was no difference for any other congeners and ΣPCBs between the microplastic-exposed and control animals. Also, higher size-specific egg production in the animals carrying PCB and receiving food mixed with microplastics was observed. However, the effects of the microplastic exposure on fecundity were of low biological significance, because the PCB body burden and the microplastic exposure concentrations were greatly exceeding environmentally relevant concentrations.

Gerdes, Z., et al. (2019). "A novel method for assessing microplastic effect in suspension through mixing test and reference materials." Scientific Reports **9**(1): 10695.

The occurrence of microplastic in the environment is of global concern. However, the microplastic hazard assessment is hampered by a lack of adequate ecotoxicological methods because of conceptual and practical problems with particle exposure. In the environment, suspended solids (e.g., clay and cellulose) in the same size range as microplastic, are ubiquitous. Therefore, it must be established whether the addition of microplastic to these background levels of particulate material represents a hazard. We present a novel approach employing a serial dilution of microplastic and reference particles, in mixtures, which allows disentangling the effect of the microplastic from that of the other particulates. We demonstrate the applicability of the method using an immobilization test with Daphnia magna exposed to polyethylene terephthalate (test microplastic; median particle diameter ~5 micro m) and kaolin clay (reference material; ~3 micro m). In the range of the suspended solids test concentrations (0-10 000 mg L⁻¹), with microplastic contributing 0-100% of total mass, the LC₅₀ values for the plastic mixtures were significantly lower compared to the kaolin exposure. Hence, the exposure to polyethylene terephthalate was more harmful to the daphnids than to the reference material alone. The estimated threshold for the relative contribution of the test microplastic to suspended matter above which significantly higher mortality was observed was 2.4% at 32 mg of the solids L⁻¹. This approach has a potential for standardization of ecotoxicological testing of particulates, including microplastic.

Gerlach, E., et al. (1985). "The vascular endothelium: A survey of some newly evolving biochemical and physiological features." Basic Research in Cardiology **80**(5): 459-474.

The morphological, biochemical and functional characterization of the vascular endothelium has become possible through the broad use of electron microscopic methods, the successful elaboration and application of techniques for the isolation and cultivation of endothelial cells in vitro and through sophisticated studies on vessel and organ preparations, both in vitro and in vivo. In this survey emphasis is placed on certain methodological aspects of endothelial cell culture as well as on biochemical, physiological and pathophysiological features of the vascular endothelium. Endothelial cells can be propagated in culture dishes, the most commonly applied method, on suspended microbeads (dextrane, polyacrylamide), a technique giving large yields, or on thin porous membranes, a procedure suited for the study of transport processes across the endothelial layer. Different structural, biochemical and functional properties of the luminal (apical) and abluminal (basal) cell membrane determine important polarity features of the endothelium. Endothelial cells exhibit a variety of biochemical pathways and are characterized by high metabolic activities. Of particular interest is the large content of ATP in endothelial cells of different vascular origin. The rapid intracellular degradation of adenine nucleotides to nucleosides and bases, which are constantly released, is balanced on synthesis, mainly via salvage pathways. In endothelial cells of microvascular origin uric acid predominates by far as the final purine degradative because of the presence of xanthine dehydrogenase in these cells; in the macrovascular endothelium purine breakdown proceeds only to hypoxanthine, since xanthine dehydrogenase is lacking. In this connection interrelations between nucleotide catabolism in myocardial tissue and in coronary endothelial cells are discussed, also with respect to the participation of endothelial xanthine oxidase in the formation of oxygen radicals during post-ischemic reperfusion of the heart. Vascular endothelial cells of different origin are also capable of a rapid extracellular degradation of ATP, ADP and AMP to adenosine by means of specific ecto-nucleotidases. The subsequent fate of extracellularly formed adenosine appears to be different for endothelial cells of microvascular (preferential adenosine uptake) and macrovascular origin (preferential extracellular adenosine accumulation), thus implying functional consequences for platelet aggregation. Experimentally well supported aspects of endothelial functions under physiological and pathophysiological conditions include: - the involvement of metabolic properties of the endothelium in the separation of the intra- and extravascular space (barrier function, e.g. intraendothelial trapping of adenosine, active participation in leukocyte emigration); - the facilitation of CO<inf>2</inf>-release in the lung (endothelial carboanhydrases); - the participation in the regulation of vascular resistance (formation of angiotensin II and degradation of bradykinin by means of angiotensin converting enzyme, formation of not yet identified endothelium derived relaxing factor(s) [EDRF] in response to various intraluminally present vasodilating substances); - the establishment of an antithrombogenic luminal surface of the vessel wall (release of PGI<inf>2</inf>, adenosine, antithrombin III and plasminogen activator, intravascular degradation of adenine nucleotides to adenosine by endothelial ecto-nucleotidases, activation of protein C by endothelial thrombomodulin, heparan and antithrombin III containing endothelial glycocalyx).

Gerlach, G. F., et al. (2015). "Microbead Implantation in the Zebrafish Embryo." Journal of Visualized Experiments(101).

The zebrafish has emerged as a valuable genetic model system for the study of developmental biology and disease. Zebrafish share a high degree of genomic conservation, as well as similarities in cellular, molecular, and physiological processes, with other vertebrates including humans. During early ontogeny, zebrafish embryos are optically transparent, allowing researchers to visualize the dynamics of organogenesis using a simple stereomicroscope. Microbead implantation is a method that enables tissue manipulation through the alteration of factors in local environments. This allows researchers to assay the effects of any number of signaling molecules of interest, such as secreted peptides, at specific spatial and temporal points within the developing embryo. Here, we detail a protocol for how to manipulate and implant beads during early zebrafish development.

Germanov, E. S., et al. (2018). "Microplastics: no small problem for filter-feeding megafauna." Trends in Ecology & Evolution **33**(4): 227-233.

Microplastic pollution can impact filter-feeding marine megafauna, namely mobulid rays, filter-feeding sharks, and baleen whales. Emerging research on these flagship species highlights potential exposure to microplastic contamination and plastic-associated toxins. Research and its wide communication are needed to understand the magnitude of the issue and improve marine stewardship.

Gestoso, I., et al. (2019). "Plasticrusts: A new potential threat in the Anthropocene's rocky shores." Science of the Total Environment **687**: 413-415.

Plastic debris is one of the most extensive pollution problems our planet is facing today and a particular concern for marine environment conservation. The dimension of the problem is so large that it is possible our current era will generate an anthropogenic marker horizon of plastic in earth's sedimentary record. Here we present a new type of plastic pollution, the 'plasticrusts', plastic debris encrusting the rocky surface, recently discovered in the intertidal rocky shores of a volcanic Atlantic island. The potential impact that these new 'plasticrusts' may have needs to be further explored, as e.g. potential ingestion by intertidal organisms could suppose a new pathway for entrance of plastics into marine food webs. Consequently, its inclusion as a potential new marine debris category in management and monitoring actions should be pondered.

Gewert, B., et al. (2017). "Abundance and composition of near surface microplastics and plastic debris in the Stockholm Archipelago, Baltic Sea." Marine Pollution Bulletin **120**(1-2): 292-302.

We collected plastic debris in the Stockholm Archipelago using a manta trawl, and additionally along a transect in the Baltic Sea from the island of Gotland to Stockholm in a citizen science study. The samples were concentrated by filtration and organic material was digested using hydrogen peroxide. Suspected plastic material was isolated by visual sorting and 59 of these were selected to be characterized with Fourier transform infrared spectroscopy. Polypropylene and polyethylene were the most abundant plastics identified among the samples (53% and 24% respectively). We found nearly ten times higher abundance of plastics near central Stockholm than in offshore areas (4.2 x 10⁵ plastics km⁻² compared to 4.7 x 10⁴ plastics km⁻²). The abundance of plastic debris near Stockholm was similar to urban areas in California, USA, and the overall abundance in the Stockholm Archipelago was similar to plastic abundance reported in the northwestern Mediterranean Sea. Ghadiriasli, R., et al. (2018). "Identification of odorous compounds in oak wood using odor extract dilution analysis and two-dimensional gas chromatography-mass spectrometry/olfactometry. (Special Issue: Fading lemonade challenge/Where are modern flow techniques heading to?/Current trends in supercritical fluid chromatography/Instrumental analysis of microplastics.)." Analytical and bioanalytical

chemistry **410**(25): 6595-6607.

Over the centuries, oak wood has been used in the maturation process of alcoholic beverages imparting aroma and flavor notes. Whereas several studies have dealt with the impact of oak wood on the chemical composition of, for example, wine aroma, only limited information is available on the odorant composition of unmodified and raw oak wood itself. To close this gap, a combination of human sensory and chemo-analytical techniques was applied for the elucidation of the chemical composition of oak odor, comprising extraction of the volatile fraction of oak wood by means of solvent-assisted flavor evaporation (SAFE) and subsequent mild concentration of the distillate. Odor extract dilution analysis (OEDA), which is based on gas chromatography-olfactometry (GC-O), was then applied for the targeted characterization of the odor-active compounds. Overall, a total of 97 odorants was identified via gas chromatography-mass spectrometry/olfactometry (GC-MS/O) and heart-cut two-dimensional gas chromatography-mass spectrometry/olfactometry (2D-GC-MS/O). The majority of these odorants comprised a series of terpenes, mainly mono- and sesquiterpenes, aldehydes, acids, and lactones, as well as a number of odorants containing a phenolic core moiety. Several odorants are reported here for the first time as volatile organic compounds in oak wood. Identification of the molecular composition of oak wood odor helps to establish a better understanding of the distinctive smell of oak wood, and offers the basis for unveiling its potential effects on humans when being exposed to oak wood smell in daily life.

Ghamsari, L., et al. (2016). "Genome-scale neoantigen screening using ATLASTM prioritizes candidates for immunotherapy in a non-small cell lung cancer patient." Journal for ImmunoTherapy of Cancer. Conference: 31st Annual Meeting and Associated Programs of the Society for Immunotherapy of Cancer, SITC **4**(Supplement 1).

Background Despite the unprecedented efficacy of checkpoint inhibitor (CPI) therapy in treating some cancers, the majority of patients fail to respond. Several lines of evidence support that the mutational burden of the tumor influences the outcome of CPI therapies. Capitalizing on neoantigens derived from non-synonymous somatic mutations may be a good strategy for therapeutic immunization. Current approaches to neoantigen prioritization involve mutanome sequencing, in silico epitope prediction algorithms, and experimental validation of cancer neoepitopes. We sought to circumvent some of the limitations of prediction algorithms by prioritizing neoantigens empirically using ATLASTM, a technology developed to screen T cell responses from any subject against their entire complement of potential neoantigens. Methods Exome sequences were obtained from peripheral blood mononuclear cells (PBMC) and tumor biopsies from a non-small cell lung cancer patient who had been successfully treated with pembrolizumab. The tumor exome was sequenced and somatic mutations identified. Individual DNA sequences (399 nucleotides) spanning each mutation site were built, cloned and expressed in E. coli co-expressing listeriolysin O. Polypeptide expression was validated using a surrogate T cell assay or by Western blotting. Frozen PBMCs, collected pre- and post-therapy, were used to derive dendritic cells (MDDC), and CD8⁺ T cells were enriched and expanded using microbeads. The E. coli clones were pulsed onto MDDC in an ordered array, then co-cultured with CD8⁺ T cells overnight. T cell activation was detected by analyzing cytokines in supernatants. Antigens were identified as clones that induced a cytokine response that exceeded 3 standard deviations of the mean of ten negative controls, then their identities compared with T cell epitopes predicted using previously described algorithms. Results Peripheral CD8⁺ T cells, screened against 100 mutated polypeptides derived from the patient's tumor, were responsive to five neoantigens prior to CPI intervention and seven post-treatment. One was identified as a T cell target both pre- and post-CPI therapy. Five neoantigens did not contain epitopes predicted by in silico methods. Conclusions These data represent evidence that multiple patient-specific neoantigens can be identified through functional evidence of T cell response from peripheral blood without epitope prediction. By profiling natural and CPI-enhanced immunity to neoantigens, a broad catalog of T cell targets can be identified for development of immunotherapies that engage T cells against cancer to improve outcomes for patients for whom current therapies are insufficient.

Ghamsari, L., et al. (2017). "Genome-scale neoantigen screening using ATLASTM prioritizes candidate antigens for immunotherapy in a non-small cell lung cancer patient." Cancer Research. Conference: American Association for Cancer Research Annual Meeting **77**(13 Supplement 1).

Despite the unprecedented efficacy of checkpoint blockade (CPB) therapy in treating some cancers, the majority of patients fail to respond. Several lines of evidence support that the combination of CPB and neoantigen vaccine prolongs survival curves in cancer patients. Capitalizing on neoantigens derived from non-synonymous somatic mutations is a good strategy for therapeutic immunization. Current approaches to neoantigen prioritization involve mutanome sequencing, in silico epitope prediction algorithms, and experimental validation of cancer neoepitopes. Even the best in class in silico epitope prediction algorithms lack the accuracy necessary for efficacious personalized cancer vaccines. We sought to circumvent some of the limitations of currently available prediction algorithms by prioritizing neoantigens empirically using ATLASTM, a technology developed to screen T cell responses from any subject against their entire complement of potential neoantigens. Exome sequences were obtained from peripheral blood mononuclear cells (PBMC) and tumor biopsies from a non-small cell lung cancer patient who had been successfully treated with pembrolizumab. The tumor exome was sequenced and somatic mutations were identified. Individual DNA sequences (399 nucleotides) spanning each mutation site were built, cloned and expressed in E. coli co-expressing listeriolysin O. Polypeptide expression was validated using a surrogate T cell assay or by Western Blotting. Frozen PBMCs, collected pre- and post-therapy, were used to derive dendritic cells (MDDC). Both CD4+ and CD8+ T cells were enriched and expanded using microbeads. The E. coli clones were pulsed onto MDDC in an ordered array, then co-cultured either with CD8+ or with CD4+ T cells overnight. T cell activation was detected by analyzing cytokines in supernatants. Antigens were identified as clones that induced a cytokine response that exceeded three standard deviations of the mean of all negative control wells, then their identities compared with T cell epitopes predicted using previously described algorithms. We found biological evidence for neoantigens that were specifically responsive to peripheral CD8+ and CD4+ T cells, derived from the patient's tumor, pre- and post-CPB intervention. Some of these neoantigens were identified as a T cell target both pre- and post-CPB therapy. We identified neoantigens for which no epitopes were predicted by in silico methods. These data represent evidence that multiple patient-specific neoantigens can be identified through functional evidence of T cell response from peripheral blood without epitope prediction. By profiling natural and CPB-enhanced immunity to neoantigens, a broad catalog of T cell targets can be identified for development of immunotherapies that engage T cells against cancer to improve outcomes for patients for whom current therapies are ineffective.

Ghayebzadeh, M., et al. (2020). "Estimation of plastic waste inputs from land into the Caspian Sea: A significant unseen marine pollution." Marine Pollution Bulletin **151 (no pagination)**(110871).

It has been proven that there is an extensive bulk of plastic debris in marine ecosystems. The present study analyzed solid waste generation, its management and final disposal methods in Caspian Sea coastal countries, and the amount of plastic waste entering the Caspian Sea. The results showed that, on average, more than 90% of waste in the Caspian Sea coastal countries is mismanaged. According to our estimates, 425 kilotons (Kt) of plastic waste was generated by Caspian Sea coastal countries in 2016, of which, with high probability, 58-155 Kt find their way to the Caspian Sea. It is estimated that without improved waste management infrastructures, the amount of plastic waste entering the Caspian Sea will increase to 68-182 Kt by 2030, an increase of about 15%. Accordingly, the related cumulative environmental and health problems could be more severe. All countries located in the coastal areas of the Caspian Sea should revise their solid waste and plastic waste management programs to protect that sensitive marine ecosystem. Ghazarian, A. and S. B. Oppenheimer (2014). "Microbead analysis of cell binding to immobilized lectin. Part II: Quantitative kinetic profile assay for possible identification of anti-infectivity and anti-cancer reagents." Acta Histochemica **116**(8): 1514-1518.

There has been a re-emergence of the use of lectins in a variety of therapeutic venues. In addition lectins are often responsible for the binding of pathogens to cells and for cancer cell clumping that increases their escape from body defenses. It is important to define precisely the activity of inhibitors of lectin-binding that may be used in anti-infection and anti-cancer therapeutics. Here we describe a kinetic assay that measures the activity of saccharide inhibitors of lectin binding using a model system of yeast (Saccharomyces cerevisiae) and lectin (Concanavalin A, Con A) derivatized agarose microbeads that mimics pathogen-cell binding. We show that old methods (part I of this study) used to identify inhibitor activity using only one sugar concentration at one time point can easily provide wrong information about inhibitor activity. We assess the activity of 4 concentrations of 10 saccharides at 4 different times in 400 trials and statistically evaluate the results. We show that d-melezitose is the best inhibitor of yeast binding to the lectin microbeads. These results, along with physical chemistry studies, provide a solid foundation for the development of drugs that may be useful in anti-infectivity and anti-cancer therapeutics.

Ghimire, S., et al. (2020). "Sampling and degradation of biodegradable plastic and paper mulches in field after tillage incorporation." Science of the Total Environment **703**: 135577.

Plastic biodegradable mulch (plastic BDM) is tilled after use, but there is concern about incomplete degradation and potential impact on subsequent crops, and we lack a reliable method to measure mulch degradation post soil-incorporation. We conducted two field experiments to (i) develop a sampling method to estimate the amount of mulch (fragments size >2.36 mm) in the field post soil-incorporation, and (ii) assess the amount of BDM in the soil after four consecutive years of mulch incorporation. In Expt. 1, we used the quartering method to reduce soil from a 1 m² field sample area to a representative 19 L sample. In Expt. 2, we applied and tilled four plastic BDMs: BioAgri, Naturecycle, Organix AG, and an experimental mulch; and one paper mulch, WeedGuardPlus, in their respective plots for four consecutive years. Starting in year 2, we sampled soil with the quartering method each spring and fall to determine mulch recovery. With respect to the total amount of mulch applied, average mulch recovery in the fall for the three commercial plastic BDMs was 71%, 50%, and 35% after second, third and fourth applications, respectively. For the experimental mulch, the average recovery was 80%, 69%, and 54% in the fall after second, third, and fourth applications, respectively. Recovery was slightly lower in spring than in preceding fall all years. For WeedGuardPlus, average recovery was 14%-20% in each fall, and no recovery in any spring (complete degradation). The results show that the quartering method reliably estimates the amount of mulch in a field and BDMs degrade over time in the field even with repeated

applications, but complete degradation takes >1 year. While a few standards (e.g., ASTM D5988) specify how to determine biodegradation of plastics in soil under controlled laboratory conditions, our sampling method assesses plastic degradation under diverse field conditions.

Ghioltean, L. M. (2015). "CONDIDERATION CONCERNING THE NEED OF SUSTAINABLE ECOLOGICAL DESIG." Journal of Industrial Design and Engineering Graphics **10**(2): 15.

In the case of each new product the ecological design for a sustainable development imposes the choices of correct materials and "clean" technologies with minimum energy consumption, of proper technologies of materials recycling with full awareness of consumers. The paper presents the stages the industrial product devising passed through. References are made to the principles and key factors of modern design with emphases on policies of material recycling. Plastic materials and possibilities of their recuperation are in focus. Products made from recycled materials are presented. Finally, the use of plastic waste in Romania is analysed, by comparing the activity of firms in different regions of the country.

Ghodbane, M., et al. (2015). "Development of a low-volume, highly sensitive microimmunoassay using computational fluid dynamics-driven multiobjective optimization." Microfluidics & Nanofluidics **18**(2): 199-214.

Immunoassays are one of the most versatile and widely performed biochemical assays and, given their selectivity and specificity, are used in both clinical and research settings. However, the high cost of reagents and relatively large sample volumes constrain the integration of immunoassays into many applications. Scaling the assay down within microfluidic devices can alleviate issues associated with reagent and sample consumption. However, in many cases a new device is designed and empirically optimized for each specific analyte, a costly and time consuming approach. In this paper, we report the development of a microfluidic bead-based immunoassay which, using antibody coated microbeads, can potentially detect any analyte or combination of analytes for which antibody coated microbeads can be generated. We also developed a computational reaction model and optimization algorithm that can be used to optimize the device for any analyte. We applied this technique to develop a low volume IL-6 immunoassay with high sensitivity (358 fM, 10 pg/mL) and a large dynamic range (4 orders of magnitude). This device design and optimization technique can be used to design assays for any protein with an available antibody and can be used with a large number of applications including biomarker discovery, temporal in vitro studies using a reduced number of cells and reagents, and analysis of scarce biological samples in animal studies and clinical research settings.

Ghodbane, M., et al. (2015). "Development of microfluidic immunoassays for multiplexed biomarker measurements." Artificial Organs **39 (5)**: A19-A20.

Objective: Immunoassays are widely utilized due to their ability to quantify a vast assortment of biomolecules relevant to biological research and clinical diagnostics. We seek to develop microfluidic approaches to performing multiplex assays capable of simultaneously measuring multiple analytes, especially inflammation markers, in a single sample. Method(s): Several approaches have been explored towards miniaturizing multiplexed immunoassays based on cytometric bead assays. The first approach is a continuous flow immunoassay which automates the serial incubation steps required using magnetic microbeads. The device uses a magnetic actuation scheme to transfer microbeads into a blood sample and subsequent reagents required for the assay. A second device is a batch format which uses a packed bead bed which allows each solution to be serially infused over the packed beads. Finally, we are exploring a semi-batch approach utilizing beads suspended in aqueous droplets. Using magnetic and

electrical actuation beads can be separated and recombined with sample, and reagent droplets allowing serial processing of discrete measurements. Result(s): We have demonstrated the ability to track the concentration of a time-varying sample with multiple analytes simultaneously (cytokines IL-6 and TNF-alpha) (Figure 1) as well as measuring 6 proteins in 32 samples simultaneously using only 4.2 muL of sample volume (Figure 2). We expect the semi-batch approach will allow high frequency sampling and analysis of temporal varying biomarker concentration in blood. Conclusion(s): We expect a fully integrated assay to allow high frequency measurements of inflammatory biomarkers during mechanical circulatory support procedures such as CPB and ECMO. Serial determination of biomarker levels during the early post-operative period promises to be a valuable tool for the evaluation of peri-operative morbidity in pediatric patients, especially myocar-dial and cerebral damage.

Ghorashian, S., et al. (2016). "A novel second generation CD19 CAR for therapy of high risk/relapsed paediatric CD19⁺ acute lymphoblastic leukaemia and other haematological malignancies: Preliminary results from the carpall study." Blood. Conference: 58th Annual Meeting of the American Society of Hematology, ASH **128**(22).

Introduction: Recent clinical trials with T cells engineered to express 2nd generation CD19 chimeric antigen receptors (CARs) unprecedented anti-leukemic responses. We have developed a novel CD19CAR with a new scFv in the 41BBz format (CAT-41BBz CAR) which confers enhanced cytotoxicity and cytokine secretion in response to stimulation with CD19⁺ targets in vitro as well as equivalent in vivo anti-tumour efficacy to the FMC63 41BBZ CAR in use in clinical studies. We have designed, optimized and validated GMP-grade CAR T cell production using this novel CAR. Based on these data, we have recently initiated a Phase I clinical study (CARPALL) of this novel CAR in pediatric patients with relapsed ALL and other CD19⁺ hematological malignancies to determine the safety profile and durability of responses to CD19CART therapy. This will be critical in determining whether CD19CAR T cells are best used as a stand-alone therapy or as a bridge to stem cell transplant (SCT). Method(s): We initially optimized our GMP production methodology in terms of activation method, cytokine milieu and expansion conditions on healthy donor peripheral blood mononuclear cells (PBMCs) to give optimal transduction efficiency and preserve early memory subsets within the CAR T cell product. We have subsequently validated this methodology using unstimulated leucaphereses from 5 lymphopenic patients with ALL. PBMCs were activated with anti-CD3/CD28 microbeads (Dynabeads CTS) and then lentivirally transduced with the CAT CAR vector. T cells were then expanded in the WAVE bioreactor before bead removal on a magnetic system and cryopreservation. Patients on study receive lymphodepletion with fludarabine and cyclophosphamide followed by a single dose of 10⁶ CAR⁺ T cells/kg and are then monitored as an in-patient for 14 days post infusion for toxicities such as cytokine release syndrome or neurotoxicity. The primary endpoints of the study are toxicity and the proportion of patients achieving molecular CR at 1 month post CD19CAR T cell infusion. Following this, patients undergo intensive monitoring of disease status for a total of 2 years post infusion. To determine the durability of responses, patients achieving a molecular CR will be monitored closely for the re-emergence of molecular level disease without additional consolidative therapy or SCT Results: We were able to generate the target dose of 1x10⁶ CAR⁺ T cells/kg in 6 of 7 production runs (involving 2 healthy donors and 5 patients) to date, all of which met sterility release criteria. Transduction efficiency was on average 37% (range 7-84%, see table 1). Mean viral copy was 4.2 (range 1.2-5.8). Memory T cells of stem cell-like phenotype (CAR⁺ CCR7⁺ CD45RA⁺ CD95⁺ CD127⁺) formed a mean of 9% (range

0-31%), central memory T cells (CAR⁺ CCR7⁺ CD45RA⁻) formed a mean of 43% (range 16-70%) and effector memory T cells formed a mean of 31% (range 0-77%) of the final CAR T cell product. The percentage of CAR T cells expressing dual exhaustion markers (TIM3⁺ PD-1⁺) was on average 5% (range 2-8%). So far 2 patients have been treated. Conclusions We have optimized and successfully validated a robust GMP production method for CD19CAR T cells lentivirally transduced with a novel CD19CAR. Preliminary results of therapy with CAT- 41BBz CAR T cells in initial patients on the clinical study will be presented.

Ghosal, S., et al. (2018). "Molecular identification of polymers and anthropogenic particles extracted from oceanic water and fish stomach - a Raman micro-spectroscopy study." Environmental Pollution **233**: 1113-1124.

Pacific Ocean trawl samples, stomach contents of laboratory-raised fish as well as fish from the subtropical gyres were analyzed by Raman micro-spectroscopy (RMS) to identify polymer residues and any detectable persistent organic pollutants (POP). The goal was to access specific molecular information at the individual particle level in order to identify polymer debris in the natural environment. The identification process was aided by a laboratory generated automated fluorescence removal algorithm. Pacific Ocean trawl samples of plastic debris associated with fish collection sites were analyzed to determine the types of polymers commonly present. Subsequently, stomach contents of fish from these locations were analyzed for ingested polymer debris. Extraction of polymer debris from fish stomach using KOH versus ultrapure water were evaluated to determine the optimal method of extraction. Pulsed ultrasonic extraction in ultrapure water was determined to be the method of choice for extraction with minimal chemical intrusion. The Pacific Ocean trawl samples yielded primarily polyethylene (PE) and polypropylene (PP) particles >1 mm, PE being the most prevalent type. Additional microplastic residues (1 mm - 10 micro m) extracted by filtration, included a polystyrene (PS) particle in addition to PE and PP. Flame retardant, deca-BDE was tentatively identified on some of the PP trawl particles. Polymer residues were also extracted from the stomachs of Atlantic and Pacific Ocean fish. Two types of polymer related debris were identified in the Atlantic Ocean fish: (1) polymer fragments and (2) fragments with combined polymer and fatty acid signatures. In terms of polymer fragments, only PE and PP were detected in the fish stomachs from both locations. A variety of particles were extracted from oceanic fish as potential plastic pieces based on optical examination. However, subsequent RMS examination identified them as various non-plastic fragments, highlighting the importance of chemical analysis in distinguishing between polymer and non-polymer residues.

Ghosal, S., et al. (2018). "Molecular identification of polymers and anthropogenic particles extracted from oceanic water and fish stomach – A Raman micro-spectroscopy study." Environmental Pollution **233**: 1113-1124.

Pacific Ocean trawl samples, stomach contents of laboratory-raised fish as well as fish from the subtropical gyres were analyzed by Raman micro-spectroscopy (RMS) to identify polymer residues and any detectable persistent organic pollutants (POP). The goal was to access specific molecular information at the individual particle level in order to identify polymer debris in the natural environment. The identification process was aided by a laboratory generated automated fluorescence removal algorithm. Pacific Ocean trawl samples of plastic debris associated with fish collection sites were analyzed to determine the types of polymers commonly present. Subsequently, stomach contents of fish from these locations were analyzed for ingested polymer debris. Extraction of polymer debris from fish stomach using KOH versus ultrapure

water were evaluated to determine the optimal method of extraction. Pulsed ultrasonic extraction in ultrapure water was determined to be the method of choice for extraction with minimal chemical intrusion. The Pacific Ocean trawl samples yielded primarily polyethylene (PE) and polypropylene (PP) particles >1 mm, PE being the most prevalent type. Additional microplastic residues (1 mm - 10 µm) extracted by filtration, included a polystyrene (PS) particle in addition to PE and PP. Flame retardant, deca-BDE was tentatively identified on some of the PP trawl particles. Polymer residues were also extracted from the stomachs of Atlantic and Pacific Ocean fish. Two types of polymer related debris were identified in the Atlantic Ocean fish: (1) polymer fragments and (2) fragments with combined polymer and fatty acid signatures. In terms of polymer fragments, only PE and PP were detected in the fish stomachs from both locations. A variety of particles were extracted from oceanic fish as potential plastic pieces based on optical examination. However, subsequent RMS examination identified them as various non-plastic fragments, highlighting the importance of chemical analysis in distinguishing between polymer and non-polymer residues. [ABSTRACT FROM AUTHOR]

Ghosh, S., et al. (2014). "Measurement of spatiotemporal intracellular deformation of cells adhered to collagen matrix during freezing of biomaterials." Journal of Biomechanical Engineering **136**(2): 021025.

Preservation of structural integrity inside cells and at cell-extracellular matrix (ECM) interfaces is a key challenge during freezing of biomaterials. Since the post-thaw functionality of cells depends on the extent of change in the cytoskeletal structure caused by complex cell-ECM adhesion, spatiotemporal deformation inside the cell was measured using a newly developed microbead-mediated particle tracking deformetry (PTD) technique using fibroblast-seeded dermal equivalents as a model tissue. Fibronectin-coated 500 nm diameter microbeads were internalized in cells, and the microbead-labeled cells were used to prepare engineered tissue with type I collagen matrices. After a 24 h incubation the engineered tissues were directionally frozen, and the cells were imaged during the process. The microbeads were tracked, and spatiotemporal deformation inside the cells was computed from the tracking data using the PTD method. Effects of particle size on the deformation measurement method were tested, and it was found that microbeads represent cell deformation to acceptable accuracy. The results showed complex spatiotemporal deformation patterns in the cells. Large deformation in the cells and detachments of cells from the ECM were observed. At the cellular scale, variable directionality of the deformation was found in contrast to the one-dimensional deformation pattern observed at the tissue scale, as found from earlier studies. In summary, this method can quantify the spatiotemporal deformation in cells and can be correlated to the freezing-induced change in the structure of cytosplasm and of the cell-ECM interface. As a broader application, this method may be used to compute deformation of cells in the ECM environment for physiological processes, namely cell migration, stem cell differentiation, vasculogenesis, and cancer metastasis, which have relevance to quantify mechanotransduction.

Ghosh, S. and A. R. Horrocks (1996). "THE PRODUCTION OF HIGH TENACITY TAPES FROM WASTE POLYPROPYLENE." Recycling Textile & Plastic Waste: 127-133.

The article discusses the production of high tenacity tapes from recycled polymer wastes. Many recycled polyolefins were converted to plant containers and timber substitutes but only high quality products are capable of maintaining high levels of mechanical, physical and chemical performance. In the textile industry, the reuse of poly-ethylene terephthatlate or pressurized drink containers as raw materials for melt extrusion into fibers is considered important. A study was conducted on the effects of adding waste on the tensile, physical and chemical properties of polypropylene tapes. It was revealed that tape strength decreased with increasing recycled material concentration.

Ghosh, S. K., et al. (2010). "Anharmonic interaction signals for acoustic detection of analyte." Analytical Chemistry **82**(9): 3929-3935.

The challenges with frequency-based acoustic detection systems in sensitive, selective, and reliable quantitative estimation of surface-bound analyte are well-known. These systems are traditionally used in their linear incarnations; i.e., the measurement frequency is the same as the driving frequency. However, it was found in this work that interactions of adsorbents with sensor surface show significant anharmonicity even at low drive amplitudes. In particular, using streptavidin-coated polystyrene microbeads on an oscillating quartz surface in air, it has been demonstrated through modeling and experiments that the anharmonic signal from microparticle to surface interaction is significantly higher relative to that from bare quartz and orders of magnitude higher than relative shifts in resonant frequency. The signal is proportional to the number of microparticles and holds a well-defined functional relationship with the amplitude of oscillation, distinct to the nature of interaction with the surface for a given analyte. This approach, thus, can be used for ultrasensitive and quantitative detection of surface adsorbents and characterization of different kinds of surface interactions, distinguishing specific from nonspecific adsorbents. The modeling also reveals a direct functional relationship between the measured anharmonic signal and the interaction potential of the adsorbent with the surface.

Ghubade, A., et al. (2009). "Dielectrophoresis assisted concentration of micro-particles and their rapid quantitation based on optical means." Biomedical Microdevices **11**(5): 987-995.

The detection and counting of micro particles having sizes comparable to biological entities can provide a tremendous impetus to rapid diagnostics and clinical applications. MEMS technology has already been used in capture and detection of such micron size entities in miniscule concentrations. For this purpose a concentration step is normally added prior to the detection process. A variety of methodologies are used for quantization of such micron size particles/entities including change in permittivity, medium impedance, magnetic permeability and other means. Although optical studies have been extensively performed prior to this, it has not been used for quantization of the micro particles. We have designed, developed and characterized a MEMS counter which captures micron size fluorescent beads using delectrophoresis (DEP) and monitors their accumulation in a 12 mumx230 mum size channel and monitors this accumulation as growth of overall fluorescence. The field is generated by a set of finely placed interdigitated microelectrodes. As we apply an alternating voltage at 10 V<inf>pp</inf> for a range of different frequencies we are able to capture the flowing beads and concentrate them by several orders of magnitude. This is also followed by their quantification in terms of growing fluorescence signal. For quantitating the fluorescence values a CCD (charge couple device) module fitted over an inverted fluorescence microscope is used that visualizes the whole capture process and a Labview based image acquisition software simultaneously calculates the signal intensity over these frames and arranges it temporally. Our work will have tremendous utility in developing a rapid bacterial counting procedure and will be a valuable tool in microbiological laboratories. © 2009 Springer Science+Business Media, LLC.

Giacalone, J. C., et al. (2019). "Generation of an immortalized human choroid endothelial cell line (iChEC-1) using an endothelial cell specific promoter." Microvascular Research **123**: 50-57.

Age-related macular degeneration (AMD) is a common cause of blindness worldwide. While recent studies have revealed that the loss of choroidal endothelial cells (ChECs) is critical to the disease pathogenesis of dry AMD, in vitro studies are needed to fully elucidate the disease mechanism. However, these studies remain hindered due to the lack of publically available human ChEC lines. To address this need, ChECs were harvested form donor tissue and enriched for by using magnetic cell separation using anti-CD31 conjugated microbeads. Next, lenti-viral vectors with endothelial-specific promoters driving genes necessary for immortalization, CDH5p-hTERT and CDH5p TAg, were generated. Stable integration of both gene cassettes allowed cells to maintain their proliferative state and yielded an immortalized cell line (iChEC-1). Immunocytochemical analysis of iChEC-1 confirmed the expression of important ChEC markers such as CA4, a marker of choriocapillaris endothelial cells, CDH5, and CD34, pan-endothelial cell markers. qRT-PCR analysis of expanded clones from iChEC-1 further showed that the line maintained expression of other important endothelial markers, vWF, PECAM1, and PLVAP, similar to primary cells. Functional responses were characterized by tube-forming assays and repopulation of decellularized choroid with the immortalized cell line. In conclusion, the iChEC-1 line presents a suitable immortalized human ChEC line for future in vitro studies of AMD.

Giaever, I. (1978). "A simple visual surface immunology test." Journal of Immunological Methods **24**(1-2): 57-61.

A new general immunology test is described which is capable of detecting protein in the 1 mug/ml range. First an antigen is adsorbed in a small area of a glass surface. The glass is exposed to an antibody solution and the antibody will attach specifically to the antigen. Next the slide is washed, dried and sprayed lightly with plastic particles that stick to the protein layers on the glass. Now when the glass slide is exposed to an acid the antigen-antibody bonds are broken, the antibodies will leave the surface removing some of the plastic particles and leaving an easily visible spot behind.

Giallongo, C., et al. (2016). "Mesenchymal stem cells (MSC) promotes tumor microenvironment transformation driving granulocyte-like myeloid derived suppressor cells (G-MDSC) activation in smoldering and multiple myeloma patients." Haematologica **101 (Supplement 1)**: 251.

Background: A well-recognized feature of multiple myeloma (MM) is the intimate relationship between plasma cells (PC) and BM microenvironment, which is mainly composed of mesenchymal stromal cells (MSC), endothelial cells, immune cells and extracellular matrix. Granulocytic-Myeloid-derived suppressor cells (G-MDSC) accumulate in the tumor microenvironment during tumor development. MDSC promote tumor growth and invasion, immunosuppression and host immune evasion by suppressing lymphocyte activation and antigen recognition. Even though it has been demonstrated that G-MDSC are increased in MM microenvironment, the role of MSC in promoting immunosuppressive microenvironment through activation of G-MDSC remains unexplored. Aim(s): Analyzing MSC from MGUS, Smoldering myeloma (SMM) and MM patients in promoting tumor microenvironment transformation. Method(s): Human peripheral blood mononucleated cells (PBMC) isolated from

healthy subjects (HS) were cultured alone, with HS- (n=8), MGUS- (n=6), SMM- (n=4) or MM-MSC (n=12, 8 patients at diagnosis and 4 relapsed) at 1:100 ratio. After one week, PBMC were collected. G-MDSC were isolated using anti- CD66b magnetic microbeads and the phenotype (CD11b+CD33+CD14- HLADR-) was confirmed by cytofluorimetric analysis. Immunosuppression was analyzed after incubation with autologous T cells CFSE+ stimulated by phytohaemagglutinin (PHA-P). Result(s): G-MDSC educated by SMM- and MM-MSC co-cultures (MSCed-GMDSC) exhibited suppressive effect with a reduction of T cell proliferation (p<0.001) compared to G-MDSC control (isolated from PBMC cultured in medium alone). Notably, neither MDSC control nor HS- or MGUS-MSCed-G-MDSC showed suppressive ability. Before incubation with T cells, the expression of immunomodulatory factors was investigated by real-time PCR in SMM- and MM-MSCed-G-MDSC compared to MGUS-MSCed-G-MDSC. SMM- and MMMSCed-G-MDSC up-regulated Arg1 (56.4+/-18.2 and 24.9+/-13, p<0.001), NOS2 (82+/-35 and 21+/-18, p<0.001), TNFalpha (10+/-3 and 45.7+/-28.8, p<0.05) and CEBPA (90+/-23 and 65+/-19, p<0.001), a transcription factor promoting suppressive phenotype. Adding Bortezomib (5 nM) to co-culture of SMM- and MM-MSC with PBMC, isolated G-MDSC lost immunosuppressive ability. Analysis of MM-MSC from 4 patients revaluated after 3 bortezomib-based therapy followed by autologous stem cell transplantation showed that their immunological dysfunction was reverted after therapy. Since it has been reported that neutrophils can acquire monocytic characteristics in response to inflammatory signals, G-MDSC control and MSCed-G-MDSC were plated onto dentine disks (DDs) for 3 days. A significant digestive activity was observed only in DDs with MM-MSCed-GMDSC (p=0.002) and was lost by MM-MSCed-G-MDSC isolated from co-culture with Bortezomib. Moreover, compared to MGUS-MSCed-G-MDSC, SMM- and MM-MSCed-G-MDSC up-regulated PROK2 expression (5.2+/-1.2 and 7.6+/-2, p<0.05), a chemotactic and pro-angiogenic factor. Investigating effect on angiogenesis in vitro, MM-MSCed-G-MDSC induced tube formation. On the contrary, this effect was not observed in the condition with MM-MSCed-G-MDSC isolated from co-culture with Bortezomib. Summary/Conclusions: MSC from SMM and MM but not MGUS patients are able to activate G-MDSC favoring indirectly transformation of microenvironment in a "tumor" milieu with consequent immune escape and PC growth and survival. Their immunological dysfunction can be reverted by bortezomib exposure.

Giambona, A., et al. (2016). "Embryo-fetal erythroid cell selection from celomic fluid allows earlier prenatal diagnosis of hemoglobinopathies." Prenatal Diagnosis **36**(4): 375-381.

OBJECTIVE: Celocentesis, which involves aspiration of celomic fluid at 7-9 weeks' gestation, can potentially provide early prenatal diagnosis of single-gene disorders. The main barrier to wide acceptability of this technique is contamination of the sample by maternal cells. This problem can be overcome through selection of embryo-fetal erythroid precursors, which are found in celomatic fluid.

METHOD: Embryo-fetal erythroid precursors were selected by an anti-CD71 MicroBeads method or by direct micromanipulator pickup of the cells selected on the basis of their morphology.

RESULTS: In our series of 302 singleton pregnancies at high risk for hemoglobinopathies, Celocentesis provided a sample of celomic fluid in all cases. In 100 (33.1%) samples, maternal contamination was absent or very low (< 5%), and unambiguous results were obtained without the need for any preliminary procedures. In 160 (53%) cases, the contamination was between 5% and 60%, and selection of embryo-fetal erythroid precursors was successfully achieved by anti-CD71 MicroBeads. In 42 (13.9%) cases, the contamination was > 60%, and selection of embryo-fetal cells was achieved by micromanipulation. In all 302 cases, there was concordance between DNA obtained from celomic fluid samples and fetal or newborn DNA.

CONCLUSIONS: Celocentesis can be a reliable procedure for earlier prenatal diagnosis of fetal monogenic diseases.

Giambona, A., et al. (2015). "Earlier antenatal diagnosis of hemoglobinopathies by coelocentesis." Blood **126 (23)**: 2133.

Embedded Image In countries with a high prevalence of hemoglobinopathy carriers, the only realistic approach to control the birth of new patients with thalassemia major or sickle cell disease is population screening in combination with invasive prenatal diagnosis[1]. In the early 1990's, molecular definition of the thalassemia defects, development of procedures for their detection by DNA analysis and introduction of amniotic fluid sampling (amniocentesis) or chorionic villus sampling (CVS) led to early prenatal diagnosis at 16 and 11 weeks, respectively [2]. An alternative technique for earlier diagnosis is celocentesis [3]. At the end of week 4 of gestation, the developing exocoelomic cavity (ECC) splits the extra-embryonic mesoderm into two layers, the somatic mesoderm lining the trophoblast and the splanchnic mesoderm covering the secondary yolk sac and the embryo. The ECC is the largest anatomical space inside the gestational sac between 5 and 9 weeks of gestation and is surrounded by celomic fluid (CF), which contains cells of fetal origin [4-5]. This fluid can be sampled by a technique that involves the ultrasound-guided insertion of a needle through the vagina from as early as 7 weeks of gestation. Previous studies utilizing coelocentesis for prenatal determination of single-gene defects reported variable success ranging from 58 to 95% because of presence of maternal cell contamination (MCC) [6]. In this work we demostred as this problem can be overcome through the identification of embryo-fetal erythroid precursors presented in the coelomatic fluid and their specific selection. 302 couples from different regions of Italy, at risk for s thalassemia or sickle cell disease asked for prenatal diagnosis by coelocentesis that was carried out at between 6+6 and 9+2 weeks' gestation. Coelomic fluid samples with no or very low (<5%) maternal contamination (100 samples) were successfully analyzed without preliminary treatment. In samples with >5% maternal contamination, two different procedures were used to isolate embryo-fetal cells: the first technique involved positive selection of embryo-fetal erythroid precursors by anti-CD71 MicroBeads (160 samples), the second procedure was through the use of a micromanipulator (42 samples). In 68/300 (22.6%) cases the fetus was affected by s-thalass/s-thalassemia and 66 women chosen to terminate the pregnancy. Two families decided to continue the pregnancy for ethical reasons despite the documented presence of an affected fetus. The antenatal diagnosis was confirmed in all 66 cases by molecular analysis of placental tissue after termination (Table 1). In 232/300 (77.4%) cases the fetus was diagnosed as being normal or a carrier for s-thalassemia or sicke cell disease. The results obtained after coelocentesis were confirmed by amniocentesis or postnatally. In two case (0.66%) was no obtained a reliable diagnosis because no fetal cells were found (Table 1). The findings of this study in a large number of pregnancies investigated by coelocentesis, demonstrate that embryo-fetal erytroid cell selection from coelomatic fluid allows reliable and earlier prenatal diagnosis of hemoglobinopathies. This technique is attractive to parents because it provides prenatal diagnosis of genetic disease at least 4 weeks earlier respect to traditional procedures reducing anxiety of parents and from a clinical point of view this procedure would allow women to undergo medical TOP at 8-10 weeks of gestation which is less traumatic and safer than second trimester surgical TOP. (Table Presented).

Giangrande, A., et al. (1985). "Electron microscopy and microprobe analysis of dialysis contaminants." Life Support Systems **3 Suppl 1**: 73-76.

A migration of plastic particles from haemodialysis circuit to blood has been recognized to be cause of storage inflammation. Its origin from segments of silicone tubing has been demonstrated by in vivo and in vitro experiments. A similar finding with a peculiar histology picture has been observed in patients who used only PVC and PU-PVC tubing. In this case too microprobe analysis revealed the presence of silicon (Si) in fibril inclusions of liver and spleen cells. TEM, SEM and EDS of cuprophane dialyzer perfusates filtered through Nuclepore revealed the presence of particles with an intense Si Ka. The release from the dialyzer of silicon containing contaminants seems to be an additional risk for uremic patients.

Giani, D., et al. (2019). "Microplastics occurrence in edible fish species (Mullus barbatus and Merluccius merluccius) collected in three different Geographical Sub-Areas of the Mediterranean Sea." Marine Pollution Bulletin **140**: 129-137.

The gastrointestinal tracts of 229 demersal fish belonging to two species (Mullus barbatus, Merluccius merluccius) were examined for microplastic ingestion. Samples were collected in 3 different FAO Geographical Sub-Areas (GSA-9, GSA-17, GSA-19) of the Mediterranean Sea. Ingested microplastics were characterized using a stereo-microscope: observed, photographed, measured and categorized according to size class, shape and colour. Plastic fragments (ranging from 0.10 to 6.6 mm) were detected in 23.3% of the total investigated fish; a total of 65 plastic particles (66% constituted by fibers) were recorded. The percentage of plastic ingestion shows high variability between the two species and among the different sampling area. The highest frequency (48%) was found in European hake from GSA-19. These preliminary results represent a baseline for the implementation of the Marine Strategy Framework Directive descriptor 10 in Italy as well as an important step for detecting microplastics in bioindicator species from different GSAs.

Giarrizzo, T., et al. (2019). "Amazonia: the new frontier for plastic pollution." Frontiers in Ecology & the Environment **17**(6): 309-310.

Brazil's Amazon region is currently subject to increasing deforestation as well as hydropower development, mining, and other activities associated with adverse environmental impacts (Fearnside [6]). Recent pilot studies in the lower Xingu River and the Amazon estuary revealed microplastic particles in the digestive tracts of 13 freshwater and 14 marine fish species, 20 of which are commonly consumed by humans (Pegado I et al i . First account of plastic pollution impacting freshwater fishes in the Amazon: ingestion of plastic debris by piranhas and other serrasalmids with diverse feeding habits. [Extracted from the article]

Gibbs, J. G. and Y. P. Zhao (2009). "Design and characterization of rotational multicomponent catalytic nanomotors." SMALL **5**(20): 2304-2308.

Multicomponent rotational nanomotors consisting of Pt-coated TiO(2) nanoarms grown upon approximately 2.01-microm-diameter silica microbeads designed by dynamic shadowing growth are presented. When exposed to H(2)O(2), the structures rotate about an axis through the center of the microbead and perpendicular to the TiO(2) nanoarm at a rate of 0.15 Hz per % H(2)O(2) concentration. The rotational frequency increases parabolically when the surface tension of the solution is altered by the addition of sodium dodecyl sulphate; both relationships are explainable by a nanobubble-ejection model.

Gicquel, T., et al. (2014). "Monosodium urate (MSU) induced IL-1beta via a purinergic receptor/NLRP3-inflammasome pathway from macrophages." Fundamental and Clinical Pharmacology **1)**: 3.

Monosodium Urate (MSU) has been described as a danger signal activating NLRP3-inflammasome pathway. We investigated the role of P2 purinergic receptors in the activation of NLRP3-inflammasome pathway after MSU treatment in human macrophages. Monocytes from healthy donors were obtained from buffy coat (EFS, Rennes) using human CD14 Microbeads separation kit. Macrophages were obtained after differentiation from monocytes by incubation with rhGM-CSF for 7 days. P2R transcription was extinguished by electroporating specific siRNA. mRNA expression was evaluated by RT-qPCR and production of proinflammatory cytokines was measured in the supernatant using ELISA. MSU crystals (500mug/ mL) were able to induce the release of IL-1beta from human monocyte-derived macrophages induced by low concentration of LPS (0.1mug/mL) at 6 h. Moreover, caspase-1 inhibitor (z-YVAD-fmk) dose-dependently decreased production of IL-1beta after LPS + MSU treatment. Quantitative PCR analysis showed that treatment with LPS and MSU induced a significant increase in the expression of NLRP3 and IL-1beta after treatment with LPS alone or associated with MSU at 6 h. Furthermore, we also showed that MSU treatment induced P2X7R mRNA expression at 6 h by RT-qPCR. Electroporation of siRNAs directed against P2 receptor led to an efficient knock-down of P2R mRNA in macrophages at 24 h and 48 h. We showed that siP2X7R, but not siP2X4R, was able to reduce the release of IL-1beta from macrophages stimulated by LPS + MSU at 6 h. Moreover we observed that A-740003, a P2X7 purinergic receptor antagonist decreased IL-1beta production after treatment with LPS and MSU. Our results show the involvement of purinergic receptor and NLRP3 inflammasome pathway in the secretion of IL-1beta from MSU-stimulated human macrophages and suggest that blockade of the NLRP3 inflammasome or P2X7 receptor represents a novel potential therapeutic approach to control inflammation.

Gicquel, T., et al. (2013). "Involvement of purinergic receptors and NLRP3-inflammasome pathway in the ATP-induced cytokine release from macrophages." American Journal of Respiratory and Critical Care Medicine. Conference: American Thoracic Society International Conference, ATS **187**(MeetingAbstracts).

Idiopathic pulmonary fibrosis (IPF) is a progressive interstitial pneumonitis consecutive to recurrent episodes of acute lung injury associated with inflammatory process and collagen deposition in the interstitium. Adenosine triphosphate (ATP) has been described as a danger signal activating NLRP3-inflammasome and the pro-inflammatory cytokine IL-1beta release in lung in chronic inflammation and in tissue remodelling. NLRP3-inflammasome pathway activation appears as the corner stone of many inflammatory diseases including pulmonary fibrosis. We investigated the role of ATP and P2X<inf>2</inf> purinergic receptor in the activation of NLRP3-inflammasome pathway in human macrophages. Monocytes from healthy donors were obtained from buffy coat (EFS, Rennes) using human CD14 Microbeads separation kit. Macrophages were obtained after differentiation from monocytes by incubation with rhGM-CSF for 7 days. mRNA expression was evaluated by RT-qPCR, cytokines production was measured in the supernatant using ELISA. NLRP3 and P2X<inf>2</inf>R expression was evaluated by immunohistochemistry. We showed that ATPgammaS (300 muM) and BzATP (250 muM), stable analogs of ATP are able to potentiate the release of IL-1beta from human monocyte-derived macrophages induced by low concentration of LPS (0.1 mug/mL), if supernatant was removed, the effect disappeared at 24h. Furthermore LPS and BzATP induced

an increase in IL-1beta mRNA expression at 5h by RT-qPCR. LPS also elicited IL-1alpha and IL-6 expression and production but was not affected by ATP agonists treatment. Immunochemistry revealed that NLRP3 and P2X<inf>2</inf>R proteins were constitutively expressed by macrophages compared with the control. Quantitative PCR analysis showed that treatment with LPS and BzATP induced NLRP3 expression however P2X<inf>2</inf>R transcript levels were not significantly increased after treatment with LPS alone or associated with BzATP at 5h. We also observed that P2X<inf>2</inf>R antagonists, A-438079 (100 muM) and A-740003 (100 muM), were able to reduce the release of IL-1beta, but not IL-1alpha and IL-6 production from macrophages stimulated by purinergic receptor agonists. Our results show the involvement of P2X<inf>2</inf>R-NLRP3 inflammasome pathway in the secretion of IL-1beta from ATP-stimulated human macrophages and suggest that P2X<inf>2</inf>R were not involved in IL-1alpha and IL-6 release and suggests that blockade of the P2X<inf>2</inf> receptor represents a novel potential therapeutic approach to control fibrosis in lung injury.

Gicquel, T., et al. (2012). "Involvement of purinergic receptors and NLRP3 inflammasome pathway in the ATP-induced cytokine release and MMPs/TIMP imbalance in macrophages." Fundamental and Clinical Pharmacology **26 (SUPPL.1)**: 44.

Adenosine triphosphate (ATP) has been described as a danger signal activating Nod-like receptor family, pyrin domain containing 3 (NLRP3) Inflammasome and the proinflammatory cytokine IL-1beta release in lung. This pathway has been previously described to be involved in various inflammatory diseases including fibrosis. We investigated the role of ATP as a danger signal and purinergic receptors in the activation of NLRP3-Inflammasome pathway in human macrophages. Moreover, we evaluated the influence of the activation by ATP in the release of proinflammatory cytokines and the balance MMPs/TIMP. Monocytes from healthy donors were obtained from buffy coat (EFS, Rennes) using human CD14 Microbeads (Miltenyi) separation kit. Macrophages were obtained after differentiation from monocytes by incubation with rhGM-CSF for 7 days. Cytokines and MMPs production was measured in the supernatant using ELISA or zymography. NLRP3 expression was evaluated by immunohistochemistry. LPS and ATP elicited an increased production of IL-6, IL-18 or IL-1beta at 4 h 30 and 24 h. TIMP-1 secretion, a pro-fibrogenic cytokine was also increased at 4 h 30 and 24 h. Gelatinase expression, mainly MMP-9 was increased at 24 h as observed in zymography and confirmed by ELISA. In addition, NLRP3 protein expression was increase at 24 h in LPS+ATP primed cells. To investigate the involvement of purinergic receptors, macrophages were pretreated with suramine, an antagonist of P2 receptors. Suramine significantly reduced the production of TIMP-1 at 4 h 30 and 24 h as well as IL-1beta and IL-6. These results showed that ATP could be a major endogenous danger signal that engages NLRP3 and P2 receptor leading to inflammatory process and cytokine release. This probably alters the MMPs/TIMP equilibrium which influences the extracellular matrix deposition and fibrosis.

Gieck, C. (2017). "Microplastics: The invisible danger." Pharmazeutische Zeitung **162**(23).

Gieseler, F., et al. (2014). "Using annexin V-coated magnetic beads to capture active tissue factor-bearing microparticles from body fluids." Cell Biology International **38**(2): 277-281.

Microparticles, found in all body fluids including peripheral blood, are important elements that regulate cellular interactions under both physiological and pathological conditions. They play an important role in blood clot formation and increased cell aggregation. However, little is known about the components of the microparticles and their mechanism of action. A method to quantify and assess the underlying mechanism of action of microparticles in pathologies is therefore desirable. We present a specific method to isolate cell-derived microparticles from malignant effusions using annexin V-coated magnetic microbeads. The microparticles can be detected by flow cytometry. Our results show that the microparticles can be isolated with >80% specificity when bound to annexin V-coated magnetic beads, which was originally developed for the detection of apoptotic cells. We also show that the isolated microparticles were still functionally active and can be used for further analysis. Thus, our method enables isolation as well as structural and functional characterisation of the microparticles which are produced in numerous patho-physiological situations. This should help gain a deeper insight into various disease situations, which in turn should pave the way for the development of novel drugs and specific therapy strategies.

Gifford, G. (2016). A Plethora of Plastic. Rockville, Maryland, American Speech-Language-Hearing Association. **21:** 4-4.

A letter to the editor is presented discussing the impact of plastic waste on the human body and the human food chain.

Gilbert, J. M., et al. (2016). "PLASTIC INGESTION IN MARINE AND COASTAL BIRD SPECIES OF SOUTHEASTERN AUSTRALIA." Marine Ornithology **44**(1): 21-26.

Plastic pollution is a significant problem in all oceans of the world and accounts for up to 90% of marine debris. Ingestion of plastic by seabirds and its effects are well documented, particularly in the Northern Hemisphere. However, fewer data exist for levels of plastic in seabird and coastal bird species in Australian waters or the southwestern Pacific. In this study, the stomach contents of a variety of seabirds and coastal birds (migratory and resident) were analysed for plastic. Nine (30%) of the birds sampled contained plastic. The median mass of plastic per bird was 41.7 mg and median number of pieces was 3.0. Shearwaters Puffinus spp. had significantly higher plastic mass and number of pieces than other species, and the most common type of plastic was manufactured. However, industrial pellets also contributed substantially. Plastics were primarily dark in colour. No clear indication of the influence of plastic ingestion on body condition could be found, however, internal physical damage and intestinal blockage was noted. Further assessment of the incidence and the effects of plastic ingestion in seabird and coastal bird species in Australian waters is required.

Gilbert, R. G., et al. "Trickle Irrigation: Emitter Clogging and Other Flow Problems." Agricultural Water Management Vol 3, No 3, p 159-178, 1980/1981. 7 Fig, 7 Tab, 17 Ref.

Emitter clogging is the greatest problem of the trickle irrigation systems which are used to deliver water to row and tree crops. A comprehensive four-year study was conducted to develop water treatment methods for preventing emitter clogging and maintaining long-term operation of the trickle irrigation system under actual field conditions. The study evaluated eight trickle emitter systems in combination with six water treatments using Colorado River water in southwestern Arizona. Emitter clogging was found to be related to emitter design and to the degree of filtration treatments of the river water. Only the long-path, spiral-grooved, manual flush emitter design performed efficiently with only screen filtration. Although the expandable diaphragm emitter never developed clogging problems, it failed because of increased flow rates caused by eight reactions with the chemically conditioned water or physical and biological decomposition of the flexible rubber diaphragm. The automatic flushing emitters were most susceptible to malfunction and clogging problems, especially if they were not installed verticaly on the lateral lines. For emitters unaffected by material deterioration, the continuous acid treatment alone was just as effective in reducing emitter clogging as a combination of continuous or intermittent chlorine and acid treatments. The dominant cause of emitter clogging and flow reduction was physical factors. The combined development of biological and chemical deposits was the second, relatively minor, cause of these problems. The major physical factors involved were sand grains and plastic particles. Care should be taken to avoid the introduction of these particles into the lines during installation and repair. (Carroll-FRC)

Gilbreath, A., et al. (2019). "Multiyear Water Quality Performance and Mass Accumulation of PCBs, Mercury, Methylmercury, Copper, and Microplastics in a Bioretention Rain Garden." Journal of Sustainable Water in the Built Environment **5**(4).

A multiyear water quality performance study of a bioretention rain garden located along a major urban transit corridor east of San Francisco Bay was conducted to assess the efficacy of bioretention rain gardens to remove pollutants. Based on data collected in three years between 2012 and 2017, polychlorinated biphenyls (PCBs) and suspended sediment concentrations (SSCs) were reduced (>90%), whereas total mercury (Hg), methylmercury (MeHg), and copper (Cu) were moderately captured (37%, 49%, and 68% concentration reduction, respectively). Anthropogenic microparticles including microplastics were retained by the bioretention rain garden, decreasing in concentration from 1.6 particles/L to 0.16 particles/L. Based on subsampling at 50- and 150-mm intervals in soil cores from two areas of the unit, PCBs, Hg, and MeHg were all present at the highest concentrations in the upper 100 mm in the surface media layers. Based on residential screening concentrations, the surface media layer near the inlet would need to be removed and replaced annually, whereas the rest of the unit would need replacement every 8 years. The results of this study support the use of bioretention in the San Francisco Bay Area as one management option for meeting load reductions required by San Francisco Bay total maximum daily loads, and provide useful data for supporting decisions about media replacement and overall maintenance schedules.

Gil-Delgado, J. A., et al. (2017). "Presence of plastic particles in waterbirds faeces collected in Spanish lakes." Environmental Pollution **220**(Part A): 732-736.

Plastic intake by marine vertebrates has been widely reported, but information about its presence in continental waterfowl is scarce. Here we analyzed faeces of waterbirds species (European coot, Fulica atra, mallard, Anas platyrhynchos and shelduck, Tadorna tadorna) for plastic debris in five wetlands in Central Spain. We collected 89 faeces of shelduck distributed in four lakes, 43.8% of them presented plastic remnants. Sixty percent of 10 faeces of European coot and 45% of 40 faeces of mallard contained plastic debris. Plastic debris found was of two types, threads and fragments, and were identified as remnants of plastic objects used in agricultural fields surrounding the lakes. Differences in prevalence of plastic in faeces, number of plastic pieces per excrement and size of the plastic pieces were not statistically significant between waterfowl species. Thus, our results suggest that plastic may also be frequently ingested by waterfowl in continental waters, at least in our study area. Future studies should address this potential problem for waterbird conservation in other wetlands to evaluate the real impact of this pollutant on waterbirds living in inland water.

Gilicze, O., et al. (2012). "Autoantibody and cardiovascular marker quantification in pericardial fluid and blood samples." European Journal of Clinical Investigation **1)**: 4.

Background: Cardiac involvement plays an important role in the morbidity and mortality of patients with antiphospholipid syndrome (APS) or other systemic autoimmune disorders, moreover mitral valve replacement surgery is quite often indicated among those who suffer from APS. Our aim was to screen for autoantibodies in pericardial fluid (PF) and blood samples

of patients undergoing bypass or valve replacement surgery without special symptoms of autoimmune diseases and to compare the level of cardiovascular factors among the autoantibody positive (AP) and negative cases and the previously diagnosed autoimmune cardiac surgery patients. Material(s) and Method(s): Antinuclear antibodies, anti-beta-2-glycoprotein I and anti-cardiolipin antibodies were determined by diagnostic ELISA kits. Multiplex microbead assay was used to measure cardiovascular factors (tPA, sCD40L, MCP-1, IL-8, IL-6, P-selectin). Result(s): Regarding the cardiovascular factors and cytokines no differences could be found between the bypass and valve groups. Whereas comparing the AP group to the valve- and the autoimmune group significant differences were found. The serum concentrations of sCD40L and t-PA were 1000 times higher in valve- than in autoimmune group, while the APs were half way between. In PF MCP-1 reached the highest level in valve group and the lowest in AP cases, and P-selectin also had noteworthy alterations. Analysing the blood-PF pairs: t-PA, MCP-1, sCD40L concentrations showed significant differences. Conclusion(s): Alternating levels of cytokines and cardiovascular factors of circulation and pericardial fluid may become biomarkers of several cardiovascular diseases or even diagnostic yield of this can be certain. We can also conclude that autoimmune diseases may be underdiagnosed.

Gilicze, O., et al. (2012). "Identification of lymphocyte populations and cardiovascular factors in pericardial fluid and blood samples among patients undergoing open heart surgery." International Journal of Cardiology **1)**: S129-S130.

Objective: Recent studies suggest that the composition of pericardial fluid (PF) is responsive to different conditions. Whereas scant literature is available on the normal - especially on the immunological composition of it. Lymphocytes are considered to have key role in the development of AMI and atherosclerosis. Numerous heart diseases are associated with altered levels of circulating cytokines and factors, but their presence and role is still unknown in the pericardium. Cytokines are regarded as possible therapeutic targets or biomarkers. Our aim was to identify and quantify lymphocyte populations and cardiovascular factors in PF and blood samples, correlate these findings with clinical parameters in the group of patients undergoing CABG versus those who underwent valve replacement surgery. Furthermore we divided the CABG group into 2 subgroups and compared our findings among those who had myocardial infarction and those did not. Method(s): Peripherial blood and PF samples were drawn simultaneously during open heart surgery with careful bloodless preparation of the pericardium. The study included 36 strictly selected patients - with 12 participants in each group. Cellular parameters were determined by flow cytometry after immunofluorescence staining. Multiplex microbead assay was used to measure cardiovascular factors. Result(s): As regarding the distribution of lymphocyte populations in both specimens no differences were shown between the CABG and the valve group. In the PF of both groups T-cells represented the dominant cell type - with a high percentage of memory type T-cells. We describe the first time the presence of lymphocytes of the natural immune system in PF. The level of monocyte chemoattractant protein 1 and interleukin-6 were higher in PF than in blood. The concentration of soluble CD40 ligand in blood was unexpectedly high. The level of monocyte chemoattractant protein 1 was significantly higher in the blood of CABG patients than in the valve group. We compared parameters in CABG patients who previously developed AMI with those who did not. The ratio of activated helper and cytotoxic T cells in pericardial fluid reached significantly higher level in the PF of AMI group than in non-AMI group. In pericardial fluid of AMI group the concentration of interleukin-6 was increased comparing to the non-AMI group. In blood samples tissue plasminogen activator showed significant differences. Conclusion(s): Our findings show that pericardial fluid is not only an ultafiltrate but also a transudate which composition may refer to

the statement of the cardiomyocytes thus diagnostic yield of this can be certain.

Gill, M. A., et al. (2008). "Plasmacytoid Dendritic Cells from Asthma Patients Secrete Less Interferon-[alpha] Upon Exposure to Respiratory Viruses." Journal of Allergy and Clinical Immunology **121**(2).

Methods Blood pDCs from 5 patients with allergic asthma and 4 healthy control subjects were purified using antibody-coated magnetic microbeads (Miltenyi Biotec) and cultured for 36 hours with either no virus, respiratory syncytial virus (RSV), or influenza A. IFN-Î± concentrations in the pDC culture supernatants were subsequently determined by ELISA.

Gillard, M., et al. (2018). "[Cutaneous foreign body granulomas following cervico-facial arterial embolization: Three cases]." Annales de Dermatologie et de Venereologie **145**(11): 659-664.

BACKGROUND: Foreign body granuloma is an inflammatory tissue reaction to exogenous material. Classically it appears on the face after aesthetic procedures. Herein we report for the first time three cases of facial granulomatous reactions to microbeads after arterial cervico-facial embolization.

PATIENTS AND METHODS: Three patients underwent embolization of the facial arteries using Embogold microbeads in a setting of epistaxis or tumoral hemostasis. Within 10 to 45 days painful, inflammatory, subcutaneous nodules appeared on the homolateral side of the face. Histological samples showed an inflammatory response with giant cells as well as the presence of microbeads in the skin. A favorable outcome was achieved with colchicine in one patient and with surgery in another; the third patient was lost to follow-up.

DISCUSSION: The embolizing microspheres produced a local inflammatory reaction, with destruction of the vascular wall and bead migration to facial tissue leading to a granulomatous reaction. The occurrence of three cases within a period of few weeks, with several different operators and batches of products, is surprising considering the long-standing use of the product. There was no common comorbidity in the patients and no suggestion of trauma. Retrospective analysis of the product batches was normal. Gold staining could play a role in severe inflammatory response to Embogold particles.

CONCLUSION: These three cases illustrate the value of discussing potential foreign body granulomatous reaction in cases of facial nodules following cervico-facial embolization. Colchicine may offer a valuable therapeutic alternative.

Gillibert, R., et al. (2019). "Raman Tweezers for Small Microplastics and Nanoplastics Identification in Seawater." Environmental Science & Technology **53**(15): 9003-9013.

Our understanding of the fate and distribution of micro- and nano- plastics in the marine environment is limited by the intrinsic difficulties of the techniques currently used for the detection, quantification, and chemical identification of small particles in liquid (light scattering, vibrational spectroscopies, and optical and electron microscopies). Here we introduce Raman Tweezers (RTs), namely optical tweezers combined with Raman spectroscopy, as an analytical tool for the study of micro- and nanoplastics in seawater. We show optical trapping and chemical identification of sub-20 mum plastics, down to the 50 nm range. Analysis at the single particle level allows us to unambiguously discriminate plastics from organic matter and mineral sediments, overcoming the capacities of standard Raman spectroscopy in liquid, intrinsically limited to ensemble measurements. Being a microscopy technique, RTs also permits one to assess the size and shapes of particles (beads, fragments, and fibers), with spatial resolution only limited by diffraction. Applications are shown on both model particles and naturally aged environmental samples, made of common plastic pollutants, including polyethylene, polypropylene, nylon, and polystyrene, also in the presence of a thin eco-corona. Coupled to suitable extraction and concentration protocols, RTs have the potential to strongly impact future research on micro and nanoplastics environmental pollution, and enable the understanding of the fragmentation processes on a multiscale level of aged polymers.

Gimenez-Lirola, L. G., et al. (2014). "Development and validation of a 4-plex antibody assay for simultaneous detection of IgG antibodies against Torque teno sus virus 1 (TTSuV1), TTSuV2, and porcine reproductive and respiratory syndrome virus types 1 and 2." Research in Veterinary Science **96**(3): 543-550.

A fluorescent microbead-based immunoassay (FMIA) for simultaneous detection of IgG antibodies against Torque teno sus virus 1 (TTSuV1), TTSuV2, porcine reproductive and respiratory syndrome virus type 1 (PRRSV-1) and PRRSV-2 was developed. Serum samples were obtained over time from 20 pigs. Twelve of 20 were exposed to TTSuV2 on day 0, 20/20 were vaccinated with a PRRSV-2 vaccine on day 35, and 20/20 were exposed to PRRSV-2 on day 63. Anti-TTSuV antibodies were detected in 30% of the pigs on day 0, and 90% by day 35. All PRRSV-2 vaccinated pigs had detectable anti-PRRSV-2 IgG 21 days after vaccination. Field samples from 17 farms were also tested. The seroprevalence of both PRRSV and TTSuV increased with age. Comparison of the PRRSV-2 FMIA to an ELISA revealed good correlation in young pigs but a high rate of false positives in older pigs. Cross-reaction between PRRSV types was a problem. © 2014.

Gimenez-Lirola, L. G., et al. (2014). "Simultaneous detection of antibodies against Apx toxins ApxI, ApxII, ApxIII, and ApxIV in pigs with known and unknown actinobacillus pleuropneumoniae exposure using a multiplexing liquid array platform." Clinical and Vaccine Immunology **21**(1): 85-95.

Surveillance for the presence of Actinobacillus pleuropneumoniae infection in a population plays a central role in controlling the disease. In this study, a 4-plex fluorescent microbead-based immunoassay (FMIA), developed for the simultaneous detection of IgG antibodies to repeat-in-toxin (RTX) toxins (ApxI, ApxII, ApxIII, and ApxIV) of A. pleuropneumoniae, was evaluated using (i) blood serum samples from pigs experimentally infected with each of the 15 known A. pleuropneumoniae serovars or with Actinobacillus suis, (ii) blood serum samples from pigs vaccinated with a bacterin containing A. pleuropneumoniae serovar 1, 3, 5, or 7, and (iii) blood serum samples from pigs with an unknown A. pleuropneumoniae exposure status. The results were compared to those obtained in a previous study where a dual-plate complement fixation test (CFT) and three commercially available enzyme-linked immunosorbent assays (ELISAs) were conducted on the same sample set. On samples from experimentally infected pigs, the 4-plex Apx FMIA detected specific seroconversion to Apx toxins as early as 7 days postinfection in a total of 29 pigs inoculated with 14 of the 15 A. pleuropneumoniae serovars. Seroconversion to ApxII and ApxIII was detected by FMIA in pigs inoculated with A. suis. The vaccinated pigs showed poor humoral responses against ApxI, ApxII, ApxIII, and ApxIV. In the field samples, the humoral response to ApxIV and the A. pleuropneumoniae seroprevalence increased with age. This novel FMIA (with a sensitivity of 82.7% and a specificity of 100% for the anti-ApxIV antibody) was found to be more sensitive and accurate than current tests (sensitivities, 9.5 to 56%; specificity, 100%) and is potentially an improved tool for the surveillance of disease and for monitoring vaccination compliance. Gimenez-Lirola, L. G., et al. (2016). "Detection of African swine fever virus antibodies in serum and oral fluid specimens using a recombinant protein 30 (p30) dual matrix indirect ELISA." PLoS ONE **11**(9).

In the absence of effective vaccine(s), control of African swine fever caused by African swine fever virus (ASFV) must be based on early, efficient, cost-effective detection and strict control and elimination strategies. For this purpose, we developed an indirect ELISA capable of detecting ASFV antibodies in either serum or oral fluid specimens. The recombinant protein used in the ELISA was selected by comparing the early serum antibody response of ASFV-infected pigs (NHV-p68 isolate) to three major recombinant polypeptides (p30, p54, p72) using a multiplex fluorescent microbead-based immunoassay (FMIA). Non-hazardous (non-infectious) antibody-positive serum for use as plate positive controls and for the calculation of sample-to-positive (S:P) ratios was produced by inoculating pigs with a replicon particle (RP) vaccine expressing the ASFV p30 gene. The optimized ELISA detected anti-p30 antibodies in serum and/or oral fluid samples from pigs inoculated with ASFV under experimental conditions beginning 8 to 12 days post inoculation. Tests on serum (n=200) and oral fluid (n=200) field samples from an ASFV-free population demonstrated that the assay was highly diagnostically specific. The convenience and diagnostic utility of oral fluid sampling combined with the flexibility to test either serum or oral fluid on the same platform suggests that this assay will be highly useful under the conditions for which OIE recommends ASFV antibody surveillance, i.e., in ASFV-endemic areas and for the detection of infections with ASFV isolates of low virulence.

Gimenez-Lirola, L. G., et al. (2012). "Development of a novel fluorescent microbead-based immunoassay and comparison with three enzyme-linked immunoassays for detection of anti-Erysipelothrix spp. IgG antibodies in pigs with known and unknown exposure." Journal of Microbiological Methods **91**(1): 73-79.

A novel fluorescent microbead immunoassay (FMIA) using the recombinant polypeptide SpaA415 was developed for detection of anti- Erysipelothrix spp. IgG in pig sera. The diagnostic performance of the FMIA was evaluated on samples from pigs with known and unknown Erysipelothrix spp. exposure and compared to an in-house enzyme-linked immunosorbent assay (ELISA-1) based on the same capture antigen, and two commercially available ELISAs (ELISA-2 and ELISA-3). Sera from pigs experimentally infected with Erysipelothrix rhusiopathiae serotype 1a (n = 60) or 19 (n = 12), sera from pigs vaccinated with a commercial attenuated-live vaccine based on serotype 1a (n = 12) or a commercial bacterin based on serotype 2 (n = 12), and 90 field samples were utilized. The sensitivity on 22 true positive samples collected in the later stages of infection/post-vaccination was 100% for the FMIA and ELISA-1, 63.6% for ELISA-2 and 81.8% for ELISA-3. The earliest antibody response was detected 7. days post inoculation with the FMIA (77.8%) and ELISA-1 (11.1%), and at 14. days post-vaccination (dpv) with FMIA (50%) and ELISA-1 (50%). On field samples, a higher seroprevalence was found in pigs older than 21. days with all four assays. Kappa analysis indicated that the FMIA and ELISA-1 had almost complete agreement whereas the agreement was slight with ELISA-2 and fair with ELISA-3. The sensitivity of both immunoassays based on the rSpaA415 antigen was higher compared to that of the two commercial ELISAs. The rSpaA415 FMIA has great potential as an inexpensive ELISA alternative for detection of antibodies against E. rhusiopathiae in the future. © 2012 Elsevier B.V.

Gimenez-Lirola, L. G., et al. (2013). "Improving ante mortem diagnosis of Erysipelothrix rhusiopathiae infection by use of oral fluids for bacterial, nucleic acid, and antibody detection." Journal of Microbiological Methods **92**(2): 113-121.

Swine erysipelas is an economically important disease caused by Erysipelothrix rhusiopathiae. Pen-based collection of oral fluids has recently been utilized for monitoring infection dynamics in swine operations. The diagnostic performance of bacterial isolation, real-time PCR, and antibody detection by enzyme-linked immunosorbent assay (ELISA) and fluorescent microbead-based immunoassay (FMIA) methods were evaluated on pen-based oral fluid samples from pigs experimentally infected with E. rhusiopathiae (n=112) and from negative controls (n=32). While real-time PCR was a sensitive method with an overall detection rate of 100% (7/7 pens) one day post inoculation (dpi), E. rhusiopathiae was successfully isolated in only 28.6% (2/7 pens). Anti-Erysipelothrix IgM and IgG antibodies in pen-based oral fluids were detected at 4 to 5 dpi by FMIA and at 5 and 8 dpi by ELISA. The number of infected animals per pen, and in particular the timing of antimicrobial treatment administration impacted bacterial isolation and ELISA results. In oral fluid field samples, E. rhusiopathiae DNA was found in 23.3% of the samples while anti-E. rhusiopathiae IgG and IgM antibodies were found in 59.6% and 5.5% of the samples, respectively. The results suggest that an algorithm integrating oral fluids as specimen and real-time PCR and FMIA as detection methods is effective for earlier detection of an erysipelas outbreak thereby allowing for a more effective treatment outcome. © 2012 Elsevier B.V.

Gimenez-Lirola, L. G., et al. (2017). "Reactivity of porcine epidemic diarrhea virus structural proteins to antibodies against porcine enteric coronaviruses: diagnostic implications." Journal of Clinical Microbiology **55**(5): 1426-1436.

The development of porcine epidemic diarrhea virus (PEDV) antibody-based assays is important for detecting infected animals, confirming previous virus exposure, and monitoring sow herd immunity. However, the potential cross-reactivity among porcine coronaviruses is a major concern for the development of pathogen-specific assays. In this study, we used serum samples (n=792) from pigs of precisely known infection status and a multiplex fluorescent microbead-based immunoassay and/or enzyme-linked immunoassay platform to characterize the antibody response to PEDV whole-virus (WV) particles and recombinant polypeptides derived from the four PEDV structural proteins, i.e., spike (S), nucleocapsid (N), membrane (M), and envelope (E). Antibody assay cutoff values were selected to provide 100% diagnostic specificity for each target. The earliest IgG antibody response, mainly directed against S1 polypeptides, was observed at days 7 to 10 postinfection. With the exception of nonreactive protein E, we observed similar antibody ontogenies and patterns of seroconversion for S1, N, M, and WV antigens. Recombinant S1 provided the best diagnostic sensitivity, regardless of the PEDV strain, with no cross-reactivity detected against transmissible gastroenteritis virus (TGEV), porcine respiratory coronavirus (PRCV), or porcine deltacoronavirus (PDCoV) pig antisera. The WV particles showed some cross-reactivity to TGEV Miller and TGEV Purdue antisera, while N protein presented some cross-reactivity to TGEV Miller. The M protein was highly cross-reactive to TGEV and PRCV antisera. Differences in the antibody responses to specific PEDV structural proteins have important implications in the development and performance of antibody assays for the diagnosis of PEDV enteric disease.

Ginaldi, L., et al. (1997). "Altered lymphocyte antigen expressions in HIV infection: a study by quantitative flow cytometry." American Journal of Clinical Pathology **108**(5): 585-592.

To identify surface antigen changes that may contribute to the immune deficiency in infection with the human immunodeficiency virus (HIV), we quantified, by double-staining flow cytometry, the number of antigens of the main peripheral blood lymphocyte subsets from 30 HIV-positive persons and compared them with those of 19 HIV-negative healthy donors. Standard microbeads with different capacities to bind mouse immunoglobulins were used to convert the mean fluorescence intensity values into numbers of antigen molecules per cell, measured as antibody binding capacity. The level of expression of different lymphocyte antigens in HIV-infected patients differs from that seen in normal blood lymphocytes. Some of these

surface markers are decreased, whereas others are increased, and their expression is modulated depending on the specific cell subset considered. The expression of CD3, CD4, and CD8 on T lymphocytes is significantly decreased; moreover, CD3 is down-regulated on activated and nonactivated T lymphocytes and on CD4 and CD8 cells. In contrast, the expression of CD2 on T cells is significantly increased. Natural killer cells exhibit down-regulation of CD7, normal levels of CD8 and CD56, and overexpression of CD2. Our results also identified, for most of these antigens, quantitative differences in membrane expression according to different disease stages, as assessed by the CD4 T-cell count. Quantitative flow cytometry therefore may provide useful insights into the lymphocyte functional defects characterizing HIV infection.

Ginaldi, L., et al. (1998). "Levels of expression of CD19 and CD20 in chronic B cell leukaemias." Journal of Clinical Pathology **51**(5): 364-369.

Aims - To investigate whether the antigen levels of the B cell lineage markers CD19 and CD20 can distinguish between normal and neoplastic B cells or characterise distinct expression patterns among the chronic B cell leukaemias. Methods - Peripheral blood cells from 70 patients with B cell disorders and 17 healthy donors were analysed by quantative flow cytometry. Direct immunofluorescence staining was performed with phycoerythrin cojugated CD19 and CD20 monoclonal antibodies. Standard microbeads with different capacities to bind mouse immunoglobulins were used to convert the mean fluorescence intensity (MFI) values into number of antigen molecules/cell, expressed as antibody binding capacity (ABC). Results - CD19 and CD20 ABC values in leukaemic B cells differed from those of normal blood B lymphocytes. The results identified distinct profiles of CD19 and CD20 expression in the various types of B cell leukaemias. In all leukaemias studied except hairy cell leukaemia (HCL), CD19 expression was significantly lower than the mean (SD) value in normal B cells (22 (7) x 10³ molecules/cell), as follows: chronic lymphocytic leukaemia (CLL), 13 (7) x10³; B prolymphocytic leukaemia (B-PLL), 16 (9) x10³; splenic lymphoma with villous lymphocytes (SLVL), 15 (11) x 10³; mantle cell lymphoma (MCL), 10 (7) x 10³. In HCL there was strong CD19 expression (38 (16) x 10³). In contrast, the level of expression of membrane CD20 was higher than the mean (SD) value in normal B cells (94 (16) x 10³ molecules/cell) in MCL (123 (51) x 10³); B-PLL (129 (47) x 10³); SLVL (167 (72) x 10³); and HCL (312 (110) x 10³); while it was significantly lower (65 (11) x 10³) in CLL compared wtih normal B cells and the other B cell leukaemias. Conclusions - Quantitative determination of CD19 and CD20 may provide useful diagnostic information for the study of B lymphoproliferative disorders.

Ginaldi, L., et al. (1996). "Differential expression of T cell antigens in normal peripheral blood lymphocytes: a quantitative analysis by flow cytometry." Journal of Clinical Pathology **49**(7): 539-544.

AIMS: To obtain reference values of the level of expression of T cell antigens on normal lymphocyte subsets in order to disclose differences which could reflect their function or maturation stages, or both.

METHODS: Peripheral blood from 15 healthy donors was processed by flow cytometry with triple colour analysis. For each sample phycoerythrin (PE) conjugated CD2, CD4, CD5, CD8, and CD56 monoclonal antibodies were combined with Cy5-R-phycoerythrin (TC) conjugated CD3 and fluorescein isothiocyanate (FITC) conjugated CD7; CD2- and CD7-PE were also combined with CD3-TC and CD4-FITC. Standard microbeads with different capacities to bind mouse immunoglobulins were used to convert the mean fluorescence intensity (MFI) values of the lymphocyte subsets identified by multiparametric flow cytometry into the number of antigen molecules per cell, measured as antibody binding capacity (ABC).

RESULTS: CD4+ (helper/inducer) T cells exhibit a higher CD3 antigen expression compared with CD8+ (suppressor/ cytotoxic) T lymphocytes. Within the CD4+ T cells, the CD4+CD7- subset expressed a lower level of CD3 compared with CD4+CD7+ and CD8+CD7+ cells, and higher CD2 and CD5 expression than the main CD3+CD7+ subset. Major differences in antigen expression were also detected between CD3+ T cells and CD3-CD56+ natural killer (NK) cells: NK cells exhibited higher levels of CD7 and CD56 and lower levels of CD2 and CD5 than T cells. Significantly lower CD5 expression was also detected in the small CD5+ B lymphocyte subset compared with T cells.

CONCLUSIONS: Quantitative flow cytometry with triple colour analysis may be used to detect antigen modulations in disease states and to increase the accuracy of diagnosis by comparison with findings in normal counterparts.

Girardet, H. (2019). "Regenerative Economics for a sustainable world." Resurgence & Ecologist(313): 20-24.

The article discusses the regenerative practices towards sustainable development amid challenges facing in an ever-increasing understanding of the planetary crisis. The reliance of a global systemic externality of an urban-industrial civilisation on vast annual inputs of fossil fuel energy is tackled. Also explored are the underreported systemic crisis, pollution of the oceans with plastic detritus and significant value of ecosystems services.

Gladstone, D. E., et al. (2011). "Desensitization for mismatched Hematopoietic Stem Cell Transplantation (HSCT)." Blood. Conference: 53rd Annual Meeting of the American Society of Hematology, ASH **118**(21).

Introduction: Sensitization to donor HLA antigens is associated with an increased risk of engraftment failure in HLA mismatched hematopoietic stem cell transplantation (HSCT). However, the use of partially mismatched donors is increasing since, at best, only 30% of patients have an HLA identical sibling donor available for transplantation, and many are unable to find a matched unrelated donor in a timely fashion. A non-myeloablative, T cell replete regimen for HSCT that utilizes post-transplant high dose, cyclophosphamide for graft-versus-host-disease (GVHD) prophylaxis was pioneered at Johns Hopkins and has permitted transplantation of over 200 patients with HLA-haploidentical related donors. The use of HLA haplo-identical donors greatly increases the numbers of potential donors for most HSCT candidates. Review of the evaluations of 148 consecutive candidates for haplotransplantation revealed that 95% had at least one haplo-identical donor with an average of 2.7 donors/patient. However donor specific HLA antibody (DSHA) was observed in 10.8% of patients. We report here, successful desensitization of (DHSA) to levels safe for HSCT in six broadly sensitized patients who had poor-risk hematologic malignancies and for whom there were no other donors for whom HLA specific antibodies were not an issue. Method(s): The desensitization protocol was modified from that developed for renal transplant patients at the Johns Hopkins University Comprehensive Transplant Center and included alternate day, single volume plasmapheresis (PP) with low dose, 100mg/kg, anti-CMV hyper immune immunoglobulin (IVIg) under immunosuppression with tacrolimus and mycophenolate mofetil. Varying numbers of PP/IVIg treatments were scheduled prior to the non-myeloablative conditioning regimen according to each patient's DHSA level. PP/IVIg was stopped during conditioning. All but one patient received one additional PP/IVIg at transplant day -1. HLA antibodies were assessed by solid phase immunoassays using panels of pooled HLA antigens, HLA phenotypes, and single HLA antigens in microbead suspension array immunoassays (GenProbe Lifecodes Inc., San Diego, CA; One Lambda, Inc., Canoga Park, CA) Result(s) and Conclusion(s): All six patients prior to desensitization had DHSA at levels sufficient to yield positive flow cytometric crossmatch (FCXM)

tests defined as 12K molecules of equivalent soluble fluorochromes (MESFs). The donor specific antibodies were reduced to levels well below a positive FXCM in all six patients by the end of the PP/IVIG treatments and before transplantation through an average of 4.2 PP/IVIg treatments. The average reduction in the donor specific antibody strength was 71.5% (range: 52-91%). In three patients, the DHSA levels were reduced to negative by time of transplant. A fourth patient was transplanted with a DHSA level just below that consistent with a positive FCXM, but by three months post-transplant had completely eliminated the DHSA. Two patients received one additional post-transplant PP/IVIg, resulting in stable DSA levels well below a +FCXM. Sufficient post-transplant follow-up of more than four months was available for four patients of which 3 received grafts from haploidentical donors and 1 from an HLA-mismatched unrelated donor. All four of these fully engrafted with no acute GVHD episodes. These results demonstrate that desensitization can extend the opportunity for HSCT to sensitized patients with no other donor options. [Table Presented].

Glander, H. J., et al. (2002). "Deterioration of spermatozoal plasma membrane is associated with an increase of sperm lyso-phosphatidylcholines." Andrologia **34**(6): 360-366.

Spermatozoa with plasma membranes that lost their asymmetry or permeability for larger molecules can be identified by binding of annexin V to membrane phosphatidylserine (PS). Paramagnetic annexin-V-conjugated microbeads (AN-MB) can be used to eliminate these spermatozoa by magnetic activated cell sorting (MACS). Semen samples of six healthy volunteers with normal spermiogram parameters were divided into two sperm fractions by MACS as a function of bound AN-MB, and their individual lipid compositions were examined by matrix-assisted laser desorption and ionisation time-of-flight mass spectrometry (MALDI-TOF MS). As a model system, liposomes composed of phosphatidylcholines (PC) from egg yolk were digested by phospholipase A2 (PLA2). The MALDI-TOF mass spectra of organic extracts of both sperm subpopulations differed significantly. The ratio between lyso-phosphatidylcholine LPC 16 : 0 and PC 16 : 0/22 : 6 was approximately 2.5-4.7-fold higher (median 2.9) in the sperm group binding AN-MB than in spermatozoa with intact membrane unable to bind AN-MB. The ratio between LPC 22 : 6 and PC 16 : 0/22 : 6 was also enhanced in the spermatozoa with impaired membrane structure (factor in the range: 1.9-3.9; median 2.6). These alterations corresponded to the effects of PLA2 on artificial phospholipids. It is concluded that spermatozoa with deteriorated membrane and exposed PS are characterized by an increased lyso-phosphatidylcholine content that is likely generated by phospholipases.

Glaser, J. (2015). "Microplastics in the environment." Clean Technologies & Environmental Policy **17**(6): 1383-1391.

This section offers news briefs concerning clean technology and environmental policy, as of August 2015. Topics discussed include the celebration of the 150-year anniversary of German chemical company BASF, the release of the anticipated 180-page encyclica "Laudato Si" of Pope Francis which is focused on environmental concerns, and the release of the analytical report entitled "Energy and Climate Change by the International Energy Agency.

Glenn, J. (1990). "Progress in Plastics Recycling." BioCycle **31**(12): 50.

Pressure from municipal recycling programs has encouraged the plastics industry to address technologic and infrastructure problems in ensuring the recyclability of their products. Plastic waste from the consumer stream, as well as that from industrial streams such as the transportation and construction industries, has been earmarked for recycling in these programs.

Glynn, M. T., et al. (2014). "Rapid, low-cost and instrument-free CD4+ cell counting for HIV diagnostics in resource-poor settings." Lab on a Chip **14**(15): 2844-2851.

We present a novel, user-friendly and widely autonomous point-of-care diagnostic to enable HIV monitoring in resource-poor regions where the current pandemic is most prevalent. To specifically isolate magnetically tagged CD4+ cells directly from patient blood, the low-cost and disposable microfluidic chip operates by dual-force CD4+ cell magnetophoresis; whereby the interplay of flow and magnetic fields governs the trajectory of target cells depending on whether the cell binds to a magnetic microbead. Instrument-free pumping is implemented by a finger-actuated elastic membrane; tagged beads are laterally deflected by a small and re-useable permanent magnet. The single-depth and monolithic microfluidic structure can easily be fabricated in a single casting step. After their magnetophoretic isolation from whole blood, estimation of CD4+ cell concentrations is then measured by bright-field inspection of the capture chamber. In addition, an optional fluorescence measurement can be used for confirmation of the bright-field result if required. On-chip CD4+ estimation produces a linear response over the full range of medically relevant CD4+ cell concentrations. Our technology combines high-efficiency capture (93.0 plus or minus 3.3%) and cell enumeration.

Gnanaprakash, K., et al. (2011). "A review on floating drug delivery system of H<inf>2</inf> receptors." Research Journal of Pharmacy and Technology **4**(4): 502-509.

Peptic ulcer is the disorder of the upper gastro intestinal tract; hyperacidity is one of the main causes of peptic ulcer. Worldwide accepted clinical therapy of acid disease is based on H2 receptor antagonists. The four H<inf>2</inf> receptor antagonists currently available on market are cimetidine, ranitidine, famotidine, and nizatidine. Of the various technologies for gastro retentive dosage forms, the floating drug delivery system (FDDS). It's widely investigated since they are most promising dosage form to achieve reproducibility in a wide spectrum of biological conditions. This article presents, Factors affecting the gastric emptying and, hence, the gastric retention time of oral dosage forms, advantages and disadvantages of floating drug delivery system, potential drug candidates for gastroretentive drug delivery systems, drugs those are unsuitable for gastroretentive drug delivery systems, mechanism of floating systems, classification of anti ulcer drugs, H<inf>2</inf> receptor antagonists pharmacology, approaches of floating drug delivery system based on the mechanism of buoyancy, gastroretentive products available in the market, evaluation parameters. © RJPT All right reserved.

Gniadek, M. and A. Dabrowska (2019). "The marine nano- and microplastics characterisation by SEM-EDX: The potential of the method in comparison with various physical and chemical approaches." Marine Pollution Bulletin **148**: 210-216.

The marine microplastic (MMs) is an interdisciplinary problem. The polymer debris are ubiquitous (soil, hydrosphere, atmosphere) and the majority ends, transported by the freshwaters, in the global ocean system: from pelagial waters, surface gyres and benthos up to the animals at different trophic levels. Their quantitative, qualitative and eco-toxicological analyses, based on analytical, physical and chemical methods, are still a challenge due to the complex matrices, materials weathering, limited concentration, and size. Moreover, further fragmentation due to the waves and UV radiation leads to the constant increase of their surface. The aim of this article is to present the advantages, drawbacks and future perspectives of using SEM-EDX method in the analyses of marine polymer debris from macro to the nanoscale. Theoretical issues are presented in comparison to the commonly used approaches. The practical aspects will be discussed based on case studies. Examples of the results, high-resolution SEM pictures are included.

Gocenoglu Sarikaya, A., et al. (2016). "Adsorption of cinnabarinic acid from culture fluid with magnetic microbeads." Biomedical Chromatography **30**(2): 88-96.

In this study, antimicrobial pigment cinnabarinic acid (CA) was produced from Pycnoporus cinnabarinus in laboratory-scale batch cultures. Magnetic poly(ethylene glycol dimethacrylate-N-methacryloyl-l-tryptophan methyl ester) [m-poly(EGDMA-MATrp)] beads (average diameter = 53-103 micro m) were synthesized by copolymerizing of N-methacryloyl-l-tryptophan methyl ester (MATrp) with ethylene glycol dimethacrylate (EGDMA) in the presence of magnetite (Fe3O4) and used for the adsorption of CA. The m-poly(EGDMA-MATrp) beads were characterized by N2 adsorption/desorption isotherms (Brunauer Emmet Teller), X-ray photoelecron spectroscopy, scanning electron microscopy, infrared spectroscopy, thermal gravimetric analysis, electron spin resonance and swelling studies. The efficiency of m-poly(EGDMA-MATrp) beads for separation of CA from culture fluid was evaluated. The effects of pH, initial concentration, contact time and temperature on adsorption were analyzed. The maximum CA adsorption capacity of the m-poly(EGDMA-MATrp) beads was 272.9 mg g(-1) at pH 7.0, 25 degreeC. All the isotherm data can be fitted with the Langmuir, Freundlich and Dubinin-Radushkevich isotherm models. The adsorption process obeyed pseudo-second-order kinetic model. Thermodynamic parameters DELTAH = 5.056 kJ mol(-1), DELTAS = 52.44 J K(-1) mol(-1) and DELTAG = -9.424 kJ mol-(1) to -11.27 kJ mol-(1) with the rise in temperature from 4 to 40 degreeC indicated that the adsorption process was endothermic and spontaneous.

Gock, A., et al. (2018). "Legal Strategies to Cure the Plastic Planet: Corporate Marriage and Public Health Regulation of Single-Use Non-Biodegradeable Plastics." Journal of Law & Medicine **26**(2): 311-321.

The 2018 export ban of recyclables to China provides an additional important reason for Australia in particular to act internationally and domestically to reduce its plastic waste. The problems Australia faces from single-use non-biodegradable plastics are replicated in every nation on Earth. Focusing on the Australian context, this article examines regulatory approaches to the problem of plastic production, consumption and disposal and its negative impact on public and ecosystem health. It scrutinises the current legal framework for managing plastic waste at Commonwealth, State and international levels, advocating greater regulation. Its regulatory recommendations include a Pigouvian tax in the form of an excise on plastic production to alter consumer behaviour and raise revenue for further investment in reusable alternatives. They also involve mandatory corporate responsibility obligations, a concept we term "corporate marriage". Other alternative and additional measures to combat single-use plastic waste as utilised in other jurisdictions are proposed for Australian implementation.

Goddijn-Murphy, L. and B. Williamson (2019). "On Thermal Infrared Remote Sensing of Plastic Pollution in Natural Waters." Remote Sensing **11**(18).

Plastic pollution in the world's natural waters is of growing concern and currently receiving significant attention. However, remote sensing of marine plastic litter is still in the developmental stage. Most progress has been made in spectral remote sensing using visible to short-wave infrared wavelengths where optical physics applies. Thermal infrared (TIR) sensing could potentially monitor plastic water pollution but has not been studied in detail. We applied radiative transfer theory to predict TIR sensitivity to changes in the surface fraction of water covered by plastic litter and found that the temperature difference between the water surface and the surroundings controls the TIR signal. Hence, we mapped this difference for various months and times of the day using global SST (sea surface temperature) and t2m (temperature

at 2 m height) hourly estimates from the European Centre for Medium-Range Weather Forecasts (ECMWF), ERA5. The maps show how SST-t2m difference varied, altering the anticipated effectivity of TIR floating plastic litter remote sensing. We selected several locations of interest to predict the effectivity of TIR sensing of the plastic surface fraction. TIR remote sensing has promising potential and is expected to be more effective in areas with a high air–sea temperature difference.

Godoy, V., et al. (2019). "The potential of microplastics as carriers of metals." Environmental Pollution **255**(Pt 3): 113363.

Microplastics can adsorb chemical pollutants such as metals or pharmaceuticals, and transferred them along the food chain. In this work, an investigation of the adsorption of Cd, Co, Cr, Cu, Ni, Pb and Zn by five different types of microplastics was performed in Milli-Q water and natural waters (seawater, urban wastewater and irrigation water) via a series of batch adsorption experiments. The effects of concentration of metals and physicochemical characteristics of polymers were particularly studied.

Godoy, V., et al. (2019). "Physical-chemical characterization of microplastics present in some exfoliating products from Spain." Marine Pollution Bulletin **139**: 91-99.

Plastic pollution in oceans is a global problem, with growing research efforts focusing on the threat of microplastics (<5mm fractions). A source of microplastics pollution is derived from personal care products that contain polyethylene micro-spheres which are not captured by wastewater plants. In this work, ten personal care products (mainly scrubs) containing microplastics and marketed in Spain, were physico-chemically characterized. The obtained results proved that those microplastics had different particle size and are presented in high percentages in some cases, between 6 and 7% of the total product. Products with smaller particles usually showed higher concentrations than products with larger particles. Although all the microplastics were shown to be polyethylene, some impurities were observed that demonstrated the presence of silicates and oxides in the microplastics. Regards to morphology, the shape of the particles was irregular in general, although some completely spherical particles can be observed.

Gokcinar-Yagci, B., et al. (2016). "Isolation, characterisation and comparative analysis of human umbilical cord vein perivascular cells and cord blood mesenchymal stem cells." Cell & Tissue Banking **17**(2): 345-352.

Perivascular cells are known to be ancestors of mesenchymal stem cells (MSCs) and can be obtained from heart, skin, bone marrow, eye, placenta and umbilical cord (UC). However detailed characterization of perivascular cells around the human UC vein and comparative analysis of them with MSCs haven't been done yet. In this study, our aim is to isolate perivascular cells from human UC vein and characterize them versus UC blood MSCs (UCB-MSCs). For this purpose, perivascular cells around the UC vein were isolated enzymatically and then purified with magnetic activated cell sorting (MACS) method using CD146 Microbead Kit respectively. MSCs were isolated from UCB by Ficoll density gradient solution. Perivascular cells and UCB-MSCs were characterized by osteogenic and adipogenic differentiation procedures, flow cytometric analysis [CD146, CD105, CD31, CD34, CD45 and alpha-smooth muscle actin (alpha-SMA)], and immunofluorescent staining (MAP1B and Tenascin C). Alizarin red and Oil red O staining results showed that perivascular cells and MSCs had osteogenic and adipogenic differentiation capacity. However, osteogenic differentiation capacity of perivascular cells were found to be less than UCB-MSCs. According to flow cytometric analysis, CD146

expression of perivascular cells were appeared to be 4.8-fold higher than UCB-MSCs. Expression of alpha-SMA, MAP1B and Tenascin-C from perivascular cells was determined by flow cytometry analysis and immunfluorescent staining. The results appear to support the fact that perivascular cells are the ancestors of MSCs in vascular area. They may be used as alternative cells to MSCs in the field of vascular tissue engineering.

Gokhale, P. C., et al. (2015). "Modeling patient-derived lung cancer in mice: Preclinical tool for drug development." Cancer Research. Conference: 106th Annual Meeting of the American Association for Cancer Research, AACR **75**(15 SUPPL. 1).

Background: Genotype directed treatment is the standard of care for patients with advanced non-small cell lung cancer (NSCLC). However, acquired drug resistance invariably develops. There is a need to develop clinically relevant animal models from patients who have developed acquired resistance in order to study mechanisms of resistance and validate new therapeutic strategies. We have generated a portfolio of clinically relevant, early passage, patient-derived xenograft (PDX) models of lung cancer. Method(s): Tumor biopsies (core biopsies (n = 8), pleural effusions (n = 28) and surgical samples (n = 11)) were implanted subcutaneously (n = 39) or into the sub-renal capsule (n = 8) of NSG mice under an IRB approved protocol. After implanting 35 specimens, mostly from pleural effusions, several mice exhibited weight and fur loss. Histopathology revealed infiltration of the liver, skin and lungs by human derived T-cells consistent with graft-versus-host disease (GVHD). Subsequent pleural effusions were then subjected to CD45 depletion using a human CD45 microbead separation kit which eliminated the incidence of GVHD. Tumors from all three sources were allowed to grow and subsequently passaged only as subcutaneous implants in NSG mice. Molecular characterization of PDX models was performed using targeted next generation sequencing and tumor histology confirmed by H&E staining. Some established tumor models have also been propagated as cell lines in vitro. Result(s): 47 specimens were implanted with an overall take rate of ~30%. The initial take rate was 22% but increased to 66% following CD45 depletion. We have established 11 NSCLC adenocarcinoma and 3 small-cell lung cancer (SCLC) PDX models from patient samples. The models established thus far range from erlotinib resistant EGFR mutant models with T790M mutation (n = 3), MET amplification (n = 1), SCLC transformation (n = 2) or an unknown mechanism (n = 1); to models including SCLC with an NRAS Q61K mutation (n = 1); EML4-ALK resistant to crizotinib and ceritinib (n = 1); KRAS G12C mutation (n = 1); NUT-mid line carcinoma with BRD4 rearrangement (n = 1); pan wild-type (n = 2) and a PIK3CA mutation (n = 1). We have used these models to study therapeutic interventions. Treatment of the NRAS Q61K mutant SCLC with trametinib resulted in complete tumor regression. Pharmacodynamic analyses revealed inhibition of pERK 1/2 and induction of apoptosis. Data will be presented with further characterization and platform development of the lung PDX models. Notably, >50% of the models do show pulmonary metastases from the subcutaneous implant site. Conclusion(s): PDXs can be established from lung cancer patients undergoing routine clinical biopsies. Establishment of models from pleural effusions is also feasible following CD45 depletion to prevent GVHD. These models will provide unique information on mechanisms of drug resistance and can be used to evaluate pre-clinical therapeutic strategies.

Goldberger, J. R. (2018). "2018 AFHVS presidential address." Agriculture and Human Values **35**(4): 899-904.

In this address I discuss agricultural plastic use and plastic pollution mitigation strategies. I focus on agricultural plastic mulches, which offer many benefits to farmers, such as weed control, better moisture retention, and increased yield. The removal and disposal of widely used

polyethylene (PE) plastic mulch, however, have detrimental environmental and health impacts. Are biodegradable plastic mulches a promising alternative? Biodegradable plastic mulches ideally offer the same benefits as PE plastic mulch, but biodegrade in soil or composting environments. I describe social science research findings from a large USDA-funded project focused on the performance and adoptability of biodegradable plastic mulches for U.S. specialty crop production. I also provide agrifood scholars with ideas for future research on plastics.

Goldraich, M. and J. Kost (1993). "Glucose-sensitive polymeric matrices for controlled drug delivery." Clinical Materials **13**(1-4): 135-142.

Hydrogel matrices were prepared by chemical polymerization of solutions containing 2-hydroxyethyl methacrylate, N,N-dimethyl-aminoethyl methacrylate, tetraethylene glycol dimethacrylate, ethylene glycol and water solutions containing glucose oxidase, bacitracin or insulin. The hydrogels displayed faster and higher swelling and release rates at lower pH or at higher glucose concentrations. Swelling and release kinetics were also responsive to step changes in glucose concentration in the physiological range. The kinetics of the soluble and immobilized enzyme followed Michaelis Menten's kinetics. In the soluble state the enzyme was more active than the immobilized one due to mass transfer limitations, which may be overcome by preparation of microbead configuration.

Goldstein, M. C. (2012). Abundance and ecological implications of microplastic debris in the North Pacific Subtropical Gyre.

Plastic pollution in the North Pacific Subtropical Gyre (NPSG), dubbed the "Great Pacific Garbage Patch," has been the subject of substantial public concern. However, there is relatively limited scientific understanding of how microplastic affects pelagic ecosystems. The motivation for this dissertation is to provide scientific information on the extent and impact of microplastic in the NPSG. The dissertation is organized around two central questions: 1) What are the abundance, distribution, and characteristics of plastic microdebris in the NPSG? 2) What is the impact of this microplastic on the neustonic zooplankton and plastic-associated rafting communities? I documented widespread, though spatially and temporally variable, plastic pollution in the NPSG and adjacent water masses. The numerical majority of objects are small particles, but the majority of debris surface area is found in large objects. While plastic was highly variable on the submesoscale, an analysis of all available data showed that overall NPSG microplastic concentrations increased by two orders of magnitude between 1972-1988 and 1999-2010. I performed a laboratory weathering experiment on plastic pre-production pellets that suggested that changes in microplastic composition over the eastern North Pacific may be explained by differential rates of weathering between plastic types, and that carbonyl formation may be a proxy for the length of time a plastic object has weathered in the ocean. Microplastic interacted with marine life through its direct ingestion and by providing a hard substrate for oviposition and settlement. Thirty-three percent of lepadid barnacles collected in 2009 contained microplastic in their gastrointestinal tract. In contrast, neustonic zooplankton did not show significant ingestion of plastic microspheres during a series of at-sea incubation experiments. Oviposition in the oceanic insect Halobates sericeus was positively correlated with microplastic abundance. Most plastic-associated macroinvertebrates were known members of the rafting assemblage, but several potentially invasive taxa were also associated with debris. The diversity of taxa in the rafting assemblage increased with debris surface area, as predicted by the concept of island biogeography. This dissertation demonstrated that microplastic pollution is pervasive at the surface of the NPSG, and that ecological impacts include direct ingestion, release from substrate limitation, and enhanced dispersal. The introduction of microplastic to the NPSG may therefore represent a widespread alteration of the pelagic ecosystem.

Goldstein, M. C. and D. S. Goodwin (2013). "Gooseneck barnacles (Lepas spp.) ingest microplastic debris in the North Pacific Subtropical Gyre." PeerJ **1**: e184.

Substantial quantities of small plastic particles, termed "microplastic," have been found in many areas of the world ocean, and have accumulated in particularly high densities on the surface of the subtropical gyres. While plastic debris has been documented on the surface of the North Pacific Subtropical Gyre (NPSG) since the early 1970s, the ecological implications remain poorly understood. Organisms associated with floating objects, termed the "rafting assemblage," are an important component of the NPSG ecosystem. These objects are often dominated by abundant and fast-growing gooseneck barnacles (Lepas spp.), which predate on plankton and larval fishes at the sea surface. To assess the potential effects of microplastic on the rafting community, we examined the gastrointestinal tracts of 385 barnacles collected from the NPSG for evidence of plastic ingestion. We found that 33.5% of the barnacles had plastic particles present in their gastrointestinal tract, ranging from one plastic particle to a maximum of 30 particles. Particle ingestion was positively correlated to capitulum length, and no blockage of the stomach or intestines was observed. The majority of ingested plastic was polyethylene, with polypropylene and polystyrene also present. Our results suggest that barnacle ingestion of microplastic is relatively common, with unknown trophic impacts on the rafting community and the NPSG ecosystem.

Goldstein, M. C., et al. (2012). "Increased oceanic microplastic debris enhances oviposition in an endemic pelagic insect." Biology Letters **8**(5): 817-820.

Plastic pollution in the form of small particles (diameter less than 5 mm)-termed 'microplastic'-has been observed in many parts of the world ocean. They are known to interact with biota on the individual level, e.g. through ingestion, but their population-level impacts are largely unknown. One potential mechanism for microplastic-induced alteration of pelagic ecosystems is through the introduction of hard-substrate habitat to ecosystems where it is naturally rare. Here, we show that microplastic concentrations in the North Pacific Subtropical Gyre (NPSG) have increased by two orders of magnitude in the past four decades, and that this increase has released the pelagic insect Halobates sericeus from substrate limitation for oviposition. High concentrations of microplastic in the NPSG resulted in a positive correlation between H. sericeus and microplastic, and an overall increase in H. sericeus egg densities. Predation on H. sericeus eggs and recent hatchlings may facilitate the transfer of energy between pelagic- and substrate-associated assemblages. The dynamics of hard-substrate-associated organisms may be important to understanding the ecological impacts of oceanic microplastic pollution.

Goldstein, M. C., et al. (2013). "Scales of spatial heterogeneity of plastic marine debris in the northeast pacific ocean." PLoS ONE [Electronic Resource] **8**(11): e80020.

Plastic debris has been documented in many marine ecosystems, including remote coastlines, the water column, the deep sea, and subtropical gyres. The North Pacific Subtropical Gyre (NPSG), colloquially called the "Great Pacific Garbage Patch," has been an area of particular scientific and public concern. However, quantitative assessments of the extent and variability of plastic in the NPSG have been limited. Here, we quantify the distribution, abundance, and size of plastic in a subset of the eastern Pacific (approximately 20-40degreeN, 120-155degreeW) over multiple spatial scales. Samples were collected in Summer 2009 using surface and subsurface plankton net tows and quantitative visual observations, and Fall 2010 using surface net tows only. We documented widespread, though spatially variable, plastic pollution in this portion of the NPSG and adjacent waters. The overall median microplastic numerical concentration in Summer 2009 was 0.448 particles m(-2) and in Fall 2010 was 0.021 particles m(-2), but plastic concentrations were highly variable over the submesoscale (10 s of km). Size-frequency spectra were skewed towards small particles, with the most abundant particles having a cross-sectional area of approximately 0.01 cm(2). Most microplastic was found on the sea surface, with the highest densities detected in low-wind conditions. The numerical majority of objects were small particles collected with nets, but the majority of debris surface area was found in large objects assessed visually. Our ability to detect high-plastic areas varied with methodology, as stations with substantial microplastic did not necessarily also contain large visually observable objects. A power analysis of our data suggests that high variability of surface microplastic will make future changes in abundance difficult to detect without substantial sampling effort. Our findings suggest that assessment and monitoring of oceanic plastic debris must account for high spatial variability, particularly in regards to the evaluation of initiatives designed to reduce marine debris.

Golumbeanu, M., et al. (2017). "Marine litter watch app as a tool for ecological education and awareness raising along the Romanian Black Sea coast." Journal of Environmental Protection and Ecology **18**(1): 348-362.

Apart from their severe impact on the environment, marine and beach litter are causing problems to human activities that use and depend on the sea, while also raising human health concerns. European Member States are developing measures to tackle marine litter with the Marine Strategy Framework Directive (MSFD), but the database is still insufficient. The National Institute for Marine Research and Development 'Grigore Antipa' Constanta (NIMRD) has been actively involved in marine litter related activities, such as the participation in the CLEANSEA and MARLISCO projects, sea surveys for seabed marine litter monitoring, terrestrial surveys along Romanian Black Sea coast sectors for beach marine litter monitoring, laboratory analyses for macro- and micro-plastics, participation in actions to identify the main polluters, developing proposals for measures to reduce litter pollution of the marine environment (MSFD), beach cleaning activities, education and awareness raising campaigns, and introducing the Marine Litter Watch Mobile Application. Marine Litter Watch App was developed by the European Environment Agency and combines citizen engagement and modern technology to help tackle marine litter. Marine Litter Watch offers tools to collect and share comparable data on marine litter on beaches. It also provides a platform for marine litter communities to come together, share their knowledge and co-create approaches to monitoring marine litter. NIMRD is part of the Perseus and School Community and three Romanian beaches were included in the programme: 2 sandy beaches (Ammos - 417 m - and Flora - 181 m, in the Mamaia resort - urban) and 1 mixed beach (Vame Veche - 2 Mai - 2,323 m - rural). Surveys have been implemented both off-season (January, April 2015), as well as during the high tourist season (summer 2015), and the main wastes identified were cigarette butts and plastic containers.

Gomathi, N. and P. L. Rupesh (2016). "Study on the performance of plastic waste oil in CI engines: A review." Research Journal of Pharmaceutical, Biological and Chemical Sciences **7**(6): 1689-1696.

A sustainable energy and environment needed to be created by using alternate energy \instead of fossil fuels, creating a sustainable energy and environment. The consumption and production of plastic has been rising very rapidly due to its strength, durability, lighter weight and flexibility. The disposal of plastic has become a major problem due to its non-biodegradable nature. Pyrolysis is one of the common processes used to treat plastic waste. This paper deals with the study of pyrolysis process to convert plastic waste into crude oil. Comparison of various catalysts used for the pyrolysis process was also studied. The effects of the Plastic waste oil on the performance of diesel engines were also discussed in this study. It was observed that the pyrolysis process is the effective method to treat plastic waste and the obtained oil can be used as alternate fuel for CI engine.

Gómez-Sanabria, A., et al. (2018). "Carbon in global waste and wastewater flows – its potential as energy source under alternative future waste management regimes." Advances in Geosciences **45**: 105-113.

This study provides a quantification of the maximum energy that can be generated from global waste and wastewater sectors in the timeframe to 2050, as well as of the potential limitations introduced by different future waste and wastewater management regimes. Results show that considerable amounts of carbon are currently stored in waste materials without being recovered for recycling or made available for energy generation. Future levels of energy recovery when maintaining current states of waste and wastewater management systems are contrasted with those that can be attained under a circular system identified here as a system with successful implementation of food and plastic waste reduction policies, maximum recycling rates of all different types of waste streams, and once the recycling capacity is exhausted, incineration of remaining materials to produce energy. Moreover, biogas is assumed to be produced from anaerobic co-digestion of food and garden wastes, animal manure, and anaerobically treated wastewater. Finally, we explore the limits for energy generation from waste and wastewater sources should the efficiency of energy recovery be pushed further through development of existing technology. We find that global implementation of such an ideal system could increase the relative contribution of waste and wastewater sources to global energy demand from 2 % to 9 % by 2040, corresponding to a maximum energy potential of 64 EJ per year. This would however require widespread adoption of policies and infrastructure that stimulate and allow for large-scale waste prevention and separation, as well as highly advanced treatment processes. Giving priority to such efforts would enable circularity of the waste-energy system.

Gomgnimbou, M. K., et al. (2013). "Tuberculosis-spoligo-rifampin-isoniazid typing: an all-in-one assay technique for surveillance and control of multidrug-resistant tuberculosis on Luminex devices." Journal of Clinical Microbiology **51**(11): 3527-3534.

As a follow-up of the "spoligoriftyping" development, we present here an extension of this technique which includes the detection of isoniazid resistance-associated mutations in a new 59-plex assay, i.e., tuberculosis-spoligo-rifampin-isoniazid typing (TB-SPRINT), running on microbead-based multiplexed systems. This assay improves the synergy between clinical microbiology and epidemiology by providing (i) mutation-based prediction of drug resistance profiles for patient treatment and (ii) genotyping data for tuberculosis (TB) surveillance. This third-generation microbead-based high-throughput assay for TB runs on the Luminex 200 system and on the recently launched MagPix system (Luminex, Austin, TX). Spoligotyping patterns obtained by the TB-SPRINT method were 100% (n = 85 isolates; 3,655/3,655 spoligotype data points) concordant with those obtained by microbead-based and membrane-based spoligotyping. Genetic drug susceptibility typing provided by the TB-SPRINT method was 100% concordant with resistance locus sequencing (n = 162 for rpoB gene sequencing and n = 76 for katG and inhA sequencing). Considering phenotypic drug susceptibility testing (DST) as the reference method, the sensitivity and specificity of TB-SPRINT regarding Mycobacterium tuberculosis complex (n = 162 isolates) rifampin resistance were both

100%, and those for isoniazid resistance were 90.4% (95% confidence interval, 85 to 95%) and 100%, respectively. Used routinely in national TB reference and specialized laboratories, the TB-SPRINT assay should simultaneously improve personalized medicine and epidemiological surveillance of multidrug-resistant (MDR) TB. This assay is expected to play an emerging role in public health in countries with heavy burdens of MDR TB and/or HIV/TB coinfection. Application of this assay directly to biological samples, as well as development for extensively drug-resistant (XDR) TB detection by inclusion of second-line antituberculosis drug-associated mutations, is under development. With bioinformatical methods and data mining to reduce the number of targets to the most informative ones, locally adapted formats of this technique can easily be developed everywhere.

Gomiero, A. (2014). "The Contribution of OMICS Publishing Group to the Topic of Marine Litter and Micro Plastic Studies." Journal of Marine Science. Research & Development **4**(2): 1.

The environmental problem of marine litter is gaining even more scientific attention as more data are becoming available on its occurrence, abundance and geographical distribution. Due to its versatile chemical structure, plastic is extensively exploited in several industrial, commercial and medical applications. Approximately 50 percent of total production is made up of goods disposed of within one year of purchase and breaking down in the environment at an uncontrollable rate. Macroplastic litter often undergoes to mechanical, chemical and photo-degradation reaching microscopic size and thus harming marine organisms as it can be easily ingested or filter-fed. Given the continual fragmentation of plastic items, particle concentrations are likely to increase with decreasing size. This poses the attention on the emerging toxicological implications of even higher environmental concentrations of even smaller "microplastic" compounds.

Gomiero, A., et al. (2019). "First record of characterization, concentration and distribution of microplastics in coastal sediments of an urban fjord in south west Norway using a thermal degradation method." Chemosphere **227**: 705-714.

Plastic waste is of increasing concern in the aquatic environment. A large proportion of plastic waste is generated onshore from where it eventually reaches the marine environment, which is considered the main sink of plastic debris To date there is a substantial lack of knowledge on the composition of these accumulated polymers, their environmental levels and distribution in marine and coastal areas. Current efforts are underway to develop standardized methods to characterize and quantify the occurrence of microplastic in different environmental matrices using microscopy-oriented methods using Fourier Transformed Infra-Red (FTIR) or Raman techniques. However, time-consuming sample preparation, processing and interpretation of complex data limits their use within monitoring programs. As an alternative, a thermal degradation method based on a gas chromatographic mass spectrometer coupled with pyrolysis represents a validated method for qualitative and quantitative polymer analyses. A technique has been developed that combines sample preparation and thermo-analysis for identifying microplastics in samples of marine sediment. Quantification and polymeric composition of plastic particles found in sediment samples taken from ten sites located in Boknafjorden subjected to diverse sources of pollution and anthropogenic pressure were investigated. Plastic microparticles were extracted from 8kg of wet sediments per site, purified, size-fractionated thorough a set of stainless-steel certified sieves covering the range of 10-250 mum mesh size, pre-concentrated on fiberglass filters and whole filters analyzed by thermal desorption pyrolysis gas chromatography/mass spectrometry. Most of the detected polymers were identified as polypropylene, polyethylene, polyethylene terephthalate, polyvinylchloride, polystyrene or

polyamide. In most of the sites, the largest fraction of the extracted micro debris fell in the size range 10-40mum. Some shifts in size distribution were also observed in some sites and were likely related to the marine sea bottom currents and the influence of specific anthropogenic activities. The adopted thermal degradation method showed good sensitivity, reliability and rapidity and therefore represents a promising technique for microplastic analysis within monitoring activities.

Gomiero, A., et al. (2019). "First occurrence and composition assessment of microplastics in native mussels collected from coastal and offshore areas of the northern and central Adriatic Sea." Environmental Science & Pollution Research **26**(24): 24407-24416.

In recent years, the occurrence of microplastics in the aquatic environment has gathered increasing scientific interest. Several studies have shown that the ingestion of microplastics may negatively influence the physiology of marine organisms having different feeding strategies, particularly in those species which cannot discriminate between food sources. Recent studies highlighted the potential for such particles to accumulate in the food web, posing risks to human health via the consumption of seafood. Furthermore, early findings also indicated the role of microplastics as vectors of chemical pollutants either used as additives during synthesis of the plastics or adsorbed directly from seawater, i.e., PAHs, PCB, and surfactants. Despite the importance of microplastics in adsorption and transport of hydrophobic pollutants, little is known about their distribution and accumulation in marine food webs, or their direct and indirect harmful effects. The Adriatic Sea represents a semi-enclosed basin with a low water recirculation rate and high anthropogenic pressures associated with unsustainable fishing and inputs of contaminants. The body burden, accumulation rates, polymer composition, and recurring morphotypes of microplastics in native blue mussels (M. galloprovincialis) were examined. Organisms collected offshore were compared to those collected in coastal areas. Microplastics were recovered from the soft tissues of all analyzed mussels. Coastal organisms showed a load of 1.06-1.33 fragments g⁻¹ (wet weight) and 0.62-0.63 fibers g⁻¹ (wet weight) while offshore organisms showed an accumulation of 0.65-0.66 fragments g⁻¹ (wet weight) and 0.24-0.35 fibers g⁻¹ (wet weight). The size class distribution revealed a marked prevalence of smaller particles (20 mum to 40 mum range) and the most recurring polymer type in analyzed organisms was PE followed by PP, PET, and equal amounts of PS, PLY, and PVC. A significant site-, time-, and oceanographic-related distribution trend was observed. Based on the findings presented here, there is a clear need to implement a seafood safety monitoring program to better understand actual human health-related risks.

Gonçalves, C., et al. (2018). "Development of a method for the detection of polystyrene microplastics in paraffin-embedded histological sections." Histochemistry & Cell Biology **149**(2): 187-191.

The concerns about the presence of microplastics (MPs) in marine ecosystems have widely increased in the past years. This is reflected in a growing number of studies addressing the effects of exposure to these materials in indigenous, farmed and even laboratory marine animals subjected to toxicity-oriented bioassays. There have been, however, many constraints in the detection of MPs in biological tissues, as routine histological techniques tend to degrade these materials, which are especially sensitive to organic solvents. This issue hinders the application of standard histopathological procedures based on convenient paraffin wax-embedding protocols, with consequences for biomonitoring and bioassay procedures. The method described here was developed and validated for the detection of polystyrene microplastics in biological tissue processed for paraffin-based histology. The strategy was developed and tested from whole-soft body sections of marine mussels that internalised the MPs following dedicated bioassays. The protocol is based on the replacement of xylenes with isopropanol for the purpose of intermediate infiltration and deparaffinization. Special modifications for staining, mounting and archiving are needed and are detailed as well. The protocol is shown to be a highly cost- and time-effective procedure compatible with formalin-based fixatives plus standard sectioning and staining, yielding complete preservation of MPs and optimal tissue conditioning. The method also produced excellent results with pre-stained MPs, with fluorochromes included, altogether providing excellent localisation of polystyrene MPs in paraffin-processed biological tissue.

Goncalves, C., et al. (2019). "An assessment of the ability to ingest and excrete microplastics by filter-feeders: a case study with the Mediterranean mussel." Environmental Pollution **245**: 600-606.

Plastic debris has been recognized as a growing threat to marine biota due to its widespread distribution and possible interactions with marine species. Concerns over the effects of plastic polymers in marine ecosystems is reflected in the high number of toxicological studies, regarding microplastics (<5 mm) and marine fauna. Although several studies reported that organisms ingest and subsequently eliminate microplastics (MP), the potential effects at organ and tissue level remain unclear, especially considering exposure to different microplastic sizes and concentrations. The present study aimed at investigating potential pathophysiological effects of the ingestion of MP by marine filter-feeders. For the purpose, Mediterranean mussel (Mytilus galloprovincialis) was exposed to spherical polystyrene MP (2 and 10 micro m O) over short- and medium-term exposure periods, under single and combined concentrations that represent high, yet realistic doses (10 and 1000 MP mL⁻¹). Overall, results suggest rapid MP' clearance from water column by filtering, regardless of MP size. Ingestion occurred, identified by MP in the lumen of the gut (mostly in midgut region), followed by excretion through faeces. However, no MP were found in gills or digestive gland diverticula. Biochemical indicators for oxidative stress were generally irresponsive regardless of organ and time of exposure. Small foci of haemocytic infiltration in gastric epithelia were found, albeit not clearly related to MP ingestion. Globally, no evident histopathological damage was recorded in whole-body sections of exposed animals. The present findings highlight the adaptative ability of filter-feeding bivalves to cope with filtration of suspended MP, resulting in rapid elimination and reduced internal damage following ingestion of spherical MP. Nevertheless, the fact that the animals are able to translocate MP to the gut reveals that filter feeding organisms may indeed became a target of concern for fragmented materials with smaller, mixed sizes and sharper edges.

Gondal, M. A. and M. N. Siddiqui (2007). "Identification of different kinds of plastics using laser-induced breakdown spectroscopy for waste management." Journal of Environmental Science & Health Part A-Toxic/Hazardous Substances & Environmental Engineering **42**(13): 1989-1997.

Laser-Induced Breakdown Spectroscopy (LIBS) was applied for the identification of various kinds of plastics for management and recycling of plastic waste. In order to fingerprint these plastics, a laser-produced plasma emission was recorded for spectral analysis of various kinds of plastics. The plasma was generated by focusing a Nd:YAG laser radiation at wavelength = 1064 nm having laser energy = 40 mJ. The 6 main family of plastics tested are: Low Density Polyethylene (LDPE), High Density Polyethylene (HDPE), Polypropylenes (PP), Polystyrene (PS), Polyethylene Terephthalate (PET) and Polyvinyl chloride (PVC). The capability of this technique is demonstrated by the analysis of the major constituents carbon and hydrogen present in polymer matrices. The LIBS signal intensity measured for carbon and hydrogen was detrimental

for the fingerprinting of various kinds of plastics. The C/H line intensity ratio was 1.68, 1.51, 1.42, 1.16, 1.01 and 0.91 for HDPE, LDPE, PS, PP, PET and PVC respectively. The detection limits of carbon and hydrogen were found to be approximately 6 micro g/g by applying 20 laser shots. The unique features of LIBS are: it is a simple, rapid, remote, real-time analysis without sampling requirements. The study demonstrated that LIBS could be applied as a best tool for sorting out different kinds plastics on a fast scale for waste management. The health hazards of different kinds of plastics are also described.

Gong, J., et al. (2018). "Biodegradation of Microplastic Derived from Poly(ethylene terephthalate) with Bacterial Whole-Cell Biocatalysts." Polymers **10**(12): 30.

At present, the pollution of microplastic directly threatens ecology, food safety and even human health. Polyethylene terephthalate (PET) is one of the most common of microplastics. In this study, the micro-size PET particles were employed as analog of microplastic. The engineered strain, which can growth with PET as sole carbon source, was used as biocatalyst for biodegradation of PET particles. A combinatorial processing based on whole-cell biocatalysts was constructed for biodegradation of PET. Compared with enzymes, the products can be used by strain growth and do not accumulated in culture solution. Thus, feedback inhibition of products can be avoided. When PET was treated with the alkaline strain under high pH conditions, the product concentration was higher and the size of PET particles decreased dramatically than that of the biocatalyst under neutral conditions. This shows that the method of combined processing of alkali and organisms is more efficient for biodegradation of PET. The novel approach of combinatorial processing of PET based on whole-cell biocatalysis provides an attractive avenue for the biodegradation of micplastics.

Gong, M., et al. (2009). "Centrifugal sedimentation for selectively packing channels with silica microbeads in three-dimensional micro/nanofluidic devices." Analytical Chemistry **81**(5): 2022-2026.

Incorporation of nanofluidic elements into microfluidic channels is one approach for adding filtration and partition functionality to planar microfluidic devices, as well as providing enhanced biomolecular separations. Here we introduce a strategy to pack microfluidic channels with silica nanoparticles and microbeads, thereby indirectly producing functional nanostructures; the method allows selected channels to be packed, here demonstrated so that a separation channel is packed while keeping an injection channel unpacked. A nanocapillary array membrane is integrated between two patterned microfluidic channels that cross each other in vertically separated layers. The membrane serves both as a frit for bead packing and as a fluid communication conduit between microfluidic channels. Centrifugal force-assisted sedimentation is then used to selectively pack the microfluidic channels using an aqueous silica bead suspension loaded into the appropriate inlet reservoirs. This packing approach may be used to simultaneously pack multiple channels with silica microbeads having different sizes and surface properties. The chip design and packing method introduced here are suitable for packing silica particles in sizes ranging from nanometers to micrometers and allow rapid (approximately 10 min) packing with high quality. The liquid/analyte transport characteristics of these packed micro/nanofluidic devices have potential utility in a wide range of applications, including electroosmotic pumping, liquid chromatographic separations, and electrochromatography.

Gong, M., et al. (2019). "Microbial biofilm formation and community structure on low-density polyethylene microparticles in lake water microcosms." Environmental Pollution **252**(Pt A): 94-102.

The occurrence of microplastics (MPs) in the environment has been gaining widespread attention globally. MP-colonizing microorganisms are important links for MPs contamination in

various ecosystems, but have not been well understood. To partially address this issue, the present study investigated biofilm formation by microorganisms originating from lake water on low-density polyethylene (LDPE) MPs using a cultivation approach and the surface-related effects on the MP-associated microbial communities using 16S rRNA high-throughput sequencing. With the addition of nonionic surfactants and UV-irradiation pretreatment that changed the surface properties of LDPE MPs, more microorganisms were colonized on LDPE surface. Microbial community analysis indicated that LDPE MPs were primarily colonized by the phyla Proteobacteria, Bacteroidetes and Firmicutes, and the surface roughness and hydrophobicity of MP were important factors shaping the LDPE MP-associated microbial community structure. Half of the top 20 most abundant genera colonizing on LDPE were found to be potential pathogens, e.g., plant pathogens Agrobacterium, nosocomial pathogens Chryseobacterium and fish pathogens Flavobacterium. This study demonstrated rapid bacterial colonization of LDPE MPs in lake water microcosms, the role of MPs as transfer vectors for harmful microorganisms in lake water, and provided a first glimpse into the effect of surface properties on LDPE MP-associated biofilm communities.

Gong, W., et al. (2019). "Comparative analysis on the sorption kinetics and isotherms of fipronil on nondegradable and biodegradable microplastics." Environmental Pollution **254**(Pt A): 112927.

Biodegradable plastics have been introduced and widely used as a promising alternative to traditional nondegradable plastics. However, the differences in sorption behavior of pesticides on nondegradable and biodegradable microplastics has been insufficiently studied. Here, four types of nondegradable [polyethylene (PE), polystyrene (PS), polyvinyl chloride (PVC), polypropylene (PP)] and two types of biodegradable [polylactic acid (PLA), polybutylene succinate (PBS)] microplastics were selected to investigate the sorption mechanism of fipronil based on their sorption kinetics and isotherms. The results indicated that the sorption rates of PLA and PBS were much higher than those of PE, PP, PVC and PS and that the sorption capacities of fipronil on microplastics followed the order of PBS>PLA>PP>PE>PS>PVC. The sorption kinetics followed a pseudo-second-order kinetics model (R²=0.953-0.998) for all tested microplastics. External mass transport and intraparticle diffusion were the main rate controlling steps of the sorption of fipronil on microplastics. Furthermore, isotherm results indicated that a Langmuir model provided the best fit for fipronil sorption on PE, PS, PVC and PP (R²=0.997-0.999), while a Freundlich model was the most appropriate model for PLA and PBS (R²=0.998-0.999). The presence of surface O-containing functional groups and the spatial arrangement of rubbery domains are likely to affect the sorption process. The results from this work suggest that microplastics, especially biodegradable ones, may play an important role in the fate and transport of pesticides, and their effects on soil organisms (e.g., earthworms) require further investigation.

Gong, X., et al. (2016). "High-performance fluorescence-encoded magnetic microbeads as microfluidic protein chip supports for AFP detection." Analytica Chimica Acta **939**: 84-92.

Fluorescence-encoded magnetic microbeads (FEMMs), with the fluorescence encoding ability of quantum dots (QDs) and magnetic enrichment and separation functions of Fe3O4 nanoparticles, have been widely used for multiple biomolecular detection as microfluidic protein chip supports. However, the preparation of FEMMs with long-term fluorescent encoding and immunodetection stability is still a challenge. In this work, we designed a novel high-temperature chemical swelling strategy. The QDs and Fe3O4 nanoparticles were effectively packaged into microbeads via the thermal motion of the polymer chains and the hydrophobic interaction between the nanoparticles and microbeads. The FEMMs obtained a highly uniform fluorescent property and long-term encoding and immunodetection stability and could be quickly magnetically separated and enriched. Then, the QD-encoded magnetic microbeads were applied to alpha fetoprotein (AFP) detection via sandwich immunoreaction. The properties of the encoded microspheres were characterized using a self-designed detecting apparatus, and the target molecular concentration in the sample was also quantified. The results suggested that the high-performance FEMMs have great potential in the field of biomolecular detection.

Gonzalez, C. T., et al. (2015). "Comparison of two methods for anti-platelet antibody detection: Flow cytometry and luminex." Tissue Antigens **85 (5)**: 368-369.

Platelet antibodies are the cause of several disease conditions as idiopathic thrombocytopenic purpura, neonatal alloimmune thrombocytopenia or multiplatelet transfusion refractoriness. Flow cytometry has been considered the most reliable method for detection of platelet reactive antibodies, displacing previous solid phase methods. Recently a new method based on LuminexO technology has been developed. Microbeads are coated with platelet antigens, allowing a highly sensitive detection of platelet antibodies. The aim of this study was to compare both methods for screening of platelet antibodies. A total of 19 sera were received for platelet antibodies detection during 1-year and tested in parallel by flow cytometry and by LuminexO method (PAK LxTM, Immucor). Flow cytometry method was performed according to the protocol described by Kiefel (2001), the relative fluorescence intensity was expressed as a mean channel number (MCN) and a MCN greater than 25% was considered positive. PAK LxTM Luminex method was performed according to the manufacturer's specifications. Results were concordant in all sera tested. Both methods identified the same six positive sera of nineteen received. PAK LxTM method also allowed the identification of platelet antigens recognized by antibodies (HPA) or HLA-I antigen. PAK LxTM can be a highly sensitive and specific method for detection of platelet antibodies in several auto/allo-immune conditions compared to flow cytometry. The major advantages of PAK LxTM method over flow cytometry are: 1) identification of platelet antigens recognized by antibodies (including HLA-I antigen); and 2) patients' platelets are not needed for detection of antibodies, which is important in cases of severe thrombocytopenia.

Gonzalez, E. J., et al. (2018). "Dry micro-polymeric inoculant of Azospirillum brasilense is useful for producing mesquite transplants for reforestation of degraded arid zones." Applied Soil Ecology **129**: 84-93.

Massive clear-cutting of wild stands of mesquite trees in the Mexican part of the Sonoran Desert result from high demand for this wood by the charcoal industry. Consequently, there is a need to develop techniques for reforestation of this tree in the desert and maintain its natural diversity at the same time. An outdoor nursery procedure to produce mesquite transplants from diversely originated seeds for reforestation of arid zones was developed. This procedure involved: (1) inoculation of the seedlings in the nursery with the plant growth-promoting bacteria (PGPB) Azospirillum brasilense immobilized in dry microbeads of alginate, and (2) developing a reliable way to monitor plant development and aerial volume in the nursery for the entire growth period of seven months before transplantation. Dry microbeads containing the PGPB and maintained at room temperature were tested for survival of bacteria for up to seven months. These dry microbeads maintained sufficient population levels of A. brasilense to inoculate the plant for the entire period. Inoculation with the PGPB enhanced all growth parameters of the plants, including biomass, aerial volume, root system, and chlorophyll pigments, but not the auxiliary photosynthetic pigments. The PGPB was specifically identified colonizing the roots of the transplants by fluorescent in situ hybridization for the entire growth period. Measuring a few simple parameters allowed development of a workable model for plant growth. This model was confirmed by data obtained from sacrificed plants whose parameters were measured directly. This study shows that outdoor nursery cultivation of inoculated mesquite transplants is feasible.

Gonzalez Siso, M. I., et al. (1997). "Enzyme encapsulation on chitosan microbeads." Process Biochemistry **32**(3): 211-216.

alpha -Amylase and invertase were immobilized on chitosan microbeads (typical size 2.5-4 micro m), and the influence of 2 variables (crosslinking and protein concentration) on the activity shown by the immobilized enzymes was studied by means of full factorial experimental designs. Microencapsulation on chitosan beads has shown to be an effective immobilization method for both enzymes. The immobilization yield (activity of immobilized enzyme per unit activity of free enzyme) was 0.4% for alpha -amylase and 11% for invertase; a value of 10.7% was previously found for lactase. The difference in behaviour is explained in terms of substrate MW: it is probable that disaccharide molecules (sucrose or lactose) are small enough to enter the microbeads, whereas starch molecules are too large.

Gonzalez-Fernandez, C., et al. (2018). "Cellular responses of Pacific oyster (Crassostrea gigas) gametes exposed in vitro to polystyrene nanoparticles." Chemosphere **208**: 764-772.

While the detection and quantification of nano-sized plastic in the environment remains a challenge, the growing number of polymer applications mean that we can expect an increase in the release of nanoplastics into the environment by indirect outputs. Today, very little is known about the impact of nano-sized plastics on marine organisms. Thus, the objective of this study was to investigate the toxicity of polystyrene nanoplastics (NPs) on oyster (Crassostrea gigas) gametes. Spermatozoa and oocytes were exposed to four NPs concentrations ranging from 0.1 to 100 mg L⁻¹ for 1, 3 and 5 h. NPs coated with carboxylic (PS-COOH) and amine groups (PS-NH₂) were used to determine how surface properties influence the effects of nanoplastics. Results demonstrated the adhesion of NPs to oyster spermatozoa and oocytes as suggested by the increase of relative cell size and complexity measured by flow-cytometry and confirmed by microscopy observations. A significant increase of ROS production was observed in sperm cells upon exposure to 100 mg L⁻¹ PS-COOH, but was not observed with PS-NH₂, suggesting a differential effect according to the NP-associated functional group. Altogether, these results demonstrate that the effects of NPs occur rapidly, are complex and are possibly associated with the cellular eco-corona, which could modify NPs behaviour and toxicity.

Gonzalez-Fernandez, C., et al. (2019). "Do transparent exopolymeric particles (TEP) affect the toxicity of nanoplastics on Chaetoceros neogracile?" Environmental Pollution **250**: 873-882.

The potential presence of nanoplastics (NP) in aquatic environments represents a growing concern regarding their possible effects on aquatic organisms. The objective of this study was to assess the impact of polystyrene (PS) amino-modified particles (50nmPSNH₂) on the cellular and metabolic responses of the diatom Chaetoceros neogracile cultures at two essential phases of the growth cycle, i.e. exponential (division) and stationary (storage) phases. Both cultures were exposed for 4 days to low (0.05mugmL⁻¹) and high (5mugmL⁻¹) concentrations of PS-NH_{2.} Exposure to NP impaired more drastically the major cellular and physiological parameters during exponential phase than during the stationary phase. Only an increase in ROS production was observed at both culture phases following NP exposures. In exponential phase cultures, large decreases in chlorophyll content,

esterase activity, cellular growth and photosynthetic efficiency were recorded upon NP exposure, which could have consequences on the diatoms life cycle and higher food-web levels. The observed differential responses to NP exposure according to culture phase could reflect i) the higher concentration of Transparent Exopolymer Particles (TEP) at stationary phase leading to NP aggregation and thus, probably minimizing NP effects, and/or ii) the fact that dividing cells during exponential phase may be intrinsically more sensitive to stress. This work evidenced the importance of algae physiological state for assessing the NP impacts with interactions between NP and TEP being one key factor affecting the fate of NP in algal media and their impact to algal' cells.

Gonzalez-Jauregui, M., et al. (2019). "Stomach flushing technique applied to quantify microplastics in Crocodilians." MethodsX **6**: 2677-2685.

The impact of microplastics on wildlife is a recent problem for which methods to evaluate exposure still need development. Being able to identify and quantify microplastics (particles < 5mm) in the gastric contents of live crocodiles allows us to evaluate exposure, at both individual and population level, and also its contribution as transporter of other contaminants. The method was validated to determine and quantify microplastics in crocodile stomach contents recovered during an experiment where a known amount of this contaminant was given to crocodiles via oral administration. Through stomach flushing we were able to recover more than 80 % of the total volume of microplastic administrated to each crocodile. In summary, the method used during the experiment consists of 1) immobilization of the crocodile; 2) extraction of microplastics from stomach contents obtained through stomach flushing; 3) separation, identification and quantification of recovered microplastic fragments using microscopy and FTIR. *Low cost method that uses a small number of materials, does not take long to produce results and can easily be performed in the field or the laboratory.*Effective in extracting stomach contents (95 %).*High (>80 %) and good (>60 %) recovery efficiencies within two and four days after ingestion of microplastics by crocodiles.

Gonzalez-Pujana, A., et al. (2018). "Alginate microcapsules for drug delivery." Springer Series in Biomaterials Science and Engineering **11**: 67-100.

Currently, conventional drug delivery systems do not provide adequate therapeutic profiles for the management of multiple diseases. In this regard, cell encapsulation technology emerges as a suitable alternative. Undoubtedly, one of the most employed biomaterials for this purpose is alginate, since it presents multiple advantages that favor the development of this technology. Importantly, the thorough study concerning the purification and modification of the polymer has led to biocompatible alginates, a vital advancement for the correct function of the system. Furthermore, the possibility to entrap different cell types together with the plausibility of engineering cells to produce disparate therapeutic biomolecules has given rise to numerous applications. That is the case of relevant and prevalent diseases nowadays such as diabetes, cancer, or neurological diseases. Intensive research in the field has resulted in promising preclinical studies in animal models that have instigated the conduction of several clinical trials. Nonetheless, addressing some current challenges regarding aspects such as biosafety or biofunctionalization seems to be a prerequisite before the clinical translation. Gonzalez-Soto, N., et al. (2019). "Impacts of dietary exposure to different sized polystyrene microplastics alone and with sorbed benzo[a]pyrene on biomarkers and whole organism responses in mussels Mytilus galloprovincialis." Science of the Total Environment **684**: 548-566.

Due to their hydrophobicity and relatively large surface area, microplastics (MPs) can act as carriers of hydrophobic pollutants in the ocean and may facilitate their transfer to organisms. This study examined effects of dietary exposure to polystyrene MPs of 0.5 and 4.5 micro m alone and with sorbed benzo[a]pyrene (BaP) on mussels Mytilus galloprovincialis in order to elucidate the effects of MP size and the presence of sorbed BaP on the organism. MPs were provided daily, mixed with algae, during 26 days at equivalent mass (0.058 mg/L), corresponding to 1000 particles/mL for 4.5 micro m MPs and to 7.44x10⁵ particles/mL for 0.5 micro m MPs. Effects were determined on early cellular biomarkers in hemocytes, structure and cell type composition of digestive tubules (DTs), histopathology and whole organism responses (condition index (CI), clearance rate (CR), food absorption efficiency (AE), respiration rate (RR) and scope for growth (SFG)). BaP concentrations in mussels increased with time, in particular when sorbed to smaller MPs. Large MPs were abundant in the lumen of stomach and DTs, but were also occasionally found within epithelial cells. Effects in all treatments increased with exposure time. MPs with sorbed BaP were more toxic than MPs alone according to hemocyte viability and catalase activity and to the quantitative structure of DT epithelium. Higher toxicity of small MPs compared to larger ones was recorded for DNA damage and cell composition of DTs. At tissue level a slight increase in prevalence of inflammatory responses occurred in all exposed groups. At whole organism level a compensatory effect was observed on absorption efficiency across MP treatments at day 26, resulting in increased SFG in mussels exposed to small MPs with sorbed BaP. This could be related to an increased energy need to deal with stress observed in biomarkers. Further work is required to understand the Trojan horse effect of a variety of plastic type, size, shape combinations together with a wide variety of pollutants.

Goodey, A., et al. (2001). "Development of multianalyte sensor arrays composed of chemically derivatized polymeric microspheres localized in micromachined cavities." Journal of the American Chemical Society **123**(11): 2559-2570.

The development of a chip-based sensor array composed of individually addressable polystyrene-poly(ethylene glycol) and agarose microspheres has been demonstrated. The microspheres are selectively arranged in micromachined cavities localized on silicon wafers. These cavities are created with an anisotropic etch and serve as miniaturized reaction vessels and analysis chambers. A single drop of fluid provides sufficient analysis media to complete approximately 100 assays in these microetch pits. The cavities possess pyramidal pit shapes with trans-wafer openings that allows for both fluid flow through the microreactors/analysis chambers and optical access to the chemically sensitive microspheres. Identification and quantitation of analytes occurs via colorimetric and fluorescence changes to receptor and indicator molecules that are covalently attached to termination sites on the polymeric microspheres. Spectral data are extracted from the array efficiently using a charge-coupled device allowing for the near-real-time digital analysis of complex fluids. The power and utility of this new microbead array detection methodology is demonstrated here for the analysis of complex fluids containing a variety of important classes of analytes including acids, bases, metal cations, metabolic cofactors, and antibody reagents.

Goosen, M. F. A., et al. (1997). "Electrostatic droplet generation for encapsulation ion of somatic tissue: Assessment of high-voltage power supply." Biotechnology Progress **13**(4): 497-502.

The production of alginate microbeads with and without somatic tissue was investigated using an electrostatic droplet generator with a custom-made fixed (5.7 kV) and variable (0-20 kV) high-voltage power supply. The effects of applied potential, needle size, and alginate concentration were assessed as well as the immobilization of carnation callus cells. The high-voltage output from the power supply depended on whether the low-voltage input was increasing or decreasing. This hysteresis effect may be due to the electrical properties of the oscillator in the high-voltage source. While a short electrode distance and a high needle gauge were important for producing small alginate bead diameters (e.g., 100 mu m), alginate concentration in the range 1-3% (w/v) was not a key factor. Somatic tissue encapsulated using 2% sodium alginate retained viability over a 2-month culture period.

Goosen, M. F. A., et al. (1997). "Electrostatic droplet generation for encapsulation of somatic tissue: assessment of high-voltage power supply." Biotechnology Progress **13**(4): 497-502.

The production of alginate microbeads with and without somatic tissue was investigated using an electrostatic droplet generator with a custom-made fixed (5.7 kV) and variable (0-20 kV) high-voltage power supply. The effects of applied potential, needle size, and alginate concentration were assessed as well as the immobilization of carnation (Dianthus caryophyllus) callus cells. The high-voltage output from the power supply depended on whether the low-voltage input was increasing or decreasing. This hysteresis effect may be due to the electrical properties of the oscillator in the high-voltage source. While a short electrode distance and a high needle gauge were important for producing small alginate bead diameters (e.g., 100 micro m), alginate concentration in the range 1-3% (w/v) was not a key factor. Somatic tissue encapsulated using 2% sodium alginate retained viability over a 2-month culture period.

Gordon, J. N., et al. (2008). "Matrix metalloproteinase-3 production by gut IgG plasma cells in chronic inflammatory bowel disease." Inflammatory Bowel Diseases **14**(2): 195-203.

BACKGROUND: In both ulcerative colitis (UC) and Crohn's disease (CD) there is a marked increase in mucosal IgG plasma cells (PC), although their precise role is not well established. In this study we isolated gut PCs from patients with IBD and normal controls and analyzed cytokine production, matrix metalloproteinase (MMP)-3 and tissue inhibitor of metalloproteinase (TIMP)-1 production, and PC longevity ex vivo.

METHODS: Lamina propria mononuclear cells (LPMCs) were isolated from patients with CD (n = 19), UC (n = 27), and normal controls (n = 42). PCs were further selected by immunomagnetic isolation using CD138 microbeads. Cytokine, MMP-3, and TIMP-1 expression was investigated by Taqman polymerase chain reaction (PCR), enzyme-linked immunosorbent assay (ELISA), Western blotting, and confocal microscopy. PC lifespan in vitro was studied by ELISpot analysis.

RESULTS: PCs from both controls and IBD patients contained high levels of transcripts for TGFbeta, whereas they did not contain significant transcripts for IL-4, IL-5, IL-10, IFNgamma, TNF, or IL-12p40. PCs from patients with CD and UC expressed significantly higher levels of MMP-3 protein and transcripts than controls ($P < 0.0001$). The vast majority of MMP-3-expressing PCs were IgG+ve. In culture, IgA PCs from both IBD patients and controls persisted for only a few days, but IgG PCs from IBD patients persisted for at least 3 weeks.

CONCLUSIONS: We have demonstrated that IgG PCs from patients with IBD express large amounts of MMP-3 and that they appear to be long-lived. These results identify a new pathway by which IgG PCs may damage the gut.

Gore, P. M., et al. (2017). "Keratin-Nylon 6 engineered microbeads for adsorption of Th (IV) ions from liquid effluents." Journal of Environmental Chemical Engineering **5**(6): 5655-5667.

The applicability of novel porous microbeads (average diameter of about 2.0 mm) of alpha -keratin engineered with Nylon 6, have been investigated for the adsorption of radioactive and non-biodegradable Th (IV) ions from the effluents. Thorium ion uptake on the intrinsically compatible adsorbent system was investigated using experimental analysis and kinetic studies.

The developed system demonstrates maximum adsorption efficiency of 66.26% under ecologically optimal conditions i.e. pH=7, with 1000 ppm initial Th (IV) concentration at 303 K for 120 min. The experimental results reveal that the adsorption kinetics study best fits with the Dubinin-Radushkevich isotherm model (R²=0.993) and Intra-particle diffusion kinetics model (R²=0.995). The kinetic models namely Pseudo-first order, Pseudo-second order, particle diffusion, & Elovich were used for the adsorption study, and were compared and calculated using linear & nonlinear regression methods thermodynamic analysis revealed the spontaneity, viability and exothermic nature of the adsorption process with free energy change (Delta G⁰) of -11.48 kJ/mol. Further, the inter-polymer miscibility and compatibility was explored by atomistic molecular modelling and extended Flory-Huggins theory via Materials Studio software on geometrically minimized repeat units of Cysteine (functional group of alpha -keratin) and Nylon 6, employing Discover, Amorphous Cell, Forcite and Blends modules, which showed results to be consistent with FT-IR studies, revealing strong hydrogen bonding.

Gorman, D., et al. (2019). "Organic contamination of beached plastic pellets in the South Atlantic: Risk assessments can benefit by considering spatial gradients." Chemosphere **223**: 608-615.

Microplastics are important vectors for the transport and accumulation of persistent organic contaminants in coastal and marine environments. We determined the concentration of polycyclic aromatic hydrocarbons (PAHs) and polychlorinated biphenyls (PCBs) associated with microplastic pellets collected along a 39-km stretch of Brazil's South Atlantic coastline to understand the spatial dynamics and potential risk posed by these contaminants. Total PAH concentrations ranged from 1,454 to 6,002ngg⁻¹ and regularly exceeded the threshold effect level (TEL) for sediments defined by the United States Environmental Protection Agency. Sampling stations, spaced evenly along the coastline (i.e., 3-km intervals) exhibited a general north-to-south decline in the concentrations of some PAHs, but this spatial gradient was complicated by small-scale differences in the concentrations and composition of associated contaminants. Similarly, analysis of individual isomer ratios revealed further complexity driven by differences in the contribution of petrogenic versus pyrolytic inputs which pose different levels of risk to marine organisms. PCB concentrations ranged from 0.8 to 104.6ngg⁻¹ and were dominated by low chlorinated congeners likely to have originated from major industrial areas to the north. Overall, this study highlights the challenge of directly linking microplastic pollution with the potential toxicological effects of organic contaminants in coastal waters. We recommend that monitoring programs should explicitly consider both the origin (i.e., pellet sources and dispersal pathways) and nature of organic contamination (i.e., concentration and composition) when assessing the risks for biota and human health.

Gorodetsky, R., et al. (1999). "Fibrin microbeads (FMB) as biodegradable carriers for culturing cells and for accelerating wound healing." Journal of Investigative Dermatology **112**(6): 866-872.

We have developed biodegradable fibrin-derived microbeads as potent cell carriers. The fibrin-derived microbeads, 50-200 microm in diameter, were tested for their attachment to a wide range of cell types. Fibrin-derived microbeads were shown to be greatly haptotactic to cells (such as endothelial cells, smooth muscle cells and fibroblasts), which respond to fibrinogen in contrast to keratinocytes and different cell lines derived from leukocytic lineage. The cells on fibrin-derived microbeads could be maintained for more than 10 d and achieved a high density. 31P-nuclear magnetic resonance was employed to monitor phosphate metabolism in cells, with densities on the order of 100 million cells per g of fibrin-derived microbeads. The 31P-nuclear

magnetic resonance adenosine triphosphate and phosphocreatine signals, equivalent to the signal obtained with perfused normal skin, indicated that metabolism of cells on fibrin-derived microbeads was responsive to oxygenation and nutrients. Light, fluorescent, and confocal laser microscopy revealed that the porous fibrin-derived microbeads accommodate up to 200-300 cells due to their high surface area which minimized contact inhibition. Cells could degrade the fibrin-derived microbeads and be transferred to seed culture flasks without trypsinization. In a pig skin wound healing model, fibrin-derived microbeads + fibroblasts were transplanted into full thickness punch wounds. This procedure was compared with other treatment modalities, such as the addition of human platelet-derived growth factor BB or fibrin-derived microbeads alone. By the third day after wounding, only the wounds in which fibroblasts on fibrin-derived microbeads were added showed significant formation of granulation tissue. Based on the above, we project many uses of our novel fibrin-derived microbead technology for cell culturing, wound healing and tissue engineering.

Gorokhova, E. (2015). "Screening for microplastic particles in plankton samples: how to integrate marine litter assessment into existing monitoring programs?" Marine Pollution Bulletin **99**(1/2): 271-275.

Microplastics (MPs) are a newly recognized type of environmental pollution in aquatic systems; however no monitoring of these contaminants is conducted, mostly due to the lack of routine quantification. In the net samples collected with a 90- micro m WP2 net, pelagic MP abundance was quantified by light microscopy and evaluated as a function of inshore-offshore gradient, depth, and season; the same samples were used for zooplankton analysis. The MP abundance was ~10²-10⁴ particles m⁻³, with no significant inshore-offshore gradient during summer but increasing offshore in winter. MP abundance in deeper layers was positively affected by zooplankton abundance in the upper layers and significantly lower during winter compared to summer. These findings indicate heterogeneity of MP distribution due to biotic and abiotic factors and suggest that samples collected for other purposes can be used for quantification of MPs in the Baltic Sea, thus facilitating integration of MP assessment into existing monitoring schemes.

Gorschluter, A., et al. (2002). "Electro-magnetic base technology for estremely sensitive immunosensors and DNA-chips." Biomedizinische Technik **47 Suppl 1 Pt 1**: 213-216.

We report on the development of an innovative electro-magnetic base technology for estremely sensitive sensors allowing the electrical detection of biological analytes like antigenes or DNA as well as a simple multiple detection of binding forces occurring at specific bonds between proteins. The technology is based on the strong impact of specifically captured magnetic microbeads on an electrical current generated in a fluid by a small sensor chip with an array of activated microelectrodes. The new technological principle with the on-chip detection of analytes will be suitable for large scale applications due to its mass production compatible technologies and allow an alternative way to monitor relevant substances without the consumption of critical additional solutions and reagents.

Goss, H., et al. (2018). "Thalassia testudinum as a potential vector for incorporating microplastics into benthic marine food webs." Marine Pollution Bulletin **135**: 1085-1089.

Seagrasses are among the most productive shallow water ecosystems, serving a diverse assemblage of fish and invertebrates. Tropical seagrass communities are dominated by the turtle grass Thalassia testudinum, whose wide, flattened blades host diverse epibiont communities. Amidst its epibionts, T. testudinum may also be accumulating microplastics, which are a ubiquitous marine pollutant even in remote locales. To assess the extent of microplastic

accumulation, seagrass samples were collected from Turneffe Atoll, which lies offshore but parallel with a major urban center. Seventy-five percent of Thalassia blades had encrusted microplastics, with microfibers occurring more than microbeads and chips by a ratio of 59:14. Grazers consumed seagrasses with higher densities of epibionts. Potential mechanisms for microplastic accumulation include entrapment by epibionts, or attachment via biofilms. This study is the first to document microplastics on marine vascular plants, suggesting that macroherbivory is a viable pathway for microplastic pollution to enter marine food webs. Goth, W., et al. (2018). "Rapid empirical characterization of sub-diffuse reflectance imaging from MOHS surgery skin samples." Lasers in Surgery and Medicine **50 (Supplement 29)**: S10.

Background: Spatial Frequency Domain Imaging (SFDI) is a label free imaging technique which is sensitive to tissue microstructure. Recent studies have used SFDI in the sub-diffuse regime (sd-SFDI), where the influence of absorption is minimized and the signal is predominantly sensitive to differences in cellular and nuclear structure relevant to tumour pathology. As abnormal microstructure is the primary diagnostic indicator in Mohs micrographic surgery (MMS), sd-SFDI provides the opportunity for tumour identification without sectioning and staining the sample, a significant bottleneck in MMS workflows. However, the processing time for existing non-linear sd-SFDI models needs further improvements to realize near real-time image rendering. Here, we present a linearized empirical model of sub-diffusive scattering and apply it to sf-SFDI data from optical phantoms and human MMS skin samples. Study Design/Materials and Method: Optical phantoms of polystyrene microbeads [d=0.1-1.0mm] at varying reduced scattering coefficients [mus'=1-3 mm-1] were imaged at high spatial frequencies [f>0.5mm-1], corresponding to the tissue sub-diffuse scattering regime. Excised human MMS skin samples were imaged and compared to accompanying H&E stained histology, which were examined by expert histopathologists. An existing non-linear model and our new linearized empirical model were fit to collected sd-SFDI data. Result(s): Our empirical model coefficients showed high sensitivity to changes in scattering particle concentration and size in the optical phantoms. The model parameters highlighted regions of basal cell carcinoma tumour, epidermis, dermis, fat, and other features on the human skin cancer samples. These parameters were additionally used to segment the MMS samples, and corresponded well with the regions demarcated by histology. Our linearized model required less than 1 second to process 1 million pixels, whereas the non-linear model required over 5 hours. Conclusion(s): The proposed empirical model is a rapid and powerful tool to quantify sd-SFDI data without the need for extensive modeling and fitting, reducing the processing time of existing non-linear models by several orders of magnitude. The high sensitivity of our model to different microstructural constituents in experimental results provides a potential path to a streamlined MMS workflow.

Gotze, R., et al. (2016). "Physico-chemical characterisation of material fractions in residual and source-segregated household waste in Denmark." Waste Management **54**: 13-26.

Physico-chemical waste composition data are paramount for the assessment and planning of waste management systems. However, the applicability of data is limited by the regional, temporal and technical scope of waste characterisation studies. As Danish and European legislation aims for higher recycling rates evaluation of source-segregation and recycling chains gain importance. This paper provides a consistent up-to-date dataset for 74 physico-chemical parameters in 49 material fractions from residual and 24 material fractions from source-segregated Danish household waste. Significant differences in the physico-chemical properties of residual and source-segregated waste fractions were found for many parameters related to organic matter, but also for elements of environmental concern. Considerable differences in potentially toxic metal concentrations between the individual recyclable fractions within one material type were observed. This indicates that careful planning and performance evaluation of recycling schemes are important to ensure a high quality of collected recyclables. Rare earth elements (REE) were quantified in all waste fractions analysed, with the highest concentrations of REE found in fractions with high content of mineral raw materials, soil materials and dust. The observed REE concentrations represent the background concentration level in non-hazardous waste materials that may serve as a reference point for future investigations related to hazardous waste management. The detailed dataset provided here can be used for assessments of waste management solutions in Denmark and for the evaluation of the quality of recyclable materials in waste. Goudanavar, P. S., et al. (2010). "Design and Characterization of diclofenac sodium microbeads by ionotropic gelation technique." International Journal of Pharma and Bio Sciences **1 (2) (no pagination)**(44).

Sustained release oral product namely microbeads for Diclofenac sodium prepared by ionotropic gelation technique using Sodium alginate alone and combination with Hydroxypropyl methyl cellulose, Chitosan, Pectin as release rate modifiers, and investigated for flow behavior, particle size, swelling properties, surface study by SEM, and in vitro drug release potential. While increase in the concentration of sodium alginate and other polymer dispersions increased sphericity, size distribution, mean particle size. Drug entrapment efficiency approached nearly 95%. Increasing calcium chloride concentration decreases the mean diameter of the microbeads, no appreciable change in morphology, and drug release behaviors. In vitro drug release was dependent on the pH of the medium and concentration of polymer dispersions. Among the nine formulation batches F5, F7 and F9 were found to show optimum sustained effect. The mechanism of drug release from the microbeads was found to be followed super case-II transport.

Gouin, T., et al. (2019). "Toward the Development and Application of an Environmental Risk Assessment Framework for Microplastic." Environmental Toxicology & Chemistry **38**(10): 2087-2100.

Emissions of plastic waste to the environment and the subsequent degradation into microplastic particles that have the potential to interact with biological organisms represent a concern for global society. Current understanding of the potential impacts on aquatic and terrestrial population stability and ecosystem structure and function associated with emissions of microplastic particles is limited and insufficient to fully assess environmental risks. Multistakeholder discussions can provide an important element in helping to identify and prioritize key knowledge gaps in assessing potential risks. In the present review, we summarize multistakeholder discussions from a 1-d International Council of Chemical Associations-sponsored symposium, which involved 39 scientists from 8 countries with representatives from academia, industry, and government.

Gouin, T., et al. (2011). "A thermodynamic approach for assessing the environmental exposure of chemicals absorbed to microplastic." Environmental Science & Technology **45**(4): 1466-1472.

The environmental distribution and fate of microplastic in the marine environment represents a potential cause of concern. One aspect is the influence that microplastic may have on enhancing the transport and bioavailability of persistent, bioaccumulative, and toxic substances (PBT). In this study we assess these potential risks using a thermodynamic approach, aiming to prioritize

the physicochemical properties of chemicals that are most likely absorbed by microplastic and therefore ingested by biota. Using a multimedia modeling approach, we define a chemical space aimed at improving our understanding of how chemicals partition in the marine environment with varying volume ratios of air/water/organic carbon/polyethylene, where polyethylene represents a main group of microplastic.

Gove, J. M., et al. (2019). "Prey-size plastics are invading larval fish nurseries." Proceedings of the National Academy of Sciences of the United States of America **116**(48): 24143-24149.

Life for many of the world's marine fish begins at the ocean surface. Ocean conditions dictate food availability and govern survivorship, yet little is known about the habitat preferences of larval fish during this highly vulnerable life-history stage. Here we show that surface slicks, a ubiquitous coastal ocean convergence feature, are important nurseries for larval fish from many ocean habitats at ecosystem scales. Slicks had higher densities of marine phytoplankton (1.7-fold), zooplankton (larval fish prey; 3.7-fold), and larval fish (8.1-fold) than nearby ambient waters across our study region in Hawai'i. Slicks contained larger, more well-developed individuals with competent swimming abilities compared to ambient waters, suggesting a physiological benefit to increased prey resources. Slicks also disproportionately accumulated prey-size plastics, resulting in a 60-fold higher ratio of plastics to larval fish prey than nearby waters. Dissections of hundreds of larval fish found that 8.6% of individuals in slicks had ingested plastics, a 2.3-fold higher occurrence than larval fish from ambient waters. Plastics were found in 7 of 8 families dissected, including swordfish (Xiphiidae), a commercially targeted species, and flying fish (Exocoetidae), a principal prey item for tuna and seabirds. Scaling up across an ~1,000 km² coastal ecosystem in Hawai'i revealed slicks occupied only 8.3% of ocean surface habitat but contained 42.3% of all neustonic larval fish and 91.8% of all floating plastics. The ingestion of plastics by larval fish could reduce survivorship, compounding threats to fisheries productivity posed by overfishing, climate change, and habitat loss.

Govindasamy, S., et al. (2019). "Dataset on controlled production of polyhydroxyalkanoate-based microbead using double emulsion solvent evaporation technique." Data in Brief **23**: 103675.

A significant source of microplastics is from the usage of microbeads in the market since petrochemical plastic bead is a material used in cosmetic scrubs. A possible way to counteract the problem is by the substitution of synthetic plastic to natural biodegradable polymer. Polyhydroxyalkanoate (PHA) is a general class of thermoplastic microbial polymer and it is the best alternative to some petrochemical plastics due to its biodegradability. Some PHA has earned its way into cosmetic application due to its biocompatibility. This data article reports data on the development of biodegradable microbeads by using the double emulsion solvent evaporation technique. Our data describe the extraction of biopolymer from marine bacteria that was cultivated in shaken flask culture, removal of endotoxins using oxidizing agent, the production of microbeads using a peristaltic pump with a specific flowrate and silicon tubing, and the cytotoxicity of the microbeads.

Goyal, P. K. and R. E. B. Hanna (1988). "Nippostrongylus brasiliensis: immunogenicity of larval and adult worms in rats." International Journal for Parasitology **18**(1): 121-123.

Plastic resin-embedded sections of adult and larval N. brasiliensis were used as test antigens for indirect immunofluorescence labelling with serially diluted antisera collected from rats throughout the course of primary and secondary infections. With sheathed infective larvae, labelling was strongest over the sheath and cuticle, while the cuticle of exsheathed larvae appeared less antigenic. With adult sections the strongest labelling was over the egg shells and uterus wall, and over the cuticle. The early and vigorous humoral response of rats to N. brasiliensis infection may indicate that the host's immune system is particularly reactive to common antigens expressed by nematodes. The failure of the secondary infection to engender an anamnestic response may indicate that the immune system is fully saturated with parasite antigens from the earliest stages of infection. IgG formed the only measureable component of the circulating antibody pool except in the earliest stages of infection when IgM was present in significant amounts.

Grabias, B. and S. Kumar (2015). "A non-amplification, oligonucleotide-based sandwich hybridization assay for the detection of pathogens in blood." American Journal of Tropical Medicine and Hygiene **93 (4 Supplement)**: 551.

Novel technologies for the sensitive and reliable detection of infectious agents in blood are still needed. While the standard method of nucleic acid-based pathogen detection generally relies on PCR amplification of target DNA or RNA, complex genome sequences can be resistant to amplification, due to factors such as secondary or tertiary structure, and the potential for nonspecific amplification or sample interference could result in false positive or false negative results. Here, we describe a novel nanoparticle-based sandwich hybridization assay (SHA) for the detection of Plasmodium falciparum and Babesia microti parasites without the need for amplification of target sequences in genomic DNA. A uniquely identifiable "barcoded" magnetic microbead and biotinylated silica nanoparticle are conjugated to either P. falciparum- or B. microtispecific 30-mer oligonucleotides corresponding to sequences of the 18S ribosomal gene. For each parasite, the magnetic microbead and silica nanoparticle bead sets hybridize to a unique but adjacent region in the genome. Parasite burden can then be quantified and analyzed upon the binding of an Avidin-PE fluorophore to the target capture complexes via a Bio-Plex 200 instrument. Determination of the analytical sensitivity of the SHA for short complementary oligonucleotide sequences revealed a limit of detection of 10-10 M for both P. falciparum and B. microti probe sets. Analytical sensitivity studies conducted by spiking human blood with known counts of parasites revealed that SHA can reliably detect up to 10 P. falciparum- or B. microti-infected red cells per mL of blood. For comparison, in our hands PCR can detect 100 P. falciparum- or 1000 B. microti-infected red cells per mL of spiked blood. Thus, SHA offers a 10-100 fold enhanced sensitivity for the detection of these two intraerythrocytic parasites of global public health significance. Studies to determine the clinical sensitivity of SHA for these pathogens are in progress. Details of the method development and sensitivity and specificity data will be presented.

Graca, B., et al. (2017). "Sources and fate of microplastics in marine and beach sediments of the Southern Baltic Sea-a preliminary study." Environmental Science & Pollution Research **24**(8): 7650-7661.

Microplastics' (particles size <=5 mm) sources and fate in marine bottom and beach sediments of the brackish are strongly polluted Baltic Sea have been investigated. Microplastics were extracted using sodium chloride (1.2 g cm⁻³). Their qualitative identification was conducted using micro-Fourier-transform infrared spectroscopy (muFT-IR). Concentration of microplastics varied from 25 particles kg⁻¹ d.w. at the open sea beach to 53 particles kg⁻¹ d.w. at beaches of strongly urbanized bay. In bottom sediments, microplastics concentration was visibly lower compared to beach sediments (0-27 particles kg⁻¹ d.w.) and decreased from the shore to the open, deep-sea regions. The most frequent microplastics dimensions ranged from 0.1 to 2.0 mm, and transparent fibers were predominant. Polyester, which is a popular fabrics component, was the most common type of microplastic in both marine bottom (50%) and beach sediments (27%). Additionally, poly(vinyl

acetate) used in shipbuilding as well as poly(ethylene-propylene) used for packaging were numerous in marine bottom (25% of all polymers) and beach sediments (18% of all polymers). Polymer density seems to be an important factor influencing microplastics circulation. Low density plastic debris probably recirculates between beach sediments and seawater in a greater extent than higher density debris. Therefore, their deposition is potentially limited and physical degradation is favored. Consequently, low density microplastics concentration may be underestimated using current methods due to too small size of the debris. This influences also the findings of qualitative research of microplastics which provide the basis for conclusions about the sources of microplastics in the marine environment.

Graca, B., et al. (2017). "Sources and fate of microplastics in marine and beach sediments of the Southern Baltic Sea—a preliminary study." Environmental science and pollution research international **24**(8): 7650-7661.

Microplastics' (particles size ≤5 mm) sources and fate in marine bottom and beach sediments of the brackish are strongly polluted Baltic Sea have been investigated. Microplastics were extracted using sodium chloride (1.2 g cm^{-3}). Their qualitative identification was conducted using micro-Fourier-transform infrared spectroscopy (μFT-IR). Concentration of microplastics varied from 25 particles kg^{-1} d.w. at the open sea beach to 53 particles kg^{-1} d.w. at beaches of strongly urbanized bay. In bottom sediments, microplastics concentration was visibly lower compared to beach sediments (0–27 particles kg^{-1} d.w.) and decreased from the shore to the open, deep-sea regions. The most frequent microplastics dimensions ranged from 0.1 to 2.0 mm, and transparent fibers were predominant. Polyester, which is a popular fabrics component, was the most common type of microplastic in both marine bottom (50%) and beach sediments (27%). Additionally, poly(vinyl acetate) used in shipbuilding as well as poly(ethylene-propylene) used for packaging were numerous in marine bottom (25% of all polymers) and beach sediments (18% of all polymers). Polymer density seems to be an important factor influencing microplastics circulation. Low density plastic debris probably recirculates between beach sediments and seawater in a greater extent than higher density debris. Therefore, their deposition is potentially limited and physical degradation is favored. Consequently, low density microplastics concentration may be underestimated using current methods due to too small size of the debris. This influences also the findings of qualitative research of microplastics which provide the basis for conclusions about the sources of microplastics in the marine environment.

Graham, E. R. and J. T. Thompson (2009). "Deposit- and suspension-feeding sea cucumbers (Echinodermata) ingest plastic fragments." Journal of Experimental Marine Biology and Ecology **368**(1): 22-29.

Weathering of plastic bottles, bags, fishing line, and other products discarded in the ocean causes tiny fragments to break off. These plastic fragments may accumulate biofilms, sink, and become mixed with sediment, where benthic invertebrates may encounter and ingest them. Here we show that four species of deposit-feeding and suspension-feeding sea cucumbers (Echinodermata, Holothuroidea) not only ingest small (0.25 mm < maximum dimension <15 mm) nylon and polyvinyl chloride (PVC) fragments along with sediment, but also ingest significantly more plastic fragments than predicted given the ratio of plastic to sand grains in the sediment. During four-hour feeding trials, holothurians ingested between 2- and 20-fold more plastic per individual than expected for PVC fragments, and between 2- and 138-fold more for nylon line. In addition, two species ingested 4 mm diameter PVC pellets. The ecological relevance of plastic ingestion was assessed in the laboratory by counting and characterizing small plastic particles

discovered in sediment samples from the same field sites where our holothurians were collected. Substantial numbers of plastic fragments (105 to 214 fragments per liter of sediment) were found in samples from three different locations along the east coast of the U.S.A. In addition, plastic collected from the sediment from two of our field sites was analyzed for polychlorinated biphenyls (PCBs). Plastic from one site tested positive for Aroclor 1254 at a concentration of 0.0106 micro g g⁻¹. While the negative effects of macroscopic marine plastic debris on a host of organisms are well documented, ingestion of small plastic debris by a wide range of benthic organisms, including both primary and secondary consumers, has received little attention. Given that plastics readily adsorb PCBs and other organic pollutants in marine environments, ingestion of plastic from sediment may provide a heretofore-undescribed pathway of exposure for benthic marine invertebrates.

Graham, P., et al. (2019). "Microplastics uptake and egestion dynamics in Pacific oysters, Magallana gigas (Thunberg, 1793), under controlled conditions." Environmental Pollution **252**(Pt A): 742-748.

Microplastics debris (<5mm) are increasingly abundant in the marine environment, therefore, potentially becoming a growing threat for different marine organisms. Through aquatic animals, these can enter in the human food chain, and can be perceived as a risk for consumers' health. Different studies report the presence of particles in marketable shellfish including the world wide commercially grown Pacific oyster Magallana gigas (Thunberg, 1793). The aim of this study is to examine the potential risk of microplastics entering in the human food chain through this shellfish species, investigating the dynamics of the uptake, egestion (faeces) and rejection (pseudofaeces) of microplastics in Pacific oysters under controlled conditions. M. gigas collected from a farm in the San Teodoro lagoon (Italy), were exposed to 60 fluorescent orange polystyrene particles L⁻¹ of known sizes (100, 250 and 500mum). The uptake of each particle size was 19.4+/-1.1%, 19.4+/-2% and 12.9+/-2% respectively. After exposure M. gigas were left to depurate for 72h, during which 84.6+/-2% of the particles taken up were released whilst 15.4+/-2% were retained inside the shell cavity. No microplastic particles were found in the animals' soft tissues. The results of this study, suggest that depuration is an effective method to reduce presence of large microplastic particles, in the size range 100-500mum, in M. gigas. Importantly, the data suggests that the burden that could theoretically be up taken by consumers from these shellfish is negligible when compared to other routes.

Gramatzki, M., et al. (2014). "M.D." Biology of Blood and Marrow Transplantation **1)**: S160-S161.

In AML patients despite intensive chemotherapy and additional stem cell transplantation, residual leukemic stem cells (LSC) may lead to relapse. Therefore, elimination of LSC by targeted therapy may represent a promising therapeutic approach. Recently CD96was identified as marker antigen on AML LSC (Hosen et al., PNAS 104: 11008, 2007). Here, strategies for engineering autologous stem cell grafts as well as for in vivo targeting of residual AML stem cells by addressing CD96 for magnetic cell sorting (MACS) or antibody dependent cellular cytotoxicity (ADCC) are described. To evaluate the efficacy of purging LSC by MACS technology, stem cell containing grafts were spiked with CD96 positive AML cells. Using biotinylated CD96 antibody TH111 raised in our laboratory in combination with anti-Biotin-microbeads (Miltenyi) up to a 1000-fold depletion of targeted cells was achieved. Viability, cell count and the potential of HPC to proliferate and differentiate were not affected by this procedure as shown by flow cytometry and colony forming assays. Eradication of AML stems cells is also an issue after allogeneic stem cell transplantation. To target CD96+ AMLLSC by ADCC, chimeric antibodies containing wild type or affinity maturated variable regions in combination with an optimized human IgG1 Fc were generated. As shown by flow cytometry, the antigen binding affinity of the maturated antibody was enhanced (EC50 0.6 mug/ml vs. 2 mg/ml). Moreover, also NK cell mediated lytic properties against CD96-positive target cells were elevated (EC50: 0.02 mug/ml vs. 0.15 mug/ml) as analyzed in standard ADCC assays. Thus, the purging strategy may be beneficial for the development of graft-engineering strategies to avoid transplantation of AML-LSC and revitalize autologous stem cell transplantation in this indication. The in vivo application may possibly open additional therapeutic avenues in eliminating residual disease in autologous as well as allogeneic situations.

Gramatzki, M., et al. (2016). "CD96 antibody TH-111 eradicates AML-LSC from autografts and the Fc-engineered variant MSH-TH111e may be used in vivo." Biology of Blood and Marrow Transplantation **1)**: S200.

Introduction: Residing leukemic stem cells (LSC) account for the high rate of relapse in acute myeloid leukemia (AML) patients after autologous stem cell transplantation (ASCT). To improve the outcome of AML therapy the efficient elimination of these LSC is a prerequisite. CD96 detected by our monoclonal antibody TH-111 has been proposed as a target structure for selective elimination of LSC in AML. Here, a strategy is implemented to remove CD96-positive LSC from autologous grafts of AML patients by magnetic cell sorting (MACS). Since certain situations require the elimination of AML-LSC in the patient, a novel TH-111 based Fc-engineered CD96 antibody was designed for in vivo use. Method(s): Following biotinylation antibody TH-111 was used for MACS based separation of AML-LSC cells. Depletion efficiency of AML-LSC, cell viability and differentiation capacity of healthy hematopoietic progenitor cells (HPC) after depletion were analyzed. CD96 antibodies with Fc variants optimized for antibody-dependent cell-mediated cytotoxicity (ADCC) were generated and effector mechanisms evaluated. ADCC activity against cell lines and freshly isolated tumor cells was tested. Colony forming assays were performed to detect impact on healthy HPC. Result(s): The efficiency of antibody mediated LSC purging was determined by spiking a graft with AML. Using biotinylated CD96 antibody TH-111 and anti-biotin-microbeads, targeted cells could be depleted approx. 1000-fold with MACS technology. Viability of healthy HPC as well as their potential to proliferate and differentiate was not affected. Primary CD96-positive AML-LSC could be efficiently eliminated. The variable regions of an affinity maturated scFv were used to generate a full length CD96 antibody with an engineered IgG1-based Fc variant designated MSH-TH111e optimized for ADCC activity. FcgRIIIa (CD16a) expressing NK cells were efficiently recruited to lyse KG1a myeloid blasts as well as primary AML cells. For comparison a similarly designed CD34 antibody lysing CD34⁺ HPC of healthy donors as well as CD34⁺/CD96⁺ KG1a cells was used. Fc-optimized MSH-TH111e did not affect CD34⁺ HPC but eliminated KG1a blasts. The capacity of healthy HPC to proliferate and differentiate was not altered by MSH-TH111e treatment. Conclusion(s): Using CD96 as marker for AML-LSC, column based purging technology eliminates LSC from mixed cell populations. Therefore, graft-engineering strategies focusing on CD96 are feasible and avoid contamination of the autograft with AML-LSC. This may help to revitalize ASCT in AML. Fc-engineered CD96 antibody MSH-TH111e may provide an additional therapeutic option to eliminate residual disease in certain clinical situations including the setting of allogeneic stem cell transplantation.

Gramatzki, M., et al. (2015). "New strategy in stem cell transplantation for AML: CD96 antibody TH-111 removes leukemic stem cells from autografts." Annals of Hematology **1)**: S99.

Background: High relapse rates observed in AML patients after autologous stemcell transplantation (ASCT) due to residual leukemic stemcells (LSC) in the graft limit this approach. The monoclonal antibody TH111, raised in our laboratory, targets the CD96 antigen characteristically expressed on AML-LSC. Study design: Here, a strategy is developed to remove CD96 positive LSC from autologous grafts by magnetic cell sorting (MACS). In addition, antibody engineering improves antibody dependent cell-mediated cytotoxicity (ADCC) against residual LSC allowing therapeutic targeting in other situations. The efficiency of antibody mediated LSC purging was determined by spiking a graft with AML cells. Using biotinylated CD96 antibody TH111 and anti-biotin-microbeads, targeted cells could be depleted approx. 1000-fold with MACS technology. Viability of healthy hematopoietic progenitor cells (HPC) as well as their potential to proliferate and differentiate was not affected. Importantly, primary CD96-positiveAMLLSC could be efficiently eliminated from bone marrow aspirate of an AML patient. Recombinant DNA technologies were used to generate affinity maturated and ADCC-optimized CD96 antibodies. A chimeric antibody containing affinity maturated variable regions in combination with anADCC optimized human IgG<inf>1</inf> Fc was generated. In contrast to an Fc knock-out variant, this construct efficiently recruited NK cells and lysed CD96-positive AML-LSC. Result(s): Using CD96 as marker typical for AML-LSC, column based purging technology eliminates LSC from mixed cell populations. Moreover, a chimeric affinity maturated and Fc-optimized CD96 antibody was able to recruit NK cells for lysis of AML-LSC. Conclusion(s): Therefore, graft-engineering strategies focusing on CD96 may be feasible and avoid contamination with AML-LSC of the autograft. This strategy may help to revitalize ASCT in AML. The design of CD96 antibodies may open additional therapeutic avenues in eliminating residual disease in allogeneic situations as well.

Granby, K., et al. (2018). "The influence of microplastics and halogenated contaminants in feed on toxicokinetics and gene expression in European seabass (Dicentrarchus labrax). (Special Section: Environmental contaminants in seafood: new findings & innovation challenges.)." Environmental Research **164**: 430-443.

When microplastics pollute fish habitats, it may be ingested by fish, thereby contaminating fish with sorbed contaminants. The present study investigates how combinations of halogenated contaminants and microplastics associated with feed are able to alter toxicokinetics in European seabass and affect the fish. Microplastic particles (2%) were added to the feed either with sorbed contaminants or as a mixture of clean microplastics and chemical contaminants, and compared to feed containing contaminants without microplastics. For the contaminated microplastic diet, the accumulation of polychlorinated biphenyls (PCBs) and brominated flame retardants (BFRs) in fish was significantly higher, increasing up to 40 days of accumulation and then reversing to values comparable to the other diets at the end of accumulation. The significant gene expression results of liver (cyp1a, il1 beta , gst alpha) after 40 days of exposure indicate that microplastics might indeed exacerbate the toxic effects (liver metabolism, immune system, oxidative stress) of some chemical contaminants sorbed to microplastics. Seabass quickly metabolised BDE99 to BDE47 by debromination, probably mediated by deiodinase enzymes, and unlike other contaminants, this metabolism was unaffected by the presence of microplastics. For the other PCBs and BFRs, the elimination coefficients were significantly lower in fish fed the diet with contaminants sorbed to microplastic compared to the other diets. The results indicate that microplastics affects liver detoxification and lipid distribution, both of which affect the concentration of contaminants.

Grandhi, T. S., et al. (2014). "Aminoglycoside antibiotic-derived anion-exchange microbeads for plasmid DNA binding and in situ DNA capture." Acs Applied Materials & Interfaces **6**(21): 18577-18589.

Plasmid DNA (pDNA) therapeutics are being investigated for gene therapy and DNA vaccines against diseases including cancer, cystic fibrosis and AIDS. In addition, several applications in modern biotechnology require pDNA for transient protein production. Here, we describe the synthesis, characterization, and evaluation of microbeads ("Amikabeads") derived from the aminoglycoside antibiotic amikacin for pDNA binding and in situ DNA capture from mammalian cells. The parental aminoglycoside-derived microbeads (Amikabeads-P) acted as anion-exchange materials, and demonstrated high capacities for binding pDNA. Binding of pDNA was significantly enhanced following quaternization of the amines on the microbeads (Amikabeads-Q). Amikabeads were further employed for the disruption and extraction of DNA from mammalian cells, indicating their utility for in situ DNA capture. Our results indicate that Amikabeads are a novel material, with multiple reactive groups for further conjugation, and can have several applications in plasmid DNA biotechnology.

Gray, A. D. and J. E. Weinstein (2017). "Size- and shape-dependent effects of microplastic particles on adult daggerblade grass shrimp (Palaemonetes pugio)." Environmental Toxicology and Chemistry **36**(11): 3074-3080.

The incidence of microplastics in marine environments has been increasing over the past several decades. The objective of the present study was to characterize the size- and shape-dependent effects of microplastic particles (spheres, fibers, and fragments) on the adult daggerblade grass shrimp (Palaemonetes pugio). Grass shrimp were exposed to 11 sizes of plastic: spheres (30, 35, 59, 75, 83, 116, and 165 mum), fragments (34 and 93 mum), and fibers (34 and 93 mum) at a concentration of 2000 particles/400 mL (= 50 000 particles/L) for 3 h. Following exposure, grass shrimp were monitored for survival, ingested and ventilated microplastics, and residence time. Mortality ranged from 0% to 55%. Spheres and fragments <50 mum were not acutely toxic. Mortality rates in experiments with spheres and fragments >50 mum ranged from 5% to 40%. Mortality was significantly higher in the exposure to 93-mum fibers than other sizes tested (p < 0.001). The shape of the particle had a significant influence on the number of particles ingested by the shrimp (p < 0.001). The residence time of particles in the gut ranged from 27 to 75 h, with an average of 43.0 +/- 13.8 h. Within the gills, the residence time ranged from 27 to 45 h, with an average of 36.9 +/- 5.4 h. The results suggest that microplastic particles of various sizes and shapes can be ingested and ventilated by adult daggerblade grass shrimp, resulting in acute toxicity. Gray, A. D., et al. (2018). "Microplastic in two South Carolina Estuaries: Occurrence, distribution, and composition." Marine Pollution Bulletin **128**: 223-233.

Here we report on the distribution of microplastic contamination in two developed estuaries in the Southeastern United States. Average concentration in intertidal sediments of Charleston Harbor and Winyah Bay, both located in South Carolina, U.S.A., was 413.8+/-76.7 and 221.0+/-25.6particles/m², respectively. Average concentration in the sea surface microlayer of Charleston Harbor and Winyah Bay was 6.6+/-1.3 and 30.8+/-12.1particles/L, respectively. Concentration in intertidal sediments of the two estuaries was not significantly different (p=0.58), however, Winyah Bay contained significantly more microplastics in the sea surface microlayer (p=0.02). While microplastic concentration in these estuaries was comparable to that reported for other estuaries worldwide, Charleston Harbor contained a high abundance of black microplastic fragments believed to be tire wear particles. Our research is the first to survey microplastic contamination in Southeastern U.S. estuaries and to provide insight on the nature and extent of contamination in these habitats.

Gray, M. W., et al. (2015). "Particle processing and gut kinematics of planktotrophic bivalve larvae." Marine Biology **162**(11): 2187-2201.

Although the clearance rates of planktotrophic bivalve larvae have been widely reported, post-oral particle processing is less well understood. Using a series of exposures to differently colored fluorescent polystyrene microbeads, we quantify several post-oral process in the larval gut, including gut fullness, gut passage time, and degree of mixing by modeling larval guts as a continuously stirred tank reactor (CSTR), plug flow reactor (PFR) or combinations of the two in series. We also varied several experimental conditions to understand how these affected estimates of gut kinematic parameters. We found the larval guts of M. galloprovincialis aged 2 and 7 days post-fertilization, had gut exchange time >1h and were best described either as a CSTR or CSTR in series with a PFR. Mixing stomach contents likely aids post-oral particle selection, physical breakdown of ingested material, and accelerates the diffusion of digestive enzymes in the gut volume. Reactor models also provided estimates of ingestion rates, which were compared to those obtained by other authors who measured rates of bead accumulation. In accordance with reactor theory, ingestion rates were negatively and nonlinearly correlated with gut passage times and positively related to maximal gut fullness. Collectively, these studies provide new insight on the digestive strategy of planktotrophic bivalve larvae.

Greco, A., et al. (2014). "Gene expression profiling of IgM monoclonal gammopathy of undetermined significance (IgM-MGUS)." Blood. Conference: 56th Annual Meeting of the American Society of Hematology, ASH **124**(21).

The 2nd IWWM tried to define reproducible criteria for the diagnosis of IgM-MGUS and Waldenstrom's Macroglobulinemia. IgM-MGUS was defined as asymptomatic condition characterized by serum IgM monoclonal protein (MC) without morphologic evidence of bone marrow (BM) lymphoplasmacytic infiltration. The proposal of the guidelines was to classify as MGUS also patients with equivocal evidence of BM infiltration, such as those presenting clonal B-cells by multiparameter flow cytometry (MFC) in the absence of morphologic evidence of BM infiltration, as well as those with equivocal BM infiltrates not confirmed by immunophenotypic studies. Patients The diagnosis of IgM-MGUS was made in 11 patients (6 males, 5 females) according to the consensus panel criteria. The median age at diagnosis was 73 (range, 60-77). Ten patients had K light chains. The median erythrocyte sedimentation rate was 11. The MC level at diagnosis ranged from 0.1 to 1.2 g/dL (median 0.4). Only one patient had MC value > 1.0 g/dL. The median IgM value was 697 mg/dL (range 116-1790). Five of 11 IgM-MGUS patients showed a small clonal B-cell population (light-chain-isotype-positive B-cells) detected by MFC without histologic evidence of BM infiltration. Therefore, patients were divided in 2 groups: group 1 (n=5) showing a clonal B-cell population, and group 2 (n=6) with polyclonal B-cells at MFC. Methods and results We isolated BM CD19+ cells in the 11 IgM-MGUS patients using Miltenyi Microbeads and performed microarray with Affymetrix-HG-U133 Plus 2.0 array. Gene set enrichment analysis (GSEA) was performed and different sets of genes were defined based on REACTOME pathways, KEGG pathways and GO Biological Process Terms. Interestingly, 17 top-ranking gene sets including differently expressed genes, reached a nominal p-value lower than 0.001; 2 gene sets were upregulated (while 15 gene sets were downregulated in monoclonal vs. polyclonal IgM-MGUS (table 1). No genes resulted significantly differentially expressed between group 1 and group 2 using a classic SAM test for microarrays and correcting for multiple testing with a false discovery rate (FDR) threshold of 5%. Similarly, IgM and MC were not differentially expressed between the two groups, although IgM showed a nominal p-value of 0.09 (t-test). However, when using linear regression to explain each gene expression data as a function of both IgM and MC, UBTF, TRIM5, FLJ35816, RDH10 genes were selected based on a FDR equal to 5%, applied to the F-statistic p-value. In particular, the model fitting UBTF had a p-value of 9.461e-07 and an adjusted R-squared of 0.9786; table 2 displays the coefficients of the model and the related p-values, showing a positive co-regulation of UBTF with MC. Conclusions In conclusion, microarray of IgM-MGUS gives insights into gene expression differences in IgM-MGUS. Notably, UBTF is a transcription factor which plays a crucial role in the transcription of rRNA in ERK-pathway, suggesting a possible role of ERK-pathway in IgM-MGUS. Additional gene expression measurements are ongoing in a larger cohort of IgM-MGUS patients. (Table Presented).

Green, B. C. and C. L. E. Johnson (2019). "Characterisation of microplastic contamination in sediment of England's inshore waters." Marine Pollution Bulletin **(no pagination)**(110788).

Plastic litter is an increasingly significant problem in the marine environment. Our study looks at a cost-effective method to quantify larger fractions of microplastics in marine sediments as an opportunistic addition to standard benthic infauna sampling. A subsample of microplastics (>1 mm) were enumerated and categorised from sediment samples collected as part of standard benthic habitat monitoring in twenty-two Marine Protected Areas across English inshore waters. Microplastic particles were found in 61.2% of the samples collected, with mean density per study site ranging from 0.2 in Dover to Deal MCZ to 42.7 in The Mersey Estuary Special Protection Area microplastic particles per 0.1 m². High densities of plastic were found at remote sites, as well as those closer to urban or industrialised areas. Spatial protection measures such as MPAs are not themselves a suitable tool to tackle marine plastic pollution which should be addressed upstream at source. Copyright © 2019

Green, D. S. (2016). "Effects of microplastics on European flat oysters, Ostrea edulis and their associated benthic communities." Environmental Pollution **216**: 95-103.

Plastic pollution is recognised as an emerging threat to aquatic ecosystems, with microplastics now the most abundant type of marine debris. Health effects caused by microplastics have been demonstrated at the species level, but impacts on ecological communities remain unknown. In this study, impacts of microplastics on the health and biological functioning of European flat oysters (Ostrea edulis) and on the structure of associated macrofaunal assemblages were assessed in an outdoor mesocosm experiment using intact sediment cores. Biodegradable and conventional microplastics were added at low (0.8 mug L(-1)) and high (80 mug L(-1)) doses in the water column repeatedly for 60 days. Effects on the oysters were minimal, but benthic assemblage structures differed and species richness and the total number of organisms were ~1.2 and 1.5 times greater in control mesocosms than in those exposed to high doses of microplastics. Notably, abundances of juvenile Littorina sp. (periwinkles) and Idotea balthica (an isopod) were ~2 and 8 times greater in controls than in mesocosms with the high dose of either type of microplastic. In addition, the biomass of Scrobicularia plana (peppery furrow shell clam) was ~1.5 times greater in controls than in mesocosms with the high dose of microplastics. This work indicates that repeated exposure to high concentrations of microplastics could alter assemblages in an important marine habitat by reducing the abundance of benthic fauna.

Green, D. S., et al. (2017). "Microplastics Affect the Ecological Functioning of an Important Biogenic Habitat." Environmental Science & Technology **51**(1): 68-77.

Biological effects of microplastics on the health of bivalves have been demonstrated elsewhere, but ecological impacts on the biodiversity and ecosystem functioning of bivalve-dominated habitats are unknown. Thus, we exposed intact sediment cores containing European flat oysters (Ostrea edulis) or blue mussels (Mytilus edulis) in seawater to two different densities (2.5 or 25

?g L-1) of biodegradable or conventional microplastics in outdoor mesocosms. We hypothesized that filtration rates of the bivalves, inorganic nitrogen cycling, primary productivity of sediment dwelling microphytobenthos, and the structure of invertebrate benthic assemblages would be influenced by microplastics. After 50 days, filtration by M. edulis was significantly less when exposed to 25 ?g L-1 of either type of microplastics, but there were no effects on ecosystem functioning or the associated invertebrate assemblages. Contrastingly, filtration by O. edulis significantly increased when exposed to 2.5 or 25 ?g L-1 of microplastics, and porewater ammonium and biomass of benthic cyanobacteria decreased. Additionally the associated infaunal invertebrate assemblages differed, with significantly less polychaetes and more oligochaetes in treatments exposed to microplastics. These findings highlight the potential of microplastics to impact the functioning and structure of sedimentary habitats and show that such effects may depend on the dominant bivalve present. [ABSTRACT FROM AUTHOR]

Green, D. S., et al. (2016). "Effects of conventional and biodegradable microplastics on a marine ecosystem engineer (Arenicola marina) and sediment nutrient cycling." Environmental Pollution **208**(Part B): 426-434.

Effects of microplastic pollution on benthic organisms and ecosystem services provided by sedimentary habitats are largely unknown. An outdoor mesocosm experiment was done to realistically assess the effects of three different types of microplastic pollution (one biodegradable type; polylactic acid and two conventional types; polyethylene and polyvinylchloride) at increasing concentrations (0.02, 0.2 and 2% of wet sediment weight) on the health and biological activity of lugworms, Arenicola marina (Linnaeus, 1758), and on nitrogen cycling and primary productivity of the sediment they inhabit. After 31 days, A. marina produced less casts in sediments containing microplastics. Metabolic rates of A. marina increased, while microalgal biomass decreased at high concentrations, compared to sediments with low concentrations or without microplastics. Responses were strongest to polyvinylchloride, emphasising that different materials may have differential effects. Each material needs to be carefully evaluated in order to assess their risks as microplastic pollution. Overall, both conventional and biodegradable microplastics in sandy sediments can affect the health and behaviour of lugworms and directly or indirectly reduce primary productivity of these habitats.

Green, D. S., et al. (2019). "Exposure to microplastics reduces attachment strength and alters the haemolymph proteome of blue mussels (Mytilus edulis)." Environmental Pollution **246**: 423-434.

The contamination of marine ecosystems with microplastics, such as the polymer polyethylene, a commonly used component of single-use packaging, is of global concern. Although it has been suggested that biodegradable polymers, such as polylactic acid, may be used to replace some polyethylene packaging, little is known about their effects on marine organisms. Blue mussels, Mytilus edulis, have become a "model organism" for investigating the effects of microplastics in marine ecosystems. We show here that repeated exposure, over a period of 52 days in an outdoor mesocosm setting, of M. edulis to polyethylene microplastics reduced the number of byssal threads produced and the attachment strength (tenacity) by ~50%. Exposure to either type of microplastic altered the haemolymph proteome and, although a conserved response to microplastic exposure was observed, overall polyethylene resulted in more changes to protein abundances than polylactic acid. Many of the proteins affected are involved in vital biological processes, such as immune regulation, detoxification, metabolism and structural development. Our study highlights the utility of mass spectrometry-based proteomics to assess the health of key marine organisms and identifies the potential mechanisms by which microplastics, both conventional and biodegradable, could affect their ability to form and maintain reefs.

Green, D. S., et al. (2018). "A comparison of sampling methods for seawater microplastics and a first report of the microplastic litter in coastal waters of Ascension and Falkland Islands." Marine Pollution Bulletin **137**: 695-701.

To date there is no gold standard for sampling microplastics. Zooplankton sampling methods, such as plankton and Neuston nets, are commonly used to estimate the concentrations of microplastics in seawater, but their ability to detect microplastics is limited by their mesh size. We compared different net-based sampling methods with different mesh sizes including bongo nets (>500mum), manta nets (>300mum) and plankton nets (>200mum and >400mum) to 1litre bottle grabbed, filtered (0.45mum) samples. Concentrations of microplastics estimated using net-based methods were ~3 orders of magnitude less than those estimated by 1litre grab samples. Some parts of the world with low human populations, such as Ascension Island and the Falkland Islands, lack baseline data on microplastics. Using the bottle grab sampling method we found that microplastic litter was present at these remote locations and was comparable to levels of contamination in more populated coastal regions, such as the United Kingdom.

Greene, K. L. and D. J. Tonjes (2014). Degradable Plastics And Their Potential For Affecting Solid Waste Systems. Southampton, W I T Press. **180**.

Plastic waste forms a substantial part of municipal solid waste and has caused environmental concerns, particularly due to the chemical contamination of the environment and effects from persistent litter. Plastics also complicate waste management processes, such as by having poor recovery rates through recycling and causing contamination in composting operations. One potential means of addressing some of these challenges is through degradable plastics, which unlike conventional plastics, are designed to decompose at an accelerated rate in specific environments. Degradable plastics aim to address the end-of-life of plastic products and are intended to reduce the environmental impacts associated with their use and management. The first generation of degradable plastics did not meet marketing claims; some of the more recent formulations, partly as a consequence of third party certifications, are more compliant. However, many plastics that are labelled as degradable do not decompose very readily, and it is not clear that litter will be diminished to any great degree through their use. In addition, user confusion regarding degradable definitions is common. Multiple formulations mean that not all degradable plastics address compost contamination and most degradable plastics do not address other problems associated with plastics waste management. Therefore it is not clear that degradable plastics constitute a major technological advance. In fact, they may be more harmful than helpful to waste management systems at this time. Here we discuss how these materials perform in different aspects of solid waste programs: recycling, composting, WTE incineration and landfills, as well as the potential for these plastics to reduce litter problems, both on land and at sea.

Gregory, M. R. (1991). "The hazards of persistent marine pollution: Drift plastics and conservation islands." Journal of the Royal Society of New Zealand **21**(2): 83-100.

Plastic litter and debris of all kinds is conspicuous on many contemporary shorelines, most frequently near populated and industrial centres, but also on remote and seldom-visited or uninhabited islands, including Raoul, Campbell and Auckland Islands. Pollution by plastics is aesthetically distasteful and unnecessary, and also creates a number of environmental problems: e.g. death and/or debilitation of wildlife through entanglement; blockages to the intestinal tract through ingestion leading to starvation and death, or ulceration of delicate tissues by jagged fragments; reduction in quality of life and reproductive performance. Larger items may also hazard shipping. An encrusting pseudoplanktic biota, similar to that found on floating Sargassum and other seaweeds has been recognised on drift plastics. Alien species, rafted on drifting plastic, could endanger the flora and fauna of protected and conservation island ecosystems. The sources of plastic pollution can be both distant (the truly 'oceanic' debris which has drifted from afar) and regional and local (e.g. shipping, fishing and recreational boating activities). Data compiled during a recent clean-up campaign on beaches of the inner Hauraki Gulf islands suggest that nearby land-based sources are also important. There is need to educate the public about the environmental problems arising from the indiscriminate disposal of plastics and other persistent synthetic compounds. It is unlikely that these problems can ever be solved by regulation, although, along with technological advances, that could alleviate them.

Gregory, M. R. (1999). "Plastics and South Pacific Island Shores: Environmental Implications." Ocean & Coastal Management **42**(6): 603.

Findings from recent studies on many of the islands of the South Pacific have indicated that waste plastics are a major pollutant of shorelines, and nearby coastal and oceanic waters. Several different environmental impacts from this type of waste plastic pollution are described, including death and debilitation of wildlife associated with entanglement or ingestion of plastic materials, reductions in reproductive performance, and hazards to shipping. In addition, waste plastics may serve as a vector for the introduction of alien taxa. Aesthetic impacts of these types of waste materials are also described. Most of these problematic plastic wastes are derived from the indiscriminate disposal of wastes by vessels at sea. Potential urban sources of these highly problematic wastes are also identified.

Greiner, A. D. and M. B. Timmons (1998). "Evaluation of the nitrification rates of microbead and trickling filters in an intensive recirculating tilapia production facility." Aquacultural Engineering **18**(3): 189-200.

Downflow floating polystyrene bead (micro-bead) and trickling media biofilters were tested simultaneously using common influent water from a 53 msuperscript 3 fish rearing tank stocked with tilapia (Oreochromis Nilotica x Aurea) at a density of 168 kg/msuperscript 3. The physical characteristics of the 2 bio-filter media used were: 1.0 mm diameter polystyrene spheres with a density of 16 kg/msuperscript 3 and specific surface area 3936 msuperscript 2/msuperscript 3 (referred to as micro-beads); and 5.1 cm diameter polyethylene packing material (Norpak) with specific surface area 164 msuperscript 2/msuperscript 3. Nitrification rates increased linearly with influent total ammonia nitrogen (TAN) concentrations up to a concentration of 2.5 mg/litre for both the micro-bead and trickling filters. There was no further increase in nitrification rate above 2.5 mg/litre that was statistically significant. The trickling filter had a specific nitrification rate 7.5 times higher than the micro-bead filter, although volumetric nitrification rates were 3.2 times greater for the micro-beads than the trickling filter. The study failed to show any relationship for either type of filter between the hydraulic loading rate and the nitrification rate at hydraulic loading rates between 469 and 1231 msuperscript 3/msuperscript 2 per day.

Greiner, J., et al. (2011). "The mutated region of cytoplasmatic nucleophosmine 1 (NPM1) elicits both CD4+ and CD8+ T cell responses." Blood. Conference: 53rd Annual Meeting of the American Society of

Hematology, ASH **118**(21).
Introduction: In AML, mutations in the nucleophosmin (NPM1) gene are one of the most frequent molecular alterations and predominantly occur in AML with normal cytogenetics. Patients with NPM1 mutation without FLT3-ITD mutation show a favourable prognosis of their disease. The functional role of mutated NPM1 for the improved clinical outcome is under evaluation. Immune responses might be involved in the clinical outcome of the disease. In this work, we demonstrate both CD4+ and CD8+ T cell responses against the mutated region of NPM1. Method(s): The entire amino acid sequences of the NPM1 wild type protein as well as of the mutated cytoplasmic NPM1 types A, B, C and D were screened for HLA-A*0201 binding T cell epitopes using the algorithms of the SYFPEITHI, the Rankpep and the HLA-Bind software programs. Ten peptides with most favourable characteristics were subjected to ELISpot analysis for interferon-gamma and granzyme B in 22 healthy volunteers and 27 AML patients to test specific T cell responses of CD8+ T cells. Tetramer assays against the two most interesting epitopes have been performed and chromium release assays have been used to show the cytotoxicity of peptide-specific T cells to lyse T2 cells and leukemic blasts. Moreover, HLA-DR binding epitopes were screened in algorithmic analysis and HLA-DR*0701 binding peptides were exploited to stimulate CD4+ T cells. In the presence of overlapping peptide stimulated CD4+ T cells, NPM1-A specific CD8+ T cells revealed augmented interferon-gamma and granzyme B secretion and up-regulation of intracellular interferon-gamma. CD4+, CD4-CD8+, CD4-CD8- cell fractions were separated from PBMCs of HLA-A2+DR*0701+ healthy volunteers using a combination of CD4 and CD8 MicroBeads. Result(s): Two epitopes (P3 and P9) derived from the NPM1-mutated protein showed specific T cell responses in healthy volunteers and AML patients. In NPM1-mutated AML patients 33% showed immune responses of CD8+ T cells against peptide P3 and 42% against peptide P9. Specific lysis was detected in chromium release assays NPM1 peptide-primed effector T cells generated from NPM1-mutated AML patients. Tetramer assays showed peptide-specific T cells. To obtain a robust and effective immune response against tumor cells, the activation of CD4 + helper T cells is crucial. Thus NPM1-peptide-A overlapping MHC class II epitopes were searched by primary structure analysis program. Based on plenary search, eight favourable overlapping peptides OL 1-8 were synthesized and exploited for CD4+ T cell stimulation. In granzyme B ELISPOT assay, OL8 co-pulsed NPM1-A CD8+ T cells indicated notable S.I., in contrast other OL1-7 disabled to increase granzyme B secretion. To ensure that Th1 cytokine secretion, under the condition of CD8+ and CD4+ T cells mixed culture, was resulted from NPM1-A CD8+ T cells but not HLA-DR epitope stimulated CD4+ T cells activation, HLA-A2 blocking effect was confirmed in ELISPOT assay. NPM1-A CD8+ T cells co-pulsed with OL6, 7 and 8 showed lesser interferon-gamma secretion after HLA-A2 blocking antibody exposure as 73, 35 and 57%. Of note, 83-94% of granzyme B secretion levels were reduced by HLA-A2 blockade administration, and by which NPM1-A CD8+ T cells seemed to be the most probable IFN-gamma and granzyme B producers and CD4+ T cells to interfere with CD8+ T cells. Conclusion(s): Taken together, mutated NPM1 is a promising target structure for specific immunotherapies in AML patients.

Grencikova, A., et al. (2018). "Microplastics as contaminants - scope, fate, and environmental impacts." Interdisciplinary Toxicology **11 (1)**: 72.
Microplastics represent emerging pollutants of global importance. They are small enough to be ingested by a wide range of organisms and at nano-scale, they may cross some biological barriers. As well as microplastics, chemical additives added to plastics during manufacture which may leach out upon ingestion, can enter food chains and potentially cause humans serious health problems. In this article, we discuss the sources of plastic microparticles, summarize

known informations about their behaviour at wastewater treatment plants and potential impacts of microplastics in the environment.

Grenvall, C., et al. (2015). "Concurrent Isolation of Lymphocytes and Granulocytes Using Prefocused Free Flow Acoustophoresis." Analytical Chemistry **87**(11): 5596.

Microchip-based free flow acoustophoresis (FFA) in combination with two-dimensional cell prefocusing enables concurrent multiple target outlet fractionation of leukocytes into subpopulations (lymphocytes, monocytes, and granulocytes); we report on this method here. We also observed significantly increased accuracy in size-based fractionation of microbeads as compared to previously presented FFA multiple outlet systems. Fluorescence microscopy illustrates the importance of two-dimensional prefocusing where a sample mixture of 3, 7, and 10 μ beads are separated into well-confined particle streams and collected in their respective target outlets. Flow cytometry data for lymphocytes and granulocytes, respectively, in their corresponding outlets verify concurrent isolation of leukocyte subpopulations with high purity (95.2 ± 0.6% and 98.5 ± 0.7%) and high recovery (86.5 ± 10.9% and 68.4 ± 10.6%). A relatively low purity and high recovery of monocytes (25.2% ± 5.4% and 83.1 ± 4.3%) was obtained in the third target outlet. No subpopulation bias was observed. These data demonstrate an unprecedented separation of leukocyte subpopulations at flow rates of ~100 μL/min and ~1 M cells/mL sample concentrations, not previously reported in acoustofluidic systems. Two-dimensional prefocusing FFA with multiple target outlets is a viable alternative to current methods for particle fractionation and cell isolation, requiring a minimum of sample preparation and lowering analysis time and cost.

Grenzi, P. C., et al. (2012). "Post-transplant anti-mica antibodies and kidney graft outcome." Transplantation **10S)**: 1159.

The aim of the study was to investigate the association between the presence of post-transplant MICA antibodies (Ab) and graft loss due to chronic allograft nephropathy (CAN). The study was conducted in a cohort of 511 first kidney graft (TX) recipients (R) transplanted in our center and with a functional graft for at least three years at the time of inclusion in the study. Two hundred Tx were with deceased donors, and 311 were with living donors. Two serum samples were collected for determination of the presence of MICA Ab: the first was collected at the beginning of the study and the second one was collected at least three years thereafter (second serum samples were collected from 362 of the 381 patients surviving with the graft). MICA Ab were determined by Luminex microbeads technology using the kit LABScreen Mixed (One Lambda). Some samples (248/511) were tested in parallel with the kit Lifecodes Single Antigen - LSATM-MIC (Gen-Probe). Curves of graft loss due to chronic allograft nephropathy (CAN) were calculated with the Kaplan-Meier method and compared with the log-rank test. Result(s): MICA Ab were detected in 10.5% and 11.3% of the first and the second serum samples, respectively. Only 8% of the R changed Ab status between the two samples collected with a minimum interval of three years: 4.4% turned positive and 3.6% turned negative. The comparison of the results obtained with the 246 sera tested with both commercial kits showed concordance in 77.2% of the sera; 2.8% and 19.9% of the sera were positive only when tested with the One Lambda and the Gen-Probe kits, respectively. Minimum follow-up of the recipients after the first Ab determination was 6.13 years. The presence of MICA antibodies was not associated with CAN-associated graft loss, considering the results obtained with any of the kits utilized for detection of MICA Ab, and also considering separately transplants of kidneys from living anddeceased donors. In conclusion, this study does not provide evidence for a relationship between the presence of post-transplant MICA antibody and graft loss due to CAN. It remains to

be tested whether different results would be obtained considering only donor specific anti-MICA antibodies.

Greve, G., et al. (2017). "Preferential in vitro and in vivo induction of endogenous retrovirus transcription from A monoallelic chromosome 7Q in Decitabine (DAC) Treated AML Blasts." Blood. Conference: 59th Annual Meeting of the American Society of Hematology, ASH **130**(Supplement 1).

Background: Hypomethylating agents (HMAs) show an encouraging but not yet well-understood activity in AML/MDS patients (pts) with adverse cytogenetics, such as-7/7q-, often embedded in A complex, monosomal karyotype (Lubbert et al., Haematologica 2012). Integrative methylome/transcriptome studies have provided evidence for aberrant hypermethylation/silencing on monoallelic gene loci, including tumor suppressor genes (TSGs, Kotini et al., Nat. Biotechnol. 2015). Recently, an alternative mechanism of HMA action was described (Roulois et al., Chiappinelli et. al, Cell 2015): induction of silenced endogenous retroviral (ERV) dsRNA transcription, resulting in activation of an interferon-mediated, antitumor immune response (", viral mimicry",). To unravel in vivo HMA activity in different (cyto)genetic backgrounds, we hypothesized that in AML haploinsufficient for 7q, transcriptional repression of monoallelic genes in this region may be preferentially reversed by HMA treatment. Material(s) and Method(s): For identification of genes induced by HMAs, two AML cell lines were selected, ELF-153 (ELF) and UCSD-AML1 (AML1): copy number variations were analyzed by Genome-Wide Human SNP Array 6.0 (Affymetrix), and revealed no monosomies but loss of 7p, in AML1 loss of one entire chromosome 7 was the only numerical aberration. Cells were treated with DAC at equitoxic and-effective concentrations for 4 days, harvested on day 5. Total RNA was depleted of ribosomal RNA (Ribo-Zero rRNA Removal Kit, Illumina) and cDNA libraries (strand-specific, 50 bp) were sequenced with >=, 33 million paired-end reads, read quality checked with FastQC (>=, 95% > Q30). Alignment to the reference genome hg19 was performed with TopHat2, read-counting with HTseq, differential expression testing with DESeq2 (protein-coding transcripts only). Selected target genes were validated by RT-qPCR. Peripheral blood mononuclear cells (PBMC) were collected from 9 AML pts (5 pts with 7q-, 4 cytogenetically normal [CN] pts) treated with DAC (i.v. 20 mg/m² for 5 days) within the DECIDER trial (NCT00867672). Leukemic blasts before treatment and at day 8 were isolated using automatic magnetic sorting of cells labeled with anti-human CD34 and CD117 MACS microbeads. Result(s): DAC treatment of AML1 and ELF cells resulted in massive transcriptome changes in both cell lines, with 1,704 genes induced in AML1 (total of 3,583) and 1,206 in ELF (total of 1,867, adjusted FDR < 0.01). Comparing DAC-induced expression changes only of genes on 7q, we identified 43 genes significantly differentially expressed only in AML1 cells (up: 15), 24 only in ELF (up: 21), and 19 in both (up: 12). The 15 genes on 7 q that were selectively upregulated in AML1 included 3 with TSG features: zyxin (ZYX, up 6.0-fold) homeodomain interacting protein kinase 2 (HIPK2, up 3.8fold), and high mobility group box transcription factor 1 (HBP1, up 3.1-fold). However, the most heavily upregulated transcripts in AML1 were the endogenous retrovirus 3 group member 1 (ERV3-1, up 86.4-fold in AML1 vs 14.3-fold in ELF) and the neighboring zinc finger 117 (ZNF117, up 119.4-fold in AML1vs. 6.5-fold in ELF), both transcribed from the ERV3-1 promoter. ERV3-1 induction was accompanied by induction of the interferon type I response genes retinoic acid inducible gene I (RIG-I) and interferon regulatory factor 7 (IRF7) in both cell lines. Therefore, we next interrogated induction of these genes by DAC in vivo, utilizing serially sorted, matched primary AML blasts (purified before and 3 days after DAC administration). Stronger induction of ERV3-1 and RIG-I mRNA was seen in the 7q-pts compared to the CN pts: By qRT-PCR, median ERV3-1 and RIG-I expression was induced 1.5-and 1.4-fold, respectively, in the pts with 7q-(range: 1.1-2.1 and 1.0-3.2), 1.1-and 0.7-fold,

respectively, in the CN pts (range: 0.8-1.7 and 0.3-0.9). Conclusion(s): We successfully developed an unbiased RNA-seq approach of AML cell lines either mono-or bi-allelic for 7q, demonstrating that DAC treatment preferential upregulates several monoallelic TSGs, and massively activates the ERV3-1 gene (implicated in ", viral mimicry",). Induction of ERV3-1 and the dsRNA sensor RIG-I was validated in vivo, and preferentially seen in 7q-AML purified primary blasts. Thus, under clinically established treatment conditions, both the ERV and an interferon response gene can be activated by DAC, supporting A combination with immunotherapy.

Greven, A. C., et al. (2016). "Polycarbonate and polystyrene nanoplastic particles act as stressors to the innate immune system of fathead minnow (Pimephales promelas)." Environmental Toxicology and Chemistry **35**(12): 3093-3100.

Water pollution with large-scale and small-scale plastic litter is an area of growing concern. Macro-plastic litter is a well-known threat to aquatic wildlife; however, the effects of micro-sized and nano-sized plastic particles on the health of organisms are not well understood. Small-scale plastic particles can easily be ingested by various aquatic organisms and potentially interfere with their immune system; therefore, the authors used a freshwater fish species as a model organism for nanoplastic exposure. Characterization of polystyrene (41.0 nm) and polycarbonate (158.7 nm) nanoplastic particles (PSNPs and PCNPs, respectively) in plasma was performed, and the effects of PSNPs and PCNPs on the innate immune system of fathead minnow were investigated. In vitro effects of PSNPs and PCNPs on neutrophil function were determined using a battery of neutrophil function assays. Exposure of neutrophils to PSNPs or PCNPs caused significant increases in degranulation of primary granules and neutrophil extracellular trap release compared to a nontreated control, whereas oxidative burst was less affected. The present study outlines the stress response of the cellular component of fish innate immune system to polystyrene and polycarbonate nanoparticles/aggregates and indicates their potential to interfere with disease resistance in fish populations.

Grewe, P. H., et al. (2000). "Coronary morphologic findings after stent implantation." American Journal of Cardiology **85**(5): 554-558.

Clinical studies demonstrated a reduction of acute complications by high-pressure stenting. This study was performed to correlate the histomorphologic changes of the vessel wall after coronary stenting with stent expansion pressure. We studied the effects of intravital and postmortem stenting on coronary morphology in human hearts. Artifact-free analysis and morphometry of the artery segments' cross section was performed after plastic resin embedding and cutting and grinding sectioning. By comparing intra- and postmortem findings we demonstrated that postmortem stent implantation can serve as an adequate model to study the mechanical effects of coronary stenting. A consistent histologic feature was eccentric stent expansion. Larger calcified areas of the vessel wall were not deformed by implanted stents. The highest degree of vessel injury and deformation was apparent in anatomically "nondiseased" or only slightly fibrotic parts of the arterial wall. Dissections were predominantly located directly adjacent to calcified plaques and appeared as "half-moon"-like tears reaching into the arterial media. A statistically significant stent lumen gain was found when the implantation pressure was increased up to 15 atm. Stent symmetry was not influenced by the applied implantation pressure but depended mostly on local coronary morphology. Thus, increasing implantation pressures during coronary stenting seemed to improve the stenting result up to 15 atm. When applying histomorphologic criteria, the higher pressures (>15 atm) did not cause further optimization of stent expansion. Morphometric analysis of stents implanted postmortemly and intravitally revealed comparable results. Postmortem stenting seems to be an appropriate model for studying stent expansion and stenting results in human coronary arteries.

Griffioen, M., et al. (2006). "Detection and functional analysis of CD8+ T cells specific for PRAME: a target for T-cell therapy." Clinical Cancer Research **12**(10): 3130-3136.

PURPOSE: Preferentially expressed antigen on melanomas (PRAME) is an interesting antigen for T-cell therapy because it is frequently expressed in melanomas (95%) and other tumor types. Moreover, due to its role in oncogenic transformation, PRAME-negative tumor cells are not expected to easily arise and escape from T-cell immunity. The purpose of this study is to investigate the usefulness of PRAME as target for anticancer T-cell therapies.

EXPERIMENTAL DESIGN: HLA-A*0201-subtyped healthy individuals and advanced melanoma patients were screened for CD8+ T cells directed against previously identified HLA-A*0201-binding PRAME peptides by IFN-gamma enzyme-linked immunosorbent spot assays and tetramer staining. PRAME-specific T-cell clones were isolated and tested for recognition of melanoma and acute lymphoid leukemia (ALL) cell lines. PRAME mRNA expression was determined by quantitative real-time reverse transcription-PCR.

RESULTS: In 30% to 40% of healthy individuals and patients, PRA(100-108)-specific CD8+ T cells were detected both after in vitro stimulation and directly ex vivo after isolation by magnetic microbeads. Although CD45RA- memory PRA(100-108)-specific T cells were found in some individuals, the majority of PRA(100-108)-tetramer+ T cells expressed CD45RA, suggesting a naive phenotype. PRA(100-108)-tetramer+ T-cell clones were shown to recognize and lyse HLA-A*0201+ and PRAME+ melanoma but not ALL cell lines. Quantitative real-time reverse transcription-PCR showed significantly lower PRAME mRNA levels in ALL than in melanoma cell lines, suggesting that PRAME expression in ALL is below the recognition threshold of our PRA(100-108)-tetramer+ T cells.

CONCLUSION: These data support the usefulness of PRAME and in particular the PRA(100-108) epitope as target for T-cell therapy of PRAME-overexpressing cancers.

Grigorakis, S. and K. G. Drouillard (2018). "Effect of Microplastic Amendment to Food on Diet Assimilation Efficiencies of PCBs by Fish." Environmental Science & Technology **52**(18): 10796.

Diet assimilation efficiencies (AEs) of polychlorinated biphenyls (PCBs) absorbed to microplastics and food were determined in goldfish (Carassius auratus). Microplastics were spiked with 14 environmentally rare PCBs and incorporated into fish pellets previously spiked with a technical PCB mixture (Aroclor 1254). Five diet treatments were created having microplastic contents of 0, 5, 10, 15, 20, and 25% and fed to fish within 24 h of the diet creation. Fish from each treatment were fed a microplastic amended food pellet and PCB AEs were determined by mass balance. Microplastic-associated PCBs had lower AEs (geomean 13.36%) compared to food matrix-associated PCBs (geomean 51.64%). There were interactions between PCB AEs and the microplastic content of the diet. PCBs affiliated with microplastics became more bioavailable with increasing microplastic content of food while food matrix-associated PCB bioavailability declined when microplastic contents exceeded 5%. Despite controlling for microplastic-food contact time, there was some evidence for redistribution of lower KOW food matrix-associated PCBs onto microplastics causing a decrease in their AE relative to nonplastic and low plastic containing diets. The low bioavailability of microplastic-associated PCBs observed in the present study provides further support to indicate that microplastics are unlikely to increase POPs bioaccumulation by fish in aquatic systems.

Grigorakis, S., et al. (2017). "Determination of the gut retention of plastic microbeads and microfibers in goldfish (Carassius auratus)." Chemosphere **169**: 233-238.

Microplastics are ubiquitous pollutants in aquatic habitats and commonly found in the gut contents of fish yet relatively little is known about the retention of these particles by fish. In this study, goldfish were fed a commercial fish food pellet amended with 50 particles of one of two microplastics types, microbeads and microfibers. Microbeads were obtained from a commercial facial cleanser while microfibers were obtained from washed synthetic textile. Following consumption of the amended pellet, fish were allowed to feed to satiation on non-amended food followed by fasting for periods ranging from 1.5 h to 6 days. Fish sacrificed at different time points were dissected to remove gut contents and the digesta contents retention and microplastic retention was determined. Although a small number of microplastic particles were retained in fish GI-tracts after 6 days (0-3 particles/50), the retention of microplastics was generally similar to the retention of bulk digesta contents. According to a breakpoint regression model fitted to digesta contents and microplastic particles, the 50% and 90% evacuation times were 10 h and 33.4 h, respectively. The results of this study indicate that neither microbeads nor microfibers are likely to accumulate within the gut contents of fish over successive meals.

Grissom, P., et al. (2013). "Microtubule-binding peptides from the long, kinetochore-associated protein, CENP-F." Molecular Biology of the Cell. Conference: Annual Meeting of the American Society for Cell Biology, ASCB **24**(24).

We have identified CENP-F as a kinetochore protein that binds better to curling oligomers of tubulin, e.g., those at the ends of kinetochore-associated microtubules (MTs), than to tubulin in the straight protofilaments characteristic of a taxol-stabilized MT. C-DNAs that encode parts of CENP-F have been expressed in bacteria and the resulting polypeptides examined for tubulin curl- and MT-binding properties. N-terminal segments of CENP-F bind better to curls than MTs, while the C-terminal region of the protein prefers MTs. Sucrose gradient sedimentation and gel filtration chromatography of a 68 kDa polypeptide from CENP-F's N-terminus (N3) indicate that this "protein" is an elongate dimer in solution and that it does not bind soluble tubulin. Electron microscopy of N3 shows a flexible rod, 45.1 +/- 4.8 nm long, which is shorter than the summed lengths of the 3 segments in N3 that are predicted by amino acid sequence to be alpha-helical coiled coils; apparently this protein is folded. Pull-downs of N3 by different amounts of tubulin in either MTs or curls suggest saturable binding with dissociation constants of 155 and 94 nM, respectively. Electron microscopy of N3 interacting with rings of tubulin induced by Dolostatin 10 have not revealed an obvious binding site, but cross-linking studies, using disuccinamidyl suberate (DSS), indicate that N3 binds tubulin on a surface that would be masked by adjacent protofilaments in a MT wall but exposed on a curling protofilament. Both N3 and a ~60 kDa fragment from CENP-F's Cterminus (C10s) will follow the ends of depolymerizing MTs in vitro. Microbeads coated with C10s show processive movement and do not affect the rate of MT shortening compared with control MTs depolymerizing in the absence of added proteins; beads coated with N3 accelerate MT shortening, suggesting that they roll and may gather up tubulin protofilaments as they peel back from the MT wall. The implications of these findings for the role(s) CENP-F may play in mitosis will be discussed.

Gross, M. (2015). "Oceans of plastic waste." Current Biology **25**(3): 93-96.

Plastic waste accumulates in the oceans and eventually breaks down to small particles known as microplastics. These can be taken up by hundreds of different species, but research is only beginning to explore their effects on organisms and their fate in the food web.

Gross, S. J., et al. (2011). "Rapid and novel prenatal molecular assay for detecting aneuploidies and microdeletion syndromes." Prenatal Diagnosis **31**(3): 259-266.

OBJECTIVES: To develop a targeted aneuploidy and microdeletion detection platform for use in the prenatal setting, to assess the integrity of the platform with a robust validation system, and to prospectively determine the performance of the platform under routine clinical conditions.

METHODS: To generate proxies for the various disorders assessed by the assay for analytical validation purposes, cells from ten microdeletion syndromes as well as from common aneuploidies were spiked into cleared amniotic fluid. Genomic DNA was isolated, labeled, and hybridized to microbeads that have been coupled to DNA derived from Bacterial Artificial Chromosome (BAC) from the relevant regions targeted by the array. Beads were read using a flow cytometric multiplex bead array detection system. In the prospective part of the study, 104 amniotic fluid samples were collected and analyzed.

RESULTS: All microdeletion syndromes and aneuploidies were validated in a blinded fashion. In the prospective study, the total number of readable samples was 101 of 104 (97%). All sample results were confirmed independently.

CONCLUSION: The bead array approach is a rapid and reliable test for detecting aneuploidies and microdeletions. This assay has the potential to provide the benefit of expanded molecular cytogenetic testing to pregnant women undergoing invasive prenatal diagnosis. This approach may be especially useful in parts of the world where cytogenetic personnel and facilities may be limited.

Grossmann, K., et al. (2014). "Simple detection of celiac-disease specific antibodies and total IgA in one reaction environment." Clinical Chemistry and Laboratory Medicine **52 (11)**: eA140.

The novel CytoBead CeliAK assay allows the simultaneous analysis of endomysial IgA-antibodies (EmA), anti-tissue transglutaminase enzyme (tTG)-and anti-deamidated gliadin peptide (DGP) IgA-antibodies as well as the determination of total IgA in one well. The assay runs on glass slides with tripartite wells, left: two different microbeads (MP) coated with tTG or DGP, middle: monkey esophagus, and right: MP coated with anti-IgA. The assay was assessed visually and by AKLIDES. Overall, sera of 377 patients and controls (155 celiac disease (CD), 5 IgA-deficient, 127 with other diseases, 90 blood donors) were run. Each CD patient was positive for at least one of anti-tTG, anti-DGP or EmA resulting in diagnostic sensitivity of 100%. All IgA-deficient patients were IgA negative. Diagnostic specificity for anti-tTG, anti-DGP, and EmA was 100%, 93.3%, and 100%, respectively. By automated evaluation, the diagnostic sensitivity for anti-tTG and anti-DGP was 97.4% and 88.3%, respectively and the diagnostic specificity within the blood donor group 100% and 97.8%, respectively. Routine anti-tTG ELISA and anti-DGP ELISA showed a diagnostic sensitivity of 99.4% and 77.9%, respectively, whereas the diagnostic specificity using the blood donor group was 97.7% and 95.5%, respectively. Thus, the novel assay provides the unique opportunity to detect CD-specific antibodies and exclude IgA-deficiency simultaneously and shows excellent diagnostic sensitivity and specificity.

Grossmann, K., et al. (2014). "A novel cytobead immunoassay for simultaneous detection of celiac-disease specific antibodies and total IgA." Clinical Chemistry and Laboratory Medicine **1)**: S283.

BACKGROUND: The novel CytoBead CeliAK assay allows the simultaneous analysis of endomysial IgA-antibodies (EmA), anti-tissue transglutaminase enzyme (tTG)-and anti-deamidated gliadin peptide (DGP) IgA-antibodies as well as the determination of total IgA in one reaction environment. METHOD(S): The assay runs on glass slides with tripartite wells, left: two different microbead populations (MP) coated with tTG or DGP, middle: monkey esophagus, and right: MP coated with anti-IgA. The assay was interpreted visually by conventional fluorescence microscope and by the digital imaging platform AKLIDES. Overall, sera of 377 patients and controls (155 celiac disease (CD) patients, 5 IgA-deficient patients, 127 patients with other

diseases, 90 blood donors) were run. RESULT(S): By visual evaluation, positivity of anti-tTG, anti-DGP, EmA, and total IgA in the CD patient group was 99.4%, 91%, 98%, and 100%, respectively. Altogether, each CD patient serum exhibited at least one positive result for anti-tTG, anti-DGP or EmA resulting in diagnostic sensitivity of 100%. All IgA-deficient patients were classified correctly as IgA negative. The diagnostic specificity using blood donors as control group for anti-tTG, anti-DGP, and EmA was 100%, 93.3%, and 100%, respectively. By automated evaluation with AKLIDES, the diagnostic sensitivity for anti-tTG and anti-DGP was 97.4% and 88.3%, respectively and the diagnostic specificity within the blood donor group 100% and 97.8%, respectively. Routine anti-tTG ELISA and anti-DGP ELISA showed a diagnostic sensitivity of 99.4% and 77.9%, respectively, whereas the diagnostic specificity using the blood donor group was 97.7% and 95.5%, respectively. CONCLUSION(S): Thus, the novel assay provides the unique opportunity to detect CD-specific antibodies and exclude IgA-deficiency simultaneously and shows excellent diagnostic sensitivity and specificity.

Grossmann, K., et al. (2011). "Multiplex assessment of non-organ-specific autoantibodies with a novel microbead-based immunoassay." Cytometry Part A: The Journal of the International Society for Analytical Cytology **79**(2): 118-125.

Advances in immunofluorescence assay development paved the way for the simultaneous detection of several antibodies in one sample, for the serological diagnosis of systemic rheumatic diseases. Standardized automated screening of such antibodies can be achieved by HEp-2 cell-based indirect immunofluorescence (IIF) using a multicolor fluorescence imaging technical platform. To create a common platform for both screening and specific antibody assessment, multiplex measurement of antibodies using fluorescence-coded immobilized microbeads was employed on the same platform. The multicolor fluorescence detection system VideoScan (AKLIDES) was used for the fluorescence analysis of a multiplex microbead-based immunoassay (MIA). First, immunoglobulin G (IgG) was covalently coupled to one microbead population in duplicate and in three independent experiments. The coupled IgG was detected by a CyTM5-conjugated secondary antibody. Thus, intra- and interassay coefficients of variation (CV) were obtained. Second, a multiplex determination of antinuclear autoantibodies (ANA) to Scl-70, Sm, dsDNA, SS-A (Ro60), CENP-B, and La/SS-B by solid-phase MIA was investigated, using 72 sera from patients with autoimmune diseases such as systemic lupus erythematosus and systemic sclerosis (SS). The reproducibility study revealed intra-assay CVs ranging from 3.2% to 9.9%, and interassay CVs ranging from 9.6% to 14.7%. The detection of Scl-70-, Sm-, CENP-B-, and La/SS-B-ANA with MIA showed very good agreement with the ELISA results (kappa = 1.0). The resulting relative sensitivities and specificities for Scl-70-, Sm-, CENP-B-, dsDNA-, and La/SS-B-ANA were 100%, respectively, with the exception of dsDNA (specificity 97%). Multiplex detection by immobilized fluorescence-coded microbeads using multicolor fluorescence is a reliable method for the assessment of rheumatic-disease-specific antibodies. Multicolor fluorescence analyses with pattern detection algorithms provide a common platform technique for both the screening of ANA by cell-based IIF and specific antibody assessment by multiplex detection.

Gruber, H. E., et al. (1997). "Human intervertebral disc cells from the annulus: three-dimensional culture in agarose or alginate and responsiveness to TGF-beta1." Experimental Cell Research **235**(1): 13-21.

Cell culture procedures were developed for use with surgical and normal control specimens of the annulus of the human intervertebral disc. Cells were established in monolayer explant culture and seeded into three-dimensional growth environments of alginate or agarose; under these growth conditions cells assumed a rounded phenotype and formed colonies. A novel

method of layering suspensions of cells onto cell well inserts proved technically much easier than the microbead culture method. Immunohistochemistry was utilized to demonstrate in vitro production of the following extracellular matrix components: types I, II, III, and VI collagen, 4-S-chondroitin sulfate, and keratan sulfate. Young and old age- and gender-matched cells grown in the presence of TGF-beta1 showed significant enhancement of proliferation after 4 days of exposure to TGF-beta with a lessened mitogenic response present after 10 days. Molecular studies of proteoglycan gene expression showed that at 4 days young normal cells had increased biglycan, but not decorin, message levels. Decorin expression was unchanged at Day 4 and decreased or shut off by Day 10.

Grundy, S., et al. (2012). "Microarray analysis of COPD pulmonary CD8 cells." American Journal of Respiratory and Critical Care Medicine. Conference: American Thoracic Society International Conference, ATS **185**(MeetingAbstracts).

Rationale CD8 cells numbers are increased in the lungs of patients with Chronic Obstructive Pulmonary Disease (COPD). Relatively little is understood about the function of these cells. It is hypothesised that there is an autoimmune component to COPD. In other autoimmune diseases down regulation of the T cell receptor (TCR) has been documented leading to T cell dysfunction. Our aim was to study the gene expression profile of TCR and associated signalling genes within CD8 cells in COPD. Methods Pulmonary CD8 cells were isolated from explanted lung distal from tumour of patients with COPD and control smokers with normal lung function undergoing surgery for lung cancer. CD8 cells were positively selected from enriched lymphocytes using magnetic microbeads (Miltenyi) and RNA extracted. Paired circulating CD8 cells were isolated from COPD PBMCs using magnetic microbeads . RNA from circulating and pulmonary CD8 cells was analysed using affymetrix human genome u133 plus 2.0 array. The regulation of the components of the TCR and its downstream signalling molecules were studied in circulating and pulmonary CD8 cells in COPD and pulmonary CD8 cells in controls. Results CD8 cells were obtained from 6 patients with COPD (Mean FEV<inf>1</inf> 57% predicted) and 6 smokers (Mean FEV<inf>1</inf> 89% predicted). The purity of pulmonary CD8s was >89% and circulating CD8s cells >93%. Principal Component Analysis revealed no differences between COPD and control pulmonary CD8 cells. There were significant differences between pulmonary and circulating CD8 cells in COPD. Taking a cut off of fold change >1.5 and q value <0.05, 6 TCR component genes were down-regulated in pulmonary CD8 cells compared to circulating CD8 cells in COPD (Table 1). Furthermore, 6 downstream signalling molecules were differentially regulated between pulmonary and circulating CD8 cells. The important effector cytokines interleukin-2 and interferon-gamma were significantly up-regulated in pulmonary CD8 cells. Conclusions The lack of difference between disease and control pulmonary CD8s suggests that the development of COPD does not alter the pulmonary CD8 phenotype in smokers. However, this study may be underpowered to detect such disease specific differences. There were differences between circulating and pulmonary CD8 cells, indicating that smokers have a specific phenotype of CD8 cells within the lungs; There is down-regulation of TCR in pulmonary CD8 cells. This has been associated with T cell dysfunction in other autoimmune diseases. The up-regulation of effector cytokines suggests there may be non-TCR dependent activation contributing to the behaviour of pulmonary CD8 cells in COPD. (Table Presented).

Gruner, M., et al. (2014). "Increased proteasome activator 28 gamma (PA28gamma) levels are unspecific but correlate with disease activity in rheumatoid arthritis." BMC Musculoskeletal Disorders **15**: 414.

BACKGROUND: PA28gamma (also known as Ki, REG gamma, PMSE3), a member of the ubiquitin-and ATP-independent proteasome activator family 11S, has been proved to show proteasome-dependent and -independent effects on several proteins including tumor suppressor p53, cyclin-dependent kinase inhibitor p21 and steroid receptor co-activator 3 (SCR-3). Interestingly, PA28gamma is overexpressed in pathological tissue of various cancers affecting e. g. breast, bowl and thyroids. Furthermore, anti-PA28gamma autoantibodies have been linked to several autoimmune disorders. The aim of this study was to develop and evaluate a novel and sensitive PA28gamma sandwich ELISA for the quantification of PA28gamma serum levels in patients with cancer and autoimmune diseases for diagnostic and prognostic purposes.

METHODS: PA28gamma-specific polyclonal antibodies and recombinant His-tagged PA28gamma were purified and used to develop a sandwich ELISA for the detection of circulating PA28gamma. With this new assay, PA28gamma serum levels of patients with various cancers, rheumatoid arthritis (RA), Sjogren's syndrome (SS), adult-onset Still's disease (AOSD) and different connective-tissue diseases (CTD) were compared with healthy control subjects. Anti-PA28gamma autoantibodies were additionally confirmed using a newly developed microbead assay.

RESULTS: The developed PA28gamma sandwich ELISA showed a high specificity with a detection limit of 3 ng/ml. A significant up-regulation of circulating PA28gamma was detected in the sera of patients with cancer, RA, SS and CTD. A significant correlation was observed dependent on age as well as anti-PA28gamma autoantibody levels with circulating PA28gamma protein levels. Furthermore, PA28gamma serum levels showed a correlation with disease activity in patients with RA under treatment with the T-cell directed biological compound abatacept according to disease activity score 28 (DAS28) and erythrocyte sedimentation rate (ESR).

CONCLUSION: The application of PA28gamma as a novel biomarker for diagnostic purposes of a specific disease is limited, since elevated levels were observed in different disorders. However, the correlation with disease activity in patients with RA suggests a prognostic value, which needs to be addressed by further studies. Therefore our results show that PA28gamma is a useful marker which should be included in studies related to novel treatments, e.g. abatacept.

Gryshkov, O., et al. (2013). "111 Cryopreservation of stem cells inside alginate 3D constructs after high-voltage encapsulation." Cryobiology **67**(3): 429.

Application of stem cells in regenerative medicine require improving cryopreservation protocols for long term storage, especially for tissue-imitating 3D constructs containing cells. Encapsulation of stem cells into alginate-based 3D constructs that repeat an extracellular matrix may provide a mild environment during cryopreservation as well as the possibility for large-scale expansion. Furthermore, smaller alginate micro-beads 3 mu m offer additional advantages over larger ones due to higher specific surface area, less water content and improved heat and mass transfer. The gel-like structure and mild environment inside alginate micro-beads may affect the metabolic activity of encapsulated cells post-cryopreservation. The effects of high voltages, alginate encapsulation and pre-incubation time on morphology, viability and proliferation of MSCs post-cryopreservation were evaluated. Mesenchymal Stem Cells derived from the Common marmoset monkey Callithrix jacchus (MSC) were encapsulated into 1.5% (w/v) sterile medium viscosity unmodified alginate (Sigma Aldrich, filter-sterilized using 0.8-0.45-0.22mm filter set) with a concentration 1*106cells per ml of alginate using electro-spraying method. Final alginate micro-beads were obtained with less then 300 mu m in diameter under the next process parameters: applied voltages 15, 20 and 25kV, spraying distance 10cm, and alginate flow rate 10ml/h. As a negative control to high voltages, the air flow encapsulation was run in parallel. Micro-beads (0.5ml) containing MSCs (0.5*106cells) were either immediately frozen after encapsulation (0h) or cultured overnight prior to cryopreservation (24h). Cryopreservation was conducted with 1 degree C/min cooling rate down to -80 degree C with 10% Me2SO (v/v) as a cryoprotective agent. After 24h of storage at low temperatures micro-beads were thawed at 37 degree C with further removing of alginate using 55mM sodium citrate for 2min with gentle shaking. Then MSCs were either seeded for MTT test at 104cells/well immediately after thawing (protocol from manufacturer) or cultured for 5days followed by MTT assay. Membrane integrity of encapsulated cells before cryopreservation and after thawing was evaluated by Trypan Blue exclusion method. Metabolic activity and proliferation efficiency of MSCs were evaluated using MTT Nonradioactive Proliferation Assay (CellTiter 96, Promega, USA). The MTT data were normalized on respective control groups. The one-way ANOVA was run for statistical analysis of obtained results. MSCs can be encapsulated into alginate micro-beads with desired concentration and without significant changes in viability and metabolic activity post-encapsulation. MSCs showed normal morphology, attached and proliferated well after thawing. The incubation of MSCs inside alginate micro-beads prior to cryopreservation resulted in lower proliferation rate as compared to immediately frozen (18 plus or minus 6% and 45 plus or minus 8% in respect to native control) and at the same rate as frozen control. The same behavior was observed for re-passage efficiency of encapsulated and frozen MSCs. However, immediately frozen cells after encapsulation recovered at the same rate as native control, indicating an effectiveness of cell cryopreservation inside alginate micro-beads. This study shows an importance of cell cryopreservation inside unmodified alginate directly after encapsulation. Due to toxic effect of Me2SO, cryopreservation of MSCs inside alginate 3D structures using other less toxic CPAs will be conducted. Gu, H., et al. (2016). "Reproducible magnetic carbon nanocomposites derived from polystyrene with superior tetrabromobisphenol A adsorption performance." Journal of materials chemistry. A, Materials for energy and sustainability **4**(26): 10174-10185.

Easily reproducible magnetic carbon nanoadsorbents (MPSNs) derived from polystyrene (PS) by direct calcination of functionalized PS with an iron salt are employed for effective tetrabromobisphenol A (TBBPA) adsorption. Batch adsorption tests indicate that MPSNs exhibited high adsorption affinity to aqueous TBBPA with a maximum adsorption capacity of 117.00 mg g super(-1). The TBBPA adsorption kinetics of MPSNs are found to obey the pseudo-second-order behavior with a calculated room temperature initial adsorption rate of 42.871 mg g super(-1) min super(-1) for the solution with an initial TBBPA concentration of 4.0 mg L super(-1) and pH value of 8.0. Monolayer adsorption of the Langmuir isotherm model is well fitted rather than the multilayer adsorption of the Freundlich isotherm model. The calculated thermodynamic parameters suggest that the TBBPA adsorption on MPSNs is spontaneous and exothermic. The optimal pH value for TBBPA adsorption on MPSNs is around 8.0 with an MPSNs dose of 30.0 mg L super(-1) and contact time of 30 min under sonication at 298 K. The TBBPA adsorption performance of MPSNs is strongly influenced by the presence of humic acid. The prepared MPSN retains around 85.5% of TBBPA adsorption capacity after 5 cycles and exhibits good reusability. The explored adsorption mechanism by Raman and Fourier transform infrared (FT-IR) spectroscopy suggests that the C-O-Fe bond in the MPSN is responsible for the superior TBBPA adsorption performance. This work provides promising magnetic adsorbents for TBBPA wastewater treatment as well as a new strategy to recycle and reuse polymer plastic waste.

Gu, J., et al. (2013). "Adsorption and Recognition Performance of Lead Ion-imprinted Micro-beads." Journal of Tongji University. Natural Science **41**(10): 1507-1512.

As to the problem of the heavy metal pollution in the water environment and the wastewater treatment, a lead ion-imprinted micro-beads, with two functional monomers 1, 12-dodecanediol-o,o'- diphenyl- phosphonic acid(DDDPA) and 4- vinylpyridine, were synthesized. Its adsorption and recognition performance were investigated. The lead ion-imprinted micro-beads were efficient for lead ions removal from the aqueous solutions in a broad pH range (pH> 5). In the presence of competitive ions Zn super(2+), Co super(2+), Ni super(2+), it shows a high selectivity for lead ions. The selectivity coefficient of Pb super(2+)/Zn super(2+), Pb super(2+)/Co super(2+) and Pb super(2+)/Ni super(2+)are 86.6, 53.0 and 46.5, respectively. Meanwhile it shows a certain adsorption capacity for Cr super(3+) and Cu super(2+), the selectivity coefficient of Pb super(2+)/Cr super(2+) and Pb super(2+)/ Cu super(2+)are 20.8 and 9.5, respectively. The desorption experiments indicate that the lower concentration of nitric acid has almost 100% removal efficiency for the low quantity of lead ions. After the recycle of adsorption-desorption experiment, the lead ion-imprinted polymer still shows a high adsorption capacity of 90.9 mg.g super(-1).

Gu, L., et al. (2014). "Development and Customization of a Color-Coded Microbeads-Based Assay for Drug Resistance in HIV-1 Reverse Transcriptase: e109823." PLoS ONE **9**(10).

Background Drug resistance (DR) of HIV-1 can be examined genotypically or phenotypically. Although sequencing is the gold standard of the genotypic resistance testing (GRT), high-throughput GRT targeted to the codons responsible for DR may be more appropriate for epidemiological studies and public health research. Methods We used a Japanese database to design and synthesize sequence-specific oligonucleotide probes (SSOP) for the detection of wild-type sequences and 6 DR mutations in the clade B HIV-1 reverse transcriptase region. We coupled SSOP to microbeads of the Luminex 100 xMAP system and developed a GRT based on the polymerase chain reaction (PCR)-SSOP-Luminex method. Results Sixteen oligoprobes for discriminating DR mutations from wild-type sequences at 6 loci were designed and synthesized, and their sensitivity and specificity were confirmed using isogenic plasmids. The PCR-SSOP-Luminex DR assay was then compared to direct sequencing using 74 plasma specimens from treatment-naive patients or those on failing treatment. In the majority of specimens, the results of the PCR-SSOP-Luminex DR assay were concordant with sequencing results: 62/74 (83.8%) for M41, 43/74 (58.1%) for K65, 70/74 (94.6%) for K70, 55/73 (75.3%) for K103, 63/73 (86.3%) for M184 and 68/73 (93.2%) for T215. There were a number of specimens without any positive signals, especially for K65. The nucleotide position of A2723G, A2747G and C2750T were frequent polymorphisms for the wild-type amino acids K65, K66 and D67, respectively, and 14 specimens had the D67N mutation encoded by G2748A. We synthesized 14 additional oligoprobes for K65, and the sensitivity for K65 loci improved from 43/74 (58.1%) to 68/74 (91.9%). Conclusions We developed a rapid high-throughput assay for clade B HIV-1 DR mutations, which could be customized by synthesizing oligoprobes suitable for the circulating viruses. The assay could be a useful tool especially for public health research in both resource-rich and resource-limited settings.

Gu, L., et al. (2014). "Development and customization of a color-coded microbeads-based assay for drug resistance in HIV-1 reverse transcriptase." PLoS ONE [Electronic Resource] **9**(10): e109823.

BACKGROUND: Drug resistance (DR) of HIV-1 can be examined genotypically or phenotypically. Although sequencing is the gold standard of the genotypic resistance testing (GRT), high-throughput GRT targeted to the codons responsible for DR may be more appropriate for epidemiological studies and public health research.

METHODS: We used a Japanese database to design and synthesize sequence-specific oligonucleotide

probes (SSOP) for the detection of wild-type sequences and 6 DR mutations in the clade B HIV-1 reverse transcriptase region. We coupled SSOP to microbeads of the Luminex 100 xMAP system and developed a GRT based on the polymerase chain reaction (PCR)-SSOP-Luminex method.
RESULTS: Sixteen oligoprobes for discriminating DR mutations from wild-type sequences at 6 loci were designed and synthesized, and their sensitivity and specificity were confirmed using isogenic plasmids. The PCR-SSOP-Luminex DR assay was then compared to direct sequencing using 74 plasma specimens from treatment-naive patients or those on failing treatment. In the majority of specimens, the results of the PCR-SSOP-Luminex DR assay were concordant with sequencing results: 62/74 (83.8%) for M41, 43/74 (58.1%) for K65, 70/74 (94.6%) for K70, 55/73 (75.3%) for K103, 63/73 (86.3%) for M184 and 68/73 (93.2%) for T215. There were a number of specimens without any positive signals, especially for K65. The nucleotide position of A2723G, A2747G and C2750T were frequent polymorphisms for the wild-type amino acids K65, K66 and D67, respectively, and 14 specimens had the D67N mutation encoded by G2748A. We synthesized 14 additional oligoprobes for K65, and the sensitivity for K65 loci improved from 43/74 (58.1%) to 68/74 (91.9%).
CONCLUSIONS: We developed a rapid high-throughput assay for clade B HIV-1 DR mutations, which could be customized by synthesizing oligoprobes suitable for the circulating viruses. The assay could be a useful tool especially for public health research in both resource-rich and resource-limited settings.

Gu, Z., et al. (2019). "Solid-phase PCR based on thermostable, encoded magnetic microspheres for simple, highly sensitive and multiplexed nucleic acid detection." Sensors and Actuators, B: Chemical **298**.
Multiplexed detection of nucleic acids is important for pathogen identification and disease diagnosis. Though real-time quantitative PCR allows for simultaneous amplification of different genes in a single test, the interferences between various primers inevitably cause difficulty in assay design, and pose limitation on multiplexing degree. Conventional solid-phase PCR (SP-PCR) on plenary microarrays can assess more targets than real-time quantitative PCR. However, they are suffering from low reaction efficiency, high background noise, and requiring special equipment and expertise for reliable analysis. Here, we addressed the challenges by performing multiplex PCR on thermostable, tailor-made host-guest encoded magnetic microspheres (Beads based PCR, BB-PCR), which were constructed by coupling magnetic host microspheres with fluorescent guest nanoparticles. As proof of concept, a 3-plex barcoded microbeads with high thermostability and low non-specific fluorescence absorption were selected as model BB-PCR carriers to amplify and detect three gene targets in Salmonella Enteritidis. After BB-PCR reaction, the barcoding and reporting signals were easily identified through flow cytometry. Attributed to the effective interactions between reagents and microspheres during PCR reaction, this method showed high sensitivity of 10 copies/reaction, which was comparable to that of liquid PCR. Thus, BB-PCR developed here allowed for simple, rapid, highly sensitive and high throughput detection of nucleic acid targets, which paves the way for routine multiplexed molecular diagnostics in clinical laboratories. 2019 Elsevier B.V.

Guan, X., et al. (2010). "Rapid detection of pathogens using antibody-coated microbeads with bioluminescence in microfluidic chips." Biomedical Microdevices **12**(4): 683-691.
Detection of pathogens was demonstrated in a polydimethylsiloxane (PDMS)/glass microfluidic chip with which microbead-based immunoseparation platform and the bioluminescence technology were integrated. Escherichia coli (E. coli) O157:H7 was used as the model bacteria. The microchamber in microfluidic chip was filled with glass beads coated with antibodies which could capture specific organism, and the capture efficiency of the chip for the bacteria was

about 91.75% approximately 95.62%. Then the concentration of bacteria was determined by detecting adenosine triphosphate (ATP) employing bioluminescence reaction of firefly luciferin-lucifera-ATP on chip. The method allowed reliable detection of E. coli O157:H7 concentrations from 3.2 x 10(1) cfu/microL to 3.2 x 10(5) cfu/microL within 20 min. This research demonstrated excellent reproducibility, stability, and specificity, and could accurately detect the pathogenic bacteria in food samples. The microfluidic chip and the equipments used in this method are easy to miniaturize, thus the method has great potential to be developed to a portable device for rapid detection of pathogens.

Guernier-Cambert, V., et al. (2019). "Diversity of Mycobacterium tuberculosis in the Middle Fly District of Western Province, Papua New Guinea: microbead-based spoligotyping using DNA from Ziehl-Neelsen-stained microscopy preparations." Scientific Reports **9**(1): 15549.

Tuberculosis remains the world's leading cause of death from an infectious agent, and is a serious health problem in Papua New Guinea (PNG) with an estimated 36,000 new cases each year. This study describes the genetic diversity of Mycobacterium tuberculosis among tuberculosis patients in the Balimo/Bamu region in the Middle Fly District of Western Province in PNG, and investigates rifampicin resistance-associated mutations. Archived Ziehl-Neelsen-stained sputum smears were used to conduct microbead-based spoligotyping and assess genotypic resistance. Among the 162 samples included, 80 (49.4%) generated spoligotyping patterns (n = 23), belonging predominantly to the L2 Lineage (44%) and the L4 Lineage (30%). This is consistent with what has been found in other PNG regions geographically distant from Middle Fly District of Western Province, but is different from neighbouring South-East Asian countries. Rifampicin resistance was identified in 7.8% of the successfully sequenced samples, with all resistant samples belonging to the L2/Beijing Lineage. A high prevalence of mixed L2/L4 profiles was suggestive of polyclonal infection in the region, although this would need to be confirmed. The method described here could be a game-changer in resource-limited countries where large numbers of archived smear slides could be used for retrospective (and prospective) studies of M. tuberculosis genetic epidemiology.

Guerranti, C., et al. (2019). "Microplastics in cosmetics: Environmental issues and needs for global bans." Environmental Toxicology & Pharmacology **68**: 75-79.

Despite the microbeads from cosmetic products do not contribute with high percentages to the microplastic pollution, they can pose a threat to the environment, being discharged into the water bodies and just partially blocked by the wastewater treatment plants. As environmental associations have been fighting for the abolition of microplastics in PCCPs, in many countries measures have been taken and bans are already operational or in process. Some cosmetic companies have voluntarily renounced the use of microbeads and some voluntary certifications of PCCPs prohibit their use. PCCPs recently analysed can contain levels of microbeads reaching 50,391 per g and can contribute with every single use to the introduction of 229,000 microbeads into the domestic sewage. Given the spread and danger of these pollutants, the problem is global and unthinkable to be solved by banning microplastic-containing products only in some countries, thus a general ban would be necessary.

Gug, J., et al. (2015). "Processing and properties of a solid energy fuel from municipal solid waste (MSW) and recycled plastics." Waste Management **35**: 283-292.

Diversion of waste streams such as plastics, woods, papers and other solid trash from municipal landfills and extraction of useful materials from landfills is an area of increasing interest especially in densely populated areas. One promising technology for recycling municipal solid

waste (MSW) is to burn the high-energy-content components in standard coal power plant. This research aims to reform wastes into briquettes that are compatible with typical coal combustion processes. In order to comply with the standards of coal-fired power plants, the feedstock must be mechanically robust, free of hazardous contaminants, and moisture resistant, while retaining high fuel value. This study aims to investigate the effects of processing conditions and added recyclable plastics on the properties of MSW solid fuels. A well-sorted waste stream high in paper and fiber content was combined with controlled levels of recyclable plastics PE, PP, PET and PS and formed into briquettes using a compression molding technique. The effect of added plastics and moisture content on binding attraction and energy efficiency were investigated. The stability of the briquettes to moisture exposure, the fuel composition by proximate analysis, briquette mechanical strength, and burning efficiency were evaluated. It was found that high processing temperature ensures better properties of the product addition of milled mixed plastic waste leads to better encapsulation as well as to greater calorific value. Also some moisture removal (but not complete) improves the compacting process and results in higher heating value. Analysis of the post-processing water uptake and compressive strength showed a correlation between density and stability to both mechanical stress and humid environment. Proximate analysis indicated heating values comparable to coal. The results showed that mechanical and moisture uptake stability were improved when the moisture and air contents were optimized. Moreover, the briquette sample composition was similar to biomass fuels but had significant advantages due to addition of waste plastics that have high energy content compared to other waste types. Addition of PP and HDPE presented better benefits than addition of PET due to lower softening temperature and lower oxygen content. It should be noted that while harmful emissions such as dioxins, furans and mercury can result from burning plastics, WTE facilities have been able to control these emissions to meet US EPA standards. This research provides a drop-in coal replacement that reduces demand on landfill space and replaces a significant fraction of fossil-derived fuel with a renewable alternative.

Guilhermino, L., et al. (2018). "Uptake and effects of the antimicrobial florfenicol, microplastics and their mixtures on freshwater exotic invasive bivalve Corbicula fluminea." Science of the Total Environment **622**(623): 1131-1142.

Microplastics and antimicrobials are widely spread environmental contaminants and more research on their toxicity is needed. The uptake and effects of the antimicrobial florfenicol, microplastics, and their mixtures on Corbicula fluminea were investigated. Bivalves were exposed for 96 h to florfenicol (1.8 and 7.1 mg/l), microplastics (0.2 and 0.7 mg/l), or mixtures of the two substances. After 96 h, all bivalves exposed to antimicrobial treatments had florfenicol in their body (e.g. 2+or-1 micro g/g). Microplastics were found in the gut, lumen of the digestive gland, connective tissue, hemolymphatic sinuses, and gills surface of animals. Florfenicol caused a significant inhibition of cholinesterase (ChE) activity (~ 32%). Animals exposed to 0.2 mg/l of microplastics showed ChE activity inhibition (31%), and no other significant alterations. Mixtures caused feeding inhibition (57-83%), significant ChE inhibition (44-57%) and of isocitrate dehydrogenase activity, and increased anti-oxidant enzymes activity and lipid peroxidation levels. Overall, the results indicate that C. fluminea take up florfenicol and microplastics from the water and accumulated or at least retained it in their body for some time; both florfenicol (low ppm range) and microplastics (ppb range) were toxic to C. fluminea, with mixtures containing florfenicol and microplastics being more toxic. Thus, the risk of exposure and toxic effects of florfenicol to C. fluminea and other bivalves, and its predators increase in ecosystems contaminated with the antimicrobial and microplastics, as well as to humans consuming contaminated species from these ecosystems.

Guillard, V., et al. (2018). "The Next Generation of Sustainable Food Packaging to Preserve Our Environment in a Circular Economy Context." Frontiers in Nutrition **5**: 121.

Packaging is an essential element of response to address key challenges of sustainable food consumption on the international scene, which is clearly about minimizing the environmental footprint of packed food. An innovative sustainable packaging aims to address food waste and loss reduction by preserving food quality, as well as food safety issues by preventing food-borne diseases and food chemical contamination. Moreover, it must address the long-term crucial issue of environmentally persistent plastic waste accumulation as well as the saving of oil and food material resources. This paper reviews the major challenges that food packaging must tackle in the near future in order to enter the virtuous loop of circular bio-economy. Some solutions are proposed to address pressing international stakes in terms of food and plastic waste reduction and end-of-life issues of persistent materials. Among potential solutions, production of microbial biodegradable polymers from agro-food waste residues seems a promising route to create an innovative, more resilient, and productive waste-based food packaging economy by decoupling the food packaging industry from fossil feed stocks and permitting nutrients to return to the soil. To respond to the lack of tools and approach to properly design and adapt food packaging to food needs, mathematical simulation, based on modeling of mass transfer and reactions into food/packaging systems are promising tools. The next generation of such modeling and tools should help the food packaging sector to validate usage benefit of new packaging solutions and chose, in a fair and transparent way, the best packaging solution to contribute to the overall decrease of food losses and persistent plastic accumulation.

Guillot-Delost, M., et al. (2008). "Clinical-grade preparation of human natural regulatory T-cells encoding the thymidine kinase suicide gene as a safety gene." Journal of Gene Medicine **10**(8): 834-846.

BACKGROUND: Human CD4+CD25+FOXP3+ natural regulatory T-cells (nTreg) have a great therapeutic potential for the induction of tolerance in allo-transplanted patients or for the control of severe auto-immune diseases. However, clinical-grade production of nTreg remains difficult to achieve because of the absence of a truly specific surface marker and of their low frequency that implies a need for their ex vivo expansion. Furthermore, safety issues should be taken into consideration due to the risk of either uncontrolled nTreg-induced immunosuppression or uncontrolled proliferation of autoreactive contaminating T-cells particularly in an auto-immune context.

METHODS: We compared different clinical-grade conditions for immuno-magnetic selection and ex vivo expansion of nTreg. For safety, expanded cells were genetically modified with retroviral vectors co-expressing human CD90 and HSV1 thymidine kinase. The CD90 surface marker and thymidine kinase allow for selection and elimination of transduced cells by ganciclovir, respectively.

RESULTS: We showed that (i) nTreg could be enriched in a one step using CD25 microbeads, were functionally suppressive and mainly FOXP3+; (ii) using anti-CD28- and anti-CD3-coated beads, interleukin-2 and rapamycin, nTreg were expanded 150-200-fold after 3 weeks. Under these clinical-grade conditions, they remained suppressive, and no major alteration of the TCR repertoire was observed; (iii) after efficient retroviral transduction and CD90 selection, nTreg maintained their suppressive activity; (iv) transduced nTreg could be eliminated by ganciclovir upon activation.

CONCLUSIONS: The efficient procedure reported here for the preparation of nTreg, whose safety has been ensured, is now applicable for further clinical trials.

Guimaraes, A. M. d. S. (2013). The genome of Mycoplasma suis and its metabolism, pathogenesis and evolution.

Mycoplasma suis is an uncultivable, red blood cell (RBC) pathogen of pigs that causes hemolytic anemia or chronic, subclinical infections. In the studies reported herein, the genome of this organism was completely sequenced, analyzed and compared to other Mollicutes; and M.suis-specific molecular and serologic assays were developed to detect infected pigs. Accordingly, the first study describes the development of a highly sensitive and specific quantitative TaqMan registered PCR (qPCR) assay that provided further insights into the blood bacterial load during acute and chronic disease. The assay was validated using samples from 80 sows and 3-6 months old pigs, a M. suis-infected, splenectomized pig (acute disease model; pig #1), and a naturally infected, non-splenectomized pig (chronic disease model, pig #2). The prevalence among field pigs was found to be 43.7% (35/80), with quantification values ranging from 6.93 x 10 super(3) to 4.02 x 10 super(9) organisms/mL of blood. An average of 4.86 x 10 super(11) organisms/mL of blood at peaks of bacteremia in pig #1 and 2.75 x 10 super(8) organisms/mL of blood in pig #2 were detected throughout the study. The difference in these values explains our ability to visualize organisms attached to the RBCs on blood smears of acutely infected pigs at peaks of bacteremia, but not in chronically infected pigs. The second study describes the whole genome sequencing and analyses of M. suis. It was observed that a great proportion of M. suis genes encodes for hypothetical proteins (61.3%), most of which are grouped into paralogous gene families (PGFs) (42.8%). We believe that some of these families are linked to antigenic variation, as observed in other mycoplasmas and blood-borne pathogens. We then used the predicted proteome to design a complete metabolic map of M. suis, which indicates metabolic reduction and evidence of adaption to the blood environment. The analysis of this map also suggests essential nutrients that may be needed in future attempts to cultivate M. suis in vitro. Interestingly, toxin orthologs were not identified. Thus, we propose that M. suis may cause disease by scavenging and competing for host nutrients, leading to decreased life-span of RBCs. The third study describes the identification of M. suis antigens and development of a microbead immunoassay (MIA) using Luminex registered technology. A total of 6 antigens, including 4 proteins from PGFs, were identified; three of these proteins (GrpE, GAPN and one PGF protein) were used to develop the MIA. The MIA is more sensitive than the indirect hemagglutination (IHA) assay. We also observed a great number of qPCR-negative, MIA-positive animals when testing field samples, which suggests the possibility of infection clearance and/or low blood bacterial load that falls below the detection limit of our qPCR. The fourth study describes the comparative genomics and phylogenomics of the eight hemoplasmas sequenced to date. It was concluded that the hemoplasmas have highly dynamic genomes. This is supported by evidence of substantial gene gain and/or loss throughout evolution, loss of gene synteny, positional shuffling of genes from PGFs, and detection of horizontal gene transfer (HGT). They experienced metabolic reduction when compared to other Mollicutes, but PGFs are likely maintained and fixed within the bacterial population through positive selection. The hemoplasmas are using HGT as means of adapting to the blood environment by acquiring genes related to its metabolism. And finally, our phylogenetic analyses shows that hemoplasmas are not part of the pneumoniae group, as previously thought, and are the most divergent clade within the Mollicutes class. The fifth and final study briefly highlights possible mechanisms of antigenic variation of immunogenic PGFs. Phase variation through slipped-strand mispairing of homopolymeric guanine tracts and homologous DNA recombination are the suggested mechanisms employed by two of these PGFs. The studies reported herein greatly expanded our knowledge of the metabolism, pathogen sis and evolution of M. suis. These results will likely serve as basis for further research related to in vitro cultivation systems, M. suis interaction with

RBCs, mechanisms of immune system evasion and diagnostics.

Guimaraes, A. M. S., et al. (2014). "Identification of Mycoplasma suis antigens and development of a multiplex microbead immunoassay." Journal of Veterinary Diagnostic Investigation **26**(2): 203-212.

The aims of the current study were to identify Mycoplasma suis antigens and develop a multiplex microbead immunoassay (MIA). A M. suis-expression library was screened for immunogens using sera from infected pigs. Based on bioinformatics, putative antigens were identified within positive inserts; gene fragments were expressed and purified as polyhistidine fusion proteins, and immunoreactivity was confirmed by Western blot. Selected antigens were used to develop a MIA. Sera from noninfected and infected pigs were used to set the median fluorescent intensity (MFI) cutoffs and as positive controls, respectively. Assay specificity was tested using sera from pigs seropositive for other pathogens (2 different pigs seropositive for each pathogen). Samples from 51 field pigs and 2 pigs during the course of acute (pig 1) and chronic (pig 2) infections were tested using MIA, indirect hemagglutination assay (IHA), and quantitative polymerase chain reaction (qPCR). Sixteen reactive plaques (52 genes) were detected. A heat-shock protein (GrpE), a nicotinamide adenine dinucleotide-dependent glyceraldehyde 3-phosphate dehydrogenase (GAPN), and 4 proteins from paralogous gene families (PGFs) were identified as antigens by Western blot. While GrpE, GAPN, and 1 PGF protein were strong antigens, the others were not suitable as MIA targets. A MIA using GrpE, GAPN, and the strongly reactive PGF protein was developed. Cross-reactivity with sera from pigs infected with Mycoplasma hyopneumoniae, Porcine circovirus-2, Porcine parvovirus, Porcine reproductive and respiratory syndrome virus, and Porcine respiratory coronavirus with this MIA was not observed. Pig 2 was consistently positive by MIA and qPCR, whereas pig 1, initially negative, seroconverted before becoming qPCR positive. Only 2 samples (from pig 1) were IHA positive. Five (9.8%) field samples were qPCR positive and 40 (78.43%) were positive for all 3 MIA antigens; however, all were IHA negative. In summary, the MIA is specific and more sensitive than qPCR and IHA, providing simultaneous evaluation of antibody response to M. suis antigens.

Guller, A. E., et al. (2015). "Cytotoxicity and non-specific cellular uptake of bare and surface-modified upconversion nanoparticles in human skin cells." Nano Research **8**(5): 1546-1562.

The cytotoxicity and non-specific cellular uptake of the most popular composition of upconversion nanoparticle (UCNP), NaYF^sub 4^:Yb^sup 3+^:Er^sup 3+^, is reported using normal human skin cells, including dermal fibroblasts and immortalized human epidermal linear keratinocytes (HaCaT). A new hydrophilization reaction of as-synthesized UCNPs based on tetramethylammonium hydroxide (TMAH) enabled evaluation of the intrinsic cytotoxicity of bare UCNPs. The cytotoxicity effects of the UCNP surface-coating and polystyrene host were investigated over the concentration range 62.5-125 [mu]g/mL with 24-h incubation, using a MTT test and optical microscopy. The fibroblast viability was not compromised by UCNPs, whereas the viability of keratinocytes varied from 52% ± 4% to 100% ± 10% than the control group, depending on the surface modification. Bare UCNPs reduced the keratinocyte viability to 76% ± 3%, while exhibiting profound non-specific cellular uptake. Hydrophilic poly(D,L-lactide)- and poly(maleic anhydride-alt-1-octadecene)-coated UCNPs were found to be least cytotoxic among the polymer-coated UCNPs, and were readily internalized by human skin cells. Polystyrene microbeads impregnated with UCNPs remained nontoxic. Surprisingly, no correlation was found between UCNP cytotoxicity and the internalization level in cells, although the latter ranged broadly from 0.03% to 59%, benchmarked against 100% uptake level of TMAH-UCNPs. [Figure not available: see fulltext.]

Gundel, D., et al. (2011). "In vitro effects of Aspergillus fumigatus on human invariant natural killer T Cells." International Journal of Medical Microbiology **1)**: 48-49.

Objectives: Invariant human Natural Killer T Cells (iNKT-Cells) are innate immune effector cells. They are characterized by their expression of both, T-and NK cell markers and therefore they are a connecting link between innate and adaptive immunity. These cells are further defined by their TCell receptor, consisting of a specific, invariant alpha-chain and a beta-chain derived from a limited repertoire. They strongly react upon stimulation with lipid antigens presented in the context of the MHC-like molecule CD1d on dendritic cells (DCs) and thus they can be expanded in vitro by stimulation with their prototypic agonist alpha-galactosylceramide (alpha-GalCer). A protective role of iNKT cells in autoimmune diseases and cancer immunity, as well as their action against different pathogens is well documented. However, little is known about their direct interaction with fungi, especially with Aspergillus fumigatus. A. fumigatus, an omnipresent mold, is the most prevalent cause of a highly devastating opportunistic infection, affecting mainly immunocompromised patients. Method(s): In order to expand human iNKT cells (iNKT⁺CD3⁺), PBMCs were treated with alpha-GalCer and rhIL-2 for 15-20 days. After expansion, purity of the iNKT+CD3+ fraction was >90%. To further purify this fraction, a positive selection with CD3 microbeads was performed. After that the purity increased above 95%. iNKT cells were cocultured with different morphologies of A. fumigatus, resting conidia and germlings. Gene induction was evaluated by microarray analysis (Affymetrix U219) and the protein release by using multiplex ELISA assays (BioRad Bio-Plex). Additionally, the induction of IFN-gamma, a major Th1 cytokine, was analyzed by flow cytometry. Finally, XTT assays were used to examine the toxic effects of iNKT cells on A. fumigatus. Result(s): Stimulating iNKT cells with different A. fumigatus morphologies, we observed a time-and morphotype-dependent induction of INF-gamma, with germlings to be shown more immunogenic than conidia. Furthermore, challenging iNKT cells with A. fumigatus germlings at an MOI=1 for 6h, we found that iNKT cells caused a significant fungal damage. We could also observe defined patterns of gene induction, especially regarding cytokine and chemokine gene expression profiles. By multiplex ELISA assays gene expression patterns could be confirmed. Conclusion(s): We found that there is a specific interaction of iNKT cells with A. fumigatus revealed, leading to defined cytokine induction and a fungicidal effect. INF-gamma, a cytokine, which has a known protective role against IA, is produced by iNKT cells when confronted with A. fumigatus.

Gundogdu, S. (2018). "Contamination of table salts from Turkey with microplastics." Food Additives & Contaminants. Part A, Chemistry, Analysis, Control, Exposure & Risk Assessment **35**(5): 1006-1014.

Microplastics (MPs) pollution has become a problem that affects all aquatic, atmospheric and terrestial environments in the world. In this study, we looked into whether MPs in seas and lakes reach consumers through table salt. For this purpose, we obtained 16 brands of table salts from the Turkish market and determined their MPs content with microscopic and Raman spectroscopic examination. According to our results, the MP particle content was 16-84 item/kg in sea salt, 8-102 item/kg in lake salt and 9-16 item/kg in rock salt. The most common plastic polymers were polyethylene (22.9%) and polypropylene (19.2%). When the amounts of MPs and the amount of salt consumed by Turkish consumers per year are considered together, if they consume sea salt, lake salt or rock salt, they consume 249-302, 203-247 or 64-78 items per year, respectively. This is the first time this concerning level of MPs content in table salts in the Turkish market has been reported.

Gundogdu, S. and C. Cevik (2019). "Mediterranean dirty edge: High level of meso and macroplastics pollution on the Turkish coast." Environmental Pollution **255**(Pt 3): 113351.

It has become apparent that the coastal zones of aquatic environments are significantly affected by plastics pollution. The accumulation of marine plastic litter on beaches is an important problem due to their significant environmental impacts. In this study, 13 coastal areas in Iskenderun Bay (NE Levantine coast of Turkey) were sampled in May 2018 to investigate meso and macroplastic (0.5-123.4cm) pollution. A total of 1424 meso and macroplastic items in five categories (filament, film, foam, fragments, and pellets) were collected. The average meso and macroplastic concentration was 12.2+/-3.5 pcs m⁻² (12.3+/-3.5gm⁻²) and the mean size for all stations was 3.7+/-0.16cm. The highest meso and macroplastic concentration was found in the Dortyol location (46.2+/-7.6 pcs m⁻²) and the lowest concentration was found in the Y. Lagun location (2.3+/-0.2 pcs m⁻²). Plastics were separated into 14 different groups based on their origins. The most dominant type was hard plastics (broken, fragmented, and deformed) with 59.8% and greenhouse coverage films with 11%. Our results shows that regardless their source plastics fluxes at beaches from various pathways.

Gündoğdu, S., et al. (2018). "Microplastics in municipal wastewater treatment plants in Turkey: a comparison of the influent and secondary effluent concentrations." Environmental Monitoring & Assessment **190**(11): 1-1.

Wastewater treatment plants are one of the primary pathways through which microplastics enter aquatic environments. In this study, we have determined the microplastic concentrations of the influent and secondary effluent water of two wastewater treatment plants in Turkey. For this purpose, we have taken samples of the influent and effluent water of Seyhan and Yüreğir wastewater treatment facilities for 6 days in August 2017 and determined their microplastics' content both visually and using μ-Raman spectroscopy. The results showed that the influent of the wastewater treatment contained 1 million-6.5 million particles per day, while the effluent contained 220,000-1.5 million particles per day. The removal rate of microplastics was found to be between 73 and 79%. In total, seven different types of polymers were detected. The most frequently observed polymer type was polyester. Guo, C., et al. (2010). "Prokaryotic expression and RNase activity analysis of rice XIOsPR10." China Biotechnology **30**(7): 39-42.

It has been regarded that PR10s played an important role in systemic acquired resistance (SAR). Furthermore, many PR10 proteins have been reported to exhibit RNase activity and predicted to be responsible for its antibiotic activity. So the Prokaryotic Expression Vector pET28a-XIOsPR10 was constructed and transferred to BL21(DE3). The recombinant protein XIOsPR10 was obtained by Prokaryotic expression and purification of magnetic microbeads, and showed the RNase activity.

Guo, G. H., et al. (2008). "In vivo anti-tumor effect of hybrid vaccine of dendritic cells and esophageal carcinoma cells on esophageal carcinoma cell line 109 in mice with severe combined immune deficiency." World Journal of Gastroenterology **14**(8): 1167-1174.

AIM: To develop a fusion vaccine of esophageal carcinoma cells and dendritic cells (DC) and observe its protective and therapeutic effect against esophageal carcinoma cell line 109 (EC109).

METHODS: The fusion vaccine was produced by fusing traditional polyethyleneglycol (PEG), inducing cytokine, sorting CD34+ magnetic microbead marker and magnetic cell system (MACS). The liver, spleen and lung were pathologically tested after injection of the fusion vaccine. To study the therapeutic and protective effect of the fusion vaccine against tumor EC109, mice were divided immune group and therapeutic group. The immune group was divided into P, E, D and ED subgroups, immunized by phosphate buffered solution (PBS), inactivated EC109, DC and the fusion vaccine respectively, and attacked by EC109 cells. The tumor size, weight, latent period and mouse survival period were recorded and statistically analyzed. The therapeutic group was divided into four subgroups: P, inactivated EC109, D and ED subgroups, which were attacked by EC109 and then treated with PBS, inactivated EC109, DC, and EC109-DC respectively. Pathology and flow cytometry were also used to study the therapeutic effect of the fusion vaccine against EC109 cells.

RESULTS: Flow cytometry showed that the expression of folate receptor (FR), EC109 (C), DCs (D) in human nasopharyngeal carcinoma cell line (HNE1) (B) was 78.21%, 89.50%, and 0.18%, respectively. The fusion cells (C) were highly expressed. No tumor was found in the spleen, lung and liver after injection of the fusion vaccine. Human IgG was tested in peripheral blood lymphocytes (PBL). In the immune group, the latent period was longer in EC109-DC subgroup than in other subgroups, while the tumor size and weight were also smaller than those in ED subgroup. In the therapeutic group, the tumor size and weight were smaller in ED subgroup than in P, inactivated EC109 and DC subgroups.

CONCLUSION: Fusion cells are highly expressed not only in FR but also in CD80. The fusion vaccine has a distinctive protective effect against tumor EC109 and can inhibit the growth of tumor in mice, and its immune protection against tumor attack is more significant.

Guo, H., et al. (2019). "The leaching of additive-derived flame retardants (FRs) from plastics in avian digestive fluids: The significant risk of highly lipophilic FRs." Journal of Environmental Sciences (Elsevier) **85**: 200-207.

The exposure to plastic debris and associated pollutants for wildlife is of urgent concern, but little attention has been paid on the transfer of plastic additives from plastic debris to organisms. In the present study, the leaching of incorporated flame retardants (FRs), including polybrominated diphenyl ethers (PBDEs), alternative brominated FRs (AFRs), and phosphate flame retardants (PFRs), from different sizes of recycled acrylonitrile-butadiene-styrene (ABS) polymer were investigated in avian digestive fluids. The impact of co-ingested sediment on the leaching of additive-derived FRs in digestive fluids was also explored. In the recycled ABS, BDE 209 (715 μg/g) and 1, 2-bis(2,4,6-tribromophenoxy) ethane (BTBPE, 1766 μg/g) had the highest concentrations among all target FRs. The leaching proportions of FRs were higher in finer sizes of ABS. The leaching proportions of FRs from recycled ABS increased with elevated log K OW of FRs. In the tests with coexisted ABS and sediment, hexa- to deca-BDEs, BTBPE, and decabromodiphenyl ethane (DBDPE) migrated from ABS to sediment, which resulted in the less bioaccessible fractions of these FRs in gut fluids. More lipophilic chemicals tended to be adsorbed by sediment from ABS. The results suggest the migration of additive-derived FRs from plastics to other indigestible materials in digestive fluids. The findings in this study provide insights into the transfer of additive-derived FRs from plastics to birds, and indicate the significant contribution of FR-incorporated plastics to bioaccumulation of highly lipophilic FRs. Guo, L., et al. (2018). "A sensitive and innovative detection method for rapid C-reactive proteins analysis based on a micro-fluxgate sensor system." PLoS ONE **13**(3).

A sensitive and innovative assay system based on a micro-MEMS-fluxgate sensor and immunomagnetic beads-labels was developed for the rapid analysis of C-reactive proteins (CRP). The fluxgate sensor presented in this study was fabricated through standard micro-electro-mechanical system technology. A multi-loop magnetic core made of Fe-based amorphous ribbon was employed as the sensing element, and 3-D solenoid copper coils were used to control the sensing core. Antibody-conjugated immunomagnetic microbeads were strategically utilized as signal tags to label the CRP via the specific conjugation of CRP to polyclonal CRP antibodies. Separate Au film substrates were applied as immunoplatforms to immobilize CRP-beads labels through classical sandwich assays. Detection and quantification of the CRP at different concentrations were implemented by detecting the stray field of CRP labeled magnetic beads using the newly-developed micro-fluxgate sensor. The resulting system exhibited the required sensitivity, stability, reproducibility, and selectivity. A detection limit as low as 0.002 μg/mL CRP with a linearity range from 0.002 μg/mL to 10 μg/mL was achieved, and this suggested that the proposed biosystem possesses high sensitivity. In addition to the extremely low detection limit, the proposed method can be easily manipulated and possesses a quick response time. The response time of our sensor was less than 5 s, and the entire detection period for CRP analysis can be completed in less than 30 min using the current method. Given the detection performance and other advantages such as miniaturization, excellent stability and specificity, the proposed biosensor can be considered as a potential candidate for the rapid analysis of CRP, especially for point-of-care platforms.

Guo, X., et al. (2019). "Sorption of sulfamethoxazole onto six types of microplastics." Chemosphere **228**: 300-308.

Microplastics and sulfamethoxazole (SMX) are ubiquitous in aquatic environment. In this study,

we investigated the sorption of SMX onto six types of microplastics (polyamide (PA), polyethylene (PE), polyethylene terephthalate (PET), polystyrene (PS), polyvinyl chloride (PVC) and polypropylene (PP)). The sorption rate and mass transfer steps of SMX was studied by using the phenomenological kinetics models. The effect of pH and salinity on SMX sorption was examined. The results showed that the sorption of SMX onto microplastics reached equilibrium within 16 h. The external mass transfer was the slowest sorption step. The linear and Freundlich isotherms fitted well the sorption equilibrium data. PA had the highest sorption capacity (2.36 mg g−1 at SMX concentrations of 12 mg L−1), with high distribution coefficient (K d) value (284 L kg−1). The K d values of PE, PS, PET, PVC, and PP ranged from 22.2 to 30.9 L kg−1. The sorption capacity of SMX decreased with increase of pH and salinity in the solution. • Microplastics and sulfamethoxazole are ubiquitous in aquatic environments. • Sorption of SMX onto six types of microplastics was investigated. • The sorption rate of SMX was studied using phenomenological kinetics models. • The effect of pH and salinity on the sorption of SMX was examined. [ABSTRACT FROM AUTHOR]

Guo, X., et al. (2019). "Sorption of sulfamethazine onto different types of microplastics: A combined experimental and molecular dynamics simulation study." Marine Pollution Bulletin **145**: 547-554.

Microplastics are becoming a global concern due to their potential to accumulate pollutants in aquatic environments. In this paper, sulfamethazine (SMT) sorption onto six types of microplastics, including polyamide (PA), polyethylene (PE), polyethylene terephthalate (PET), polypropylene (PP), polystyrene (PS), and polyvinyl chloride (PVC) was investigated by experimental and molecular dynamics simulation methods. The experimental results indicated that SMX sorption reached equilibrium within 16h. The kinetics of SMT sorption by PA, PVC, PE, and PP could be fitted by pseudo first-order model, while SMT sorption by PA and PET could be described by pseudo second-order model. The partition coefficient K_d values were 38.7, 23.5, 21.0, 22.6, 18.6 and 15.1L.kg⁻¹ for PA, PE, PS, PET, PVC and PP, respectively. SMT sorption onto microplastics decreased when pH and salinity increased. The molecular dynamics simulation results indicated that the main mechanisms involved in sorption are electrostatic and Van der Waals interaction.

Guo, X., et al. (2018). "Sorption properties of tylosin on four different microplastics." Chemosphere **209**: 240-245.

After oxidation, abrasion and crushing, microplastics (MPs) can enter the aqueous environment and may adsorb surrounding organic pollutants, altering its migration and spatial distribution. Therefore, an investigation of the sorption properties and mechanism of organic pollutant on MPs can offer a theoretical basis for scientific evaluation of their ecological risks. Using tylosin (TYL) as a model pollutant, the sorption performance of MPs was examined via a series of batch equilibrium experiments which resulted the sorptive removal of TYL on MPs reached equilibrium at 36h, and the sorption ability of TYL on the MPs followed the order of PE (polyethylene)<PP (polypropylene)<PS (polystyrene)<PVC (polyvinyl chloride). The pseudo-second-order model well fit for the sorption kinetics data, and the adsorption isotherms could be better described by Freundlich equation rather than Langmuir model. Additionally, the initial solution pH and ionic

strength played important roles across the adsorption. The sorption procedure of TYL on MPs was dominated by electrostatic interaction, surface complexation and hydrophobic interaction.

Guo, X. and J. Wang (2019). "The chemical behaviors of microplastics in marine environment: A review." Marine Pollution Bulletin **142**: 1-14.

Microplastics are widely existed in marine and coastal environments, which aroused global concern in recent years. This review mainly summarized the interactions of organic pollutants and metals with microplastics based on environmental monitoring results and laboratory results reported by literatures. Firstly, the type, properties, and distribution of microplastics in the environment were briefly reviewed. Secondly, the property changes of microplastics after degradation were discussed. Thirdly, the concentrations of pollutants on microplastics in global environments were summarized. Then the effect of the factors (e.g. types and properties of microplastics, types of pollutants, and environmental conditions) on the sorption behaviors of microplastics were discussed in detail. Finally, the influences of microplastics on marine organisms were briefly evaluated.

Guo, Y., et al. (2019). "Effects of microplastics on growth, phenanthrene stress, and lipid accumulation in a diatom, Phaeodactylum tricornutum." Environmental Pollution: 113628.

Most laboratory studies have focused on the effects of nanoplastics instead of plastics at the micrometer scale, which are the major microplastics (MPs) discarded in marine environments. Knowledge on the potential effects of micrometer scale plastics on marine microalgae remains limited. It remains unknown whether the micrometer scale plastics also affect microalgal growth, lipid accumulation and resistance to organic contaminants? In addition, the role of polymer-size on the potential hazardous effects of MPs on microalgae is unknown. In the present study, cell populations of a marine diatom, Phaeodactylum tricornutum, were treated with micrometer scale polyethylene (PEMP, 150 mum) and unplasticized polyvinyl chloride (uPVCMP, 250 mum) powders in the laboratory. Growth was assessed using a hemacytometer and neutral lipid concentrations were evaluated using the Nile Red staining method under short-term (four days) and long-term (nine days) exposure. The effects of combined PEMP and phenanthrene (Phe), and uPVCMP and Phe exposures over four days on growth were investigated. Importance scores and SHapley Additive exPlanations (SHAP) values were calculated to assess the contributions of seven factors in exposure systems to the hazardous effects of MPs on microalgae using a machine-learning prediction based on 165 data sets. Both MP types did not influence algal growth and lipid accumulation but minimized algal inhibition by the action of Phe at four days. In addition, lipid accumulation was induced at nine days. Both importance scores and SHAP values indicated that MP polymer-size was the key factor influencing MP toxicity in microalgae. In conclusion, MPs had adverse effects only in chronic tests and the potential adsorption of MPs could have led to the lower levels of toxicity in a combined MP-Phe exposure system. Compared to nanoplastics, MPs in the hundred-micrometer range do not significantly affect growth and their adsorption would not be influenced by size. Therefore, MP size is the most critical factor that should be considered in future laboratory tests and eco-toxicological risk assessments for microalgae.

Guo, Z., et al. (2017). "The optimal dose of arsenic trioxide induced opposite efficacy in autophagy between K562 cells and their initiating cells to eradicate human myelogenous leukemia." Journal of Ethnopharmacology **196**: 29-38.

ETHNOPHARMACOLOGICAL RELEVANCE: Arsenic trioxide (As2O3), a main component of arsenolite which is a common traditional Chinese medicine (TCM) wildly used as a therapeutic

agent for more than 2400 years in china, has been accepted as a standard treatment for the patients with acute promyelocytic leukemia (APL) based on the principle in TCM of "using a poison to fight against other poisons or malignancy illnesses". However, it remains unknown that which mechanism is actually responsible for the therapeutic effects against these blood malignancies.

AIM OF THE STUDY: The purpose of this study was to explore the actual mechanism that ATO exerts its effects in K562 cells and their initiating cells (K562s).

MATERIALS AND METHODS: K562s cells were separated and enriched for CD34+/CD38- cells using magnetic microbeads. Cell proliferation was determined by incorporation of BrdU. Cell apoptosis was evaluated by Annexin-V binding and PI uptake. Autophagy was estimated by acridine orange and immunofluorescence staining of LC3-B and p62. MC colonic formation was used to examine cell self-renew. ROS generation inside living cells was measured by DCFH-DA. Cell differentiation was assessed by the benzidine staining. The SA-beta-gal assay was used to detect cell senescence. Protein expression was examined by western blotting and immunohistochemical staining.

RESULTS: K562s cells were stronger in self-renew and resistance to ATO cytotoxicity and starvation-induced apoptosis than K562 cells. Unexpectedly, we found that ATO at a dose of 0.5muM which had no effect on cell proliferation resulted in maximum suppression on self-renew in both cells and maximum starvation-induced apoptosis in K562s cells but minimum starvation-induced apoptosis in K562 cells. Next, we found that ATO no more than 0.5muM selectively induced K562s cell differentiation indicated by benzidine staining, gamma-globin and CD235a expression. More importantly, we found that ATO no more than 0.5muM led to opposite efficacy in autophagy between K562 and K562s cells, and the opposite autophagy could induced late-phase senescence in both cells. Finally, we used the optimal dose of ATO to eradicate leukemia cells and obtained a satisfied therapeutic outcomes in vivo.

CONCLUSIONS: Our results suggest that the used dose of ATO may determine the fate of cell differentiation senescence or malignant transformation, and the optimal dose of ATO induced opposite efficacy in autophagy between K562 cells and their initiating cells and ultimately leads both cells to late-phase senescence.

Guo, Z., et al. (2015). "Differentiating endothelial cells from human induced pluripotent stem cells." Journal of Investigative Dermatology **1)**: S73.

Induced pluripotent stem cells (iPSCs) can provide an unlimited number of cells for cell therapy, disease modeling and drug development. Realization of the potential of iPSCs depends on the capacity to efficiently generate cell lineages specific for different applications. Previously published protocols of differentiating endothelial cells (ECs) from iPSCs often require a purification step by FACS or magnetic microbeads to isolate EC-like cells from a heterogeneous population containing cells such as pericytes, and the functionality of iPSC-derived ECs has not been widely utilized to construct vascularized 3D skin equivalents. Here, we aimed to improve differentiation efficiency of iPSCs into ECs for vascularization of 3D skin constructs. Integration-free iPSCs were generated from human fibroblasts by introduction of an episomal vector-based system. Endothelial cells (ECs) were differentiated by manipulation of the transforming growth factor beta (TGF-beta) signaling pathways. Specifically, treatment with TGF-beta2 for 6 days in the presence of retinoic acid differentiated iPSCs into endothelial cells. Subsequent inhibition of TGF-beta with SB431542 prevented the epithelial to mesenchymal transition, and maintained the identity of ECs. Proliferative CD31-positive endothelial cells (ECs) were obtained with high purity without the need for FACS or magnetic microbeads-based purification. These iPSC derived ECs formed vascular structures on Matrigel and in collagen gels,

demonstrating their functionality. We have incorporated these ECs into 3D vascularized skin constructs to advance the application of these cells for wound healing.

Gupta, P. (2017). "Management of plastic waste: a step towards clean environment." International Journal of Renewable Energy Technology **8**(3-4): 387-392.

Plastic pollution may be defined as the accumulation of plastic products in the environment that may affect human life as well as wildlife. Plastics waste contributes a major proportion to the total municipal solid waste. Plastic is composed of various chemical elements and it does not degrade naturally even after its usage. It is properties such as durability, light weight and low cost, which makes it so useful also makes it problematic when it comes to its end of life phase. Mismanagement of plastics waste may pose environmental hazards such as when littered it may interfere with the natural beauty of the city and it may also result in choked drains, may cause air pollution when burnt with garbage containing plastics, interferes in waste processing facilities when garbage is mixed with plastics. Therefore plastic waste management techniques are required for proper management of plastic waste in a way which is environment friendly and may help in the proper utilisation of plastic material. The solution to tackle this problem lies in following 3R namely reduce, reuse and recycle. Waste plastics can be recycled and used in several ways including construction of roads.

Gupta, S., et al. (2013). "Ex vivo expanded human regulatory t cells are potent suppressors but may be short-lived." American Journal of Transplantation **5)**: 229.

Infusion of host derived ex vivo expanded regulatory T cells (eTregs) is an attractive therapeutic strategy for promotion of transplant tolerance. We report herein that human eTregs cultivated for in vivo therapy abundantly express the death molecules T-cell Immunoglobulin and Mucin domain-3 protein (TIM-3) and program death 1(PD-1), are highly potent yet fragile. We studied the functional and phenotypic features of sorted peripheral CD4+CD25hiCD127lo Tregs expanded in the presence of anti-CD3 and anti-CD28 coated micro beads and IL-2 for 14 days. Notably, >95% of eTregs generated using protocols under investigation for Treg cellular therapy are TIM-3+ of which ~60% co-expressed PD-1, both molecules known to contribute to effector T cell apoptosis, exhaustion or dysfunction. Contrastingly, only ~10% of nTregs in peripheral blood express TIM-3. Compared to their nTregs, expanded TIM-3+ Tregs are more potent suppressors of in vitro Teff proliferation and robustly express CD25, CTLA-4, CD39, CD45RO, IL-10, but are programmed for apoptotic cell death. Exposure to the TIM-3 ligand galectin-9 in a dose and time dependent manner or absence of a continuous proliferative micro environment led to eTreg death; though these cells could be rescued by TCR stimulation and/or IL-2. Thus these studies indicate that the highly potent eTregs are terminally differentiated Tregs expressing death molecules TIM-3 and PD-1 and may be short lived in vivo. As use of eTregs is a promising therapeutic strategy our findings provide further insight into novel properties and fate of expanded human Tregs instructive for advancement of Treg cellular therapeutic approaches.

Gupta, S. S., et al. (2016). "Preparation and optimization of floating microbeads of ciprofloxacin HCL." Research Journal of Pharmacy and Technology **9**(7): 848-852.

The objective of this work is to generate a gastro retentive sustained release dosage form of a water soluble drug, Ciprofloxacin, from a fully aqueous environment avoiding the utilize of any organic solvent. A new emulsion gelation system is used to arrange emulsion gel beads by sodium alginate as the polymer. The gel beads containing is set up by gently mixing or homogenizing oil and water phase containing sodium alginate which is then extruded in to calcium chloride solution. The effects of factors like concentration of oil, curing time, and drug:

polymer ratio, alginate: pectin proportion and therapeutic agent on drug entrapment efficiency, floating lag time, and morphology and drug release are study. Minimizing the curing time of beads leaded to enhanced drug entrapment efficiency. The use of sodium alginate and combinations of sodium alginate and pectin are used to study the effect on the sustaining property of the formed beads. It is found that sodium alginate was not sufficient to uphold the drug release at gastric pH. Instead of it, suitable amalgamation of alginate and pectin could afford the sustain release of drug. The results confirm that these beads can entrap even a water soluble drug as Ciprofloxacin in sufficient amount and also can successfully distribute the drug in stomach for a extend duration of time.

Gurevich, O., et al. (2002). "Fibrin Microbeads for Isolating and Growing Bone Marrow-Derived Progenitor Cells Capable of Forming Bone Tissue." Tissue Engineering **8**(4): 661-673.

It has been demonstrated that bone marrow (BM)-derived pluripotent stem cells can be incorporated into muscle, bone, nerve, lung, stomach, intestine, and skin. Fibrin-based biodegradable microbeads (FMB) were developed for culturing, in suspension, a high density of cells, mostly of mesenchymal origin. In the current study, FMB were used to isolate and expand mesenchymal progenitor cells from BM of mice and rats. Cells from BM isolated on FMB (FMB-BM cells) were visualized by fluorescent confocal microscopy and quantified by a modified MTS colorimetric assay. Downloading the BM cells from FMB onto plastic induced their differentiation into islets of cells with osteogenic phenotype that secreted mineralized extracellular matrix. This was augmented by inducers of osteogenesis, such as ascorbic acid, beta -glycerophosphate, and dexamethasone, or osteoblast-growth peptides (OGP). Implanting FMB-BM cells under the kidney capsule in mouse tested the osteogenic potential of these cells in vivo. Thirty days after implantation, bone structures with typical BM elements were seen in 8/53 kidneys in 6-Gy-irradiated mice and in 1/10 kidneys in nonirradiated recipients; bone formation was verified by soft x-ray imaging and elemental analysis that showed elevated Ca and Fe in the implant region. FMB-BM cells--downloaded onto plastic flasks, cultured for 2 weeks, mechanically harvested and then implanted--induced 100% bone formation in both irradiated (6/6) and nonirradiated (3/3) mice. Histology revealed well-organized bone structures under the kidney capsule, including osteoblasts and typical elements of BM. Our findings demonstrate that FMB are capable of isolating and expanding progenitor cells from BM for osteogenesis and possibly for regenerating other mesenchymal tissues.

Gusmão, F., et al. (2016). "In situ ingestion of microfibres by meiofauna from sandy beaches." Environmental Pollution **216**: 584-590.

Microfibres are widespread contaminants in marine environments across the globe. Detecting in situ ingestion of microfibres by small marine organisms is necessary to understand their potential accumulation in marine food webs and their role in marine pollution. We have examined the gut contents of meiofauna from six sandy beaches in the Atlantic Ocean and the Mediterranean. Out of twenty taxonomic groups, three species of the common sandy beach annelid Saccocirrus displayed in situ ingestion of microfibres in all sites. Laboratory observations showed that species of Saccocirrus are able to egest microfibres with no obvious physical injury. We suggest that their non-selective microphagous suspension-feeding behaviour makes Saccocirrus more prone to ingest microfibres. Although microfibres are rapidly egested with no apparent harm, there is still the potential for trophic transfer into marine food webs through predation of Saccocirrus . [ABSTRACT FROM AUTHOR]

Gutierrez, C., et al. (2013). "KRAS mutational status analysis of peripheral blood isolated circulating tumor cells in metastatic colorectal patients." Oncology Letters **6**(5): 1343-1345.

The present study describes an optimized method for isolating peripheral blood circulating tumor cells (CTCs) and performing KRAS mutation analysis. The approach combines isolation of peripheral blood mononuclear cells and immunomagnetic labeling with CD45 and CD326 human microbeads with KRAS analysis performed with a Therascreen KRAS kit by quantitative PCR. KRAS mutations were detected in the CTCs of patients with metastatic colorectal cancer (mCRC). CTCs may represent an alternative to invasive procedures and their analysis may be representative of the current disease status of the patient. This proposed analysis may be performed in a daily clinical practice.

Gutman, D. (2018). "Q&A: UN's Jordi Pon describes region's waste-management challenges." EcoAmericas **20**(12): 12.

In an interview, UN's Jordi Pon describes Latin America and Caribbean region's waste-management challenges. On what were the UN Environment report's main findings, he said one is that while waste management in the region has improved in recent years, a third [of waste] is still sent to open-air dumps with no type of treatment or control. That's the worst option, given the impacts on the environment and health. It [involves] 145,000 [metric] tons per day, of which 17,000 are plastic waste. Meanwhile, we still have a long way to go in the reuse of waste, since in the region an average of barely 10% is recycled and reused. We are wasting 90% of what we generate. Another significant fact is that half of the waste is organic. Adequate management is more expensive if we only consider the direct cost, but if one quantifies pollution's environmental and health costs, the equation changes.

Gutow, L., et al. (2019). "Gastropod pedal mucus retains microplastics and promotes the uptake of particles by marine periwinkles." Environmental Pollution **246**: 688-696.

The rapid dissemination of microplastics in many habitats of the oceans has raised concerns about the consequences for marine biota and ecosystems. Many adverse effects of microplastics on marine invertebrates are consequences of ingestion. Accordingly, the identification of mechanisms that facilitate the uptake of microplastics is essential for the evaluation of possible implications for marine organisms and food webs. Gastropods produce mucus for locomotion. Gastropod pedal mucus naturally retains formerly suspended micro-organisms, such as bacteria, microalgae, and seaweed spores. The retained organisms are consumed by gastropods that forage on pedal mucus. Here, we investigated the potential of gastropod pedal mucus to retain suspended microplastic particles and make them available for ingestion by periwinkles that forage on the contaminated mucus. In laboratory experiments, mucus of the periwinkles Littorina littorea and Littorina obtusata efficiently retained microplastics. Retention of microplastics varied between mucus from conspecifics of different size but not between mucus from either species. The density of microplastics in mucus trails increased concomitantly with the experimental particle concentration but was independent of incubation time. Aging of mucus and, particularly, desiccation affected the retention of microplastics. Periwinkles ingested microplastics when foraging on the contaminated mucus. Our results reveal a functional link between biogenic accumulation of microplastics and their

trophic transfer by marine benthic herbivores into marine food webs.

Gutow, L., et al. (2016). "Experimental Evaluation of Seaweeds as a Vector for Microplastics into Marine Food Webs." Environmental Science & Technology **50**(2): 915-923.

The ingestion of microplastics has been shown for a great variety of marine organisms. However, benthic marine mesoherbivores such as the common periwinkle Littorina littorea have been largely disregarded in studies about the effects of microplastics on the marine biota, probably because the pathway for microplastics to this functional group of organisms was not obvious. In laboratory experiments we showed that the seaweed Fucus vesiculosus retains suspended microplastics on its surface. The numbers of microplastics that adhered to the algae correlated with the concentrations of suspended particles in the water. In choice feeding assays L. littorea did not distinguish between algae with adherent microplastics and clean algae without microplastics, indicating that the snails do not recognize solid nonfood particles in the submillimeter size range as deleterious. In periwinkles that were feeding on contaminated algae, microplastics were found in die stomach and in the gut. However, no microplastics were found in the midgut gland, which is the principle digestive organ of gastropods. Microplastics in the fecal pellets of the periwinkles indicate diat the particles do not accumulate rapidly inside the animals but are mostly released with the feces. Our results provide the first evidence that seaweeds may represent an efficient pathway for microplastics from the water to marine benthic herbivores. [ABSTRACT FROM AUTHOR]

Guttentag, R. M. (2006). "Plastics recycling, chapter 2: Whose bag is it?" Resource Recycling **25**(3): 51-54.

The article reports on the 10th anniversary of Recycling in Cyberspace, which made significant effort to reduce plastic shopping bag (PSB) waste. Canada's MyPlasticbags.ca site sponsored by the Environment and Plastics Council in Mississauga, Ontario, provides information about where PSBs can be recycled through municipal and retail operations. Planet Ark web sites, an Australian environmental organization that started in 1991, provided information on communities that have decided to become PSB-free communities. In Ireland, Irish government in March 2002, imposed a 15-cent-per-bag tax on all single use PSBs paid by the consumer at the point of sale. The basic purpose of this tax is to use a pricing system as a way to affect consumer preferences regarding shopping bags.

Gutzman, Y., et al. (2006). "Bead injection for biomolecular assays: Affinity chromatography enhanced by bead injection spectroscopy." Analyst **131**(7): 809-815.

Selective capture of target biomolecules by ligands immobilized on a solid support is a cornerstone of two seemingly unrelated techniques: micro-Affinity Chromatography (microAC) and micro-Bead Injection Spectroscopy (microBIS). This work shows, for the first time, how these techniques can be carried out using the same instrument and how the data obtained this way complement each other, yielding complete information on retention and elution of target biomolecules. Biomolecular association and dissociation were investigated by microAC and microBIS, using computer-controlled programmable flow and the same instrument for

automated bead transport, packing of a micro-column, assay of the analyte, and bead disposal. The absorbance of the analyte was monitored within the fiber optic flow cell configured either for monitoring directly on the beads or post-column after elution. The separation, binding, and elution of immunoglobulins (human IgG, rabbit IgG, and horse IgG) on protein G-coated Sepharose beads were studied as model systems. The limit of detection of the microAC technique was determined to be 5 ng microL(-1) IgG, and that of the microBIS technique was 50 ng microL(-1) IgG.

Guven, H., et al. (2003). "Expansion of natural killer (NK) and natural killer-like T (NKT)-cell populations derived from patients with B-chronic lymphocytic leukemia (B-CLL): a potential source for cellular immunotherapy." Leukemia **17**(10): 1973-1980.

B-cell chronic lymphocytic leukemia (B-CLL) is the most common leukemia in the Western world. It is currently an incurable disease, making new treatment options such as immunotherapy desirable. Monoclonal antibodies (Mabs) to surface antigens of the tumor cell is one option. Administration of cytotoxic cells such as natural killer (NK) and natural killer-like T (NKT) cells expanded in vitro might be a useful treatment modality alone or in combination with MAbs. A limiting step in the development of successful cellular immunotherapy has been the availability of appropriate cytotoxic cells. Here, we report the feasibility of expanding populations of the human killer cells, CD3-CD56+ NK and CD3+CD56+ NKT cells, from peripheral blood mononuclear cells (PBMCs) of B-CLL patients. The influence of tumor B cells on the in vitro expansion of killer cells was assessed by depleting B cells from PBMCs by microbead separation before culture. The 21-day cultures from both B-cell- and non-B-cell-depleted PBMC showed a marked expansion of NK cells, and also of T cells, among which almost half had the NKT phenotype. Depletion of B cells before culture did not change the expansion rates of NK and NKT cells significantly. In patients with progressive B-CLL, NK cell expansion capacity was improved after fludarabine treatment when compared to samples obtained before treatment. Repeated samples of PBMCs from individual untreated patients with both indolent and progressive disease cultured under identical conditions gave similar NK cell expansion rates. Expanded killer cell populations had cytotoxic function against the NK-sensitive target K562 cell line and expressed high levels of Granzyme B. From our studies, we conclude that NK cells as well as NKT cells from the peripheral blood of B-CLL patients can be expanded, and that these cells have cytotoxic capacity.

Guven, O., et al. (2018). "Microplastic does not magnify the acute effect of PAH pyrene on predatory performance of a tropical fish (Lates calcarifer)." Aquatic Toxicology **198**: 287-293.

Microplastic (MP) leads to widespread pollution in the marine ecosystem. In addition to the physical hazard posed by ingestion of microplastic particles, concern is also on their potential as vector for transport of hydrophobic contaminants. We experimentally studied the single and interactive effects of microplastic and pyrene, a polycyclic aromatic hydrocarbon, on the swimming behaviour and predatory performance of juvenile barramundi (Lates calcarifer). Juveniles (18+ days post hatch) were exposed to MPs, or pyrene (100 nM), or combination of both, and feeding rate and foraging activity (swimming) were analysed. Exposure to MPs alone did not significantly influence feeding performance of the juveniles, while a dose-effect series of pyrene showed strong effect on fish behaviour when concentrations were above 100 nM. In the test of combined MP and pyrene exposure, we observed no effect on feeding while swimming speed decreased significantly. Thus, our results confirm that short-time exposure to pyrene impacts the performance of fish juveniles, while additional exposure to microplastic at the given conditions influenced their activity only and not their feeding rate. Further studies of the combined effects of microplastics and pollutants on tropical fish behaviour are encouraged.

Guven, O., et al. (2017). "Microplastic litter composition of the Turkish territorial waters of the Mediterranean Sea, and its occurrence in the gastrointestinal tract of fish." Environmental Pollution **223**: 286-294.

Microplastic pollution of marine environment is receiving increased publicity over the last few years. The present survey is, according to our knowledge, the survey with the largest sample size analyzed, to date. In total, 1337 specimens of fish were examined for the presence of plastic microlitter representing 28 species and 14 families. In addition, samples of seawater and sediment were also analyzed for the quantification of microplastic in the same region. Samples of water/sediment were collected from 18 locations along the Mediterranean coast of Turkey. 94% of all collected plastic microlitter from the sea was in the size range between 0.1 and 2.5 mm, while the occurrence of other sizes was rare. The quantity of microplastic particles in surface water samples ranged from 16 339 to 520 213 per km². Fish were collected from 10 locations from which 8 were either shared with or situated in the proximity of water/sediment sampling locations. A total of 1822 microplastic particles were extracted from stomach and intestines of fish. Majority of ingested particles were represented by fibers (70%) and hard plastic (20.8%), while the share of other groups: nylon (2.7%), rubber (0.8%) and miscellaneous plastic (5.5%) were low. The blue color of plastic was the most dominant color. 34% of all examined fish had microplastic in the stomach. On average, fish which had microplastic contained 1.80 particles per stomach. 41% of all fish had microplastic in the intestines with an average of 1.81 particles per fish. 771 specimens contained microplastic in either stomach and/or intestines representing 58% of the total sample with an average of 2.36 particles per fish. Microplastic was found in all species/families that had sample size of at least 2 individuals. The number of particles present in either stomach or intestines ranged between 1 and 35. Ingested microplastic had an average diameter +/-SD of 656 +/- 803 mum, however particles as small as 9 mum were detected. The trophic level of fish species had no influence whatsoever on the amount of ingested microplastic. Pelagic fish ingested more microplastic than demersal species. In general, fish that ingested higher number of microplastic particles originated from the sites that also had a higher particle count in the seawater and sediment. Copyright © 2017 Elsevier Ltd

Guzzetti, E., et al. (2018). "Microplastic in marine organism: Environmental and toxicological effects." Environmental Toxicology & Pharmacology **64**: 164-171.

Microplastics are tiny ubiquitous plastic particles present in marine environments. They are not an individual entity, but constitute a cocktail of polymers and additives that can absorb substances from the surrounding environment, including living substances, nutrients and marine pollutants. Given their small size (< 5 μm), microplastics can be ingested by a wide range of marine organisms with the potential to cause harms. Microplastics are a growing threat for marine biota and ecosystem. For organisms, the risks associated with microplastic ingestion are not only due to the material itself, but also to its ability to absorb and concentrate environmental contaminants in seawater and subsequently transfer them through food chains. Moreover, microplastics could influence ecological processes. Recently, plastic debris are recognized as emerging pollutants and represent a great risk for marine biodiversity worldwide. Here, we summarize the main effects of plastics and microplastics on some marine organisms and ecosystem. [ABSTRACT FROM AUTHOR]

Gwada, B., et al. (2019). "Composition of plastic waste discarded by households and its management approaches." Global Journal of Environmental Science and Management **5**(1): 83-94.
Among the emerging environmental issues within Sub-Saharan Africa is the haphazard disposal of plastic waste, some of which end up downstream in the marine environment leading to negative effects. Notably there have been cases of humpback whales getting entangled in 'ghost' fishing nets, and endangered turtles ingesting plastic wastes in Watamu beach in Kenya. The aim of the current study was to assess the composition and management of plastic waste discarded by households in Watamu ward. Stratified random sampling was used to collect data from households in four sub-locations within Watamu ward. Data were analysed using descriptive and inferential statistics (the Freeman-Halton extension of the Fisher's Exact test). The composition of plastics usually discarded as waste by households in order of dominance were low density polyethylene, polyethylene terephthalate, high density polyethylene and polypropylene (FH=37.959, p=0.000). From the results, only 0.7% of respondents recycled their plastic waste. The most preferred disposal method of household plastic waste was open dumpsites (61.4%) followed by burning (12.9%) and discards (6.4%). Majority of respondents (93.6%), re-use some plastic containers for food, water, and oil storage. There was a significant difference in terms of how the respondents re-used their plastic waste in the four sub-locations (FH=36.437, p=0.005). In conclusion, the current plastic waste disposal methods at Watamu are not environmentally friendly and recycling is still at a smaller scale despite its potential to generate income and clean the environment, and promote ecosystem services and human wellbeing.

Gyekye, L. (2009). "Viridor fined on plastics." Materials Recycling Week **193**(19): 7-7.
The article reports on the £75,000 fine imposed by Maidstone Crown Court to Viridor Resource Management for the illegal shipping of mixed plastic waste to Dubai, United Arab Emirates (UAE). The court ruled that the company has violated the Transfrontier Shipment of Waste Regulations and the environmental policy of the UAE Federal Environment Agency. The court also ordered the company to pay £35,000.

H, M. T., et al. (2012). "Haploidentical stem cell transplantation with CD3/CD19 depleted grafts in paediatric patients with aplastic anaemias and haemoglobinopathies." Bone Marrow Transplantation **1)**: S382-S383.
We investigated a cohort of 13 pediatric patients with non-malignant diseases transplanted with T- and B-cell depleted peripheral stem cell grafts from haploidentical donors between 2004 and 2011. 5 patients had myelodyslastic syndrome with refractory cytopenia (MDS-RC), 5 had severe aplastic anemias (SAA) and 3 patients had hemoglobinopathies. 3 out of 13 patients received a 2nd SCT after rejecting the graft from matched related or unrelated donors. Median age was 8.3 years. Standard conditioning regimen consisted of Fludarabin (4x40 mg/m2), Thiotepa (1x10 mg/kg), Melphalan (2x70 mg/m2) and OKT3. Since 2009, patients received upfront additional total lymphoid irradiation (TLI, n=3) to prevent graft rejection. In the current protocol, OKT3 will be substituted by ATG. Graft manipulation was carried out by direct depletion using antiCD3/19 coated magnetic microbeads. A median number of 15.6x106 CD34+ Progenitorcells and 53x103 T-cells/kg body weight (BW) were transfused. Pharmacological Graft vs.Host Disease (GvHD)

prophylaxis was carried out with Mycofenolate until day 60, if residual T-cells in the graft exceeded 25000/kg BW. Primary engraftment occurred in all patients. 5/10 patients with non irradiation regimen rejected the haplo graft and needed reconditioning with Fludarabine (3x40 mg/m2), Thiotepa (1x5 mg/kg), ATG, OKT3, 7 Gy TLI and a second stem cell donation from a different parental donor. Thus, final engraftment was achieved in 13/13 patients. None of the patients rejected the second graft. None of the patients receiving upfront preventive TLI rejected the first graft. Median time to reach 500/mul neutrophiles was 9 days (9-14). Independence from platelet substitution was reached after 11 days (8-16). 7/13 patients (54%) had no signs of GvHD or GvHD grade I, 5 patients (38%) had GvHD grade II, 1 patient developed grade III (8%). TRM at day+100 and after 1 year was 0% and 15%, respectively. Event free survival (EFS) at 3 years was 85%. Conclusion(s): Haploidentical SCT with T-cell depleted grafts is a therapeutic option for non-malignant diseases if no matched donor is available. TRM was low, even if retransplantation was necessary. Fast recoveries of neutrophiles and platelets were achieved. Rejection could be avoided by adding TLI to the initial conditionig regimen. If a non-irradiation regimen is used, possible graft failures can be rescued by reconditioning with TLI and a second stem cell donation from a different parental donor.

Ha, J. and M. K. Yeo (2018). "The environmental effects of microplastics on aquatic ecosystems." Molecular and Cellular Toxicology **14**(4): 353-359.

Purpose of review: Contamination of aquatic ecosystems by plastics under 5 mm in size, which are classified as microplastics (MPs), is becoming increasingly serious, and research on the ecotoxicity of MPs is needed. In this study, we aimed to present solutions to the problem of MPs through a review of the current state of research on the definition of MPs, usage, leakage, toxicity, and domestic and overseas circulation of plastics. Recent findings: Long-term exposure to MPs results in ecotoxicity. MPs not only deliver chemical substances within organisms, but also act as mediators for chemicals or other contaminants in aquatic environments. Co-exposure to MPs and chemical contaminants has been reported to increase toxicity in several organisms. Copyright © 2018, The Korean Society of Toxicogenomics and Toxicoproteomics and Springer Nature B.V.

Ha, N., et al. (2011). "An autotransporter protein from Orientia tsutsugamushi mediates adherence to nonphagocytic host cells." Infection and Immunity **79**(4): 1718-1727.

Orientia tsutsugamushi, the causative agent of scrub typhus, is an obligate intracellular pathogen whose mechanism of cellular adhesion and invasion is poorly characterized. Bioinformatic analyses of two O. tsutsugamushi genomes revealed the presence of a group of genes that encode autotransporter proteins. In this study, we identified 10 autotransporter gene products and categorized them into five groups of orthologs (ScaA to ScaE) based on their sequence similarities. Sequence homology was highest between members of ScaC group, suggesting the functional conservation of bacterium-host interactions. ScaC was actively expressed on the surface of O. tsutsugamushi and induced antibody responses in scrub typhus patients. Experiments using microbeads conjugated to recombinant ScaC or a surrogate Escherichia coli expression system showed that ScaC was sufficient to mediate attachment to, but not invasion of, nonphagocytic mammalian cells. In addition, preincubation of host cells with recombinant ScaC significantly inhibited their interaction with O. tsutsugamushi. Finally, fibronectin was identified as a potential receptor for ScaC by using yeast two-hybrid screening, and this was confirmed using a glutathione S-transferase (GST) pulldown assay. Taken together, these results demonstrate that ScaC is involved in the interaction of O. tsutsugamushi with mammalian host cells and suggest that ScaC may play a critical role in bacterial pathogenesis.

Haag, L. C. (2013). "Range of fire determination from the pseudostippling of skin by shotshell buffer material." American Journal of Forensic Medicine & Pathology **34**(1): 56-62.

The plastic buffer material in certain American shotgun shells emerges from the muzzle with the same velocity as the pellets that it was intended to protect from deformation during the very high accelerative forces associated with the discharge process. These small plastic particles spread out quickly over distance in a predictable, reproducible, and uniform manner as they lose velocity because of air resistance. If these plastic particles strike skin with sufficient velocity and energy, they will produce stipple marks whose distribution and density can be used to establish range of fire. This can be of critical importance in the reconstruction of a shooting involving this type of ammunition.

Haapasalo, M., et al. (1996). "Hyaluronan, a possible ligand mediating Treponema denticola binding to periodontal tissue." Oral Microbiology & Immunology **11**(3): 156-160.

Binding of Treponema denticola ATCC 35405 to glycosaminoglycans, fibrinogen, type I collagen and porcine periodontal ligament epithelial cells was studied using an enzyme-linked immunosorbent assay. T. denticola bound to hyaluronan (hyaluronic acid) and its hexameric fragments. whereas little or no binding was detected to chondroitin-4-sulfate or dermatan sulfate proteoglycan. Binding of T. denticola to hyaluronan gradually increased during the 2-h incubation time. In contrast, binding to fibrinogen and type I collagen was more rapid, peaking within 5 min. T. denticola also bound to microbeads coated with hyaluronan and formed visible aggregates in solution. Pretreatment of the bacteria with hyaluronan or fibrinogen inhibited binding to hyaluronan. Gelatin, bovine serum albumin, chondroitin-4-sulfate, chondroitin-6-sulfate, heparin, dermatan sulfate, glucuronic acid, N-acetylglucosamine and N-acetyl-galactosamine did not inhibit binding. Binding was also inhibited by heating T. denticola and by pretreatment of the spirochetes with sodium periodate, phenylmethylsulfonyl fluoride, and p-chloromercurybenzoic acid. All these treatments also inhibited the chymotrypsin-like activity of T. denticola. Hyaluronan strongly inhibited binding of T. denticola to epithelial cells, whereas the other glycosaminoglycans and N-acetyl-glucosamine did not. The results show that T. denticola binds to hyaluronan, possibly by a mechanism involving the chymotrypsin-like surface protein of T. denticola.

Haave, M., et al. (2019). "Different stories told by small and large microplastics in sediment - first report of microplastic concentrations in an urban recipient in Norway." Marine Pollution Bulletin **141**: 501-513.

Microplastics (MP) in sediments from discharge sites for wastewater and deposition sites in deep regions in an urban fjord in Norway were extracted by density separation in a Microplastic Sediment Separator with ZnCl₂. Particles (>11mum) were identified using FTIR. Twenty different polymer types were identified, at concentrations from 12,000 to 200,000 particles kg⁻¹ dw. Over 95% of the MP were smaller than 100mum. High deposition of small MP agreed with known areas for organic deposition. Polyurethane acrylate resins dominated the small MP while polyamide fibers dominated the larger MP. Particles >500mum showed different maximum concentrations and spatial distribution from the smaller particles. This study is the first to report concentration ranges of identified plastic particles from a Norwegian fjord, down to sizes below the limit of visual identification. The results provides a baseline for future comparison, and point at relevant sizes for environmental risk assessments.

Habib, R. Z., et al. (2019). "Analysis of microbeads in cosmetic products in the United Arab Emirates." Environmental Pollution **258**: 113831.

The microparticle content of 37 common facial and body scrubs commercially available in the United Arab Emirates was analyzed. The chemical composition, ash content, physical characteristics, loading, particle size and shape of the microparticles were determined. Only 11 out of 37 products were found to have microplastic content. Many of the remaining products exhibited microparticles composed of microcrystalline cellulose and crushed walnut shells. Differential scanning calorimetry showed that microplastic products had softening points as low as 84 degreeC. Plastic microbeads of 2 products were found to fuse at 100 degreeC. The fusion altered the flotation characteristics of the microbeads of one product. Heat treatment of the product at 100 degreeC in the presence of silica gel led to entrainment of the silica and partial fragmentation of the beads upon cooling. This may be understood as one mechanism of fragmentation of a microplastic with a low softening point in the presence of hard soil particles under temperature cycling.

Habtour, E., et al. (2016). Damage precursor index (DPI) methodology for aviation structures. 8th European Workshop on Structural Health Monitoring, EWSHM 2016, July 5, 2016 - July 8, 2016, Bilbao, Spain, NDT.net.

In this study, a Damage Precursor Index (DPI) methodology is proposed to track the evolution of fatigue damage precursors immediately after establishing the dynamic behavior of a structure. The DPI is used to measure the change in the state of fatigue damage precursors in structures exposed to vibration loads. The DPI is based on estimating the nonlinear dynamic parameters in isotropic materials prior to crack formation. The model accounts for the incubation and evolution of localized material microplasticity. Structural compliance due to the presence of the micro-plasticity is observed experimentally. The change in the dynamic response as a result of damage precursors is used to update the global dynamic parameters, which are used to calculate a corresponding DPI. The fatigue damage precursors are verified through series of macro/micromechanical characterizations of isotropic structures under vibration loads. The application of the DPI methodology to structural health monitoring systems may considerably improve health awareness in complex systems due to the addition of sensitivity to damage precursors.

Hached, F., et al. (2014). "Mesenchymal stromal cells encapsulation in innovative biomaterials: Application to osteoarthritis treatment." Osteoarthritis and Cartilage **1)**: S444.

Osteoarthritis (OA) is a very common disease affecting a growing part of aging population. It is a degenerative joint disease accompanied by degradation of the articular cartilage and variable degrees of synovium inflammation. Mesenchymal Stromal Cells (MSC) have generated significant medical consideration since they secrete immuno-modulatory and anti-inflammatory factors. Unfortunately, the intra-articular injection of MSC suffers some major limitations including: (i) a massive cell death upon injection in the articular space making difficult to detect the injected cells for a sustained time; (ii) a risk of cell leak outside the articular space due to the propensity of MSC to migrate. Purpose(s): The present project is devoted to the development of a therapeutic strategy for OA, based on the exploitation of the immunomodulatory properties of MSC. To overcome the limitations of the crude intraarticular injections (cell death and leakage of MSC), we propose to entrap bioactive MSC prior to their injection within cytoprotective and permeable microcapsules made of innovative biomaterials. Materials: Alginate and silylated hydroxypropyl methylcellulose (Si- HPMC) were chosen as biocompatible biomaterials able to support the viability and bioactivity of encapsulated MSC. MSC were isolated from human adipose tissue (hADSC: human adipose tissue stromal cells). We selected a dropwise method in $CaCl_2$ solution to obtain alginate capsules. To produce SI-HPMC microcapsules, we developedwater in oil (w/o) emulsion protocol with or without surfactant. To assess pore size of microcapsules, the diffusion of FITC-dextran molecules (sizes ranging from 20 to 2000 KDa) through alginate and Si-HPMC microcapsules were followed by confocal microscopy. For MSC encapsulation, a hADSC suspension of 2.106 cells/ml was added either to the alginate solution or to the Si-HPMC solution (without surfactant). The microbeads were then collected by filtration, washed with HEPES buffer and seeded in culture medium. Culture medium was changed every 2 days after cell encapsulation. hADSC viability after encapsulation in alginate and Si- HPMC was followed for a period of 24 h to 2 months using a Live/Dead Viability/Cytotoxicity kit. Result(s): By dropwise method, we obtained alginate capsules with an average size of 1,1 +/-0,2 mm. Preliminary results have shown that their pore size was between 10 nm and 21 nm. With Si-HPMC, we managed to develop a suitable microencapsulation method by varying operating parameters such as surfactant, temperature or rotating speed. In optimal conditions, we obtained Si-HPMC microbeads with a size of 50,3 +/-4,9 mum (when a surfactant was used) and 1 +/-0,9 mm (without surfactant). Their pore size was ranging from 10 nm to 21 nm. Then we encapsulated hADSC in both polymers.We detected a high rate of viable encapsulated cells in 1 mm alginate capsules (about 93% of viability at 2 months post-encapsulation). In addition, we observed a lower rate of viable encapsulated hADSC in 1 mm Si-HPMC capsules (less than 50% of viability at 48 h post-encapsulation). Conclusion(s): Alginate and Si-HPMC appear as suitable biomaterials for producing permeable microcapsules. Dropwise and emulsion methods allow us to obtain capsules with different sizes. Our data strongly suggest that capsule porosity is appropriate to maintain cell viability (diffusion of nutrients and oxygen) and biological functions. Further experiments are now under investigation to determine whether hADSC encapsulated in permeable biomaterials may be a relevant strategy to prevent cartilage degradation and inflammation in OA.

Hackstein, H., et al. (2011). "Human mesenchymal stem cells can promote phenotypic maturation of human plasmacytoid dendritic cells via Tolllike receptor 7/8." Transfusion Medicine and Hemotherapy **1)**: 20.

Background: Human mesenchymal stem cells (hMSC) represent important multipotent cells hitherto believed to exert primarily immunosuppressive effects on human dendritic cells. We show here that this view is incomplete by providing evidence that hMSC can efficiently promote phenotypic maturation of purified plasmacytoid dendritic cells (pDC). Method(s): hMSC were generated from bone marrow employing standard procedures and human BDCA-4+ pDC precursors were microbead-sorted according from human buffy coat samples. Cocultures of purified pDC and hMSCs were stimulated through different toll-like receptor (TLR) ligands and pDC activation was analyzed by flow cytometry and ELISA. Result(s): Triggering of hMSC pDC cocultures through TLR4 (LPS) or TLR9 (CpG ODN) did not affect upregulation of T cell costimulatory m,olecule expression CD40, CD80, CD86 and HLA-DR on pDCs. In contrast TLR7/8 activation of hMSC pDC cocultures resulted in marked upregulation of CD80 and CD86 surface expression on pDC when compared to pDC-only controls. Moreover, pDC maturation by hMSC was dose-dependent and a hMSC-pDC ration of 1:10 was already sufficient to increase pDC CD80 and CD86 surface expression (mean fluorescence intensity; MFI) by >75% and 190%, respectively. Increasing the hMSC concentration to 20% resulted in further stimulation of pDC CD80 and CD86 MFI after TLR7/8 activation by 331% and 669%, again compared to pDC-only controls. Furthermore, whereas presence of hMSC resulted in moderate reduction of TLR9-triggered interferon-alpha production by pDC, it was not inhibited after TLR7/8-mediated stimulation. Conclusion(s): These data indicate that hMSC are not per se immunosuppressive. The results identify TLR7/8 as a candidate pathway circumventing the immunoregulatory function of hMSC. Given the fact that TLR7/8 activation plays a critical role in the development of autoimmune diseases such as lupus erythematodes and during viral infection, our results may add to the understanding of basic principles of autoimmunity.

Hadzic, R., et al. (2005). "The CD19 molecule is crucial for MID-dependent activation of tonsillar B cells from children." Scandinavian Journal of Immunology **61**(2): 165-172.

The Moraxella immunoglobulin (Ig) D-binding protein (MID) induces a strong proliferative response in human peripheral blood IgD+ B cells from adults isolated by positive selection using anti-CD19-conjugated microbeads. Here, we show that tonsillar B cells from children isolated with positive selection are unable to respond to MID stimulation. The proliferative response was very low or absent at various concentrations of MID tested and at different time points analysed, whereas the MID response of tonsillar B cells from adults isolated with positive selection was considerably higher. Tonsillar B cells from children isolated with positive selection responded to formalin-fixed preparations of Moraxella catarrhalis and Staphylococcus aureus Cowan strain I. In comparison to cells isolated with positive selection, a much higher proliferative response was recorded in tonsillar B cells from children isolated with negative selection, indicating that occupation of the CD19 molecule (i.e. positive selection) inhibited the response. Indeed, the addition of anti-CD19 monoclonal antibodies (MoAb) to MID-activated tonsillar B cells from children isolated with negative selection strongly inhibited the proliferative response. In contrast, anti-CD21 MoAb at the same concentration did only show a minor inhibition on the MID-induced response. Pre-incubation of tonsillar B cells isolated from children with anti-CD19 or anti-CD21 MoAb did not affect the binding of biotin-conjugated MID as analysed by flow cytometry. These results suggest that MID-activated tonsillar B cells from children have a strong requirement for signalling through the CD19 molecule. Future experiments will further reveal the importance of CD19 and possibly other molecules for optimal activation of tonsillar B cells isolated from both children and adults.

Haegerbaeumer, A., et al. (2019). "Impacts of Micro- and Nano-Sized Plastic Particles on Benthic Invertebrates: A Literature Review and Gap Analysis." Frontiers in Environmental Science.

As documented by the numerous publications that have appeared in recent years, plastic pollution of the environment and the effects on the respective ecosystems are currently one of the most intensely discussed issues in environmental science and in society at large. Of special concern are the effects of micro- and nano-sized plastics. A key issue in understanding the fate and potential effects of micro- and nano-sized plastics is their dynamic nature, as the size, shape, and charge of the particles change over time. Moreover, due to various biological processes, such as the aggregation of organic material and/or bacteria (“biofouling”), the density of plastic particles that settle in the sediments of aquatic ecosystems may be several orders of magnitudes higher than that in the surrounding waters. Consequently, the risk posed by plastic pollution to benthic fauna is considerably high. Nonetheless, the vast majority of studies examining the effects of microplastics have focused on pelagic organisms so far. We therefore conducted a comprehensive literature review to examine the impact of micro- and nano-sized plastics on benthic invertebrates, including the physical and chemical effects of leaching and the interactions of plastic particles with contaminants. Overall, 330 papers were reviewed for their fulfilment of different criteria (e.g. test species, plastic material, particle shape, particle size, exposure concentration, exposure route, assay type, assay duration), with 49 publications finally included in our survey. A comprehensive gap-analysis on the effects of plastic particles on benthic invertebrates, revealed a wide variety of effects triggered by micro- and/or nano-sized plastics but also distinct differences regarding the plastic materials tested,

the size fractions applied, the shape of the respective particles and the exposure routes tested. Our review concludes with a discussion of the important research gaps concerning freshwater ecosystems and recommendations for future areas of research.

Hafezi-Moghadam, A., et al. (2001). "L-selectin shedding regulates leukocyte recruitment." Journal of Experimental Medicine **193**(7): 863-872.

The physiologic role of L-selectin shedding is unknown. Here, we investigate the effect of L-selectin shedding on firm adhesion and transmigration. In a tumor necrosis factor alpha-induced model of inflammation, inhibition of L-selectin shedding significantly increased firm adhesion and transmigration by a lymphocyte function-associated antigen (LFA)-1 and intercellular adhesion molecule (ICAM)-1-dependent mechanism. We examined the quality of leukocyte rolling and L-selectin-mediated signaling. Blockade of L-selectin shedding significantly reduced the "jerkiness" of leukocyte rolling, defined as the variability of velocity over time. A low level of jerkiness was also observed in the rolling of microbeads conjugated with L-selectin, a model system lacking the mechanism for L-selectin shedding. Inhibition of L-selectin shedding potentiated activation of LFA-1 and Mac-1 induced by L-selectin cross-linking as shown by activation epitope expression and binding of ICAM-1-conjugated beads. We conclude that inhibition of L-selectin shedding increases leukocyte adhesion and transmigration by (a) increasing leukocyte exposure to the inflamed endothelium by decreasing jerkiness and (b) promoting leukocyte activation by outside-in signaling. These observations help to resolve the apparent discrepancy between the minor contribution of L-selectin to rolling and the significant leukocyte recruitment defect in L-selectin knockout mice.

Haghi, B. N. and M. Banaee (2017). "Effects of micro-plastic particles on paraquat toxicity to common carp (Cyprinus carpio): biochemical changes." International Journal of Environmental Science and Technology **14**(3): 521-530.

In this study, we investigated the possible effects of paraquat and micro-plastics on blood biochemical parameters in common carp (Cyprinus carpio). We exposed C. carpio for 21 days to sublethal concentrations of paraquat (0.2 and 0.4 mg L⁻¹) and micro-plastics (1 and 2 mg L⁻¹), alone or in combination. Blood biochemical analysis indicated that exposure to 0.4 mg L⁻¹ paraquat and mixture of paraquat and micro-plastics was followed by an increase in aspartate aminotransferase (AST), alkaline phosphatase (ALP), and creatine phosphokinase (CPK) activities and glucose levels. The activity of ALP and CPK showed a significant increase in fish treated with 2 mg L⁻¹ micro-plastics. No significant changes were observed in glucose level, AST, ALT, and LDH activities in fish exposed to micro-plastics. Exposure to paraquat and/or micro-plastics resulted in a significant decrease in total protein, globulin, cholesterol, and triglyceride levels and gamma -glutamyl transferase activity. When fish were exposed to paraquat or paraquat and micro-plastics, alanine aminotransferase (ALT) and lactate dehydrogenase (LDH) activities increased significantly compared to the control group. Treating fishes with a mixture of paraquat and 2 mg L⁻¹ micro-plastics caused a significant increase in albumin levels. However, a significant decrease in the albumin level was observed after exposure to paraquat or micro-plastics. Creatinine levels increased after exposure to paraquat and/or micro-plastics. The results indicate that increased doses of micro-plastics in water significantly increased toxic effects of paraquat in fish. Finally, these data support the hypothesis that changes in blood biochemical parameters were induced by exposure to paraquat and/or micro-plastics.

Hahladakis, J. N. and E. Iacovidou (2019). "An overview of the challenges and trade-offs in closing the

loop of post-consumer plastic waste (PCPW): Focus on recycling." Journal of Hazardous Materials **380**: 120887.

Recycling of post-consumer plastic waste (PCPW) is increasingly promoted as the means to achieving circular economy (CE). It converts plastic waste into a secondary material that can be fed back into the system, for use in the same or new components and products, with similar or lower functionality; hence "closing the loop". Up until today, research on examining the environmental impacts, economic implications and technicalities of plastic waste recycling deals with one particular aspect, or stage on the plastic value chain, lacking coherence and structure. To move this research forward, understanding the challenges and trade-offs in scaling up plastic waste recycling is necessary. Here, we bring together existing literature on the multi-faceted aspects of closing the plastic loop, critically debating on the multi-stakeholder endeavours of promoting circularity in the plastics value chain. We present an overview of how the design, production, collection and sorting of PCPW present challenges for plastic waste recycling, which in turn result to a number of trade-offs. We explain that the evaluation of the multi-dimensional implications of trade-offs arising from the PCPW recycling, is essential in measuring the long-term sustainability of resource recovery from waste systems. This work scrutinises the sustainability of closing the plastic waste loops and sets a future research agenda.

Hahn, A., et al. (2019). "Using FTIRS as pre-screening method for detection of microplastic in bulk sediment samples." Science of the Total Environment **689**: 341-346.

We present calibration models for the detection of two types of plastic (LDPE, PET) in sediments, developed from analysis of synthetic sediment mixtures and application of Fourier transform infrared spectroscopy (FTIRS) and partial least squares regression (PLSR) modeling. Synthetic sediment mixtures were produced using ground plastic particles mixed with various different sediment matrixes yielding LDPE and PET contents ranging from 0 to 5wt%. The resulting PLSR calibration models between the FTIRS spectral information and the defined plastic concentration of the synthetic sediment mixtures show strong cross-validated correlations (R²_{CV}=0.73 and 0.72) as well as low root-mean square errors of cross-validation (RMSE_{CV}=0.72 and 0.61; 14.4% and 12.2% when expressed as % of gradient). Application of the calibration to natural sediments shows that the method can be used to detect the presence of microplastics in sediment. The results are only semi-quantitative and semi-qualitative, and the method is suitable mainly for samples with very high microplastic concentrations (>1%). However the major advantage of this procedure is the time and cost efficiency. For studies with large amounts of samples (e.g. monitoring applications) we recommend this method as a pre-screening tool for selecting samples with plastic content for further analysis.

Hahn, Y. K., et al. (2007). "Magnetophoretic immunoassay of allergen-specific IgE in an enhanced magnetic field gradient." Analytical Chemistry **79**(6): 2214-2220.

We demonstrate a novel magnetophoretic immunoassay of allergen-specific immunoglobulin E (IgE) based on the magnetophoretic deflection velocity of a microbead that is proportional to the associated magnetic nanoparticles under enhanced magnetic field gradient in a microchannel. In this detection scheme, two types of house dust mites, Dermatophagoides farinae (D. farinae) and Dermatophagoides pteronyssinus (D. pteronyssinus), were used as the model allergens. Polystyrene microbeads were conjugated with each of the mite extracts followed by incubation with serum samples. The resulting mixture was then reacted with magnetic nanoparticle-conjugated anti-human IgE for detection of allergen-specific IgE by using sandwich immuno-reactions. A ferromagnetic microstructure combined with a permanent

magnet was employed to increase the magnetic field gradient (approximately 10(4) T/m) in a microfluidic device. The magnetophoretic velocities of microbeads were measured in a microchannel under applied magnetic field, and the averaged velocity was well correlated with the concentration of allergen-specific IgE in serum. From the analysis of pooled sera obtained from 44 patients, the detection limits of the allergen-specific human IgEs for D. farinae and D. pteronyssinus were determined to be 565 (0.045 IU/mL) and 268 fM (0.021 IU/mL), respectively. These values are 1 order of magnitude lower than those by a conventional CAP system. For evaluation of reproducibility and accuracy, unknown sera were subjected to a blind test by using the developed assay system, and they were compared with the CAP system. As a result, coefficient of variance was less than 10%, and the developed method enabled a fast assay with a tiny amount of serum (approximately 10 microL).

Hahn, Y. K., et al. (2006). Magnetophoretic immunoassay for allergen-specific immunoglobulin E (IgE) in patient samples. Micro Total Analysis Systems - Proceedings of MicroTAS 2006 Conference: 10th International Conference on Miniaturized Systems for Chemistry and Life Sciences.

This paper reports a novel magnetophoretic immunoassay using a microbead conjugated with superparamagnetic nanoparticles under the enhanced magnetic field gradient. A ferromagnetic microstructure connected with a permanent magnet is used to increase the magnetic field gradient (∼104 T m -1) and successfully applied to detect allergen-specific IgEs samples obtained from 44 patients' serum in a hospital. The detectable ranges of human IgEs are 10.68 ng mL-1 to 151 pg mL-1 (Dermatophagoides pteronyssinus) and 19.47 ng mL-1 to 104 pg mL-1 (Dermatophagoides farinae). © 2006 Society for Chemistry and Micro-Nano Systems.

Haider, T. P., et al. (2019). "Plastics of the Future? The Impact of Biodegradable Polymers on the Environment and on Society." Angewandte Chemie. International Ed. in English **58**(1): 50-62.

In recent years the littering of plastics and the problems related to their persistence in the environment have become a major focus in both research and the news. Biodegradable polymers like poly(lactic acid) are seen as a suitable alternative to commodity plastics. However, poly(lactic acid) is basically non-degradable in seawater. Similarly, the degradation rate of other biodegradable polymers also crucially depends on the environments they end up in, such as soil or marine water, or when used in biomedical devices. In this Minireview, we show that biodegradation tests carried out in artificial environments lack transferability to real conditions and, therefore, highlight the necessity of environmentally authentic and relevant field-testing conditions. In addition, we focus on ecotoxicological implications of biodegradable polymers. We also consider the social aspects and ask how biodegradable polymers influence consumer behavior and municipal waste management. Taken together, this study is intended as a contribution towards evaluating the potential of biodegradable polymers as alternative materials to commodity plastics.

Halden, R. U. (2010). "Plastics and health risks." Annual Review of Public Health **31**: 179-194.

By 2010, the worldwide annual production of plastics will surpass 300 million tons. Plastics are indispensable materials in modern society, and many products manufactured from plastics are a boon to public health (e.g., disposable syringes, intravenous bags). However, plastics also pose health risks. Of principal concern are endocrine-disrupting properties, as triggered for example by bisphenol A and di-(2-ethylhexyl) phthalate (DEHP). Opinions on the safety of plastics vary widely, and despite more than five decades of research, scientific consensus on product safety is still elusive. This literature review summarizes information from more than 120 peer-reviewed publications on health effects of plastics and plasticizers in lab animals and humans. It examines problematic exposures of susceptible populations and also briefly summarizes adverse environmental impacts from plastic pollution. Ongoing efforts to steer human society toward resource conservation and sustainable consumption are discussed, including the concept of the 5 Rs--i.e., reduce, reuse, recycle, rethink, restrain--for minimizing pre- and postnatal exposures to potentially harmful components of plastics. [References: 129]

Halden, R. U. (2015). "Epistemology of contaminants of emerging concern and literature meta-analysis." Journal of Hazardous Materials **282**: 2-9.

A meta-analysis was conducted to inform the epistemology, or theory of knowledge, of contaminants of emerging concern (CECs). The CEC terminology acknowledges the existence of harmful environmental agents whose identities, occurrences, hazards, and effects are not sufficiently understood. Here, data on publishing activity were analyzed for 12 CECs, revealing a common pattern of emergence, suitable for identifying past years of peak concern and forecasting future ones: dichlorodiphenyltrichloroethane (DDT; 1972, 2008), trichloroacetic acid (TCAA; 1972, 2009), nitrosodimethylamine (1984), methyl tert-butyl ether (2001), trichloroethylene (2005), perchlorate (2006), 1,4-dioxane (2009), prions (2009), triclocarban (2010), triclosan (2012), nanomaterials (by 2016), and microplastics (2022 +/- 4). CECs were found to emerge from obscurity to the height of concern in 14.1 +/- 3.6 years, and subside to a new baseline level of concern in 14.5 +/- 4.5 years. CECs can emerge more than once (e.g., TCAA, DDT) and the multifactorial process of emergence may be driven by inception of novel scientific methods (e.g., ion chromatography, mass spectrometry and nanometrology), scientific paradigm shifts (discovery of infectious proteins), and the development, marketing and mass consumption of novel products (antimicrobial personal care products, microplastics and nanomaterials). Publishing activity and U.S. regulatory actions were correlated for several CECs investigated.

Hale, R. C. (2018). "Are the Risks from Microplastics Truly Trivial?" Environmental Science and Technology **52**(3): 931.

Hall, N. M., et al. (2015). "Microplastic ingestion by scleractinian corals." Marine Biology **162**(3): 725-732.

We report for the first time the ingestion of microplastics by scleractinian corals, and the presence of microplastics in coral reef waters adjacent to inshore reefs on Australia's Great Barrier Reef (GRE, 18°31'S 146°23'E). Analysis of samples from sub-surface plankton tows conducted in close proximity to inshore reefs on the central GBR revealed microplastics, similar to those used in marine paints and fishing floats, were present in low concentrations at all water sampling locations. Experimental feeding trials revealed that corals mistake microplastics for prey and can consume up to ~50 [mu]g plastic cm^sup -2^ h^sup -1^, rates similar to their consumption of plankton and Artemia nauplii in experimental feeding assays. Ingested microplastics were found wrapped in mesenterial tissue within the coral gut cavity, suggesting that ingestion of high concentrations of microplastic debris could potentially impair the health of corals.

Halldorsdottir, A. M., et al. (2009). "Comparison of two platforms for HLA antibody screening in apheresis platelet donors." Transfusion **3)**: 191A-192A.

Background: HLA (Human Leukocyte Antigen) antibodies are implicated in TRALI (Transfusion-related Acute Lung Injury), the leading cause of transfusion- related fatalities. Donor screening may reduce TRALI risk. More data is needed on the frequency of HLA

alloimmunization as well as the performance of various detection techniques. This study compares two different assays at a hospital-based donor center; 1) the Dynachip, an automated assay combining ELISA with microarray technology and 2) the LABScreen Single Antigen (SA), a microbead-flow assay. Method(s): Samples from 149 apheresis platelet donors, 96 females and 53 males, who answered questions regarding pregnancy and transfusion history were tested for HLA Class I and II antibodies using two platforms. 1) DynaChipTM HLA Antibody Analysis System (Invitrogen, CA) and 2) LABScreen (SA) assay (One Lambda) for the Luminex instrument. Several thresholds were tested for both methods. In the Dynachip assay reactions are scored based on signal strength (to ?) and percent reactive antibody (PRA). Detection rate was compared for PRA > 2% vs > 5% and for reaction strength +?vs +?. The LABScreen interpretation was based on the normalized background (NBG) ratio, comparing NBG > ?10, 20, 30, 40 and 50. Donor pregnancy and transfusion history was compared to the presence of HLA antibodies. Result(s): Only 7 of 149 (5%) donors had been transfused (5 females and 2 males), whereas 65 of 96 (68%) females had been pregnant. The prevalence of Class I and/or Class II antibodies in the Dynachip and LABScreen assays using different cutoffs is displayed in the table. The prevalence of Class I and/or Class II antibodies ranged widely depending on the threshold used; the range was 16% to 59% for the LABScreen and 14% to 67% for the Dynachip. Positive pregnancy history correlated with HLA alloimmunization but this correlation was stronger in the LABScreen compared to the Dynachip assay (table). LABScreen was negative for both transfused males and one transfused nonpregnant female, but one transfused non-pregnant female reacted in the Dynachip assay. The concordance between the two methods ranged from 59% for the least stringent (NBG > ?10 and +/2%) to 84% using the most stringent criteria (NBG > ?50 and +?/5%). Conclusion(s): The prevalence of HLA antibodies in donors depends on the choice of assay and the thresholds used. The concordance between the LABScreen SA and Dynachip HLA antibody assays was poor at low thresholds. The correlation with pregnancy history was stronger in the LABScreen than in the Dynachip assay.

Halle, A. T., et al. (2017). "Nanoplastic in the North Atlantic Subtropical Gyre." Environmental Science & Technology **51**(23): 13689-13697.

Plastics can be found in all ecosystems across the globe. This type of environmental pollution is important, even if its impact is not fully understood. The presence of small plastic particles at the micro- and nanoscales is of growing concern, but nanoplastic has not yet been observed in natural samples. In this study, we examined four size fractions (meso-, large micro-, small micro-, and nanoplastics) of debris collected in the North Atlantic subtropical gyre. To obtain the nanoplastic portion, we isolated the colloidal fraction of seawater. After ultrafiltration, the occurrence of nanoscale particles was demonstrated using dynamic light scattering experiments. The chemical fingerprint of the colloids was obtained by pyrolysis coupled with gas chromatography-mass spectrometry. We demonstrated that the signal was anthropogenic and attributed to a combination of plastics. The polymer composition varied among the size classes. At the micro- and nanoscales, polyvinyl chloride, polyethylene terephthalate, polystyrene and polyethylene were observed. We also observed changes in the pyrolytic signals of polyethylene with decreasing debris size, which could be related to the structural modification of this plastic as a consequence of weathering. Halle, L. L., et al. (2020). "Ecotoxicology of micronized tire rubber: Past, present and future considerations." Science of the Total Environment **706 (no pagination)**(135694).

Micronized tire rubber has recently come into focus as black particles that are found in microplastic (MP) samples worldwide. These particles have been found in all environmental compartments with the most likely source being the abrasion of car tires on road surfaces. Thus, it is well founded that tires are a source of MPs and that tire abrasion is a primary source of anthropogenic particulates. Currently, the impact of tires has been viewed through the lens of particulate pollution together with MPs, but this is a relatively new direction for this topic. Previously ecotoxicological research into the environmental consequences of tires has primarily been related to the leached chemicals from tire particulates. This paper aims to (i) highlight similarities and differences of micronized rubber particles with the existing suite of polymer contaminants termed as 'microplastics' or 'plastic debris', (ii) survey the existing literature on environmental presence, fate, and interaction of micronized rubber particles with biota, and lastly (iii) present future research needs that require consideration in order to move this research area forward. Existing knowledge gaps that require attention include; determining the environmental presence and fate of micronized rubber within different environmental compartments, understanding the interaction of rubber particles with biota, particularly as potential impacts have so far been attributed solely to the leachate, and evaluating whether standard ecotoxicological protocols need to be adapted for particulate contaminants in general and specifically to suit rubber particulates and leachate. Halstead, J. E., et al. (2018). "Assessment tools for microplastics and natural fibres ingested by fish in an urbanised estuary." Environmental Pollution **234**: 552-561.

Microplastics and fibres occur in high concentrations along urban coastlines, but the occurrence of microplastic ingestion by fishes in these areas requires further investigation. Herein, the ingestion of debris (i.e., synthetic and natural fibres and synthetic fragments of various polymer types) by three benthic-foraging fish species Acanthopagrus australis (yellowfin bream), Mugil cephalus (sea mullet) and Gerres subfasciatus (silverbiddy) in Sydney Harbour, Australia has been quantified and chemically speciated by vibrational spectroscopy to identify the polymer type. Ingested debris were quantified using gut content analysis, and identified using attenuated total reflectance Fourier transform infrared (ATR-FTIR) and Raman microspectroscopies in combination with principal component analysis (PCA). The occurrence of debris ingestion at the time of sampling ranged from 21 to 64% for the three species, and the debris number ranged from 0.2 to 4.6 items per fish for the different species, with ~53% of debris being microplastic. There was a significant difference in the amount of debris ingested among species; however, there was no difference among species when debris counts were standardised to fish weight or gut content weight, indicating that these species ingest a similar concentration of debris relative to their ingestion rate of other material. ATR-FTIR microspectroscopy successfully identified 72% of debris. Raman spectroscopy contributed an additional 1% of successful identification. In addition, PCA was used to non-subjectively classify the ATR-FTIR spectra resulting in the identification of an additional 9% of the debris. The most common microplastics found were polyester (PET), acrylic-polyester blend, and rayon (semi-synthetic) fibres. The potential of using Raman microspectroscopy for debris identification was investigated and provided additional information about the nature of the debris as well as the presence of specific dyes (and hence potential toxicity).

Halverson, G. R. (2010). "The relative hemolytic index (RHI): A new mathematical model to predict the outcome of an incompatible blood transfusion." Transfusion **2)**: 38A.

Background: Bioassays to predict blood transfusion outcome where there is serologic incompatibility have included ⁵¹Cr-labeled survival studies, monocyte monolayer assay (MMA), antibody dependant cell-mediated cytotoxicity (ADCC) and in vivo crossmatch. These tests are costly, take time, and the results can be unclear. Introduced here is a new mathematical model, the Relative Hemolytic Index (RHI), which is intended to replace these bioassays for predicting blood transfusion outcome. Method(s): The RHI includes tests to measure total IgG concentration or titer, isotype, C1q binding capacity and Fcgamma receptor (FcgammaR) affinity. The IgG titer was determined by hemagglutination. Microbeads analyzed by flow cytometric analysis determined the isotype and the FcgammaR affinity. C1q binding was done by Elisa. Antibodies in higher concentration received a higher score than those of lower concentration. Sera that were mostly IgG1 or IgG3 scored higher than IgG2 or IgG4. IgM antibodies received a high score. Serum with high C1q binding capacity scored higher than those with low binding capacity. Antibodies with an affinity for FcgammaRI or FcgammaRIIIa scored higher than those to FcgammaRIIa. The RHI is the sum of the scores obtained. The samples were also tested by MMA to compare results obtained with the RHI. Result(s): Two human monoclonal (Mab) anti-Ds were used as controls in all four RHI assays. Based upon the results obtained with the controls, the cutoff for a significant RHI was set at 30. Assay results, scores and RHI for the Mab anti-D and three representative serum samples are shown in Table 1. The anti-D Mabs scored a high RHI at 39 and 47 respectively, and this is in agreement with a significant monocyte index (MI) of 30.5% and 44% respectively for RBC adherance and engulfment in the MMA. Of three representative serum samples, the anti-D+C and the warm/cold mixed autoantibody had significant RHI values of 57 and 46 respectively, while the anti-c serum sample did not with a score of 27. The MMA results also confirm those sera with a significant RHI scored an MI that is well above the >5% significance limit cutoff at 47.5% and 12.2% respectively. Conclusion(s): Current methods for predicting transfusion outcomes in the setting of blood incompatibility to serum antibodies are time consuming and costly, and are not immediately available for the critically ill patient requiring blood. The advantages of the RHI are that the tests can be multiplexed and run simultaneously, and can be completed within 6 hours. The RHI will not only save time and money, it will also allow for better patient care and for safer transfusions where the question of compatibility does not have a ready answer.

Halvorsen, E. H., et al. (2011). "Interleukin-15 Induces Interleukin-17 Production by Synovial T Cell Lines from Patients with Rheumatoid Arthritis." Scandinavian Journal of Immunology **73**(3): 243-249.

IL-17-producing T cells (Th17 cells) are believed to contribute to local inflammation and joint damage in rheumatoid arthritis (RA). Limited data exist on Th17 cells located within the inflamed synovial tissue (ST) of patients with RA. Here, we aimed to generate polyclonal T cell lines (TCLs) from the RA ST and assess their cytokine production, including the effects of exogenous IL-15 on IL-17 production in vitro. For five patients with RA, polyclonal TCLs were established from ST obtained by joint surgery. Synovial TCLs were expanded and stimulated by anti-CD3/CD28 microbeads and exogenous cytokines. Cytokine production was assessed by culture supernatant analyses and intracellular flow cytometry, and TCLs were sorted based on their surface expression of CCR6. In addition to IL-17, we detected IL-6, IL-10, IFN-gamma and TNF-alpha in the synovial TCL culture supernatants. Exogenous IL-15 increased the production of IL-17 as well as the other cytokines except IFN-gamma. For IL-17, this effect was more pronounced after prolonged culture times. Intracellular flow cytometry confirmed the presence of IL-17⁺ and IL-17⁺IFN-gamma⁺ CD4⁺ T cells in the TCLs. IL-17⁺ and IL-17⁺IFN-gamma⁺ T cells were enriched in the CD4⁺CCR6⁺ population. In conclusion, Th17 cells can be detected after polyclonal expansion and stimulation of RA synovial TCLs generated by joint surgery. The Th17 cells from the RA ST were enriched in the CD4⁺CCR6⁺ population, and they were sensitive to exogenous IL-15. Th17 cells present within the synovial compartment may contribute to the RA pathogenesis and local joint damage. © 2011 The Authors. Scandinavian Journal of Immunology © 2011 Blackwell Publishing Ltd.

Ham, A. S. W. (2006). Vascular drug targeting: Engineered poly(ethylene glycol) microparticle surfaces modulate receptor-specific adhesion.

In vascular disease, the expression of selectins on the endothelium signal areas of inflammation that can be used as a target drug delivery. To create a selectin targeting vehicle, microbeads were first conjugated with the monoclonal antibody HuEP5C7.g2 (HuEP), which has specificity to E- and P-selectin. While the HuEP microparticle targeting performance was not as comparatively stable as P-selectin Glycoprotein Ligand-1 microbeads, HuEP is an alternative to expensive glycoproteins which support targeting and rolling on selectin surfaces at near physiological flow conditions. To improve microparticle receptor-specific targeting, engineering a targeting moiety on the extremities of grafted tethers has been shown to increase effective tethering and to improve adhesion robustness. Therefore, microparticle surfaces were grafted with two types of poly(ethylene glycol) (PEG) tethers, a short PEG chain (MW 3400 Da), and a long PEG chains (MW 10000 Da). Under in vitro flow conditions, there was an increase in microbead avidity resulting in a 4.5-fold improvement in the tethering frequency and a 7-fold increase in the microparticle adhesion bond lifetime as the length of the PEG linker was increased. The data suggest that long PEG tethers improve targeting avidity by increasing ligand availability and lowering the dissociative forces on the adhesion bonds. PEG, as an engineered surface to modulate receptor-specific adhesion, additionally is used as a permeable repulsive barrier. The response of PEG layers under compressive forces to prevent the accessibility of buried ligand on microbeads showed that long PEG tethers provided a 2-fold increase in shielding efficiency over short PEG tethers at similar densities and pressures. Additionally, applying pressure to the PEG layer decreases the contact time necessary to achieve significant binding by 14-fold in PEG super(2000) and 17-fold in PEG super(10000) when compared to gravity mediated contact. The surface engineering of the particles with PEG largely prevented adhesion where it strongly regulates the accessibility of shielded ligands under applied pressure. The use of PEG linkers to engineer the surfaces of targeting microbeads as a mimetic of leukocyte microvilli in targeted drug delivery demonstrates the potential to use molecular polymer length and surface density to modulate the apparent adhesion kinetics of receptor-specific interactions.

Hamed, F., et al. (2020). "Shaking Table Study on PET Strips-Sand Mixtures Using Laminar Box Modelling." Geotechnical and Geological Engineering **38**(1): 683-694.

Daily increase in plastic waste amounts is a serious environmental problem and it is among the major challenges worldwide. Reusing this waste material can be therefore an appropriate solution to overcome this problem. Besides, recycling plastic waste as reinforcing material has become a cheap and viable alternative for soil improvement schemes. In the current study, PET plastic waste strips (water bottles) were randomly mixed with sandy soil to improve the soil strength parameters. Due to the lack of comprehensive seismic studies on soils reinforced with PET strips, a series of 1-g shaking table tests was performed to evaluate the dynamic properties of the sand-PET mixtures with different PET contents (0%, 0.5%, 0.75% and 1% by the sand

weight) and aspect ratios (1 and 5). Effect of various parameters, including excitation amplitude, PET strip content and PET strip aspect ratio on response of the mixtures were elaborated. It was found that addition of the PET strips to the sand, could reduce the soil brittleness under low overburden pressures. Therefore, at the inclusion ranges used in this study, increase of the PET strips content or aspect ratio, caused an increase in the damping ratio and decrease in the shear modulus values compared to the plain sand model. Opposite trends of PET strips inclusion contribution were reported under the influence of high overburden pressures through carrying out some cyclic large-scale direct shear tests.

Hamed, M., et al. (2019). "Assessment the effect of exposure to microplastics in Nile Tilapia (Oreochromis niloticus) early juvenile: I. blood biomarkers." Chemosphere **228**: 345-350.

There is a scarcity of knowledge about the impacts of microplastics (MPs) on the early juvenile stage of freshwater fish. The current study aims to inspect the exposure and post-exposure recovery of microplastics (MPs) on accumulation and blood biomarkers of Nile Tilapia (Oreochromis niloticus) early juvenile. Four groups of fishes were used; the first group was the control group, the second group was exposed to (1 mg/L of MPs), the third group was exposed to (10 mg/L of MPs), and the fourth group was exposed to (100 mg/L of MPs) for 15 days and 15 days of recovery. The results showed that significantly higher numbers of microplastics were observed in microplastics-exposed groups compared to control group. Biochemical parameters (creatinine, uric acid, AST, ALT, ALP, glucose, cholesterol, total protein, albumin, globulin, and A/G ratio) showed significant increment after exposure to microplastics for 15 days compared to control group in dose dependent manner. The hematological indices (RBC's count, Hb, Ht, MCHC, Platelets, WBC's count, and monocytes) showed a significant decline after exposure to microplastics for 15 days compared to control group, while MCV and MCH showed a significant increase after exposure to microplastics for 15 days. After the recovery period, microplastics accumulations, hemato-biochemical alterations were still detected in microplastics exposed groups compared to the control group except for WBC's count and MCV which return to normal levels. MPs caused anemia and perturbations in hemato-biochemical parameters which may cause mortality of tilapia early juvenile and should be considered in a program for monitoring hazard materials in the ecosystem.

Hämer, J., et al. (2014). "Fate of Microplastics in the Marine Isopod Idotea emarginata." Environmental Science & Technology **48**(22): 13451-13458.

Plastic pollution is an emerging global threat for marine wildlife. Many species of birds, reptiles, and fishes are directly impaired by plastics as they can get entangled in ropes and drown or they can ingest plastic fragments which, in turn, may clog their stomachs and guts. Microplastics of less than 1 mm can be ingested by small invertebrates, but their fate in the digestive organs and their effects on the animals are yet not well understood. We embedded fluorescent microplastics in artificial agarose-based food and offered the food to marine isopods, Idotea emarginata. The isopods did not distinguish between food with and food without microplastics. Upon ingestion, the microplastics were present in the stomach and in the gut but not in the tubules of the midgut gland which is the principal organ of enzyme-secretion and nutrient resorption. The feces contained the same concentration of microplastics as the food which indicates that no accumulation of microplastics happens during the gut passage. Long-term bioassays of 6 weeks showed no distinct effects of continuous microplastic consumption on mortality, growth, and intermolt duration. I. emarginata are able to prevent intrusion of particles even smaller than 1 µm into the midgut gland which is facilitated by the complex structure of the stomach including a fine filter system. It separates the midgut gland tubules

from the stomach and allows only the passage of fluids and chyme. Our results indicate that microplastics, as administered in the experiments, do not clog the digestive organs of isopods and do not have adverse effects on their life history parameters. [ABSTRACT FROM AUTHOR]

Hamlin, H. J., et al. (2015). "Migration of nonylphenol from food-grade plastic is toxic to the coral reef fish species Pseudochromis fridmani." Chemosphere **139**: 223-228.

Nonylphenol (NP) is a non-ionic surfactant used extensively in industrial applications, personal care products, and many plastics. We exposed marine orchid dottybacks (Pseudochromis fridmani) for 48 h to either glass, Teflon, or two bags labeled as FDA food-grade polyethylene (PE1 and PE2) from different manufacturers. The PE2 bags leached high levels of NP into the contact water, which were taken up by the fish, and decreased short and long-term survival. Concentrations of NP that leached from the bags were consistent with 96 h LC₅₀ values determined in this study, indicating NP is the likely toxic agent. Despite being similarly labeled, the NP concentrations that leached from the bags and the resultant toxicity to the fish varied dramatically between manufacturers. This study highlights that some plastics, labeled as food-safe, can be highly toxic to aquatic animals, and could pose a greater threat to humans than previously realized. This study also highlights risks for aquatic animals exposed to increasing quantities of plastic waste.

Hammami, M. B. A., et al. (2017). "Survey on awareness and attitudes of secondary school students regarding plastic pollution: implications for environmental education and public health in Sharjah city, UAE." Environmental Science & Pollution Research **24**(25): 20626-20633.

Since the industrial revolution in the 1800s, plastic pollution is becoming a global reality. This study aims to assess knowledge and attitude about plastic pollution among secondary school students in Sharjah city, United Arab Emirates. A cross-sectional study was conducted among 400 students in 6 different secondary schools in Sharjah city. Self-administered questionnaires were distributed through probability stratified random sampling method between February and April 2016. Majority of the population understands how harmful plastic wastes are to the environment (85.5%). However, the students' mean knowledge score was 53%, with females ($P < 0.01$), grades 11 and 12 ($P = 0.024$), and students whose mothers were more educated ($P = 0.014$) being more knowledgeable and inclined towards pro-environmental behavior. Yet, all students showed tendency to be involved in the fighting against this dilemma. Strategies which address deficiencies, provide incentives for change, and assure governmental support along with environmental education are needed to bridge the information gap and enhance opportunities to adopt pro-environmental behaviors.

Hammer, J., et al. (2012). "Plastics in the marine environment: the dark side of a modern gift." Reviews of Environmental Contamination & Toxicology **220**: 1-44.

Plastics are cheap, strong, and durable and offer considerable benefits to humanity. They potentially can enhance the benefits that both medical and scientific technology will bestow to humankind. However, it has now been several decades since the use of plastics exploded, and we have evidence that our current approach to production, use, transport and disposal of plastic materials has caused, and is still causing serious effects on wildlife, and is not sustainable. Because of frequent inappropriate waste management practices, or irresponsible human behavior, large masses of plastic items have been released into the environment, and thereby have entered the world's oceans. Moreover, this process continues, and in some places is even increasing. Most plastic debris that now exists in the marine environment originated from ocean-based sources such as the fishing industry. Plastics accumulate in coastal areas, at the ocean surface and on the seabed. Because 70% of all plastics are known to eventually sink, it is suspected that ever increasing amounts of plastic items are accumulating in seabed sediments. Plastics do not biodegrade, although, under the influence of solar UV radiations, plastics do degrade and fragment into small particles, termed microplastics. Our oceans eventually serve as a sink for these small plastic particles and in one estimate, it is thought that 200,000 microplastics per km(2) of the ocean's surface commonly exist. The impact of plastic debris has been studied since the beginning of the 1960's. To date, more than 267 species in the marine environment are known to have been affected by plastic entanglement or ingestion. Marine mammals are among those species that are most affected by entanglement in plastic debris. By contrast, marine birds suffer the most from ingestion of plastics. Organisms can also be seriously absorbed by floating plastic debris, or the contaminants may derive from plastic additives that are leached to the environment. Recent studies emphasize the important role of microplastics as they are easily ingestible by small organisms, such as plankton species, and form a pathway for contaminants to enter the food web. Contaminants leached from plastics tend to bioaccumulate in those organisms that absorb them, and chemical concentrations are often higher at higher trophic levels. This causes a threat to the basis of every food web and can have serious and far-reaching effects, even on nonmarine species such as polar bears and humans, who consume marine-grown food. Therefore, resolving the plastic debris problem is important to human kind for two reasons: we are both creator, and victim of the plastic pollution problem. Solutions to the plastic debris problem can only be achieved through a combination of actions. Such actions include the following: Legislation against marine pollution by plastics must be enforced, recycling must be accentuated, alternatives (biodegradable) to current plastic products must be found, and clean-up of debris must proceed, if the marine plastic pollution problem is to eventually be resolved. Governments cannot accomplish this task on their own, and will need help and initiative from the public. Moreover, resolving this long-standing problem will require time, money, and energy from many individuals now living and those of future generations, if a safer and cleaner marine environment is to be achieved.

Hammer, S., et al. (2016). "Plastic debris in great skua (Stercorarius skua) pellets corresponds to seabird prey species." Marine Pollution Bulletin **103**(1/2): 206-210.

Plastic is a common item in marine environments. Studies assessing seabird ingestion of plastics have focused on species that ingest plastics mistaken for prey items. Few studies have examined a scavenger and predatory species that are likely to ingest plastics indirectly through their prey items, such as the great skua (Stercorarius skua). We examined 1034 regurgitated pellets from a great skua colony in the Faroe Islands for plastics and found approximately 6% contained plastics. Pellets containing remains of Northern fulmars (Fulmarus glacialis) had the highest prevalence of plastic. Our findings support previous work showing that Northern fulmars have higher loads of plastics than other sympatric species. This study demonstrates that marine plastic debris is transferred from surface feeding seabird species to predatory great skuas. Examination of plastic ingestion in species that do not ingest plastics directly can provide insights into how plastic particles transfer vertically within the food web.

Hammill, T. B. and R. L. Crawford (1997). "Bacterial microencapsulation with three algal polysaccharides." Canadian Journal of Microbiology **43**(11): 1091-1095.

Methods for encapsulating pollutant-degrading bacteria into microbeads of carrageenan type I, carrageenan type II, and guar gum are described. Cell suspensions in solutions of encapsulating agents were passed through a low-pressure nozzle into an aqueous medium. The resultant aerosols polymerized to form microbeads that ranged in diameter from 2-70 mum. Pentachlorophenol degradation experiments with an encapsulated Sphingomonas sp. showed degradation rates similar to those seen using free cells. These results describe three additional matrices for the microencapsulation of bacteria that have potential for use in bioremediation processes.

Hammond, D. (1992). "Fast oligosaccharide separations identify fruit juice adulteration." Laboratory Equipment Digest **30**(8): 11-12.

Adulteration of orange juice with beet medium invert sugar (whose main sugars are in similar concentration ratio) may be detected via analysis for oligosaccharides present in invert syrups but not in natural juices. Sub-ppm levels of such oligosaccharides are detected in slightly more than 30 min, compared with 2 h for the standard GC method, using a Dionex DX-300 ion chromatograph having a column of Microbeads (sub-micron particles of a polymer having many anion-exchange sites at the surface) followed by HPAE-PAD (high-pH anion exchange pulsed amperometric detection).

Han, B., et al. (2009). "Ex vivo expansion and hematopoietic reconstitution ability of isolated CD34+CD59+ cells from patients with paroxysmal nocturnal hemoglobinuria." Haematologica **1)**: S31.

Paroxysmal nocturnal hemoglobinuria (PNH) is a clonal hematopoietic stem cell disorder characterized by intravascular hemolysis, venous thrombosis, and bone marrow (BM) failure. Until now, allogeneic(allo) hematopoietic stem cell transplantation is still the only way to cure PNH. Eculizumab, although very promising, is not the eradication of the disease because of raising the possibility of severe intravascular hemolysis if therapy is interrupted. Here we isolated the residual bone marrow normal progenitor cells (marked by CD34 + CD59 +) from PNH patients, tried to find a way of effectively expanding the progenitors cells ex vivo. Object. To expand CD34 + CD59 + cells isolated from patients with PNH and observed the long term hemaotopoietic reconstruction ability both ex vivo and in vivo. Method. CD34 + CD59 + cells from 13 patients with PNH and CD34 + cells from 11 normal controls were isolated from the bone marrow mononucleated cells first with immunomagnetic microbead and then by autoclone flow cytometry sorting. The sorted cells were then cultivated under different conditions for two weeks to find out the optimal expansion. The long term hematopoietic supporting ability was evaluated by long-term culture in semi-solid medium ex vitro and long-term engraftment in irradiated immunodeficient mice in vivo. Results. CD34 + CD59 + cells from patients with PNH can be expanded effectively in vitro, and the biggest expansion of CD34 + CD59 + cells was 23.49+/-3.52 fold on the 7th day. The best combination of hematopietic factors for in vitro expansion was SCF+IL-3+IL-6+FL+Tpo+Epo, and the most suitable time for harvesting was on day 7. Although the CD34 + CD59 + PNH cells have impaired ex vivo proliferation and survival compared with normal CD34 + cells, they remain strong colony-forming capacity in long-term culture. The peripheral blood cell count in lethally irradiated mice transplanted with expanded CD34 + CD59 + PNH cells recovered on day 90, which was compatible with those transplanted with normal CD34 cells (p>0.05). The survival rate and human CD45 xpression in different organs was similar between mice ransplanted ith CD34 D59 NH cells and those with normal CD34 ells p>0.05). On secondary ransplantation, the

peripheral blood cell count eturned to almost normal on day 30 in mice transplanted ither with NH cells or with normal control cells. Lower CD45 percentage was found in secondary transplantation but no difference between mice transplanted with different cells. Conclusion. Isolated CD34 CD59+cells from patients with PNH can be effectively expanded ex vivo and can sup-port hematopoiesis both in vitro and in vivo in the long term. These data provide a new potential way of managing PNH with auto-PBSCT.

Han, K. Y., et al. (2018). "SIDR: simultaneous isolation and parallel sequencing of genomic DNA and total RNA from single cells." Genome Research **28**(1): 75-87.

Simultaneous sequencing of the genome and transcriptome at the single-cell level is a powerful tool for characterizing genomic and transcriptomic variation and revealing correlative relationships. However, it remains technically challenging to analyze both the genome and transcriptome in the same cell. Here, we report a novel method for simultaneous isolation of genomic DNA and total RNA (SIDR) from single cells, achieving high recovery rates with minimal cross-contamination, as is crucial for accurate description and integration of the single-cell genome and transcriptome. For reliable and efficient separation of genomic DNA and total RNA from single cells, the method uses hypotonic lysis to preserve nuclear lamina integrity and subsequently captures the cell lysate using antibody-conjugated magnetic microbeads. Evaluating the performance of this method using real-time PCR demonstrated that it efficiently recovered genomic DNA and total RNA. Thorough data quality assessments showed that DNA and RNA simultaneously fractionated by the SIDR method were suitable for genome and transcriptome sequencing analysis at the single-cell level. The integration of single-cell genome and transcriptome sequencing by SIDR (SIDR-seq) showed that genetic alterations, such as copy-number and single-nucleotide variations, were more accurately captured by single-cell SIDR-seq compared with conventional single-cell RNA-seq, although copy-number variations positively correlated with the corresponding gene expression levels. These results suggest that SIDR-seq is potentially a powerful tool to reveal genetic heterogeneity and phenotypic information inferred from gene expression patterns at the single-cell level.

Han, L., et al. (2012). "Increased expression and function of P-glycoprotein in peripheral blood CD56+ cells is associated with the chemoresistance of non-small-cell lung cancer." Cancer Chemotherapy & Pharmacology **70**(3): 365-372.

PURPOSE: Chemoresistance is common among non-small-cell lung cancer (NSCLC), P-glycoprotein (P-gp), encoded by the human multi-drug-resistant MDR1 gene, and multidrug-resistance protein 1 (MRP1) might be major contributors. The aim of the present study was to develop an effective method to investigate the expression and function of P-gp in the peripheral CD56+ cells in order to clarify their correlation with the chemoresistance in NSCLC.

METHODS: Using microbead technology and a RT-qPCR methodology, we evaluated the expression levels of P-gp and MRP1 in the purified CD56+ cells in the chemoresistance and chemo-naive NSCLC patients compared with that in the healthy volunteers. Flow cytometric analysis was used to investigate the changes of P-gp function in the CD56+ cells between the three cohorts.

RESULTS: The MDR1 gene expression was elevated markedly (twofold-tenfold), and P-gp function was increased in the chemoresistance cohort compared with the chemo-naive and the healthy cohorts; whereas there was only about two times averagely elevated for the MRP1 gene expression. No statistical significance ($p > 0.05$) was seen with respect to the expression of MDR1 and MRP1, the function of P-gp between the chemo-naive and the healthy cohorts.

CONCLUSIONS: P-gp in peripheral CD56+ cells demonstrated possible clinical relevance as predictive biomarkers for the identification of chemoresistance in NSCLC, while MRP1 may not play a significant role in the drug resistance in NSCLC. The potential applications for this finding are provided evidence to screen the potential P-gp reversors and to diagnose and manage the chemoresistance in NSCLC patients.

Han, X., et al. (2019). "An optimized density-based approach for extracting microplastics from soil and sediment samples." Environmental Pollution **254**(Pt A): 113009.

Microplastic pollution in the environment has received growing attention worldwide. A major impediment for accurate measurements of microplastics in environmental matrixes is to extract the particles. The most commonly-used method for separation from soil or sediment is flotation in dense liquid based on the relatively low density of plastic particles. This study provides an improved and optimized process for extraction of microplastic particles by modifying the floatation technique and floatation solution. Microplastics in soils and sediments are extracted by adding 200g dry soil or sediment sample to 1.3L mix of the saturated NaCl and NaI solutions in a volume ratio of 1:1 and aerating for 40s then filtering the supernatant. The accuracy and precision of the new approach is validated by recovery experiments using soil and sediment samples spiked with six common microplastic compounds: polyethylene (PE), polyethylene terephthalate (PET), polypropylene (PP), polyvinyl chloride (PVC), polystyrene (PS) and expanded polystyrene (EPS), and comparison with the previous method. The optimized approach is further compared with the previous approach using the real soil and sediment samples.

Han, Y., et al. (2015). "Clinical significance of circulating microparticles in phmyeloproliferative neoplasms (MPN)." Haematologica **1)**: 536.

Background: Microparticles (MPs) are small membrane vesicles that are classified a as follow: platelet-derived MPs (PMPs), endothelial MPs (EMPs), red blood cell MPs (RMPs) and tissue factor MPs (TF+MPs) based on their origins. Philadelphia chromosome-negative myeloproliferative neoplasms (Ph-MPN) are disorders characterized by abnormal hematopoiesis, thrombosis and JAK2V617F mutation. Although MPs are considered as biomarkers reflecting procoagulant state in cancer patients, whether they exist in the patients with Ph-MPN remains unclear. Aim(s): Our objective in this study was to measure the variation of the four types of MPs in the patients with MPN and to Figure out their correlations with JAK2V617F mutation and some clinical complications, especially thrombosis and splenomegaly. Method(s): Ninty-two patients with MPN were enrolled in this study, including 60 essential thrombocythemia (ET), 20 polycythaemia vera (PV), and 12 primary myelofibrosis (PMF). 30 healthy volunteers were selected as normal controls. Venous blood wasanticoagulated with sodium citrate (1:9). Plasma samples were measured by flow cytometry for RMPs, PMPs, TF+MPs and EMPs with phycoerythrin (PE)-conjugated monoclonal antibodies CD235a, CD61, CD142, and CD62E, respectively. Forward scatter was set in scale using fluorescent microspheres of 0.8mum and standard fluorescent microbeads (0~0.8mum) in diameter were used to set the microparticle gate. Data were presented as mean and standard deviation. Meanwhile, genomic DNA was extracted from mononuclear cells and amplified by allele specific polymerase chain reaction (PCR). Result(s): (1) Levels of RMPs, PMPs, EMPs and TF+MPs in patients with Ph- MPN was(135.2+/-291.60)/mul, (960.7+/-1539.1)/mul, (808.8+/-1244.5)/mul and (103.2+/-303.6)/mulrespectively; they were all significantly higher than control group (P<0.05). Moreover, levels of all four types of MPs in PMF group demonstrate significantly higher than PV group (P<0.05), and RMPs in PMF group was significantly higher than ET group (P<0.05).(2) Ph-MPN patients with thrombosis complication showed higher levels of all four types of MPs

than those without thrombosis complication(P<0.01). (3) Ph-MPN patients with splenomegaly showed higher levels of all four types of MPs than those without splenomegaly (P<0.01). (4) All four types of MPs in the JAK2V617F mutation group were higher than the group in which those patients without mutation (P<0.05). Summary and Conclusion(s): Ph-MPN patients reveals higher levels of all four types of MPs than normal controls, especially in patients complicated with thrombosis or splenomegaly. MPs in PMF patients possess more obvious increase than PV and ET groups. Patients with JAK2V617F mutation showed higher levels of the four types of MPs than that without JAK2V617F mutation. Consequently, MPs play an crucial role in the pathogenesis of Ph-MPN, and the MPs released may promote the formation of thrombosis.

Han, Y., et al. (2013). "Clinical significance of circulating microparticles in Ph-myeloproliferative neoplasms (MPN)." Blood. Conference: 55th Annual Meeting of the American Society of Hematology, ASH **122**(21).

Background Microparticles (MPs) are small membrane vesicles that are classified as red blood cell MPs (RMPs), platelet-derived MPs (PMPs), tissue factor MPs (TF+MPs) and endothelial MPs (EMPs) based on their origins. Philadelphia chromosome-negative myeloproliferative neoplasms (Ph-MPN) are disorders characterized by abnormal hematopoiesis, thrombosis, JAK2V617F mutation. Although MPs are considered as biomarkers reflecting procoagulant state in cancer patients, their involvement in the patients with Ph-MPN remains unclear. Our objective in this study was to measure the alterations of the four MPs types in the patients with MPN and to evaluate their correlations with JAK2V617F mutation and some clinical complications, especially for thrombosis and splenomegaly. Methods Sixty-seven patients with MPN were enrolled in this study, including 12 polycythaemia vera (PV), 49 essential thrombocythemia (ET) and 6 primary myelofibrosis (PMF). 30 healthy donors were selected as normal controls. Venous blood was anticoagulated with sodium citrate (1:9). Using flow cytometry, plasma samples were measured for RMPs, PMPs, TF+MPs and EMPs with phycoerythrin (PE)-conjugated monoclonal antibodies CD235a, CD61, CD142, and CD62E, respectively. Forward scatter was set in scale using fluorescent microspheres of 0.8mum and standard fluorescent microbeads (0-0.8mum) in diameter were used to set the microparticle gate. Data were expressed as median (M) and interquartile range (IQR). Meanwhile, genomic DNA was extracted from mononuclear cells and amplified by allele specific polymerase chain reaction (PCR). Results (1) Patients with MPN showed significantly higher plasma levels for all four MPs compared with healthy donors (P<0.05), namely 49.0/mul (15.8-109.5/mul) vs 21.0/mul (13.8-32.6/mul) for RMPs, 181.2/mul(75.8-1111.6/mul) vs 74.9/mul (55.5-115.4/mul) for PMPs, 48.1/mul (13.1-72.4/mul) vs 31.0/mul (14.9-47.6/mul) for TF+MPs and 310.2/mul (128.6-1130.5/mul) vs 155.9/mul (100.3-227.6/mul) for EMPs. (2) Among different subtypes of MPN, PMPs were higher in patients with PMF than patients with PV and ET (P<0.05), but there was no significant difference between PV and ET group. No obvious difference was found in RMPs, TF+MPs and EMPs among different subtypes of MPN patients. (3) MPN patients with JAK2V617F mutation (n=34) were found to have higher plasma levels of TF+MPs and RMPs than those without mutation (P<0.05) and this difference was not found for PMPs and EMPs. (4) MPN patients with various thrombotic complications (n=10) showed higher levels of all four types of MPs than those without thrombotic complications (n=31) (P<0.05). Elevated MP levels were also found in patients with splenomegaly (n=19) compared to those without splenomegaly (n=14) (P<0.05). Conclusion Higher levels of MPs were observed in MPN patients compared with healthy controls, especially in patients complicated with thrombosis and splenomegaly, which reflects a prothrombotic state. Moreover, significantly increased TF+MPs and RMPs were found in MPN patients with JAK2V617F mutatioin.

Han, Y. P., et al. (2017). "Cationic polystyrene resolves nonalcoholic steatohepatitis (NASH), obesity,and metabolic disorders in an animal model by promoting eubiosis of gut microbiota and decreasing endotoxemia." Gastroenterology **152 (5 Supplement 1)**: S1014.

Background and Aims: A pandemic of metabolic diseases, consisting of type-2 diabetes, non-alcoholic fatty liver diseases (NAFLD) and obesity is occurring world-wide. Efforts to investigate the underlying mechanism and to explore low cost but effective treatments are needed. Our previous work found that vitamin D signaling through its receptor (VDR) in the ileum maintains gut microbiota in eubiosis through up-regulating Paneth cell specific alpha-defensins and tight junction proteins. Mice fed a vitamin-D-deficient-high-fat diet (VDD+HFD) develop gut dysbiosis, endotoxemia, systemic inflammation, insulin resistance, fatty liver and central obesity. Our current study was aimed at determining if the cationic polystyrene resin cholestyramine could be used to sequester negatively charged endotoxin in addition to bile acids in the gut to reverse the effects we observed with VDD+HFD. Method(s): The mice receiving VDD+HFD were treated by oral gavage of cationic cholestyramine or control uncharged polystyrene microbeads for 10-12 weeks. In another experiment, fecal bacteria derived from the cholestyramine- or control-treated mice were transplanted into mice receiving VDD+HFD to determine if the effects observed with cholestyramine were mediated through rebalancing of gut microbiome and reduction of gut produced endotoxin. Result(s): Cholestyramine, but not the control polystyrene microbeads, was able to sequester gut bacterial endotoxin, leading to reduction of plasma endotoxin levels, resolving hepatic and systemic inflammation, and improving the metabolic disorders. Moreover, gut dysbiosis, being characterized by increased phylum Firmicutes and decreased phylum Bacteroidetes and Akkermansia muciniphila, spp was resolved by the cholestyramine treatment showing large increases of Akkermansia muciniphila. Fecal bacteria transplant from cholestyramine treatment but not from the control polystyrene prevented the metabolic disorders of the recipients. Conclusion(s): These results demonstrate a potential beneficial role of cholestyramine in treating the metabolic disorders due to VDD+HFD by inhibiting endotoxemia and promoting gut eubiosis.

Han, Z., et al. (2011). "Generation of antigen-specific regulatory T cells from human umbilical cord blood." Diabetes **1)**: A122.

Regulatory T cells (Tregs) are considered vital to the maintenance of selftolerance and prevention of autoimmune disease. While proven effective for preventing type 1 diabetes (T1D) in murine models of the disease, analogous methods involving transfer of antigen-specific Tregs to prevent and/or reverse the disorder in humans have been hindered by the paucity of naive Tregs that can be effectively isolated and expanded from peripheral blood (PB). Due to their less mature state and enhanced proliferative capacity, naive Tregs isolated from umbilical cord blood (UCB) may provide a superior source in adoptive cellular immunotherapy. Using a lentiviral gene delivery system, we expressed an antigen-specific T cell receptor (TCR) recognizing glutamic acid decarboxylase (GAD)(555-567) in the context of HLA-DR4 on FACS-isolated UCB naive Tregs (CD4+CD127-/loCD25+CD45RA+ T cells). Expression of GFP, a downstream reporter, indicated a 55-60% transduction efficiency using this system. In addition, a 140-fold ex-vivo expansion of transduced Tregs was achieved upon stimulation with alphaCD3/alphaCD28-coated microbeads and IL-2 over a 14-day period. Treg phenotype and stable TCR expression were analyzed and confirmed by flow cytometry using FoxP3/ Helios and GFP/TCR Vbeta5.1 staining, respectively. GFP expression and TCR Vbeta5.1 staining of ex-vivo expanded Tregs indicated stable integration and expression of the antigen-specific TCR introduced by our lentiviral gene delivery system. Our findings indicate that naive Tregs isolated from UCB can be engineered to express antigen-specific TCRs and carry the capacity for ex-vivo expansion. While further studies to determine the activities and functions of these cells are required, our investigation provides a novel approach for TCR-specific gene therapy and carries important implications for the development of therapeutic interventions aimed to restore antigenspecific immune tolerance in patients with T1D. These studies were funded by the JDRF Collaborative Center for Cell Therapy to J.A.B., Cord Blood Center to M.A.A., and Transitional Award to T.M.B.

Hanachi, P., et al. (2019). "Abundance and properties of microplastics found in commercial fish meal and cultured common carp (<i>Cyprinus carpio</i>)." Environmental science and pollution research international **26**(23): 23777-23787.

Microplastics (MPs) are environmental contaminants that are of increasing global concern. This study investigated the presence of MPs in four varieties of marine-derived commercial fish meal, followed by identification of their polymer composition using Fourier transform infrared (FTIR) spectroscopy. Exposure experiments were conducted on cultured common carp (Cyprinus carpio) by feeding four varieties of commercially available fish meal to determine relationships between abundance and properties of MPs found both in meal and in those transferred to cultured common carp. Mean particle sizes were 452 ± 161 μm (± SD). Fragments were the predominant shape of MP found in fish meal (67%) and C. carpio gastrointestinal tract and gills (65%), and polypropylene and polystyrene were the most present plastic polymers found in fish meal (45% and 24%, respectively) and C. carpio (37% and 33%, respectively). Positive relationships were found between MP levels in fish meal and C. carpio. This study highlights that marine-derived fish meal may be a source of MPs which can be transferred to cultured fish, thus posing a concern for aquaculture.

Hanada, M., et al. (2009). "Growth inhibition and apoptosis induction by tumor necrosis factor-alpha in satellite cells of human urethral rhabdosphincter." Journal of Urology **1)**: 79-80.

INTRODUCTION AND OBJECTIVE: Human urethral rhabdospincter (HUR) cells is reported to decrease with aging due to apoptosis. This reduction of HUR cells may be a cause of urinary incontinence in the elderly, but the mechanism is not clear. There are some reports that Tumor Necrosis Factor-alpha (TNF-alpha) induces apoptosis in murine skeletal muscles and that serum concentration of TNF-alpha increases with aging. This study was performed to clarify whether TNF-alpha induces growth inhibition and/or apoptosis of HUR satellite cells. METHOD(S): HUR satellite cells were cultured from specimens of HUR tissues obtained from patients who underwent radical prostatectomy, and they were selected by magnetic affinity cell sorting using anti-CD56 antibody-conjugated microbeads. Selectively cultured HUR satellite cells were transfected with SV40 T antigen and used for the following experiments. Cell growth was examined by cell proliferation assay, and apoptosis induction was confirmed by flowcytometry, double staining with Annexin V-FITC and propidium iodide and Western blot analysis. The expressions of TNF receptors were confirmed by reverse transcriptase-PCR (RT-PCR) and Western blot analysis. Finally, we examined whether TNF-alpha antagonists (Infliximab and Etanercept) prevent the effects of TNF-alpha on HUR satellite cells. RESULT(S): Proliferation of HUR satellite cells was inhibited by TNF-alpha in dose dependent manner. Some of the HUR satellite cells treated with TNF-alpha were stained with Annexin V-FITC but not with propidium iodide, suggesting the induction of early phase apoptosis. Flowcytometry analysis revealed the increase of sub-G1 fraction in TNF-alpha treated HUR satellite cells and a tendency of the decreased G2/M fraction. The activation of caspase-8, -3 and cleavage of PARP were observed by Western blot analysis. The expressions of both mRNA and protein of TNF receptors were confirmed by RT-PCR and Western blot analysis, respectively. The phosphorylation of

IkappaBalpha was increased two to five minutes after the treatment of TNF-alpha, and quickly returned to the basal level within 10 minutes. Pretreatment of TNF-alpha antagonists prevented TNF-alpha induced growth inhibition, the increase of sub G1 fraction and the phosphorylation of IkappaBalpha. CONCLUSION(S): TNF-alpha induces growth inhibition and apoptosis of HUR satellite cells through activation of TNF receptor. Anti-TNF-alpha therapy may be useful for the treatment and/or prevention of urinary incontinence in the elderly.

Hanau, D., et al. (2012). "The appearance of exclusively anti-HLA-dqalpha1 antibodies following organ transplantation is not deleterious." Tissue Antigens **79 (6)**: 522.

The occurrence, following organ transplantation, of antibodies targeting HLA Class II molecules is associated with an increased risk of acute or chronic rejection. These anti-Class II antibodies are found to target HLA-DQ molecules more frequently than HLA-DR molecules because both the alpha and beta chains of HLA-DQ are polymorphic and bear immunogenic epitopes. Thus, these anti-HLA-DQ antibodies are considered to be anticonformational, recognizing conformations generated by combinations of DQalpha-DQbeta heterodimers. The development of the single antigen technique, well suited to screening for anti-HLA Class II antibodies, the enhancement of this technique through use of microbeads carrying DQalpha-DQbeta heterodimers and also the latest improvements in the HLAMatchmaker program (http://www.hlamatchmaker.net) have allowed us to identify 12 cases (among 1154 analyzed) in which, up until now, only anti-DQalpha1 antibodies have appeared. This immunization displays a certain number of particularities: (i) it can occur following kidney, liver, heart or lung transplantation, (ii) it is not cytotoxic (B cell cross match negative) and is not accompanied by any signs of rejection, whereas (iii) the mean fluorescence intensities (MFI) are elevated (varying from 6000 to 13000 depending on the patient) and remain stable for years. Finally, (iv) this immunization targets predominantly the eplet 41GR3, shared by the molecules DQA1*04, DQA1*05 and DQA1*06. Interestingly, in one case this type of immunization appeared "naturally", in the absence of any context of transplantation or transfusion. It targets the eplet 75SL4 (DQA1*05) with an MFI of no more than 3000.

Handgretinger, R., et al. (2011). "Transplantation of TcRalphabeta/CD19 depleted stem cells from haploidentical donors: Robust engraftment and rapid immune reconstitution in children with high risk leukemia." Blood. Conference: 53rd Annual Meeting of the American Society of Hematology, ASH **118**(21).

In haploidentical transplantation with mobilized peripheral blood stem cells (PBSC's), in vitro T-cell depletion of the graft is an effective method to prevent or completely avoid Graft-versus-Host Disease (GvHD). In order to increase the T-cell depletion efficacy of PBSC's while maintaining the anti-tumor and anti-infectious properties of the graft, we have investigated a new T-cell depletion method which removes alphabeta+ T-lymphocytes via a biotinylated anti-TcRalphabeta antibody followed by an anti-biotin antibody conjugated to magnetic microbeads while retaining gammadelta+ T-lymphocytes, Natural killer (NK) cells and other cells in the graft. In addition, CD19+ B-lymphocytes were concomitantly depleted for the prevention of posttransplant EBV-associated lymphoproliferative disease. The alphabeta+ T-cells and CD19+ B cells were then removed using the CliniMACS system. So far, 23 patients have been treated in two centers, namely Tubingen and Rome. Graft manipulation resulted in a consistent efficiency of alphabeta+ T-lymphocyte removal at the two centers. The overall depletion of alphabeta+ T-cells was 4.5 log (range 3.8-5.0) and 4.3 log (range 3.7-5.0) in Tubingen and Rome, respectively, with a median number of transplanted alphabeta+ T-cells of 14 x 10³/kg. The recovery of CD34+ stem cells was 72% and 89% in the two centers, and

the median number of infused CD34+ stem cells was 11.9 x10⁶/kg (range 7.5-30 x 10⁶/kg) and 13.3 x10⁶/kg (range 8.3-19.8 x 10⁶/kg), respectively. Patients were given 107 x 10⁶/kg (range 35-186 x10⁶/kg) and 123 x 10⁶/kg (range 51-202 x10⁶/kg) CD56+ NK cells in Tubingen and Rome, respectively. The median number of infused gammadelta+ T-lymphocytes was 11.9 x10⁶/kg (range 7.5-30.2 x 10⁶/kg) and 10.3 x10⁶/kg (range 6.5-25.1 x 10⁶/kg) respectively. The 10 patients transplanted in Tubingen had advanced/refractory leukemias (ALL, n=5; AML, n=5; active disease, n=6; 2nd transplantation, n=2; CR2, n=2). For this poor-prognosis patients, a reduced-intensity conditioning regimen (melphalan, thiotepa, fludarabin or clofarabin and OKT-3 or ATG) was used. No further post-transplant GvHD prophylaxis was given. All 10 patients engrafted. The median time to reach neutrophil (PMN) and platelet (PLT) recovery was 9 (range 8-12) and 15 days (range 6-28) respectively. All patients reached complete donor chimerism and showed a very rapid immune reconstitution with 350 (range 21-824) CD3+ T cells/mul, 66 (12-177) CD3+4+/mul and 599 (227-1390) CD56+ NK cells/mul at day +28 posttransplant. Three patients had no signs of acute GvHD, 5 patients had GvHD grade I and 2 patients had skin GvHD grade II. Only 1 patient experienced a transient grade 3 GvHD of the skin which required only topical treatment. No patient experienced chronic GvHD. Three patients relapsed after transplantation, 7 patients are in remission for 5 months (range 3-12). There was no transplant-related death sofar. The second cohort given transplantation in Rome comprised 13 patients with ALL (9), AML (3) and NHL (1). All children but 1 had relapsed/refractory disease. In particular, 11 patients were transplanted in CR and 2 with active disease. Conditioning regimen was myeloablative and consisted of fractionated TBI, Thiotepa, fludarabine and ATG (8 mg/Kg). No further post-transplant GvHD prophylaxis was given. All patients engrafted, the median time to reach PMN and PLT recovery being 11 (range 7-13) and 12 (range 10-16) days, respectively. Only 2 patients had skin grade I acute GvHD. No patient experienced chronic GvHD. With a median follow-up of 4 months (range 1-9) 10 patients are alive and disease-free; 2 patients relapsed (1 died) and 1 had fatal lung aspergillosis. In both cohorts, gammadelta+ T cells started to expand faster than alphabeta+ T cells in the early post-transplant period, whereas at day +100, alphabeta+ T-cells were predominant. In addition to a rapid reconstitution of alp abeta+ T-lymphocytes, Vbeta spectratyping revealed a broad T-cell receptor repertoire early after transplantation. Altogether, these data indicate that transplantation of TcR alphabeta+/CD19 depleted cells from a haploidentical donor results in sustained engraftment, rapid immune reconstitution and low incidence of both acute and chronic GvHD. The anti-leukemic efficacy of this approach in comparison to other methods of T-cell depletion needs to be evaluated with a longer patient follow-up.

Hani, C. (2018). "Effect of varying compression ratio and blend percentage on performance of single cylinder diesel engine operating with blends of plastic pyrolysis oil and diesel." International Journal for Research in Applied Science and Engineering Technology **6**(4): 3883-3890.

Polluting emissions are a major problem faced by operation of diesel engines. Various alternatives have been researched to address this issue. Of all alternatives, use of plastic pyrolysis oil provides additional benefit of plastic waste disposal issue. Paper presents results obtained by operating single cylinder diesel engine with blend of plastic pyrolysis oil (0%, 15% and 30%) and diesel at varying compression ratio (16, 17 and 18). Results of brake thermal efficiency, mechanical efficiency and fuel consumption are presented.

Hankett, J. M., et al. (2016). "Low-Volatility Model Demonstrates Humidity Affects Environmental Toxin

Deposition on Plastics at a Molecular Level." Environmental Science & Technology **50**(3): 1304-1312.

Despite the ever-increasing prevalence of plastic debris and endocrine disrupting toxins in aquatic ecosystems, few studies describe their interactions in freshwater environments. We present a model system to investigate the deposition/desorption behaviors of low-volatility lake ecosystem toxins on microplastics in situ and in real time. Molecular interactions of gas-phase nonylphenols (NPs) with the surfaces of two common plastics, poly(styrene) and poly(ethylene terephthalate), were studied using quartz crystal microbalance and sum frequency generation vibrational spectroscopy. NP point sources were generated under two model environments: plastic on land and plastic on a freshwater surface. We found the headspace above calm water provides an excellent environment for NP deposition and demonstrate significant NP deposition on plastic within minutes at relevant concentrations. Further, NP deposits and orders differently on both plastics under humid versus dry environments. We attributed the unique deposition behaviors to surface energy changes from increased water content during the humid deposition. Lastly, nanograms of NP remained on microplastic surfaces hours after initial NP introduction and agitating conditions, illustrating feasibility for plastic-bound NPs to interact with biota and surrounding matter. Our model studies reveal important interactions between low-volatility environmental toxins and microplastics and hold potential to correlate the environmental fate of endocrine disrupting toxins in the Great Lakes with molecular behaviors. [ABSTRACT FROM AUTHOR]

Hankins, C., et al. (2018). "Scleractinian coral microplastic ingestion: Potential calcification effects, size limits, and retention." Marine Pollution Bulletin **135**: 587-593.

The impact that microplastics (<5 mm) have on scleractinian coral is largely unknown. This study investigated calcification effects, size limits, and retention times of microbeads and microfibers in two Caribbean species, Montastraea cavernosa and Orbicella faveolata, in a series of three experiments. No calcification effects were seen in the two-day exposure to a microbead concentration of 30 mg L⁻¹. M. cavernosa and O. faveolata actively ingested microbeads ranging in size from 425 mum-2.8 mm, however, a 212-250 mum size class did not elicit a feeding response. The majority of microbeads were expelled within 48 h of ingestion. There was no difference in ingestion or retention times of 425-500 mum microbeads versus 3-5 mm long microfibers. M. cavernosa and O. faveolata have the ability to recognize and reject indigestible material, yet, there is still a need to study effects of energetics and microplastic contamination as a result of ingestion and egestion. Hanson, A. M. (2017). "Women's environmental health activism around waste and plastic pollution in the coastal wetlands of Yucatan. (Special Issue: Water, sanitation and hygiene.)." Gender and Development **25**(2): 221-234.

This article focuses on women's grassroots organisations and their role in confronting waste-induced water, health, and development challenges in low-lying tropical coastal areas. As a case study, the article will focus on women's waste management and plastics recycling organisations in Yucatan, Mexico and their role in preventing water-borne diseases and educating the community on the links between garbage and human health. Women educate the community on the links between garbage and human health; challenge exclusionary gender norms by increasing women's participation in community sustainable development, and improve urban conditions in the coastal wetlands. I draw from over 400 surveys with coastal residents and 14 oral histories with coastal women, to underscore the muddy links that connect sanitation to gendered responsibility and the exclusionary spaces of urban development and ecological restoration in the swamps. The information shared through the histories and broad surveys emphasises how gendered roles and expectations are critical variables in shaping social difference, ecological degradation, and human health in low-lying coastal areas and cities.

Hantoro, I., et al. (2019). "Microplastics in coastal areas and seafood: implications for food safety." Food Additives & Contaminants. Part A, Chemistry, Analysis, Control, Exposure & Risk Assessment **36**(5): 674-711.

Microplastics have become ubiquitous in the marine environment. Microplastics have been detected in many coastal environments and species, including commercial seafood. This triggers concern about potential economic impacts and the risks of dietary exposure, especially for coastal communities. However, data regarding the levels of microplastics in coastal seafood and their toxicological effects are still limited. Accordingly, the dietary risk is still poorly explored. This review summarizes and discusses recent scientific findings on (i) the presence of microplastics in coastal waters, (ii) the occurrence of microplastics in coastal seafood and the likelihood of trophic transfer, and (iii) the effects of microplastics on coastal fish and shellfish species. Human toxicity data are also reviewed, but the risks for human health are difficult to determine due to limited data. Based on available worldwide data, the estimation of microplastics intake through seafood consumption shows a huge variation. Additionally, a lack of standardized analytical methods complicates the comparison of results between studies and therefore seriously affects the reliability of risk assessments. It is concluded that more exposure and toxicity data are needed properly to assess human health risks of microplastics in coastal seafood, and the lack of data currently impede the derivation of a risk-based food safety standard. The pros and cons of an interim solution, i.e. setting a provisional action level, are being discussed.

Hantoro, I., et al. (2019). "Microplastic intake via shellfish consumption and its potential risks to human health." Annals of Nutrition and Metabolism **75 (3)**: 335.

Background/Aims: Microplastic contamination in marine environment and seafood has raised global concern on the human health impact. The possibility of microplastic ingested by human is very likely to occur via consumption of seafood that is eaten whole, such as shellfish. However, the risks of microplastic on human health are still under investigation. The aims of this study was to assess shellfish consumption of Semarang inhabitants and to determine their microplastic intake via shellfish consumption. Method(s): Multistage random sampling method was used to determine the respondents from districts until neighborhood level. In total there were 500 respondents invited to participate in this study. The respondents were classified based on four age groups, i.e. children (0-9 years), adolescent (10-19 years), adults (20-59 years), and elderly people (60->75 years). The daily intake of shellfish of Semarang inhabitants was obtained from FFQ and recall diet. The concentrations of microplastics were obtained from a microscopic technique following a series of alkaline digestion and filtration. To estimate the microplastic intake, the daily intake of shellfish was multiplied by the average concentration of microplastics found in shellfish collected from Semarang.

Hao, X.-d., et al. (2019). "Evolution and Fate of Microplastics in Sewage Treatment." Zhongguo ji Shui pai Shui = China Water & Wastewater(8).

Microplastics (size 5 mm) are produced due to daily discard from both daily life and industry production,in which there are two forms: primary and secondary microplastics. Numbers of microplastics vary a lot due to different testing particle sizes,and there are at least 1 000 to 100 000 n/m~3 in raw sewage, most of which are unbiodegradable. Microplastics were mainly removed by adsorption in the primary treatment facilities; some microplastics could be adsorbed in the secondary treatment process,but the role of the secondary treatment was not great; the membrane interception method in the tertiary treatment (membrane and/or filtration) could effectively remove microplastics. The average removing efficiency of microplastics via both primary and secondary treatment was around 80%,the residue (≤20%) of microplastics in the effluent would enter into the water environment,which was a major source of evolution and accumulation in the hydrosphere. Microplastics in the environment could be taken up by the human beings through drinking water,salt,seafood,etc. For this reason,the sources and hazards of microplastics were reviewed; and detecting methods in water/wastewater were summarized; evolution patterns were analyzed; fate in the environment and preventive measures into both products and the environment were elucidated.

Haque, M. S. (2019). "Sustainable use of plastic brick from waste PET plastic bottle as building block in Rohingya refugee camp: a review." Environmental Science & Pollution Research **26**(36): 36163-36183.

Bangladesh is 10th among the major plastic waste contributor countries of the globe. Throughout the world, plastic waste disposal is a major concern since it is being nonbiodegradable in nature and hazardous, because of its potential harmful effect on human health and to the environment. Various studies have shown that waste PET (polyethylene terephthalate) plastic bottle filled with sand or other inorganic materials can serve as a useful building material where plastic waste management or recycling process is not very effective and particularly, in low-income communities. Plastic brick use in existing Rohingya refugee camp and

newly proposed displacement camp in the coast island-Bhasan Char-as construction material to build new shelters, can be a sustainable use and management of country's plastic waste, and a feasible solution against the shelter issues of Rohingya people. The vulnerability due to heavy wind, monsoon rains, cyclones, and the gaps and lack in funding to build new rigid and safe shelters can be effectively mitigated by using this low-cost, environment-friendly plastic brick as building block in refugee camps.

Hara, J., et al. (2020). "Quantification of microplastic ingestion by the decapod crustacean Nephrops norvegicus from Irish waters." Marine Pollution Bulletin **152**: 110905.

Microplastics are widespread pollutants in the marine environment, yet few studies have assessed the abundance and characteristics of microplastics in commercial species. This study evaluates the presence of ingested microplastics in the gastrointestinal tract of Nephrops norvegicus (n = 150), collected from five Irish prawn grounds. The efficiency of three digesting solutions was assessed. The most efficient digestion was the KOH (10%) solution incubated at 40 degreeC for a 48 h period. An average of 1.75 +/- 2.01 items per individual was ingested by c. 69% of N. norvegicus examined. A total of 262 microplastic, predominantly fibres (98%), between 1 and 2 mm were recorded. Although, no spatial pattern was identified, samples from the North Irish Sea recorded highest occurrence of microplastics (~83%). A positive correlation was found between microplastic abundance and prawn carapace condition.

Hardesty, B. D., et al. (2015). "A biochemical approach for identifying plastics exposure in live wildlife." Methods in Ecology and Evolution **6**(1): 92-98.

1. Plastic pollution is a long-standing ubiquitous issue. Global use of plastics is continuing to rise, and there is increasing interest in understanding the prevalence and risk associated with exposure of wildlife to plastics, particularly in the marine environment. 2. In order To facilitate an assessment of ingestion of plastics in seabird populations, we developed a minimally invasive tool that allows for detection of exposure to plastics. 3. Using a simple swabbing technique in which the waxy preen oil is expressed from the uropygial gland of birds, we successfully tested for the presence of three common plasticizers: dimethyl, dibutyl and diethylhexyl phthalate [dimethyl phthalate, dibutyl phthalate and bis(2-ethylhexyl)-phthalate, respectively]. These plasticizers are prevalent in the manufacturing of plastic end-user items which often end up in the marine environment. 4. Using gas chromatography-mass spectrometry and protocols to reduce background contamination, we were confidently able to detect targeted plasticizers at low levels. 5. The method described has broad applicability for detecting plastics exposure in wildlife at individual, population and species levels. Furthermore, the approach can be readily modified as needed to survey for plastics exposure in taxa other than seabirds. 6. Applying the simple, minimally invasive approach we describe here is particularly appealing for detecting plastics exposure at population and species levels, it shows promise for quantification and it has no observed detrimental impacts to wildlife.

Hariram, V., et al. (2017). "Formulation and Characterization of Pyrolytic Oil from Waste Tyre and Waste Plastic: A Comparative Study." Nature Environment and Pollution Technology **16**(4): 1183-1188.

Elimination of solid waste generated by the engineering sector is the need of the present world. In this study, a comparative analysis has been made to formulate a petro-diesel like fuel from the waste tyre (WTPO) and waste plastic (WPPO), which is derived from unusable tyre and

plastic waste materials, by the thermal pyrolytic reaction. A pyrolysis reactor is designed and fabricated to transform the solid waste into the pyrolytic oil through thermal cracking. The characterization of WTPO and WPPO is carried out using the gas chromatography, mass spectrometry, Fourier transform infra-red and elemental analysis. The GC-MS analysis of both WPTO and WPPO indicated the presence of naphtha and limonene compounds at higher concentration levels. The content of sulphur in WTPO is at higher level. The physico-chemical properties are also determined based on IS:1448 and it is found to be comparable with the commercial petro-diesel.

Harl, B., et al. (2013). "Chloride channel blockers suppress formation of engulfment pseudopodia in microglial cells." Cellular Physiology and Biochemistry **31**(2-3): 319-337.

Background/Aims: Phagocytosis depends on the formation of engulfment pseudopodia surrounding the target. We tested in microglia, monocyte-derived cells in the brain, whether a swelling-activated Cl⁻-current (I<inf>Cl,</inf><inf>swell</inf>), required for global cell volume (CV) regulation, also contributes to local expansion and retraction of engulfment pseudopodia. Method(s): We used scanning electron microscopy (SEM) and confocal laser scanning microscopy (CLSM) to visualize and quantify the uptake of polystyrene microbeads (MBs) by microglial cells. Flow cytometry was used for cell volume measurments and I<inf>Cl,</inf><inf>swell</inf> was measured by whole-cell patch clamp. Result(s): We found that exposure of microglial BV-2 cells to MBs in Cl⁻-free extracellular solution attenuated MB uptake and that the Cl⁻-channel blockers DIOA, flufenamic acid, NPPB and DCPIB suppressed the uptake of MBs in BV-2 cells and in primary microglial cells. Microglial cells exposed to MBs in the presence of Cl⁻ channel blockers failed to extend engulfment pseudopodia. We observed that cells containing at least three MBs revealed an about twofold increase in current density of I<inf>Cl, swell</inf> compared to cells without MB. Osmotic challenges to stimulate global CV regulation before exposure to MBs modulated phagocytosis. Pre-conditioning of cells in hypo- or hypertonic medium for 12-16 hours caused a decrease in MB uptake. Conclusion(s): These findings indicate that I<inf>Cl,</inf><inf>swell</inf> contributes to formation of engulfment pseudopodia and participates in engulfment and particle uptake in microglial cells. Harris, D. A., et al. (2012). "Juvenile-onset systemic lupus erythematosus (JSLE) monocytes and macrophages express raised levels of receptors associated with apoptotic cell clearance." Annals of the Rheumatic Disease. Conference: Annual European Congress of Rheumatology of the European League Against Rheumatism, EULAR **71**(SUPPL. 3).

Background Juvenile-onset Systemic Lupus Erythematosus (JSLE) is a chronic, severe, multi-systemic autoimmune disease. Impaired apoptotic cell clearance is implicated as the initial step in the pathogenesis of JSLE, leading to exposure of autoantigens (1). We have investigated the phenotype of the macrophages and their precursors monocytes, important phagocytes whose function is impaired in adult-onset SLE (2), to determine the extent of their involvement in JSLE. This has been assessed by measurement of the gene expression of monocyte and macrophage receptors important in apoptotic cell phagocytosis. CD36 is a member of the Scavenger Receptor Class B receptor group, considered especially important in the recognition of apoptosing neutrophils (3). MER is a tyrosine kinase receptor important in the internalisation of apoptotic cells (4). CR3 is a complement receptor whose principle action is through recognition of C3bi, a complement component that attaches to apoptotic cells (5). Objectives To investigate for evidence of phagocytosis dysregulation in JSLE by determining if ineffective macrophage and monocyte function is associated with abnormal expression of phagocytic receptors. Methods Monocytes were separated using CD14 MicroBeads (MACS Miltenyi Biotec) from processed whole blood, cultured in medium (RPMI + 10% FCS + 1% PenStrep + M-CSF) over 6 days into macrophages, and RNA extracted. The RNA was assessed for quantity and quality using NanoDrop, converted to cDNA and RT-qPCR performed using SYBR Green with primers for CD36, MERKT, and CR3; with expression compared against beta2M as reference gene. Statistical analyses were performed using IBM SPSS v19 (Mann-Whitney U). We compared the relative expression ratios between JSLE patients and healthy controls (HCs; median [IQR]). Results In monocytes, CD36 expression was significantly increased in JSLE (n=6): (0.96 [0.68-1.34]) vs HCs (n=6): (0.53 [0.39-0.70]), (p=0.03), with a trend towards greater expression of MERKT: (0.47 [0.30-0.74]) vs (0.30 [0.19-0.44]), (p=0.20). Conversely, CR3 was more highly expressed in HC monocytes: (0.65 [0.49-0.96]) vs (0.77 [0.71-1.32]), although not significantly (p=0.15). Relative expression ratios for macrophages showed similar trends, with increased expression of CD36 and MERKT in JSLE (n=2 to date) approaching statistical significance compared with HCs (n=9): CD36 (1.86 [N/A]) vs (1.14 [0.35-2.23]), (p=0.06); MERKT: (2.14 [N/A]) vs (1.14 [0.78-1.73]), (p=0.10), but no difference in CR3 expression: (0.98 [N/A]) vs (1.40 [0.35-2.23]), (p=0.64). Conclusions Our preliminary findings indicate that there are features that distinguish JSLE from HC monocytes and macrophages, reflected in the observed increased expression of receptors associated with apoptotic cell clearance. Work is on-going to consolidate these data with increased sample size and investigations of other markers of phagocytosis, correlated with macrophage phagocytic function.

Harris, M., et al. (2017). "Magnetic stimuli-responsive chitosan-based drug delivery biocomposite for multiple triggered release." International Journal of Biological Macromolecules **Part B. 104**: 1407-1414.

Stimuli-responsive biomaterials offer a unique advantage over traditional local drug delivery systems in that the drug elution rate can be controllably increased to combat developing symptomology or maintain high local elution levels for disease treatment. In this study, superparamagnetic Fe<inf>3</inf>O<inf>4</inf> nanoparticles and the antibiotic vancomycin were loaded into chitosan microbeads cross-linked with varying lengths of polyethylene glycol dimethacrylate. Beads were characterized using degradation, biocompatibility, and elution studies with successive magnetic stimulations at multiple field strengths and frequencies. Thirty-minute magnetic stimulation induced a temporary increase in daily elution rate of up to 45% that was dependent on field strength, field frequency and cross-linker length. Beads degraded by up to 70% after 3 days in accelerated lysozyme degradation tests, but continued to elute antibiotic for up to 8 days. No cytotoxic effects were observed in vitro compared to controls. These promising preliminary results indicate clinical potential for use in stimuli-controlled drug delivery. Harrison, J. P., et al. (2012). "The applicability of reflectance micro-Fourier-transform infrared spectroscopy for the detection of synthetic microplastics in marine sediments." Science of the Total Environment **416**: 455-463.

Synthetic microplastics (=5-mm fragments) are globally distributed contaminants within coastal sediments that may transport organic pollutants and additives into food webs. Although micro-Fourier-transform infrared (micro-FT-IR) spectroscopy represents an ideal method for detecting microplastics in sediments, this technique lacks a standardized operating protocol. Herein, an optimized method for the micro-FT-IR analysis of microplastics in vacuum-filtered sediment retentates was developed. Reflectance micro-FT-IR analyses of polyethylene (PE) were compared with attenuated total reflectance FT-IR (ATR-FT-IR) measurements. Molecular mapping as a precursor to the imaging of microplastics was explored in the presence and absence of 150- micro m PE fragments, added to sediment at concentrations of 10, 100, 500 and 1000 ppm. Subsequently, polymer spectra were assessed across plastic-spiked sediments from fifteen offshore sites. While all spectra obtained of evenly shaped plastics were typical to PE, reflectance micro-FT-IR measurements of irregularly shaped materials must account for refractive error. Additionally, we provide the first evidence that mapping successfully detects microplastics without their visual selection for characterization, despite this technique relying on spectra from small and spatially separated locations. Flotation of microplastics from sediments only enabled a fragment recovery rate of 61 (+or-31 S.D.) %. However, mapping 3-mm² areas (within 47-mm filters) detected PE at spiking concentrations of 100 ppm and above, displaying 69 (+or-12 S.D.) % of the fragments in these locations. Additionally, mapping detected a potential PE fragment in a non-spiked retentate. These data have important implications for research into the imaging of microplastics. Specifically, the sensitivity and spatial resolution of the present protocol may be improved by visualizing the entire filter with high-throughput detection techniques (e.g., focal plane array-based imaging). Additionally, since micro-FT-IR analyses depend on methods of sample collection, our results emphasize the urgency of developing efficient and reproducible techniques to separate microplastics from sediments.

Harshita, N., et al. (2011). "Studies on biodegradation of LDPE film in the presence of potential bacterial consortia enriched soil." Biologija **57**(4): 141-147.

Low density polyethylene (LDPE) is an important commodity plastic and has a wide applicability in the modern era. In virtue of their wide applicability, the generation of the huge plastic waste became a conundrum for environment and public health. Consequently, the present study was conducted for the microbial degradation of LDPE film in natural conditions using mixture of potential polymer degrading consortia. For this purpose, the talc based formulation of bacterial consortia was inoculated into soil with LDPE film for the period of three months. Fourier transform infrared spectroscopy (FT-IR) in combination with SEM revealed that the consortia incurred significant surfacial degradation of LDPE film, introduction of hydroxyl (-OH) functionality and significant shifts in fingerprint region, respectively. The potential of the consortia towards degradation of LDPE has further been ascertained through change in bulk structural characteristics using differential scanning calorimetry (DSC). Moreover, the comparative in situ biodegradation study of LDPE film in laboratory and natural conditions indicates that environmental factors like sun-light, temperature and rainfall may enhance the rate of biodegradation of the polymer in nature.

Hart, D. N. J., et al. (2015). "Functional studies on the C-type lectin receptor CD302 present on dendritic cells and macrophages." Blood **126 (23)**: 2198.

Introduction: C-type lectin receptors (CLR) play an important role in the immune system by recognising molecular patterns expressed by exogenous and endogenous threats. They have been shown to capture and internalise antigens and to mediate other important immune cell functions. DEC205 and CLEC9A are being actively investigated as targets for clinical therapeutic cancer vaccines. We discovered CD302 as a new CLR expressed on human dendritic cells (DC), monocytes and macrophages (J Immunol 2007;179:6052). Our initial studies suggested the molecule could play a role in cell adhesion or migration due to its co-localisation with migratory structures on macrophages. Our study set out to investigate the potential immunological function of CD302 using mouse models and to define its wider tissue expression in man. Method(s): We generated CD302 knockout (KO) mice lacking exon 1 of its gene, abrogating transcription, for functional studies. We characterised the transcriptional expression of CD302 in mouse immune cells using real-time PCR. We developed monoclonal mAb to mCD302. Human studies utilized the anti-CD302 mAbs, MMRI-20 & 21 in flow cytometry and confocal microscopy studies of human immune cell populations. Result(s): CD302 was primarily expressed in mouse liver, lungs, lymph nodes (LN) and spleen. In spleen, macrophages, granulocytes and dendritic cells (DC) expressed CD302. Analysis of LN DC subsets revealed 2.5-fold higher CD302 mRNA expression in migratory compared to resident DC populations. Enumeration of various immune populations in lymphoid organs by flow cytometry uncovered a modest deficiency in migratory DC number and proportion within LN of CD302 KO mice compared to wild-type (WT) mice. In vitro studies showed CD302 KO and WT DC had an equivalent capacity to be activated by various stimuli, prime T cells and migrate towards the lymphoid-homing chemokines CCL19/CCL21. CD302 KO migratory DC exhibited a reduced in vivo migratory capacity to LN after FITC skin-painting. However, CD302 KO macrophages migrated similarly to WT macrophages in vivo in response to thioglycollate. In man, CD302 was present in high density in liver and peripheral blood monocytes and myeloid but not plasmacytoid DC. Current studies are aimed at clarifying its distribution on tissue DC and macrophage subsets. Anti-CD302 coated microbeads were taken up by human monocyte derived macrophages and anti-CD302 mAb was also internalized by DC. Confocal studies showed that CD302 co-localized with F-actin structures at the near basal surface such as filopodia and lamellipodia and podosomes of human macrophages and EGFP tagged CD302 expressed in COS-1 cells associated with F-actin. Conclusion(s): Our data suggests that CD302 may play a specialist role in DC and macrophage membrane functions. This appears to relate to its ability to associate with F-actin and may contribute to the membrane interactions required for DC to migrate towards the draining LN.

Harte, P., et al. (2019). "Adaptation and improvement of an elemental mapping method for lithium ion battery electrodes and separators by means of laser ablation-inductively coupled plasma-mass spectrometry." Analytical & Bioanalytical Chemistry **411**(3): 581-589.

In this study, laser ablation-inductively coupled plasma-mass spectrometry (LA-ICP-MS) was applied to previously aged carbonaceous anodes from lithium ion batteries (LIBs). The electrodes were treated by cyclic aging in a lithium ion cell set-up with LiNi_{0.5}Mn_{1,5}O₄ (LNMO) cathodes and hard carbon (HC)/mesocarbon microbead (MCMB) anodes. An inhomogeneous transition metal deposition pattern could be induced by replacing the spacer in a standard coin cell set-up with a washer. The inhomogeneity pattern matched the dimension of the washer depicted by the hole in the center. These transition metal (TM) patterns were used to optimize higher lateral scanning speeds and frequencies on the spatial resolution of the mapping experiments using LA-ICP-MS. Higher scanning speeds had an observable influence on the resolution of the obtained image and an overall saving of 60% with regard to time and gas consumption could be achieved. Additionally, the optimized method was applied to the cathode and separator in order to visualize the distribution and deposition pattern, respectively.

Hartmann, N. B., et al. (2019). "Are We Speaking the Same Language? Recommendations for a Definition and Categorization Framework for Plastic Debris." Environmental Science & Technology **53**(3): 1039-1047.

The accumulation of plastic litter in natural environments is a global issue. Concerns over potential negative impacts on the economy, wildlife, and human health provide strong incentives for improving the sustainable use of plastics. Despite the many voices raised on the issue, we lack a consensus on how to define and categorize plastic debris. This is evident for

microplastics, where inconsistent size classes are used and where the materials to be included are under debate. While this is inherent in an emerging research field, an ambiguous terminology results in confusion and miscommunication that may compromise progress in research and mitigation measures. Therefore, we need to be explicit on what exactly we consider plastic debris. Thus, we critically discuss the advantages and disadvantages of a unified terminology, propose a definition and categorization framework, and highlight areas of uncertainty. Going beyond size classes, our framework includes physicochemical properties (polymer composition, solid state, solubility) as defining criteria and size, shape, color, and origin as classifiers for categorization. Acknowledging the rapid evolution of our knowledge on plastic pollution, our framework will promote consensus building within the scientific and regulatory community based on a solid scientific foundation.

Hartmann, N. B., et al. (2017). "Microplastics as vectors for environmental contaminants: Exploring sorption, desorption, and transfer to biota." Integrated Environmental Assessment & Management **13**(3): 488-493.

The occurrence and effects of microplastics (MPs) in the aquatic environment are receiving increasing attention. In addition to their possible direct adverse effects on biota, the potential role of MPs as vectors for hydrophobic organic chemicals (HOCs), compared to natural pathways, is a topic of much debate. It is evident, however, that temporal and spatial variations of MP occurrence do (and will) occur. To further improve the estimations of the role of MPs as vectors for HOC transfer into biota under varying MP concentrations and environmental conditions, it is important to identify and understand the governing processes. Here, we explore HOC sorption to and desorption from MPs and the underlying principles for their interactions. We discuss intrinsic and extrinsic parameters influencing these processes and focus on the importance of the exposure route for diffusive mass transfer. Also, we outline research needed to fill knowledge gaps and improve model-based calculations of MP-facilitated HOC transfer in the environment. Integr Environ Assess Manag 2017;13:488-493. © 2017 SETAC.

Hashide, R., et al. (2012). "Insulin-containing layer-by-layer films deposited on poly(lactic acid) microbeads for pH-controlled release of insulin." Colloids & Surfaces B: Biointerfaces **89**: 242-247.

Layer-by-layer (LbL) thin films containing insulin were deposited on the surface of biodegradable poly(lactic acid) (PLA) microbeads and the pH-triggered release of insulin was studied. The LbL films were successfully prepared by the alternate deposition of insulin and poly(vinyl sulfate) (PVS) or dextran sulfate (DS) at pH 4.0 through the electrostatic force of attraction between positively charged insulin and polyanions. The loading of insulin on the microbeads was dependent on the number of insulin layers and the type of polyanions used; higher insulin loading was observed for thicker films and when PVS was used as the polyanion. Insulin was released from the microbeads when they were exposed to neutral solution (pH 7.4) due to a loss of electrostatic attraction between the insulin and polyanions in the films, which in turn was caused by the charge reversal of insulin from positive to negative in the neutral medium. The pH threshold for insulin release was found to be pH 5.0-6.0. The released insulin retained its original secondary structure as evidenced by circular dichroism spectra. The insulin loaded on the microbeads was satisfactorily stable even in the presence of a digestive enzyme (pepsin) at pH 1.5. These results suggest a potential future use for insulin-loaded microbeads in the oral delivery of insulin.

Hashimoto-Okada, M., et al. (2009). "The CD70-CD27 interaction during the stimulation with dendritic cells promotes naive CD4⁺ T cells to develop into T cells producing a broad array of

immunostimulatory cytokines in humans." International Immunology **21**(8): 891-904.

CD70 expressed on dendritic cells (DCs) has been shown to play a critical role in inducing effective CD8⁺ T cell responses and a T<inf>h</inf>1 response in mice. However, it has not been extensively examined whether human primary DCs express CD70 and whether the CD70-CD27 interaction promotes naive CD4⁺ T cells to acquire the ability to produce effector cytokines during the DC-T cell interaction in humans. Here, we show that human myeloid dendritic cells (mDCs) and plasmacytoid dendritic cells stimulated with CD40 ligand together with pro-inflammatory cytokines or Toll-like receptor ligands express CD70. Thymic stromal lymphopoietin plus prostaglandin E<inf>2</inf> also induced CD70 on mDCs. Naive CD4⁺ T cells stimulated with DCs but not with anti-CD3/CD28 microbeads expressed CD70. Stimulation with CD70 together with anti-CD3/CD28 microbeads imparted the ability to produce T<inf>h</inf>1 (IFN-gamma), T<inf>h</inf>2 (IL-4, IL-5, IL-13) cytokines, IL-2 and tumor necrosis factor-alpha to naive CD4⁺ T cells. The production of IFN-gamma was associated with the induction of T-bet. Naive CD4⁺ T cells stimulated with mDCs acquired an enhanced ability to produce a broad array of immunostimulatory cytokines in a CD70-dependent manner. These data suggest that human CD70 expressed on mDCs and activated T cells transmits a 'basal level' signal, rather than a 'polarizing' signal, to naive CD4⁺ T cells, in that CD70 promotes the development of CD4⁺ T cells that produce a variety of effector cytokines including both T<inf>h</inf>1 and T<inf>h</inf>2 types, thus contributing to the enhancement of a broad spectrum of immune responses. © The Japanese Society for Immunology. 2009. Hashizume, H., et al. (2010). "In vitro propagation and dynamics of T cells from skin biopsies by methods using interleukins-2 and -4 or anti-CD3/CD28 antibody-coated microbeads." Acta Dermato-Venereologica **90**(5): 468-473.

In order to explore the mechanisms of inflammatory skin disorders, we established two methods of expanding skin-derived lymphocytes, one using high levels of interleukin (IL)-2 and IL-4 (method A) and the other using low levels of cytokines and anti-CD3/CD28 microbeads (method B). Both methods provide advantages for functional studies. With either of these two, we could obtain more than 10(7) cells/ from a 3 mm skin biopsy in 21 days from 23 out of 26 biopsies of various skin diseases. The relevance of these cells was confirmed by shifted T-cell receptor beta chain variable region (TCR-Vbeta) repertoire and antigen-dependent proliferation in antigen-driven skin disorders. The propagation of skin-resident lymphocytes, seen especially in method A, seems to be mediated by a functional defect of regulatory T cells residing in skin sequentially expanding under the conditions of our methods.

Hasnain, J. and J. Nazia (2015). "Utilization of mustard oil for the production of polyhydroxyalkanoates by Pseudomonas aeruginosa." Journal of Microbiology, Biotechnology and Food Sciences **4**(5): 412-414.

With the unnecessary use of plastics and cumulative pressure being placed on capacities available for plastic waste disposal, the need for biodegradable plastics and biodegradation of plastic wastes has assumed increasing importance in the last few years. Bioplastic production from mustard oil was considered relatively cheap, easily available, included in vegetable oil and don't having much volatile characteristics. Total of 67 bacterial strains were isolated and purified from different regions of the Pakistan, and were checked for Polyhydroxyalkanoates (PHA) production by Sudan black and Nile blue staining. Quantitative analysis for biodegradable plastic produced by different bacterial species was performed by Modified surfactant hypochlorite method. High PHA production was detected in 35 strains belonging to different genera including

Pseudomonas, Staphylococcus, Escherichia and Enterobacter. Fermentation and PHA production was done in batch culture. The PHA production of P. aeruginosa by mustered oil cultivation was studied under six experimental conditions, such as air flow rates, pH, Temperature, optical density, substrates concentration and cell dry weight. PHA production of Pseudomonas species were subsequently authenticated at molecular level by PCR amplifications and sequence analysis. PHA polymerase 1 (PhaC1) and PHA polymerase 2 (PhaC2) from Pseudomonas aeruginosa were amplified, sequenced and submitted to gene bank.

Hassan, A. B. and P. R. Cook (1993). "Visualization of replication sites in unfixed human cells." Journal of Cell Science **105**(Pt 2): 541-550.

Sites of DNA replication in nuclei are focally concentrated, suggesting that an underlying structure organizes the activity of many polymerases. As fixation could induce aggregation into foci, we examined the distribution of replication sites in unfixed nuclei. HeLa cells were encapsulated in agarose microbeads, permeabilized in a 'physiological' buffer, their DNA polymerizing activity characterized, and replication sites directly labelled by incubation with fluorochrome-dUTP conjugates. Using conventional and digital fluorescence microscopy, 80-250 foci were seen in these unfixed cells. These foci are unlikely to be formed by the aggregation of separate polymerases as most replication activity found in vivo is retained throughout these procedures. Although commonly used fixation methods collapsed or dispersed their periphery, the central core was very stable. Foci remained when approximately 90% chromatin was removed, suggesting they were attached to an underlying structure.

Hassan, A. R. H. A. A., et al. (2015). "Highly sensitive and rapid determination of Escherichia coli O157: H7 in minced beef and water using electrocatalytic gold nanoparticle tags." Biosensors and Bioelectronics **67**: 511-515.

A simple, highly sensitive and specific immunosensing assay for rapid detection and quantification of Escherichia coli O157:H7 in meat and water samples based on the electrocatalytic properties of gold nanoparticles (AuNPs) towards hydrogen evolution reaction and superparamagnetic microbeads (MBs) as pre-concentration/purification platforms without the need of broth enrichment is developed for the first time. Minced beef and water samples inoculated with different concentrations of E. coli O157:H7 have been tested using anti-E. coli O157-magnetic beads conjugate (MBs-pECAb) as a capture platform and sandwiching afterwards with AuNPs modified with secondary antibodies (AuNPs-sECAb) and detected using chronoamperometric measurement with screen-printed carbon electrodes (SPCEs). Detection limits (LOD) of 148, 457 and 309CFU/mL were obtained in buffer solution, minced beef and tap water samples respectively, with a broad detection range of 10²-10⁵CFU/mL in all cases. Recoveries percentages after spiking of 5 different samples of both minced beef and tap water with 10³ and 10⁴CFU/mL were 94.7 and 90.4 (in beef) and 91.3 and 94.8% (in water), respectively. Specificity, reproducibility and comparison with a commercial lateral flow kit in terms of LOD and detection range were also studied showing clear advantages of the electrochemical method performance. The successful application of this AuNPs based technology in minced beef and tap water indicates the possibility of its using in various food items and other water resources. Hassani Bafrani, H., et al. (2015). "Magnetic activated cell sorting and its application for selection of human non apoptotic spermatozoa in ART." Iranian Journal of Reproductive Medicine **1)**: 60.

Introduction: Hydrogen peroxide has been implemented in literature to induce a significant

increase in caspase. Activation of caspase 9 triggers a cascade of caspase activation, including caspase 3, which promotes cellular apoptosis. Magnetic cell sorting (MACS) using annexin V-conjugated microbeads eliminates apoptotic spermatozoa with annexin V-positive. Material(s) and Method(s): A total of 20 semen samples were obtained from male partners of couples for analysis. One aliquot (0.5ml) of the sperm suspension was subjected to MACS. Motility and concentration was checked, and a sample taken for tunnel before and after MACS. The remaining sperm suspension was divided into 6 tubes (2x control, 2x peroxide, 2x peroxide/ melatonin). DNA fragmentation was evaluated using the TUNEL assay (Roche, Indianapolis, IN, USA) (14), with some modifications. Data were analyzed using Graph Pad Instat Ver. 3.10. Result(s): Results of the TUNEL assay in pretreatments of human spermatozoa with 100uM peroxidase for 24 hrs revealed that the percentage of sperm with fragmented DNA was significantly lower on the sored sperm after sorting MACS (p<0.001 vs. control). Following the pretreated human spermatozoa with peroxidase for 24 hr, percentage of sperm motility and progressive motility were significantly reduced (p<0.001 vs. control). Pretreatments of human spermatozoa for 24 hr revealed that the percentage of sperm motility and progressive motility were significantly reduced by 100 muM peroxidase and peroxidase with MACS, versus zero hour in control group (p<0.001). Conclusion(s): The sperm was treated with 100 muM peroxidase sorting using MACS retain appropriate spermatozoa and select sperm good quality. The use of MACS will select only sperm with intact this result in high percentage motility and progressive motility.

Hassanipour, F. (2009). A particulate-flow heat exchanger inspired by gas diffusion in lung capillaries.
In this study, a new cooling concept using encapsulated phase-change particles flowing with water in a parallel-plate mini-channel is presented. This novel concept is inspired by the gas exchange process in alveolar capillaries, where red blood cells (RBCs) flow with blood plasma, yielding very high gas transfer efficiency. Another important characteristic of alveolar capillary blood flow, which is related to the high efficiency of the lungs, is the snug fitting of the RBCs into the capillaries. Hence, preliminary results of experimental tests using particles with diameter similar to the flow channel spacing flowing with water through a heated parallel-plate channel test module are presented and analyzed in Chapter 3. The particles are octadecane paraffin (C sub(18)H sub(38)), a phase-change material, encapsulated in a thin melamine shell. The temperature distribution along the heated surface of the channel is measured for various water flow rates, with and without particles, and with different numbers of particles. Results are reported in terms of the channel heated surface average temperature and the average heat transfer coefficient. This study also considers modeling and simulation of the particulate enhanced convection in Chapter 4. The effect of flow velocity and particle concentration on the local heat transfer of the flow is also investigated. Time-dependent moving-mesh models, incorporating both melting and solidification, are utilized for simulating a single particle flow. Particulate flow using particles with phase-change material (PCM) in the cooling fluid enhances the convective energy transport by the fluid mainly in two ways: (1) by "storing energy" in latent heat form; and, (2) by "mixing" the flow field. The high energy storage density and small temperature variation during the heat transfer process provided by the encapsulated phase-change material has made the first role particularly interesting in recent years to many investigators. The objective of Chapter 5 is to determine, latent heat and of the mixing effects on the convection enhancement. To obtain the latent heat effect, the tests are repeated with ABS (Acrylonitrile-Butadiene-Styrene) plastic particles with no latent heat capacity (in the current test operating temperature range). We measured the temperature distribution along the heated surface of the channel for various heat fluxes, and velocities, with octadecane (C

sub(18)H sub(38)) paraffin and ABS plastic particles. The results have been also compared with clear water coolant flow.

Hastings, W., et al. (2016). "An in vitro approach to study T cell exhaustion." Cancer Research. Conference: 107th Annual Meeting of the American Association for Cancer Research, AACR **76**(14 Supplement).

Immune checkpoint inhibition is now a validated modality in the treatment of multiple cancers. In vitro immune cell assays are a key tool in the study of pharmacological agents for immune modulation. Assays often involve isolating lymphocytes from human peripheral blood followed by a T cell stimulus such as anti- CD3, staph enterotoxin B, or allogeneic APCs. While this approach is useful to probe the events of immune stimulation, it likely reflects a primary or secondary immune activation, rather than a state of exhaustion. As intra-tumoral T cells are thought to be exhausted by chronic/repeated exposure to self- antigen, we sought to define experimental conditions that would reflect this state in vitro. We reasoned that repeated stimulation of T cells using anti-CD3/anti-CD28 coated microbeads would induce an exhausted phenotype. We found that, using PBMC from normal healthy donors, frequent and repeated stimuli resulted in a loss of T cells' ability to produce IL-2, TNFa, and IFNg as measured by intracellular cytokine staining. Interestingly, only one restimulation was necessary to confer this phenotype, as repeated stimuli over a longer time course did not result in further suppression. We also found that repeat stimulation conferred a surface marker phenotype suggestive of exhausted cells. Finally, we used cell death inhibitors z-7AAD-cmk and EGTA and found no effect on cytokine loss, supporting the hypothesis that cells are exhausted and not deleted by activation induced cell death. Thus we have defined experimental conditions that possibly reflect an exhausted T cell phenotype in vitro. This may be useful for the pharmacological evaluation of different therapeutic agents for their immune modulatory activities in cancer.

Haworth Ii, K. R. (1989). PLASTIC SOLUTIONS. **36:** 6-6.

Comments on an article about plastic pollution in the February 1989 issue of the periodical "Organic Gardening".

Hayashi, T., et al. (2015). Vascular network formation for a long-term spheroid culture by co-culturing endothelial cells and fibroblasts. Proceedings of the IEEE International Conference on Micro Electro Mechanical Systems (MEMS).

In this paper, we present a poly-dimethylsiloxane (PDMS) microfluidic device to create a vascular network for a long-term spheroid culture, of which network and spheroid are consist of human umbilical vein endothelial cells (HUVEC) and normal human lung fibroblasts (LF), respectively. Following device design, fabrication, and fundamental evaluation of HUVEC sprouting conditions, we visualized that HUVEC networks were successfully formed by the co-culture with LFs and reached a LF-based spheroid. Moreover, perfusability of the network was evaluated by injecting fluorescent microbeads. This platform will be applicable for long-term tissue cultures to understand morphogenesis and modeling of blood vessel functions. © 2015 IEEE.

Hays, H. and G. Cormons (1974). "Plastic particles found in tern pellets, on coastal beaches and at factory sites." Marine Pollution Bulletin **5**(3): 44-46.

Small polystyrene particles, evidently of industrial origin, now appear as a contaminant of the sea in several parts of the world. They have been discovered in pellets of indigestible food regurgitated by gulls and terms, so are clearly entering the food chain at some point. In this

study, the authors surveyed the coast along Long Island Sound for possible sources of the plastic found in the area. It was found that the polystyrene particles were being discharged from several factories into the Sound. So far as is known at present, they are harmless but it would be as well to exercise caution in releasing plastic to the environment. To determine their effect, if any, on living things, more study is needed.

Haza, A. C., et al. (2019). "Wind-Based Estimations of Ocean Surface Currents From Massive Clusters of Drifters in the Gulf of Mexico." Journal of Geophysical Research. Oceans **124**(8): 5844-5869.
During the Lagrangian submesoscale experiment (LASER), 1,000 drifters were launched to sample the surface ocean flow in the northern Gulf of Mexico. Due to half a dozen strong winter storms, about 40% of the drifters lost their drogue. This unintended situation facilitated documentation of both near-surface (5 cm) and deeper (60 cm) flows. These depths are relevant to transport of oil spills, as well as marine debris, such as microplastics, a rapidly growing environmental problem. Here, we improve the surface Lagrangian current prediction by combining a state-of-the-art ocean forecast model with wind and wave data. The ocean surface velocities are obtained from the Navy Coordinate Ocean Model at 1-km horizontal resolution, while the wind and wave fields are from the Unified Wave INterface Coupled Model coupled atmosphere-wave-ocean model. Two Lagrangian parameterizations are tested: one is based on Ekman dynamics, and the other directly on the surface winds. LASER data set is then used to assess the performance of these formulations, as a function of wind/wave conditions, as well as geographic region. It is found that incorporation of wind and wave data into the ocean circulation model can lead to major prediction improvement, by reducing the average 2-day separation from the modeled and real LASER trajectories by a factor ranging from 1.4 to 4.9. This is a significant improvement for applications, where a rapid deployment of assets is needed, such as oil spill response, or other tracking problems. Key Points: The surface wind contributes significantly to the upper 60 cm transport in the Gulf of MexicoThe transport in the upper 5 cm differs from the upper 60 cm, due to the wave contribution [ABSTRACT FROM AUTHOR]

Hazel, B. G. (1996). "WASTE - THE POLITICS AND PHILOSOPHIES." Recycling Textile & Plastic Waste: 161-164.
The article focuses on the philosophies and theories regarding waste disposal of textile industry in the present age. Comparing the modern age with the past ages, it is considered not sustainable both economically and environmentally. In terms of recycling, the industry has two ways, first recycling within the processing chain and recycling post-consumer waste. However, one should remember that it is not the textile industry's sole responsibility for consumer waste from textiles. The protection of the environment is an issue for producer, consumer, legislator and regulator alike and can only be effectively addressed if all participants understand all its aspect and act accordingly.

He, B., et al. (2020). "Abundance, distribution patterns, and identification of microplastics in Brisbane River sediments, Australia." Science of the Total Environment **700 (no pagination)**(134467).
Plastic pollutants in aquatic ecosystems have received wide attention and research endeavours

since early 1970s. However, in comparison to marine environments, the occurrence of microplastics in a tidal river system remains largely unknown, especially in river sediments. Sediment samples taken from twenty-two sampling points along Brisbane River over the four different seasons revealed relatively high concentrations of microplastics in river sediments, with abundance ranging from 0.18 to 129.20 mg kg⁻¹, or 10 to 520 items kg⁻¹. Unfortunately, varied methods and units used for reporting do not allow the accurate comparison between related studies. The spatial distributions of microplastics hotspots indicated that microplastics abundance is distance-dominated caused by flow velocities. Lower and higher concentrations of microplastics abundance mostly occurred in dry and wet seasons, respectively. Significant temporal variations of microplastics concentrations was observed in residential and commercial areas. Polyethylene (PE), polyamide (PA) and polypropylene (PP), were the three main polymer types found in the Brisbane River sediments. Other polymer types such as polyethylene terephthalate (PET) were also detected. The majority of the detected microplastic particles were found to be <3 mm. This study reveals the abundance, spatial and temporal distribution patterns, and characteristics of microplastic pollutants in Brisbane River sediments, and provides systematic data for further research on microplastics in estuarine environments worldwide. He, D., et al. (2018). "Microplastics in soils: Analytical methods, pollution characteristics and ecological risks." TrAC - Trends in Analytical Chemistry **109**: 163-172.

Microplastics are emerging persistent contaminants of increasing concern. Although microplastics have been extensively detected in aquatic environments, their occurrence in soil ecosystems remains largely unexplored. This review focused on recent progress in analytical methods, pollution characteristics and ecological effects of microplastics in soils. In spite of the presence of microplastics in soils, no standardized methods are available for the quantification. Uniform protocols including microplastic extraction and identification are urgently needed to develop. In soil environments, main sources of microplastics include mulching film, sludge, wastewater irrigation and atmospheric deposition. The fate of microplastics is closely related to soil physio-chemistry and biota. Existing evidence shows that microplastics can influence soil biota at different trophic levels, and even threaten human health through food chains. Therefore, further research is needed to fully reveal the fate and ecological risks of microplastics in soils; and necessary action is required to control microplastic pollution in terrestrial ecosystems. He, J., et al. (2014). "A novel microbead-based microfluidic device for rapid bacterial identification and antibiotic susceptibility testing." European Journal of Clinical Microbiology & Infectious Diseases **33**(12): 2223-2230.

Effective treatment of infectious diseases depends on the ability to rapidly identify the infecting bacteria and the use of sensitive antibiotics. The currently used identification assays usually take more than 72 h to perform and have a low sensitivity. Herein, we present a microbead-based microfluidic platform that is highly sensitive and rapid for bacterial detection and antibiotic sensitivity testing. The platform includes four units, one of which is used for bacterial identification and the other three are used for susceptibility testing. Our results showed that Escherichia coli O157 at a cell density range of 10(1)-10(5) CFU/muL could be detected within 30 min. Additionally, the effects of three antibiotics on E. coli O157 were evaluated within 4-8 h. Overall, this integrated microbead-based microdevice provides a sensitive, rapid, reliable, and highly effective platform for the identification of bacteria, as well as antibiotic sensitivity testing.

He, J., et al. (2018). "Strong and oriented conjugation of nanobodies onto magnetosomes for the development of a rapid immunomagnetic assay for the environmental detection of tetrabromobisphenol-A. (Special Issue: Fading lemonade challenge/Where are modern flow techniques heading to?/Current trends in supercritical fluid chromatography/Instrumental analysis of microplastics.)." Analytical and bioanalytical chemistry **410**(25): 6633-6642.

Variable domain of heavy chain antibody (nanobody, Nb) derived from camelids is an efficient reagent in monitoring environmental contaminants. Oriented conjugates of Nbs and bacterial magnetic particles (BMPs) provide new tools for the high-throughput immunoassay techniques. An anti-tetrabromobisphenol-A (TBBPA) Nb genetically integrated with an extra cysteine residue at the C terminus was immobilized onto BMPs enclosed within the protein membrane, using a heterobifunctional reagent N-succinimidyl-3-(2-pyridyldithiol) propionate, to form a solid BMP-Nb complex. A rapid and sensitive enzyme-linked immunosorbent assay (ELISA) based on the combination of BMP-Nb and T5-horseradish peroxidase was developed for the analysis of TBBPA, with a total assay time of 30 min and a half-maximum signal inhibition concentration (IC₅₀) of 1.04 ng/mL in PBS (pH 10, 10% methanol and 0.137 moL/L NaCl). This assay can even be performed in 100% methanol, with an IC₅₀ value of 44.3 ng/mL. This assay showed quantitative recoveries of TBBPA from spiked canal water (114-124%) and sediment (109-113%) samples at 1.0-10 ng/mL (or ng/g (dw)). TBBPA residues determined by this assay in real canal water samples were below the limit of detection (LOD) and in real sediments were between <LOD and 23.4 ng/g (dw). The BMP-Nb-based ELISA shows promising application in environmental monitoring.

He, K., et al. (2018). "Adapting to new policy environment - past pattern and future trend in us-sino waste plastic trade flow." International Journal of Sustainable Development & World Ecology **25**(8): 702-711.

Plastics are one of the most used materials in human activities, where consumer consumption and industrial production together has imposed vast rise in demand for this material in last century. While plastic is ideally derived from crude oil as a primary source from manufacturers' perspective, varying crude oil prices are driving manufacturers economically to seek for alternative sources for plastics production. Waste plastic recovered from obsolete consumer products thus becomes an economic substitution for virgin plastics, which is further intensified with the possibility of international waste plastic trading. This study focuses on waste plastic trade between the US and mainland China by performing a correlation analysis of trade data. It is suggested in this study that although waste plastics are traded from the US to mainland China in general, as many of us believes, the route is gradually shifting in the past years. With tightening Chinese customs regulations, waste plastic from the US now tends to take a transit in a third destination (Hong Kong SAR for instance) for preliminary treatment to bypass Chinese customs inspection. Such phenomenon is worth noting, as a complication in waste plastic trading route hinders waste plastic transboundary movement monitoring. Furthermore, it will have adverse consequent consumer, industrial, and environmental impacts. It is thus necessary for national competent authorities to strengthen cooperative study and communication capacity in the future as a response to the changing waste plastic trade pattern. He, L., et al. (2018). "Toxic effects of micro-plastics on zebrafish embryos." Agricultural Biotechnology **7**(5): 112-115.

The large plastic produced by human production and life is degraded into micro-plastics in the environment. Micro-plastics are harmful to organisms and the environment. In order to determine the hazards of micro-plastic pollution, zebrafish embryos were used as the tested organism, and 0.6-1.0 micro m polystyrene micro-plastic was used to carry out embryo exposure experiment. The toxic effects of polystyrene plastic particles on zebrafish embryos were investigated comprehensively, and the toxicity was evaluated. The results of this study showed that 0.6-1.0 micro m polystyrene micro-plastic had certain toxicity on zebrafish embryos, and it had a lethal effect when the concentration reached 250 mg/L; 25 mg/L 0.6-1.0 micro m polystyrene particles can cause cyrtosis and pericardial edema of zebrafish embryos and oilier non-lethal toxic effects; and 250 and 1 000 mg/L exposure concentration can slow down heart rate. A hazard evaluation index system of polystyrene particles to zebrafish embryos was established, and it is determined that the exposure to 250 mg/L or lower concentration of polystyrene particles has slight hazard.

He, P., et al. (2019). "Municipal solid waste (MSW) landfill: A source of microplastics? -Evidence of microplastics in landfill leachate." Water Research **159**: 38-45.

Although landfill is suspected to be releasing microplastics to the environment, there is few empirical researches carried out. To clarify suspicions of landfills as potential sources of microplastics, twelve leachate samples from four active and two closed municipal solid waste landfills were investigated. Microplastics were found in all the landfill leachate samples. In total, seventeen different types of plastics were identified in the leachate samples with calculated concentration ranging from 0.42 to 24.58 items/L. Polyethylene and polypropylene were the predominant polymer types. 99.36% microplastics were derived from the fragmentation of plastic waste buried in landfills. The size of 77.48% microplastics was between 100 and 1000mum. The study shows that the generation, accumulation and release of microplastic in landfills is a long-term process. The results of our study provide preliminary evidence and validate that landfill isn't the final sink of plastics, but a potential source of microplastics.

He, X., et al. (2019). "A value-added insight of reusing microplastic waste: Carrier particle in fluidized bed bioreactor for simultaneous carbon and nitrogen removal from septic wastewater." Biochemical Engineering Journal **151 (no pagination)**(107300).

Turning microplastic litter into reusable products is a resource-saving and eco-friendly strategy of disposing of plastic pollution. This work realized a value-added insight of reusing microplastic waste by processing the recycled microplastic items with clay waste into composite particle (CP). Furthermore, the systematic evaluation of CP particle was carried out in a Liquid-solid fluidized bed bioreactor (LSFBBR-CP) treating septic sewage with low COD to nitrogen ratio (C/N <=3). The commercial inorganic particle, bioceramsite (BC), was tested in the LSFBBR-BC for comparison. During the 257-day stepwise operation, two LSFBBRs constantly achieved effluent of TCOD <45 mg L⁻¹ and low observed sludge yield (Y<inf>obs</inf> <=0.067 g VSS g⁻¹ COD). Comparatively, the lower fluidization velocity for the CP particles (u<inf>l</inf>, 0.67-1.20 cm s⁻¹) not only contributed to high biomass attachment (17.2 mg VSS g⁻¹ CP particles) but also favored nitrifiers (Nitrosomonas, Nitrosospira, Nitrobacter and Nitrospira) enrichment. Additionally, the LSFBBR-CP outperformed the LSFBBR-BC in energy conservation by consuming 41.1-47.4% less energy for fluidization, due

to the lower u<inf>l</inf>. Contrary to BC particles' attrition regarding to particle size decrease and surface chemicals loss, the CP particles exhibited superiority in physio-chemical stability. Those comparative advantages confirmed that the CP could be a promising alternative for BC as a carrier particle in LSFBBR, suggesting that turning microplastic litter into reusable carrier particle for FBBRs is feasible. He, Y., et al. (2017). "Comparison of different kits for Illumina RNA-seq library preparation." Genomics and Applied Biology **36**(11): 4607-4615.

RNA-seq was the transcriptome analysis technology that depended on deep sequencing. It was widely used on mainstream platform Illumina of next generation sequencing. In terms of the RNA-seq library construction for the Illumina platform, there were many types of method to support. However, there were differences among these methods on the operation steps and costs. In this study, three methods which were the preparation of TruSeq RNA library, NEBNext RNA library and RNA Kapa library were tested respectively. The lengths of these three libraries were focused on 300 bp-1 000 bp, KAPA RNA library had highest concentration. The preparation method only needed a magnetic microbeads purification, had easier operation, lower cost, and lower initial amount that required for construction. And it was suitable for large scale construction experiments.

Hebel, K., et al. (2012). "CD4⁺ T cells from human neonates are intrinsically poised towards a TH2 phenotype that can be modulated by co-stimulation." Immunology **1)**: 181.

Purpose/Objective: Interleukin 4 (IL-4) is the primary cytokine supporting the development of atopic diseases. As suggestive evidence points towards a bias of CD4 T cells of neonates and infants to become TH2 cells, we determined the capacity of TH cells of neonates and infants to do so. Material(s) and Method(s): Lymphocytes, CD4⁺CD45RA⁺, or CD4⁺CD45RA⁺CD31⁺ T cells were stimulated with anti-CD3 and anti-CD28 coated microbeads and analysed using Bio-Plex and flow cytometry. Fluorescent microscopy was used to determine subcellular localisation of IL-4. CD31-expressing cells were enriched by magneticcell sorting (MACS). Real-time-PCR was used for quantification of expression of specific mRNAs. ELIspot was performed to determine cytokine secretion of individual T lymphocytes. Result(s): In adenoids, we discovered a so far hardly appreciated TH subpopulation expressing an IL-4 splice variant which is not secreted. By fluorescent microscopy the non-secreted IL-4 was shown to accumulate in defined subcellular structures and not in undefined regions as has been reported before. Having a closer look at the subpopulation during ontogeny, naive CD4⁺ T cells from cord blood*but not from adults - with and without anti-CD3 T cell activation had a strong bias to express the non-secreted Interleukin-4 (IL-4) variant in CD45RA⁺ T cells at high frequencies that downmodulated the surface molecule CD31. Accordingly, only the CD31) subfraction of CD4⁺ T cells gained the ability to secrete IL-4. However, when the primary T-cell-triggering stimulus was enhanced by costimulation with anti-CD28, CD4⁺ T cells started to loose the intracellular IL-4, a phenomenon that was enforced by exogenous addition of IL-1beta, IL-12, or IL-6, but inhibited by TGFb reflecting the plasticity of neonatal TH cells. Conclusion(s): Neonatal T-cells show an intrinsic capacity to run a TH differentiation program. Interestingly for therapy, the final differentiation process can still be manipulated by costimulation. It is of great interest for immunpathologies driven by a TH2 response such as allergies that the secretion of this intrinsically induced, functional IL-4 additionally depends on the activation stimulus and the exogenous cytokine milieu and thus, can be manipulated.

Hebert, A., et al. (2003). "Analysis of intra-hepatic peptide-specific cell recruitment in mice immunised with Plasmodium falciparum antigens." Journal of Immunological Methods **275**(1/2): 123-132.

The liver stage of Plasmodium spp. now appears as a relevant target of immune effectors triggered by the so-called "anti-sporozoite" vaccine. Since the monitoring of immune responses at the systemic level may not faithfully reflect the local protective mechanisms, the aim of the present work was to set up a model to study the local intra-hepatic cellular responses and to compare these with the peripheral immune responses. This was achieved by intra-portal delivery of epitopic peptides, i.e. peptides containing B and T cell epitopes, which were coated onto the surface of polystyrene microbeads. The peptide-coated beads presumably mimic the hepatic schizont, and when distinct peptides are administered separately, this method of delivery allows us to decipher the immune responses resulting in mice immunised with recombinant proteins spanning several such epitopes. Using the P. falciparum liver stage antigen-3 (LSA3) molecule, which can induce protection against a sporozoite challenge, our results show that 25- micro m microbeads could easily access the liver parenchyma by intra-portal injection and were distributed evenly in the liver. Also, LSA3-derived synthetic peptides coated onto microbeads initiated specific cell recruitment within 6 h. Depending on the LSA3 peptide used, the infiltrates induced differed in size, with the strongest cell recruitment obtained using nonrepeat II peptide (NR2)-coated microbeads with a mean leukocyte number of 79 per granuloma. Immunohistological studies of liver sections revealed that, irrespective of the delivered peptide, cells infiltrating the liver towards microbeads were mainly CD3⁺ T lymphocytes, both CD4⁺ (70 to 80%) and CD8⁺ (20 to 30%) subtypes, macrophages and dendritic cells. Cells infiltrating the granuloma had features of activated cells, with evidence of VLA-4 cell-surface expression, and production of IFN- gamma and IL-4. Analysis of the peripheral B and T-cell responses in the same animals revealed that, whereas the local responses were directed mainly towards NR2 and repeat peptides (RE), the peripheral T-cell response to these peptides was weak and infrequent, although antibody production was high.

Hebisch, R. and G. Linsel (2012). "Workers' exposure to hazardous substances and biological agents in recycling enterprises." Gefahrstoffe Reinhaltung der Luft **72**(4): 163-169.

Recycling and waste management is performed in about 5,300 enterprises by about 150,000 employees in Germany. The Federal Institute for Occupational Safety and Health (BAuA) has performed a comprehensive investigation program in different recycling enterprises during the last decade. In detail, workers' exposures have been measured when recycling electronic waste, end-of life vehicles, plastics waste, textile, and paper and paperboard. During all these processes workers are exposed to airborne particles. Additionally, when recycling electronic waste and end-of life vehicles a significant exposure to heavy metals and organic solvents was found, respectively. Furthermore, for plastics, textiles, and paper and paperboard recycling exposure to biological agents may reach considerable concentrations. The results of the workplace measurements were used to establish recommendations for good practice to protect workers in recycling enterprises.

Hecht, A., et al. (2014). "Fractal dimension of microbead assemblies used for protein detection." Chemphyschem **15**(16): 3444-3446.

We use fractal analysis to calculate the protein concentration in a rotating magnetic assembly of microbeads of size 1 mum, which has optimized parameters of sedimentation, binding sites and magnetic volume. We utilize the original Forrest-Witten method, but due to the relatively small number of bead particles, which is of the order of 500, we use a large number of origins and also a large number of algorithm iterations. We find a value of the fractal dimension in the range

1.70-1.90, as a function of the thrombin concentration, which plays the role of binding the microbeads together. This is in good agreement with previous results from magnetorotation studies. The calculation of the fractal dimension using multiple points of reference can be used for any assembly with a relatively small number of particles.

Heddagaard, F. E. and P. Moller (2019). "Hazard assessment of small-size plastic particles: is the conceptual framework of particle toxicology useful?" Food & Chemical Toxicology **136**: 111106.

Humans are exposed to plastic particles, but there are no studies on environmental plastics in cell cultures or animals. The toxicological understanding arises from model particles like polystyrene, polyethylene or non-plastic particles like food-grade titanium dioxide. The majority of studies on polystyrene particles show toxicological effects on measures of oxidative stress, inflammation, mitochondrial dysfunction, lysosomal dysfunction and apoptosis. The toxic effects in cell cultures mainly occur at high concentrations. Polyethylene particles seem to generate inflammatory reactions, whereas other toxicological effects have not been assessed. There are very few studies on effects of polystyrene particles in animal models and these have not demonstrated overt indices of toxicity. Studies in animals are the likely way for hazard assessment of micro- or nanoplastics. However, co-culture systems that mimic the complex architecture of mammalian tissues can cost-efficiently determine the hazards of micro- and nanoplastics. Future studies should include low doses of micro- and nanoplastic particles, which are more relevant in the assessment of health risk than the extrapolation of effects from high doses to realistic doses. Based on studies on model particles, environmental exposure to micro- and nanoplastic particles may be a hazard to human health.

Hedman, B., et al. (2006). "Emission of PCDD/F, PCB, and HCB from combustion of firewood and pellets in residential stoves and boilers." Environmental Science & Technology **40**(16): 4968-4975.

To assess potential emissions of polychlorinated dibenzo-p-dioxins (PCDDs), polychlorinated dibenzofurans (PCDFs), polychlorinated biphenyls (PCBs), and hexachlorobenzene (HCB) from residential combustion of biofuels, experiments were performed in which various types of pellets and firewood were combusted in four types of stoves and boilers, with both full and reduced rates of air supply. Intermittent combustion of wood pellets resulted in emissions of 11 ng-(WHO-TEQ)/kg combusted fuel (dry weight). A modern, environmentally certified boiler yielded somewhat lower emissions of PCCD/F and PCB than a wood stove. Both gave <0.1 ng(WHO-TEQ)/m3n (1.3-6.5 ng(WHO-TEQ)/kg) and considerably lower emissions than an old boiler (7.0-13 ng(WHO-TEQ)/kg). No positive effect on emissions could be observed in full air combustion (simulating the use of a heat storage tank) compared to combustion with reduced air. Two of the wood combustion experiments included paper and plastic waste fuels. Chlorine-containing plastic waste gave rise to high emissions: ca. 310 ng(WHO-TEQ)/ kg over the whole combustion cycle. The homologue profiles of PCDD/Fs show characteristic differences between ashes and flue gas from combustions with different levels of air supply. These differences do not, however, seem to have any correlation to the relative amount of toxic congeners.

Heeb, N. V., et al. (2010). "Thermally-induced transformation of hexabromocyclo dodecanes and isobutoxypenta bromocyclododecanes in flame-proofed polystyrene materials." Chemosphere **80**(7): 701-708.

Abstract: Polystyrenes (PS) are produced in quantities exceeding 10Mty−1. They are used for insulation and packaging materials, often in flame-proofed forms with hexabromocyclododecanes (HBCDs) added as flame retardants. Polystyrenes are also constituents of plastic debris found in the aquatic environment. HBCDs are now considered as persistent, bioaccumulative, and toxic compounds. Lately, we reported that isobutoxypenta bromocyclododecanes (iBPBCDs), a formerly unknown class of polybrominated compounds, are also present in flame-proofed polystyrenes. It is therefore likely that iBPBCDs are released along with HBCDs from these materials. Herein, we report on changes of the HBCD- and iBPBCD-patterns when exposing expanded (EPS) and extruded (XPS) polystyrenes at temperatures of 140–160°C. Substantial transformation reactions were observed in EPS, which was rich in γ-HBCDs and δ-, η-, and θ-iBPBCDs at the beginning, but changed to materials rich in α-HBCDs and α-, β-, ε-, and ξ-iBPBCDs. Patterns of untreated XPS already resembled those of the thermally treated EPS. Upon thermal exposure, some further enrichment of α-HBCDs and α-, β-, ε-, and ξ-iBPBCDs was also noticed for the XPS samples, indicating similar transformation mechanisms. Comparable apparent first-order transformation rate constants (k trans) of −0.003, −0.008, and −0.020min−1 and −0.004, −0.009, and −0.019 min−1 are found for γ-HBCD- and δ-iBPBCD-conversion at 140, 150, and 160°C, respectively. We conclude that a thermal treatment of flame-proofed polystyrenes alters their HBCD- and iBPBCD-patterns. Thus depending on the proportions of EPS and XPS materials reaching the environment, more of the lipophilic (late-eluting) or of the more polar (early-eluting) HBCD- and iBPBCD-stereoisomers will be released. Several properties such as partitioning coefficients, degradation rates, and bioaccumulation factors are stereoisomer-specific. Therefore, the environmental fate of individual HBCDs and iBPBCDs is expected to vary, the specific stereoisomer pattern in polystyrenes at a potential source is another important aspect to consider. Heegaard, N. H. (1999). "Microscale characterization of the structure-activity relationship of a heparin-binding glycopeptide using affinity capillary electrophoresis and immobilized enzymes." Journal of Chromatography. A **853**(1-2): 189-195.

A heparin-binding glycopeptide (T3) from human serum amyloid P component was characterized by taking advantage of two important features of capillary electrophoresis: the low sample consumption and the possibility of doing on-line binding studies. Incubations with neuraminidase and proteolytic enzymes were carried out with enzymes immobilized on paramagnetic microbeads. Affinity capillary electrophoresis subsequently was used to characterize T3 and its fragments with respect to heparin binding. We find that an intact glycan moiety makes the C-terminal part of T3 relatively resistant to chymotryptic clevage. This protection is lost upon desialylation. Also, the C-terminus of T3 is involved in heparin binding while the N-terminal part of the molecule has no appreciable binding activity. The micromethods presented here make it feasible to perform structure-function studies even on the small amounts of analytes that are typically available when working with glycopeptides from natural sources.

Heemskerk, B., et al. (2010). "Microbead-assisted retroviral transduction for clinical application." Human Gene Therapy **21**(10): 1335-1342.

Retroviral transduction is the most commonly used strategy to obtain long-term expression of therapeutic genes. To efficiently transduce mammalian cells, a recombinant fibronectin molecule, RetroNectin, is generally used to juxtapose viral particles and cells, and thereby enhance viral uptake. Although this strategy has become widely adopted, in particular for the genetic modification of hematopoietic cells, several limitations apply. For example, it requires the use of culture systems that allow protein coating, something that is not possible for many of the closed cell culture systems that are used in clinical trials. Furthermore, efficient transduction is obtained only when culture systems can be exposed to centrifugation, an approach termed spin transduction. Here, we describe a novel and more potent strategy for the transduction of T cells that can be applied on a clinical scale. We show that RetroNectin can efficiently be coated onto epoxy-modified paramagnetic beads. After a blocking step, these beads can subsequently bind retroviral particles from viral supernatants, rendering such supernatants largely devoid of functional viral particles. Addition of these virus-loaded beads to activated T cells results in efficient retroviral infection. Importantly, transduction does not require the use of culture systems that are compatible with protein coating, nor is it dependent on centrifugation of either the viral supernatant or the cells. Finally, cell growth, phenotype, and function of spin-transduced versus bead-transduced cells are comparable. Viral coating of microbeads should facilitate the production of genetically modified cells, in particular for use in clinical trials.

Hegaret, H., et al. (2003). "Flow cytometric analysis of haemocytes from eastern oysters, Crassostrea virginica, subjected to a sudden temperature elevation: II. Haemocyte functions: aggregation, viability, phagocytosis, and respiratory burst." Journal of Experimental Marine Biology and Ecology **293**(2): 249-365.

The capability of an oyster to respond to environmental stresses, such as periodically high summer temperatures, as well as disease or parasite infections, depends, in large measure, upon the viability and functional capability of haemocytes. Eastern oysters (Crassostrea virginica) were subjected to a sudden increase in temperature from 20 to 28 degrees C for 1 week, and several haemocyte functions were determined before and after the temperature elevation using the flow cytometer. Previously, we described the characterization of different haemocyte types using new and modified flow cytometric methods. In this report, we provide detailed protocols for flow cytometric methods to: (1) determine haemocyte aggregation using paired samples with or without an antiaggregant solution; (2) assess haemocyte viability using propidium iodide (PI); (3) quantify haemocyte phagocytosis with fluorescent microbeads; and (4) measure the respiratory burst response of individual haemocytes using 2',7'-dichlorofluorescein diacetate (DCFH-DA) and zymosan to activate the release of reactive oxygen species (ROS). The temperature increase caused no significant change in haemocyte aggregation, although there was a trend of increasing aggregation in granulocytes and small granulocytes, but a slight decrease in hyalinocyte aggregation. Phagocytosis of all haemocyte types decreased after the temperature increase. Significantly higher percentages of dead haemocytes in all haemocyte types (attributable to a large increase in mortality of hyalinocytes, the most numerous cells) were found after the temperature increase, suggesting generally less capable immune function. Numbers of dead small granulocytes and granulocytes tended to decrease, but this was not statistically significant. Effects of temperature elevation upon respiratory burst were not statistically significant; however, a trend of increased ROS production after temperature elevation was consistent for all haemocyte types. Granulocytes, hyalinocytes, and small granulocytes showed increased production of ROS in the presence of zymosan; granulocytes showed the highest induced fluorescence.

Hegazy, S., et al. (2015). "Novel IMB-ELISA Assay for Rapid Diagnosis of Human Toxoplasmosis Using

SAG1 Antigen." Japanese Journal of Infectious Diseases **68**(6): 474-480.

Nanotechnology is important for medical diagnosis. Various nanoparticles have presented tremendous potential for diagnosing disease markers, pre-cancerous cells, fragment of viruses, specific proteins, antibodies, and other disease indicators. In general, nanoparticles are smaller than 1,000 nm and produced from different materials in different shapes such as spheres, rods, wires, and tubes. Our study aimed to develop a novel antigen-capture immunoassay based on IgG polyclonal antibody-coated magnetic microbead nanoparticles for the rapid detection of circulating surface antigen 1 of Toxoplasma gondii in human serum samples. Sandwich ELISA elicited a sensitivity of 92%, a specificity of 92.7%, a positive predictive value (PPV) of 92%, and a negative predictive value (NPV) of 92.7%. Immunomagnetic bead-ELISA showed sensitivity (98%), specificity (96.4%), PPV (96%), and NPV (98.1%) higher than that of sandwich ELISA. It is obvious that the use of magnetic microbead nanoparticles offers the potential advantage of improving the diagnostic testing of toxoplasmosis.

Hegbert, B. A., et al. (1991). Post-consumer mixed plastics recycling: Characterization, collection, costs and markets, NTIS, SPRINGFIELD, VA (USA).

Recycling of plastic discards is one method of reducing municipal solid waste. Because of its heterogeneous nature and the amount of contaminants present, separation of post-consumer mixed plastic waste is the most difficult. The purpose of the report is to identify the compositions of plastics in municipal solid waste (MSW) and in recycling programs, the post-consumer plastics contributions to recycling programs, the cost of plastics collection and some of the end uses for reprocessed post-consumer plastics. Attention is given to curbside collection of recyclables because of its high recovery rate (60-90%) in comparison to other recycling methods (10-30%).

Hegde, S. S., et al. (2013). "Transmyocardial therapeutic-delivery using real-time MRI guidance." Journal of Cardiovascular Magnetic Resonance **1)**: 213-214.

Background: Catheter-based transmyocardial injection offers a minimally invasive method to deliver therapeutics to the heart. It is typically performed under X-ray fluoroscopic guidance, which suffers from poor demarcation of myocardial boundaries and an inability to assess myocardial viability. MRI-guided intramyocardial delivery of therapeutics at 3T offers the potential for more precise targeting of these therapies with superior tissue contrast. Our group has been actively involved with (Figure presented) microencapsulated stem cell therapy to improve cell retention and prevent stem cell rejection. However, conventional microencapsulated stem cell products are too large to be administered transmyocardially. We demonstrate here intramyocardial injection of a prototype single stem cell therapeutic into the myocardium of a normal swine using real-time MR guidance and a custom active injection catheter. Method(s): Prototype alginate microbeads (50 mum diameter) impregnated with iron oxide (MyeOne) were produced using a custom microfluidic device. A custom MR- trackable, steerable intramyocardial injection catheter (10F diameter, 135 cm long, MRI Interventions, Inc.) with four built-in tracking coils (Figure 1a) was visualized on the Interactive Front End (IFE) navigation software (Siemens Corporate Research) in conjunction with a real-time tip-tracking sequence (BEAT-IRTTT, Pan.L et.al, ISMRM 2011, pp. 195). The catheter and the real-time interface were tested in a phantom, ex vivo pig heart, and an in vivo swine study at 3T (Siemens TimTrio). For the in vivo study, a breath-hold, multi-slice cine TrueFISP short-axis stack was obtained, which was segmented and converted to a 3D model (Figure 1b) for an overlay within IFE (Figure 1c). The catheter was navigated using real-time model guidance to target injection sites (Figure 1d). After ensuring correct needle placement, iron oxideimpregnated alginate

microbeads (0.02 ml/injection) were injected into the myocardium during a FLASH real-time acquisition (Figure 1e). Delivery success was confirmed using a breath hold, multi-slice 2D FLASH sequence (Figure 1f,g). Relevant imaging parameters are in the figure caption. Result(s): Left ventricular catheterization and guidance to four target sites in the myocardium was achieved. Confirmation of microbead delivery on FLASH images was possible but difficult due to the small volume and low iron concentration delivered. Follow-up imaging at one week postdelivery was unable to visualize the iron oxide-labeled therapeutic. No adverse events from transmyocardial delivery were observed. Conclusion(s): A real-time interface with active catheter tip tracking enabled successful 3T MRI-guided transmyocardial delivery of a prototype therapeutic to the in vivo heart.

Hegedus, E., et al. (2008). "Heteroduplex analysis using flow cytometric microbead assays to detect deletions, insertions, and single-strand lesions." Cytometry Part A: The Journal of the International Society for Analytical Cytology **73**(3): 238-245.

We explore the possibilities offered by flow cytometric microbead analysis to develop high throughput methods for the detection of deletions/insertions and single-strand DNA lesions. The products of PCR reactions derived from reference and test samples are denatured and reannealed, then exposed to enzymatic or chemical treatments distinguishing homoduplices from heteroduplices. The biotin- and dye labeled reaction products are immobilized on microbeads and the homo- and heteroduplices are assessed in separate fluorescence channels, by flow cytometry. Using a model system based on the mixed lineage leukemia gene breakpoint cluster region, we demonstrate that deletions and insertions in genomic DNA can be detected, using S1 nuclease and chemical cleavage to distinguish hetero- from homoduplices, or a restriction enzyme cleaving only the homoduplices. Single-strand discontinuities can also be detected, by combining nick-translation, using labeled nucleotide, and flow cytometric microbead analysis. The methodical approaches demonstrated are applicable in a versatile manner in basic cell and molecular biological research and also promise direct application for high throughput screening of genetic diseases and lesions, including insertions or deletions of short sequence elements and single-strand lesions formed at hypersensitive sites in response to apoptotic stimuli.

Hei, L., et al. (2007). "Fixing heavy metals in sludge and reducing pollution to soil using heavy metal stabilizers." Transactions of the Chinese Society of Agricultural Engineering **23**(8): 205-209.

Heavy metal stabilizers were added to sludge in used plastic containers, through artificial watering or naturally rain falling, the fertilizer components flowed out with leaching water and fertilized plants but the heavy metals retained in the sludge in the container. The leaching and pot experiments with Laetuca satiuali and Ipomoea aquatica showed that the positive effects of the mixture of the sludge and K₂SO₄ on plant production and reduction of heavy metal contents in plants were significant. Metals-bound sludge could be collected easily after treatment to prevent the secondary pollution, provided that the heavy metals were fixed within the container and significantly reduced the leaching of heavy metals to soil. This equipment meets the requirements of safe agricultural utilization of the sludge. Besides, this method permits the plastic waste recycled and realized with a low cost.

Heidbreder, L. M., et al. (2019). "Tackling the plastic problem: A review on perceptions, behaviors, and interventions." Science of the Total Environment **668**: 1077-1093.

The excessive production and consumption of plastic has serious consequences on the environment and human health. The reduction of plastic has therefore become a major global

challenge. As technical solutions might be insufficient to curb the problem, a perspective highlighting the impact of human behavior is needed. The current literature review provides an overview of the existing social-scientific literature on plastic, ranging from risk awareness, consumers' preferences, and predictors of usage behavior to political and psychological intervention strategies. By reviewing the literature, we aim to identify potential factors for future interventions to reduce plastic consumption. The 187 studies reviewed show that people much appreciate and routinely use plastic, despite a pronounced awareness of the associated problems. Habits, norms, and situational factors seem to be especially predictive for plastic consumption behavior. Both political and psychological interventions are potentially effective, although long-term effects are often uncertain. The review closes with implications for behavior-based solutions and future research, which should combine interdisciplinary approaches and take into account cultural differences.

Heidenreich, F. and T. Jovin (1996). "Synthesis of anti-acetylcholine receptor antibodies by CD5- B cells from peripheral blood of myasthenia gravis patients." Journal of Neurology **243**(1): 57-62.

An increased frequency of CD5+ B cells (or, according to a new nomenclature, B1 cells) has been detected in the peripheral blood of a proportion of patients with myasthenia gravis (MG), as in some other autoimmune diseases. To elucidate the pathogenic significance of this B-cell subset in myasthenia gravis, mononuclear cells from the peripheral blood of six MG patients were separated into T and B lymphocytes by a magnetic cell separation procedure employing superparamagnetic microbeads (MACS). Subsequently, the B-cell fraction was depleted of CD5+ B cells in a second separation. The resulting purified CD5- B-cell fraction was cultured alone or with the addition of autologous T cells. Anti-acetylcholine receptor (AChR) synthesis by CD5- B cells in cultures with T cells was significantly increased by pokeweed mitogen (176 +/- 130 fmol/ml per week/2 x 10(5) B cells) compared with unfractionated cells (75 +/- 101) or CD5- B cells alone (19 +/- 4). These results demonstrate that in MG anti-AChR are synthesized, at least in part, by CD5- B cells which are dependent on T cells. Although this does not exclude the existence of AChR-specific CD5+ B cells, it provides evidence against a pivotal role of this B-cell subset in anti-AChR synthesis.

Height, A. (2006). "Minister's recycling bags are filled with the wrong waste." Materials Recycling Week **188**(18): 7-7.

The article reports on the allegation that Local Environment Minister Ben Bradshaw has disposed his non-recyclable wastes in a recycling bin in Great Britain. The periodical "Mail on Sunday" revealed that the recycling bin contains information on the kind of garbage that should be placed on it. It has been discovered that the general rubbish sack of the minister composes of non-recyclable materials including waxed paper from a mint, foil-covered chewing gum, and chocolate wrappers. Bradshaw reacted on the issue by acknowledging the efforts of the newspaper in stressing the significance of recycling.

Height, A. (2007). "PIM process is able to fuse commingled plastics." Materials Recycling Week **189**(1): 6-6.

The article reports on the success of Environmental Polymer Technologies (EPT) in developing a process to fuse commingled plastics in Wales. After five years of development, EPT has discovered the use of powder impression molding (PIM) process to mix commingled plastic waste that can be turned into a range of quality products. Sorting ad washing are needed to attain a high-value recycled plastic product. But PIM fuses the material together than fully melting it. The final product consists of three sections, a core layer covered on either side by an outer layer, and the layer's properties can be tailor-made to suit the final product.

Heindler, F. M., et al. (2017). "Toxic effects of polyethylene terephthalate microparticles and Di(2-ethylhexyl)phthalate on the calanoid copepod, Parvocalanus crassirostris." Ecotoxicology and Environmental Safety **141**: 298-305.

Large amounts of plastic end up in the oceans every year where they fragment into microplastics over time. During this process, microplastics and their associated plasticizers become available for ingestion by different organisms. This study assessed the effects of microplastics (Polyethylene terephthalate; PET) and one plasticizer (Di(2-ethylhexyl)phthalate; DEHP) on mortality, productivity, population sizes and gene expression of the calanoid copepod Parvocalanus crassirostris. Copepods were exposed to DEHP for 48 h to assess toxicity. Adults were very healthy following chemical exposure (up to 5120 micro g L-1), whereas nauplii were severely affected at very low concentrations (48 h LC50 value of 1.04 ng L-1). Adults exposed to sub-lethal concentrations of DEHP (0.1-0.3 micro g L-1) or microplastics (10,000-80,000 particles mL-1) exhibited substantial reductions in egg production. Populations were exposed to either microplastics or DEHP for 6 days with 18 days of recovery or for 24 days. Populations exposed to microplastics for 24 days significantly depleted in population size (60+or-4.1%, p<0.001) relative to controls, whilst populations exposed for only 6 days (with 18 days of recovery) experienced less severe depletions (75+or-6.0% of control, p<0.05). Populations exposed to DEHP, however, exhibited no recovery and both treatments (6 and 24 days) yielded the same average population size at the termination of the experiment (59+or-4.9% and 59+or-3.4% compared to control; p<0.001). These results suggest that DEHP may induce reproductive disorders that can be inherited by subsequent generations. Histone 3 (H3) was significantly (p<0.05) upregulated in both plastic and DEHP treatments after 6 days of exposure, but not after 18 days of recovery. Hsp70-like expression showed to be unresponsive to either DEHP or microplastic exposure. Clearly, microplastics and plasticizers pose a serious threat to zooplankton and potentially to higher trophic levels.

Heinrich, P. and T. Braunbeck (2019). "Bioavailability of microplastic-bound pollutants in vitro: The role of adsorbate lipophilicity and surfactants." Comparative biochemistry and physiology. Toxicology & pharmacology : CBP **221**: 59-67.

The potential role of microplastic particles (MPs) as vectors for lipophilic organic pollutants enhancing their uptake by organisms has repeatedly been discussed in the scientific community. Likewise, several studies indicate an important role of surfactants in pollutant-transfer from MP to organisms. Employing polyethylene particles, the bioavailability of three MP-bound inducers of 7-ethoxyresorufin-O-deethylase (EROD) with variable lipophilicity was quantitatively compared via EROD activity in RTL-W1 cells. In addition, non-cytotoxic surfactant concentrations of Pluronic F-127, rhamnolipids, sodium deoxycholate and sodium dodecyl sulfate (SDS) supplemented to the medium were tested for their effects on pollutant desorption from MPs as well as on cellular EROD induction. Bioavailability of MP-bound pollutants was negatively correlated with lipophilicity, and all surfactants were found to modulate the cellular response towards inducers by unidentified mechanisms. After experimental correction for effects on the cellular response, all surfactants except SDS moderately increased desorption of inducer from MPs. Results on the impact of lipophilicity agree with previously published thermodynamic models, indicating that appreciable pollutant desorption from MPs may only occur for substances with comparatively low lipophilicity, the accumulation of which on MPs is negligible in the environment. However, the role of surfactants should be considered further with respect to potential effects on sorption of pollutants to and from MPs.

Heinrich, P. and T. Braunbeck (2019). "Microplastic testing in vitro: Realistic loading of pollutants, surfactant-free solid surface-dosing and bioanalytical detection using a sensitivity-optimized EROD assay." Toxicology in Vitro **54**: 194-201.

Microplastic particles (MPs) are emerging contaminants in aquatic environments, which are assumed to play a role as vectors for lipophilic pollutants, as the particles bear a potential for the accumulation of lipophilic contaminants from the water phase on the MPs' surface and subsequent release in contact with organisms. In an attempt to allow the bioanalytical detection and quantitatively estimate bioavailability of MP-bound pollutants under realistic conditions in vitro, a protocol was developed for water-based loading of lipophilic substances to MPs using a solid-phase extraction (SPE) approach and subsequent detection of the substances in a sensitivity-enhanced 7-ethoxyresorufin-O-deethylase (EROD) assay with RTL-W1 cells. Exemplarily, particles were loaded with benzo[k]fluoranthene (BkF), which was shown to bind to MPs with high affinity. Spiked particles were added to the surface of the culture medium, where they released low, but consistent amounts of BkF, which were quantified by EROD induction. Additionally, a geometrical model was developed for the estimation of numbers, surface areas and masses of MPs interacting with medium. The approach presented allows the experimental in vitro examination of the postulated function of MP as a pollutant vector in a highly sensitive animal-experimentation-free test system. Heinrich, P. and T. Braunbeck (2020). "Microplastic particles reduce EROD-induction specifically by highly lipophilic compounds in RTL-W1 cells." Ecotoxicology & Environmental Safety **189**: 110041.

Microplastic particles (MPs) from lipophilic polymers have been shown to efficiently accumulate hydrophobic organic contaminants (HOCs) in aquatic environments. MPs have, therefore, frequently been discussed as vectors for contaminants, enhancing HOC uptake by various organisms after ingestion followed by pollutant release; however, integrative models of sorption argue against this mechanism and even predict cleansing of pollutants from biological systems under particular circumstances. In order to experimentally investigate such a depuration mechanism, RTL-W1 cells were dosed with three 7-ethoxyresorufin-O-deethylase (EROD) inducers of distinct lipophilicity via the medium before adding both native and hexane-purified polyethylene MPs (20-25 mum) to the medium surface. EROD activity was significantly reduced in the presence of MP, the extent of which correlated with the inducers' lipophilicity (K_{OW}) and thus affinity to MP. For hexane-purged MPs and TCDD (K_{OW} = 6.8), MPs reduce the bioavailability by up to 79%; the effect was marginally weaker with benzo[k]fluoranthene (K_{OW} = 6.11) and almost absent with beta-Naphthoflavone (K_{OW} = 4.68). Compared to hexane-purged MPs, native particles possessed slightly less detoxification potential. These experimental results corroborate theoretically predicted mechanisms of detoxification via MPs. Yet, it is unclear if, under corresponding conditions in the environment, MPs can compete with organismal tissues for highly lipophilic compounds and, if so, to which degree they may act as a sink reducing the amount of bioavailable pollutants in situ. However, the present results suggest that in scenarios where pollutant-free MPs interact with organisms that accumulated HOCs via other routes of uptake, qualitatively the presence of such a mechanism is likely.

Heinzl, M. W., et al. (2015). "Detection of granulocyte-reactive antibodies: a comparison of different

methods." Vox Sanguinis **108**(3): 287-293.
BACKGROUND AND OBJECTIVES: Granulocyte-reactive antibodies can cause autoimmune and neonatal immune neutropenias as well as transfusion-related acute lung injury. The classical antibody-detection methods granulocyte aggregation test (GAT), granulocyte immunofluorescence test (GIFT) and monoclonal antibody-specific immobilization of granulocyte antigens (MAIGA) are time-consuming and technically challenging. In recent years, flow cytometric white blood cell immunofluorescence test (Flow-WIFT) and the microbeads assay LabScreen Multi have emerged and are still subject of evaluation. These serological tests were compared on a screening and specification level.
MATERIALS AND METHODS: For screening, the combination of GAT/GIFT was compared to Flow-WIFT testing 333 samples. Positive samples were further analysed with MAIGA and LabScreen Multi.
RESULTS: Granulocyte aggregation test/GIFT detected 77 positive samples, Flow-WIFT found 108 granulocyte-reactive samples. Six Samples were only positive in GAT/GIFT, and 37 samples were only positive in Flow-WIFT (kappa = 0.682). Antibody specification with MAIGA and the microbeads assay confirmed granulocyte-reactivity in 83 cases with 70 matching results (kappa = 0.742). However, out of six detected human neutrophil antigen (HNA) reactivities only two specificities matched in both assays.
CONCLUSION: Flow-WIFT may be a valuable addition to GIFT for granulocyte-reactive antibody screening. MAIGA remains the most reliable laboratory method for antibody specification.

Helbig, P. and C. D. Pitt (2018). "Sodium polytungstate as gravity separating fluid for polymeric blasting media evaluation." Analytical Methods **10**(25): 3039-3042.
Quality assessment of Plastic Blast Media (PBM) in order to determine heavy and light particulate contamination has been carried out traditionally using gravity separation in a medium prepared using 1,1,2-trifluorotrichloroethane (TFTCE) as high density compound. Environmental concerns require the assessment of viable alternatives to ozone depleting substances like TFTCE. Sodium polytungstate (SPT) can be used to increase the density of aqueous solutions, and has been used successfully in gravity separation of minerals and rocks. Some research was carried out into the literature regarding separating microplastics – a granular contaminant in water courses that is similar to PBM-revealing that it had been carried out using concentrated solutions of metal salts. Comparison of the results obtained from the TFTCE method with results obtained from a method using SPT revealed that there is no loss of analytical accuracy by changing to the SPT method.

Helcoski, R., et al. (2020). "Wetland soil microplastics are negatively related to vegetation cover and stem density." Environmental Pollution **256**: 113391.
Microplastics are a complex group of ubiquitous environmental contaminants of emerging concern. These particles degrade slowly, release plasticizers, and can be transferred between trophic levels. In aquatic systems, they have been identified suspended in the water column, along shorelines, and within sediment. However, the abundance and distribution of microplastics in vegetated wetlands, which are transitional ecosystems between terrestrial and aquatic environments, are poorly understood. Here we describe the spatial distribution of soil microplastics in habitats of varying vegetation density in an urban tidal wetland. Samples were wet-sieved, organic matter was oxidized using hydrogen peroxide, and microplastics separated under a dissecting microscope, counted, and weighed. A fraction (n=175) were analyzed via FTIR for validation. Positive microplastics identification was 81%-93%. Dominant polymers were polystyrene (29%) and polyethylene and synthetic rubber (both 8%). Average microplastic number to a 5-cm depth (23,200+/-2,500m⁻² or 1,270+/-150kg⁻¹)

varied between habitat types, where mudflat, channel edge, and drift line habitats all had significantly more total microplastics than the interior of dense stands of vegetation, suggesting that emergent wetland plants are a highly effective filter of microplastics. Microfibers were about eight times as abundant as microfragments, and fibers and fragments differed in their distribution patterns, with microfibers most abundant in vegetation-free mudflats and microfragments in vegetated channel edges. Our results demonstrate that vegetated wetlands are important locations for microplastic accumulation and that wetland vegetation and hydrodynamics affect spatial distribution of microplastics between habitats.

Hemmig, E., et al. (2020). "Transposing Lateral Flow Immunoassays to Capillary-Driven Microfluidics Using Self-Coalescence Modules and Capillary-Assembled Receptor Carriers." Analytical Chemistry **92**(1): 940-946.

Point-of-care (POC) immunodiagnostic tests play a crucial role in enabling rapid and correct diagnosis of diseases in prehospital care, emergency, and remote settings. In this work, we present a silicon-based, capillary-driven microfluidic chip integrating two microfluidic modules for the implementation of highly miniaturized immunoassays. Specifically, we apply state-of-the-art microfluidic technology to demonstrate a one-step immunoassay for the detection of the cardiac marker troponin I in human serum using sample volumes of ~1 muL and with a limit of detection (LOD) of ~4 ng mL⁻¹ within 25 min. The microfluidic modules discussed here broadly map functionalities found in standard lateral flow assays. We implement a self-coalescence module (SCM) for the controlled reconstitution and delivery of inkjet-spotted and dried detection antibodies (dAbs). This allows for homogeneous dissolution of 1.3 ng of fluorescently labeled dAbs in 416 nL of the sample used for the assay. We also show how to immobilize receptors inside closed microfluidic devices in <30 s using bead lane modules inside which microbeads functionalized with capture antibodies (cAbs) are self-assembled. The resulting bead lane module, with a volume of ~3 x 10⁻⁵ mm³, is positioned across the flow path and holds ~300 5 mum-diameter microbeads. Altogether, these capillary-driven elements allow for the manipulation of samples and reagents with an unprecedented precision and control, paving the way for the next generation of POC immunodiagnostics.

Hendrickson, E., et al. (2018). "Microplastic Abundance and Composition in Western Lake Superior As Determined via Microscopy, Pyr-GC/MS, and FTIR." Environmental Science & Technology **52**(4): 1787-1796.

While plastic pollution in marine and freshwater systems is an active area of research, there is not yet an in-depth understanding of the distributions, chemical compositions, and fates of plastics in aquatic environments. In this study, the magnitude, distribution, and common polymers of microplastic pollution in surface waters in western Lake Superior are determined. Analytical methodology, including estimates of ambient contamination during sample collection and processing, are described and employed. Microscopy, pyrolysis-gas chromatography/mass spectrometry (Pyr-GC/MS), and Fourier transform infrared spectroscopy (FTIR) were used to quantify and identify microplastic particles. In surface waters, fibers were the most frequently observed morphology, and, based upon PyGC/MS analysis, polyvinyl chloride was the most frequently observed polymer, followed by polypropylene and polyethylene. The most common polymer identified by FTIR was polyethylene. Despite the low human population in Lake Superior's watershed, microplastic particles (particularly fibers, fragments, and films) were identified in western-lake surface waters at levels comparable to average values reported in studies within Lake Michigan, the North Atlantic Ocean, and the South Pacific Ocean. This study

provides insight into the magnitude of microplastic pollution in western Lake Superior, and describes in detail methodology to improve future microplastics studies in aquatic systems.

Hengstmann, E., et al. (2018). "Microplastic in beach sediments of the Isle of Rugen (Baltic Sea) - Implementing a novel glass elutriation column." Marine Pollution Bulletin **126**: 263-274.

To extent the understanding on microplastics in the marine environment we performed a case study at four beaches on the Isle of Rugen considering abundance and spatial distribution of microplastics in beach sediments. For the analysis, density separation via a glass elutriation column was implemented. In advance, efficiencies were tested for two polymers, being not buoyant in water. Recovery rates of 80% for PET and 72% for PVC particles in sandy samples were achieved. A median abundance of 88.10 (Q₁=55.01/Q₃=114.72) microplastic particles per kg dry sediment or 2862.56 (Q₁=1787.34/Q₃=3727.28) particles per m² was found at the beaches on Rugen. Fibers were more abundant than fragments at all beaches. In this study, no statistically significant differences but only tendencies were determined between the beaches with different exposition and anthropogenic activity as well as for distribution patterns which showed that microplastic fragments accumulate in topographic depressions, similar to macrolitter items.

Heng-Xiang, L., et al. (2016). "Effects of Toxic Leachate from Commercial Plastics on Larval Survival and Settlement of the Barnacle Amphibalanus amphitrite." Environmental Science & Technology **50**(2): 924-931.

Plastic pollution represents a major and growing global problem. It is well-known that plastics are a source of chemical contaminants to the aquatic environment and provide novel habitats for marine organisms. The present study quantified the impacts of plastic leachates from the seven categories of recyclable plastics on larval survival and settlement of barnacle Amphibalanus (=Balanus) amphitrite. Leachates from plastics significantly increased barnacle nauplii mortality at the highest tested concentrations (0.10 and 0.50 m^2/L). Hydrophobidty (measured as surface energy) was positively correlated with mortality indicating that plastic surface chemistry may be an important factor in the effects of plastics on sessile organisms. Plastic leachates significandy inhibited barnacle cyprids setdement on glass at all tested concentrations. Setdement on plastic surfaces was significandy inhibited after 24 and 48 h, but settlement was not significantly inhibited compared to the controls for some plastics after 72--96 h. In 24 h exposure to seawater, we found larval toxicity and inhibition of setdement with all seven categories of recyclable commercial plastics. Chemical analysis revealed a complex mixture of substances released in plastic leachates. Leaching of toxic compounds from all plastics should be considered when assessing the risks of plastic pollution. [ABSTRACT FROM AUTHOR]

Henriksen, J. S., et al. (1995). "Tachykinins induce secretion of prolactin from perifused rat anterior pituitary cells by interactions with two different binding sites." Journal of Receptor and Signal Transduction Research **15**(1/4): 529-541.

Substance P and the 2 other mammalian tachykinins, neurokinin A and B, are accepted as having direct regulating effects at the anterior pituitary level. The effects of substance P (SP) and neurokinin B (NKB), alone and in combination, on prolactin release from cultured anterior pituitary cells grown on collagen-coated micro beads and placed in a perfusion system were examined. Prolactin (Prl) secretion was observed within 25 s after exposure to either secretagogue and reached a maximum within 60-80 s. Furthermore, the prolactin response induced by SP and NKB was dose-dependent. Prl secretion remained constant for up to 4 h when SP or NKB were perifused and then fell gradually towards basal levels. Simultaneous addition of submaximal concentrations of SP and NKB resulted in an additive response compared with the responses of either secretagogue alone. Continuous (8 h) perifusion with SP did not prevent a normal prolactin response by NKB or TRH. These results indicate that the tachykinins, substance P and neurokinin B, release Prl from perifused female rat anterior pituitary cells by interaction with 2 different receptors, possibly the NK1 and NK3 tachykinin receptor subtypes.

Henry, B., et al. (2019). "Microfibres from apparel and home textiles: Prospects for including microplastics in environmental sustainability assessment." Science of the Total Environment **652**: 483-494.

Textiles release fibres to the environment during production, use, and at end-of-life disposal. Approximately two-thirds of all textile items are now synthetic, dominated by petroleum-based organic polymers such as polyester, polyamide and acrylic. Plastic microfibres (<5mm) and nanofibres (<100nm) have been identified in ecosystems in all regions of the globe and have been estimated to comprise up to 35% of primary microplastics in marine environments, a major proportion of microplastics on coastal shorelines and to persist for decades in soils treated with sludge from waste water treatment plants. In this paper we present a critical review of factors affecting the release from fabrics of microfibres, and of the risks for impacts on ecological systems and potentially on human health. This review is used as a basis for exploring the potential to include a metric for microplastic pollution in tools that have been developed to quantify the environmental performance of apparel and home textiles. We conclude that the simple metric of mass or number of microfibres released combined with data on their persistence in the environment, could provide a useful interim mid-point indicator in sustainability assessment tools to support monitoring and mitigation strategies for microplastic pollution. Identified priority research areas include: (1) Standardised analytical methods for textile microfibres and nanofibres; (2) Ecotoxicological studies using environmentally realistic concentrations; (3) Studies tracking the fate of microplastics in complex food webs; and (4) Refined indicators for microfibre impacts in apparel and home textile sustainability assessment tools.

Henry, N., et al. (2017). "Pullulan microbeads/Si-HPMC hydrogel injectable system for the sustained delivery of GDF-5 and TGF-beta1: new insight into intervertebral disc regenerative medicine." Drug Delivery **24**(1): 999-1010.

Discogenic low back pain is considered a major health concern and no etiological treatments are today available to tackle this disease. To clinically address this issue at early stages, there is a rising interest in the stimulation of local cells by in situ injection of growth factors targeting intervertebral disc (IVD) degenerative process. Despite encouraging safety and tolerability results in clinic, growth factors efficacy may be further improved. To this end, the use of a delivery system allowing a sustained release, while protecting growth factors from degradation appears of particular interest. We propose herein the design of a new injectable biphasic system, based on the association of pullulan microbeads (PMBs) into a cellulose-based hydrogel (Si-HPMC), for the TGF-beta1 and GDF-5 growth factors sustained delivery. We present for the first time the design and mechanical characterization of both the PMBs and the called biphasic system (PMBs/Si-HPMC). Their loading and release capacities were also studied and we were able to demonstrate a sustained release of both growth factors, for up to 28 days. Noteworthy, the growth factors biological activity on human cells was maintained. Altogether, these data suggest that this PMBs/Si-HPMC biphasic system may be a promising candidate for the development of an innovative bioactive delivery system for IVD regenerative medicine.

Henry, T. B., et al. (2011). "Aqueous fullerene aggregates (nC60) generate minimal reactive oxygen species and are of low toxicity in fish: a revision of previous reports." Current Opinion in Biotechnology **22**(4): 533-537.

This review aims to clarify inconsistencies in previous reports regarding the potential for aqueous aggregates of fullerenes (nC60) to generate reactive oxygen species (ROS) and cause toxicity in fish.

Henschler, R., et al. (2016). "Ex vivo expansion induces substantial alterations in cell size and cytoskeletal proteins in T lymphocytes and mesenchymal stromal cells (MSCS)." Vox Sanguinis **111 (Supplement 1)**: 287.

Background: Immune cells used as cellular therapeutics in many cases undergo ex vivo expansion protocols. This includes the selection and clonal amplification of antigen-specific T cells, the generation of chimeric antigen receptor-transduced (CAR) T cells, or the generation of therapeutic MSCs. Recent data have indicated that during ex vivo expansion, MSCs or immune cells succumb to impairments in migration or antigen recognition that may affect their therapeutic potential. So far, the impact of culture expansion on proteins which are crucial for these functionalities such as actin-binding proteins are not known. Method(s): Transcription and protein content of the following actin-binding proteins or modifiers cofilin and profilin, alpha-actinin, filamin A, and the proteins linking actin and integrin signalling complexes, paxillin, vinculin and talin were analyzed. Transcription was quantified by qRT-PCR. Protein levels were quantified by flow cytometry of permeabilized cells using fluorescence-labelled antibodies pre-titrated to exceed the concentration of the analyzed antigens. Cell size was determined by flow cytometry using calibrated microbeads. Result(s): Analysis of cell size indicated that during anti-CD3/antiCD28-induced ex vivo expansion in RPMI/10% FCS 30U/ml Interleukin-2, immune-magnetically isolated murine CD3+ T lymphocytes increased in cell diameter from 7 to 14 mm and from approximately 179 to 1436 mm3 cell volume during a culture period of 7 days. In contrast, protein levels of all seven actin binding molecules remained constant on a per cell basis. Transcript mRNA levels of all seven actin-binding molecules, relative to the housekeeping gene GAPDH, were reduced between 5 and 50 fold. Expanded MSCs displayed still higher cell diamaters and >10 fold cell volumes than expanded T lymphocytes, but on a cell basis a further reduced mRNA expression levels of the investigated actin binding molecules compared to expanded T lymphocytes. Conclusion(s): Ex vivo expansion can induce substantial increases in size and intracellular volume of T lymphocytes and MSCs. In parallel, functionally relevant actinbinding proteins such as profilin, cofilin, alpha actinin, filamin A, paxillin, vinculin and talin do not undergo any parallel increase, and their transcription is strongly reduced. Our findings indicate that cell culture skews proteins with key functions in the migration and function of T lymphocytes and MSCs.

Hensher, M. (2020). "Incorporating environmental impacts into the economic evaluation of health care

systems: Perspectives from ecological economics." Resources, Conservation and Recycling **154**.
Health care is responsible for a range of negative environmental impacts, including greenhouse gas emissions, air pollution, plastics waste, and pharmaceutical pollution of ecosystems through excretion and inappropriate disposal. Evidence on the scale of these impacts has been growing in high-income countries. To date, there has been only limited discussion of how environmental impacts might be incorporated into economic evaluations of health care programs, including health technology assessment. This paper considers why and how this aim might be achieved, using perspectives from both mainstream and ecological economics. There are strong arguments for using economic evaluation to internalise the negative environmental externalities currently being generated by health care, as well as precautionary arguments for health systems to better understand their exposure to their environmental impacts. The paper tests the feasibility of incorporating the costs of greenhouse gas emissions within costing for economic evaluation, and concludes that the use of shadow prices to achieve this aim is feasible. It suggests that this cost-based approach is preferable to more convoluted attempts to incorporate environmental impacts in the outcome component of health economic evaluations. The interaction between overuse, antimicrobial resistance and environmental harms of health care is identified as an area that would benefit from investigation using innovative economic methods. © 2019 Elsevier B.V.

Henson, M. S., et al. (2011). "Immunotherapy with autologous tumour antigen-coated microbeads (large multivalent immunogen), IL-2 and GM-CSF in dogs with spontaneous B-cell lymphoma." Veterinary and Comparative Oncology **9**(2): 95-105.
Cytotoxic T-lymphocyte responses to subcellular antigens are enhanced when antigens are presented on cell-sized silica microbeads called large multivalent immunogens (LMIs). LMIs prepared with tumour cell membrane fragments have induced partial remissions in humans with melanoma and renal cell carcinoma. The purpose of this phase I study was to evaluate the safety of LMIs, prepared with autologous lymphoma cell membranes, along with subcutaneous interleukin 2 (IL-2) and granulocyte-macrophage colony stimulating factor (GM-CSF) in dogs with untreated B-cell lymphoma. After lymph node excision and induction chemotherapy, five dogs were vaccinated with three weekly doses of LMI alone; five with LMI and subcutaneous IL-2 and five with LMI, IL-2 and GM-CSF. No significant toxicity was noted, treatment did not adversely affect disease-free interval and half of the dogs showed measurable delayed-type hypersensitivity reactions to intradermal challenge with LMI, suggesting specific cell-mediated immunity.

Heo, J. (2005). Characterization and applications of microfluidic devices based on immobilized biomaterials.
Microfluidic biosensors and bioreactors based on immobilized biomaterials are described in this dissertation. Photocrosslinkable hydrogel or polymeric microbeads were used as a supporting matrix for immobilizing E.coli or enzymes in a microfluidic device. This dissertation covers a microfluidic bioreactor based on hydrogel-entrapped E.coli, a microfluidic biosensor based on an array of hydrogel-entrapped enzymes, and a microfluidic bioreactor based on microbead-immobilized enzymes. Hydrogel micropatches containing E.coli were fabricated within a microfluidic channel by in-situ photopolymerization. The cells were viable in the hydrogel micropatch and their membranes could be porated by lysating agents. Entrapment of viable cells within hydrogels, followed by lysis, could provide a convenient means for preparing biocatalysts without the need for enzyme extraction and purification. Our results suggested that hydrogel-entrapped cells, immobilized within microfluidic channels, can act as sensors for small

molecules and as bioreactors for carrying out reactions. A microfluidic biosensor based on an array of hydrogel-entrapped enzymes could be used to simultaneously detect different concentrations of the same analyte or multiple analyte in real time. The concentration of an enzyme inhibitor could be quantified using the same basic approach. Isolations of the microchannels within different microfluidic channels could eliminate the possibility of cross talk between enzymes. Finally, we characterized microfluidic bioreactors packed with microbead-immobilized enzymes that can carry out sequential, two-step enzyme-catalyzed reactions under flow conditions. The overall efficiency of the reactors depended on the spatial relationship of the two enzymes immobilized on the beads. Digital simulations confirmed the experimental results.

Her, Z., et al. (2017). "Severity of Plasma Leakage Is Associated With High Levels of Interferon gamma-Inducible Protein 10, Hepatocyte Growth Factor, Matrix Metalloproteinase 2 (MMP-2), and MMP-9 During Dengue Virus Infection." Journal of Infectious Diseases **215**(1): 42-51.

BACKGROUND: Dengue virus infection typically causes mild dengue fever, but, in severe cases, life-threatening dengue hemorrhagic fever (DHF) and dengue shock syndrome (DSS) occur. The pathophysiological hallmark of DHF and DSS is plasma leakage that leads to enhanced vascular permeability, likely due to a cytokine storm.

METHODS: Ninety patients with dengue during 2010-2012 in Singapore were prospectively recruited and stratified according to their disease phase, primary and secondary infection status, and disease severity, measured by plasma leakage. Clinical parameters were recorded throughout the disease progression. The levels of various immune mediators were quantified using comprehensive multiplex microbead-based immunoassays for 46 immune mediators.

RESULTS: Associations between clinical parameters and immune mediators were analyzed using various statistical methods. Potential immune markers, including interleukin 1 receptor antagonist, interferon gamma-inducible protein 10, hepatocyte growth factor, soluble p75 tumor necrosis factor alpha receptor, vascular cell adhesion molecule 1, and matrix metalloproteinase 2, were significantly associated with significant plasma leakage. Secondary dengue virus infections were also shown to influence disease outcome in terms of disease severity.

CONCLUSIONS: This study identified several key markers for exacerbated dengue pathogenesis, notably plasma leakage. This will allow a better understanding of the molecular mechanisms of DHF and DSS in patients with dengue.

Herber, M., et al. (2012). "Sensitive detection and analysis of plasma cells by seven-color phenotyping with combined intracellular solid phase staining on the macsquant analyzer." Cytometry Part B - Clinical Cytometry **82B (6)**: 413.

With the identification of phenotypic markers for plasma cells more than a decade ago, the discriminationand enumeration of malignant and normal plasma cells inmultiple myeloma patients has become feasible. Meanwhile,flow cytometry is well established as a valuable tool fordiagnosis, prognosis and minimal residual disease (MRD)assessment. Since there is no single marker which allowsdifferentiation between normal and malignant plasma cells,multicolor panels with at least four markers are recommendedfor immunophenotypical analysis. Furthermore, ithas been shown in various studies that additional markersimprove the discrimination of malignant plasma cells.Therefore, we propose a seven-color antibody combinationfor plasma cell phenotyping in Multiple Myeloma patients,including clonality assessment using the following antibodies:CD138-PE, CD38-FITC, CD56-APC, CD19-PE-Vio770,CD45-APC-Vio770, Anti Igkappa-PerCP, Anti Iglambda-VioBlue.Usage of optimized staining cocktails is particularly usefulin MRD assessment via multiparameter flow

cytometry, whichhas gained increasing clinical importance as being the mostrelevant prognostic factor. However, detection of rare malignantplasma cells is restricted by the total number of cellsacquired during a single MRD measurement. In general, thereproducible limit of sensitivity for MRD by flow cytometry is0.01%, which requires acquisition of at least 10⁶ total cells inorder to count 100 neoplastic cells. Magnetic pre-enrichmentallows rapid processing of larger total cell numbers, therebydramatically increasing the sensitivity of subsequent flowanalysis. The MACSQuant Analyzer integrates magnetic preenrichmentand flow cytometric analysis in a single automatedworkflow. This involves the autolabeling function for surfacestaining of the patient sample followed by automated magneticpre-enrichment of CD138-positive plasma cells via theMACSQuant Enrichment Unit. In addition, the EnrichmentUnit serves as solid phase for automated intracellular stainingof retained MicroBead-labeled plasma cells. The major advantageof solid phase intracellular staining of kappa/lambda light chains,besides minimizing manual handling, is the reduction of cellloss as repeated centrifugation steps are omitted.In summary, combining seven-color plasma cell phenotypingwith the MACSQuant Analyzer and WholeBloodCD138 MicroBeads provides a convenient automated workflowfor sensitive detection and characterization of neoplasticplasma cells in bone marrow and peripheral blood frommyeloma patients.

Herbort, A. F., et al. (2018). "Alkoxy-silyl Induced Agglomeration: A New Approach for the Sustainable Removal of Microplastic from Aquatic Systems." Journal of Polymers & the Environment **26**(11): 4258-4270.

The substance class of inert organic-chemical stressors (IOCS) describes organic-chemical (macro-) molecules, which demonstrate a high level of persistence upon entry in the ecosystem, and whose degradation is limited. These synthetically produced organic-chemical macromolecules, which are often derived from the polymerization of different monomers, are, in the form of plastics, indispensable in the everyday world. They enter the environmental compartments and cause great damage due to primary (industry, cosmetic, washing of textile), and secondary (degradation) entry. If these particles get into aquatic systems, this has fatal consequences for the ecosystem such as the death of marine animals, or bioaccumulation. Wastewater treatment plants are reaching their limits and require innovative ideas for the sustainable removal of microplastic. This article examines a new approach to the removal of polymers from aquatic systems (lab scale) by using sol-gel induced agglomeration reactions to form larger particle agglomerates. These enlarged agglomerates can be separated much more easily from the wastewater, since they float on the water surface. Separation systems, e.g. sand trap can easily be used. A further advantage is that the agglomeration can be carried out completely independently of the type, size, and amount of the trace substance concentration as well as of the external influences (pH value, temperature, pressure). Thus, this new type of particle separation can not only be used in sewage treatment plants, but can also be transferred to decentralized systems (e.g. implementation in industrial processes).Graphical Abstract: <graphic></graphic> [ABSTRACT FROM AUTHOR]

Herbort, A. F., et al. (2018). "A new approach for the agglomeration and subsequent removal of

polyethylene, polypropylene, and mixtures of both from freshwater systems - a case study." Environmental Science and Pollution Research **25**(15): 15226-15234.

Based on a new concept for the sustainable removal of microplastics from freshwater systems, a case study for a pH-induced agglomeration and subsequent removal of polyethylene and polypropylene particles from water is presented. The two-step-based process includes firstly a localization and secondly an aggregation of microplastic particles (250-350 micro M) in a physicochemical process. The research describes a strong increase in the particle size independent of pH of the aquatic milieu induced by the addition of trichlorosilane-substituted Si derivatives. The resulting Si-based microplastic aggregates (particle size after aggregation is 2-3 cm) could be easily removed by use of, e.g., sand traps. Due to the effect that microplastic particles form agglomeration products under every kind of process conditions (e.g., various pH, various polymer concentrations), the study shows a high potential for the sustainable removal of particles from wastewater.

Hermabessiere, L., et al. (2019). "Microplastic contamination and pollutant levels in mussels and cockles collected along the channel coasts." Environmental Pollution **250**: 807-819.

Nowadays, environmental pollution by microplastics (<5mm; MP) is a major issue. MP are contaminating marine organisms consumed by humans. This work studied MP contamination in two bivalve species of commercial interest: blue mussel (Mytilus edulis) and common cockle (Cerastoderma edule) sampled on the Channel coastlines (France). In parallel, 13 plastic additives and 27 hydrophobic organic compounds (HOC) were quantified in bivalves flesh using SBSE-TD-GS-MS/MS to explore a possible relationship between their concentrations and MP contamination levels. MP were extracted using a 10% potassium hydroxide digestion method then identified by mu-Raman spectroscopy. The proportion of contaminated bivalves by MP ranged from 34 to 58%. Blue mussels and common cockles exhibited 0.76+/-0.40 and 2.46+/-1.16 MP/individual and between 0.15+/-0.06 and 0.74+/-0.35MP/g of tissue wet weight. Some HOC and plastic additives were detected in bivalves. However, no significant Pearson or Spearman correlation was found between MP loads and plastic additives or HOC concentrations in bivalve tissues for the two species.

Hermsen, E., et al. (2018). "Quality Criteria for the Analysis of Microplastic in Biota Samples: A Critical Review." Environmental Science & Technology **52**(18): 10230-10240.

Data on ingestion of microplastics by marine biota are quintessential for monitoring and risk assessment of microplastics in the environment. Current studies, however, portray a wide spread in results on the occurrence of microplastic ingestion, highlighting a lack of comparability of results, which might be attributed to a lack of standardization of methods. We critically review and evaluate recent microplastic ingestion studies in aquatic biota, propose a quality assessment method for such studies, and apply the assessment method to the reviewed studies. The quality assessment method uses ten criteria: sampling method and strategy, sample size, sample processing and storage, laboratory preparation, clean air conditions, negative controls, positive controls, target component, sample (pre)treatment, and polymer identification. The results of this quality assessment show a dire need for stricter quality assurance in microplastic ingestion studies. On average, studies score 8.0 out of 20 points for "completeness of information" and 0 for "reliability". Alongside the assessment method, a standardized protocol for detecting microplastic in biota samples incorporating these criteria is provided.

Hermsen, E., et al. (2017). "Detection of low numbers of microplastics in North Sea fish using strict quality assurance criteria." Marine Pollution Bulletin **122**(1-2): 253-258.

We investigated 400 individual fish of four North Sea species: Atlantic Herring, Sprat, Common Dab, and Whiting on ingestion of >20mum microplastic. Strict quality assurance criteria were followed in order to control contamination during the study. Two plastic particles were found in only 1 (a Sprat) out of 400 individuals (0.25%, with a 95% confidence interval of 0.09-1.1%). The particles were identified to consist of polymethylmethacrylate (PMMA) through FTIR spectroscopy. No contamination occurred during the study, showing the method applied to be suitable for microplastic ingestion studies in biota. We discuss the low particle count for North Sea fish with those in other studies and suggest a relation between reported particle count and degree of quality assurance applied. Microplastic ingestion by fish may be less common than thought initially, with low incidence shown in this study, and other studies adhering to strict quality assurance criteria.

Hernandez, J., et al. (2018). "Contractility in human induced pluripotent stem cell derived cardiomyocytes is highly dependent on stochastic variability in myofilament development." Circulation. Conference **138**(Supplement 1).

Introduction: Modeling heart diseases using cardiomyocytes derived from human induced pluripotent stem cells (HIPSC-CMS) enables direct study of cellular and molecular mechanisms. However, the variable phenotypes of individual cells has limited the reproducibility of contractile measurements. We hypothesized that variability in myofibrillar development in HIPSC-CMS influences the contractile kinetics and could be controlled for by visualizing and quantifying myofilaments in vitro. Methods and Results: Control hiPSCs were differentiated into cardiomyocytes (HIPSC-CMS) and purified. HIPSC-CMS were replated at day ~25 onto 8.7 kPa polyacrylamide gels containing fluorescent microbeads and micropatterned with fibronectin in 7:1 aspect ratio rectangles (1750 um²). Single iPSC-CMs grew into the rectangular shapes and exhibited spontaneous contractions by day 2 of replating. HIPSC-CMS were stained with live-cell actin dye and imaged on day 5-7 for fluorescent bead displacements and actin videos depicting myofilaments. Traction force analysis of bead displacements was performed to calculate whole-cell force vs. time curves at 33 msec temporal resolution. Myofilament area was measured by thresholding a binary mask on the actin live cell images. Myofilament number varied markedly among individual iPSC-CMs. iPSC-CMs with few myofilaments (myofilament area/cell area <30%) developed low force (<400 uN per cell) and were not included in subsequent analyses. Among cells with myofilament area >30%, the mean traction force was 1368+/-357 uN and the myofilament area demonstrated a linear correlation with maximum force (R²=0.19, runs test p=0.8) with slope of 0.8+/-0.2 uN/um² (p=0.002 vs zero slope). Maximum contraction velocity strongly correlated with maximum force (R²=0.31, runs test p=0.4) with slope of 3.9+/-0.9 sec⁻¹ (p<0.0001 vs zero slope), as did maximum relaxation velocity (R²=0.27, runs test p=0.6, slope 4.1+1.0 sec⁻¹, p=0.0003 vs zero slope). Similar results were observed in two control cell lines and with two different purification methods. Conclusion(s): Variability in myofilament development is a critical determinant of contractile force and kinetics in individual iPSC-CMs that should be accounted for in iPSC-CM contractile experiments.

Hernandez, L. M., et al. (2019). "Plastic Teabags Release Billions of Microparticles and Nanoparticles into Tea." Environmental Science & Technology **53**(21): 12300-12310.

The increasing presence of micro- and nano-sized plastics in the environment and food chain is of growing concern. Although mindful consumers are promoting the reduction of single-use plastics, some manufacturers are creating new plastic packaging to replace traditional paper uses, such as plastic teabags. The objective of this study was to determine whether plastic

teabags could release microplastics and/or nanoplastics during a typical steeping process. We show that steeping a single plastic teabag at brewing temperature (95 degreeC) releases approximately 11.6 billion microplastics and 3.1 billion nanoplastics into a single cup of the beverage. The composition of the released particles is matched to the original teabags (nylon and polyethylene terephthalate) using Fourier-transform infrared spectroscopy (FTIR) and X-ray photoelectron spectroscopy (XPS). The levels of nylon and polyethylene terephthalate particles released from the teabag packaging are several orders of magnitude higher than plastic loads previously reported in other foods. An initial acute invertebrate toxicity assessment shows that exposure to only the particles released from the teabags caused dose-dependent behavioral and developmental effects.

Hernandez-Gonzalez, A., et al. (2018). "Microplastics in the stomach contents of common dolphin (Delphinus delphis) stranded on the Galician coasts (NW Spain, 2005-2010)." Marine Pollution Bulletin **137**: 526-532.

Plastic debris is currently recognised as one of the major global threats to marine life. However, few data exist on the presence and abundance of microplastics (plastics <5 mm in size) in marine mammals. This is the first record of the presence of microplastics in the digestive tracts of marine mammals from the Iberian Peninsula. This study made use of 35 samples of common dolphin stomach contents. Microplastics were identified in all the samples analysed, an average of 12 items per stomach although abundance varied widely from one stomach to another. Most plastic items were small fibres although some fragments and a bead were also found. Excluding the smallest fibres as possible airborne contamination, the estimated occurrence of microplastics could drop to as low as 94%. Although factors affecting accumulation of microplastics and their effect on common dolphins are unknown, the fact that all stomachs analysed contained microplastics is a cause for concern.

Hernandez-Milian, G., et al. (2019). "Microplastics in grey seal (Halichoerus grypus) intestines: are they associated with parasite aggregations?" Marine Pollution Bulletin **146**: 349-354.

Between 2012 and 2015, 13 grey seals were recovered from trammel nets targeting monkfish and rays off the south coast of Ireland. Incidence and distribution of microplastics were investigated along the intestines of bycaught seals. No macrodebris items were found, whereas microplastics were detected in all seals. A total of 363 microplastics items were identified (85% fibers, 14% fragments, 1% films). Estimation of microplastic ingestion based on prey ingestion (245 particles) was lower than the observed data. Acantocephala parasites (n=1543) were found in 12 seals, with an average of 74.5+or-67.7 parasites per seal. Distribution of microplastics varied between seals, although microplastics tended to accumulate in areas where more parasites were aggregated; however, there was no significant relationship between the number of parasites and microplastics was found. Seals recovered from nets appear to be a good source to monitor the incidence of microplastic pollution within the coastal food webs.

Hernandez-Molina, G., et al. (2012). "Regulatory B cells in primary sjogren's syndrome." Arthritis and Rheumatism **10)**: S225.

Background/Purpose: B cells have traditionally been considered as positive regulators of humoral immune response, however their negative regulatory role has recently being recognized. Objective. To characterize the phenotypes of regulatory B cells in peripheral blood of primary Sjogren syndrome (pSS) patients and compare their presence according to the clinical and/or serologic activity disease status. Method(s): We included 50 pSS patients according to the AECG classification criteria, all of them were evaluated by a rheumatologist. We defined

clinical activity as the presence of parotid enlargement or any extraglandular manifestation assessed by the SDAI or the ESSDAI indexes (except fatigue, fever or arthralgias). We defined serologic activity as IgG immunoglobulin >16 g or low C3, C4 or serum viscosity >1.9 cp. Twelve healthy age matched subjects were used as controls. PBMCs were isolated by centrifugation over a Lymphoprep gradient. CD19-mAb-coated microbeads were used to purify B cells by positive selection. We used the following mAbs: anti-CD38-PECy5, anti-CD38-PE, anti-CD24-FITC, anti-IgA-PE, anti-IgDPE, anti-IgG-PECy5, anti-IgM-APC, anti-CD5-APC, anti-CD10-APC, anti-CD20-APC, anti-CD27-APC, anti-CXCR4-APC and anti-CXCR7-Cy5. Cells immunofluorescent staining was analyzed by a FACScalibur flow cytometer. The relative % of the subtypes of Il-10 cells producers was calculated on basis of the total positive selection of the phenotype CD19+/ CD38^{bright}/CD24^{bright}. We used One way ANOVA analysis (post-hoc analysis Dunn method) with the Sigma Stat 11.2 software. Result(s): Patients were predominantly females, mean age 53+/-12 years and median disease duration of 9.7 years. Seventeen patients (34%) were clinical active (parotid enlargement, vasculitis, arthritis, leucopenia, lymphopenia, pneumonitis or optic neuritis). Patients with or without clinical activity were similar in age, disease duration but received more frequently prednisone and azathioprine. Twenty-seven (54%) patients had serologic activity regardless their clinical status. IL-10⁺ B cells represented the 0.55% of the total pSS B cell population and was higher in clinical inactive patients(0.63%), whereas controls had a lower prevalence (0.22%, p<0.05). We found a statistically significant increment in the following subtypes of Bregs cells: CD19⁺/CD38^{bright}/IgA⁺/IL10⁺ cells (pSS 79%, clinical inactive 80% vs. control 66%), CD19⁺/CD24^{bright}/CD38^{bright}/CD5⁺/IL10⁺ (clinical inactive 24% vs. control 14%), CD10⁺/IL10⁺ (pSS 23%, clinical inactive 26% vs. control 15%). IgD⁺ cells and CD27-/IL10⁺ cells were increased in all the groups regardless their clinical activity when compared vs. controls. The phenotypes CD19⁺/CD24^{bright}/CD38^{bright}IL10⁺/CD20⁺, CD27⁺, CXCR4⁺ and CXCR7⁺ were similar among groups. We did not find a difference when we analyzed by serologic activity. Conclusion(s): Most of the studied Bregs phenotypes were increased in pSS patients, particularly in those without clinical activity. The presence of these cells emphasizes the importance of the immunobiology of B cells in pSS.

Herndon, B., et al. (2013). "Urease and Helicobacter spp. antigens in pulmonary granuloma." Journal of Comparative Pathology **148**(2-3): 266-277.

Pulmonary sarcoidosis, a human disease of unknown cause, has no animal model. Sarcoidosis patients have serum antibodies specific for Helicobacter pylori and its surface enzyme urease. H. pylori do not survive in the high-oxygen pulmonary atmosphere, but urease may access the lung by oesophageal reflux. A model was established in rats to study gastro-oesophageal reflux of urease into the airways. Pathology in tissues from human sarcoidosis patients was compared with that in the rat model. Changes observed in the rat model included prominent peribronchial lymphocytic infiltration, which is seen occasionally in human sarcoidosis. Granulomas, pathognomonic for human sarcoidosis, occurred occasionally in the lungs of rats given urease protein intratracheally, but were widespread when urease was coupled to microbeads and administered intravenously. Biomarkers associated with human sarcoidosis (interleukin1-beta and platelet-activating factor) were up-regulated acutely in the rat model. Further investigations with this model may provide significant insights into the origin and pathogenesis of pulmonary

diseases in man and other species that carry gastric Helicobacter spp. and its associated enzyme.

Herrera, A., et al. (2018). "Microplastic and tar pollution on three Canary Islands beaches: An annual study." Marine Pollution Bulletin **129**(2): 494-502.

Marine debris accumulation was analyzed from three exposed beaches of the Canary Islands (Lambra, Famara and Las Canteras). Large microplastics (1-5mm), mesoplastics (5-25mm) and tar pollution were assessed twice a month for a year. There was great spatial and temporal variability in the Canary Island coastal pollution. Seasonal patterns differed at each location, marine debris concentration depended mainly of local-scale wind and wave conditions. The most polluted beach was Lambra, a remote beach infrequently visited. The types of debris found were mainly preproduction resin pellets, plastic fragments and tar, evidencing that pollution was not of local origin, but it cames from the open sea. The levels of pollution were similar to those of highly industrialized and contaminated regions. This study corroborates that the Canary Islands are an area of accumulation of microplastics and tar rafted from the North Atlantic Ocean by the southward flowing Canary Current.

Herrera, A., et al. (2019). "Microplastic ingestion by Atlantic chub mackerel (Scomber colias) in the Canary Islands coast." Marine Pollution Bulletin **139**: 127-135.

In recent years, due to the increasing concerns about their negative impact on wildlife and possible toxicity to living organisms (including humans), microplastics have become the subject of intense investigations. In the ocean, microplastics can be easily ingested by numerous marine organisms because of their small size (<5 mm). The Northwest African upwelling system is an important fishery area, and the present study is the first one in the region to reveal the presence of microplastic particles in the digestive tract of Atlantic chub mackerel (Scomber colias). From the 120 examined fish gastrointestinal tracts, 78.3% contained some type of microplastics, 74.2% contained fibres, 17.5% plastic fragments, and 16.7% paint. More studies are needed on fish, but S. colias is a candidate for being a good indicator of microplastic contamination in the region. Copyright © 2018 Elsevier Ltd

Hervás, M., et al. (2012). "Electrochemical immunosensing on board microfluidic chip platforms." TrAC - Trends in Analytical Chemistry **31**: 109-128.

Microfluidic devices as immunosensing platforms have had a great deal of attention in recent years, becoming an emergent technology in biomedical, pharmaceutical, environmental and food analysis. Combination of the remarkable features of microfluidic platforms with those of immunoassays produces a promising tool for selective, sensitive, automatic and point-of-care testing in real applications.In this article, we review and discuss different aspects of microfluidic material substrate, fluid handling, multiplexing, and, mainly, surface-modification and immunoreagent-immobilization strategies since 2005. Although different detection modes can be used in this kind of microfluidic immunosensing platform, the special features of electrochemistry have greatly expanded this technique, and electrochemical detection is common to the articles that we review. Finally, we comment on the future outlook for microfluidic immunosensing. © 2011 Elsevier Ltd.

Herzke, D., et al. (2016). "Negligible impact of ingested microplastics on tissue concentrations of persistent organic pollutants in northern fulmars off coastal Norway." Environmental Science & Technology **50**(4): 1924-1933.

The northern fulmar (Fulmarus glacialis) is defined as an indicator species of plastic pollution by the Oslo-Paris Convention for the North-East Atlantic, but few data exist for fulmars from

Norway. Moreover, the relationship between uptake of plastic and pollutants in seabirds is poorly understood. We analyzed samples of fulmars from Norwegian waters and compared the POP concentrations in their liver and muscle tissue with the corresponding concentrations in the loads of ingested plastic in their stomachs, grouped as "no", "medium" (0.01-0.21 g; 1-14 pieces of plastic), or "high" (0.11-0.59 g; 15-106 pieces of plastic). POP concentrations in the plastic did not differ significantly between the high and medium plastic ingestion group for sumPCBs, sumDDTs, and sumPBDEs. By combining correlations among POP concentrations, differences in tissue concentrations of POPs between plastic ingestion subgroups, fugacity calculations, and bioaccumulation modeling, we showed that plastic is more likely to act as a passive sampler than as a vector of POPs, thus reflecting the POP profiles of simultaneously ingested prey.

Herzke, D., et al. (2019). "Correction to Negligible Impact of ingested microplastics on tissue concentrations of persistent organic pollutants in Northern Fulmars of coastal Norway." Environmental Science & Technology **53**(24): 14769.

Hesler, M., et al. (2019). "Multi-endpoint toxicological assessment of polystyrene nano- and microparticles in different biological models in vitro." Toxicology in Vitro **61**: 104610.

Nanoplastics (NP) and microplastics (MP) accumulate in our environment as a consequence of the massive consumption of plastics. Huge knowledge-gaps exist regarding uptake and fate of plastic particles in micro- and nano-dimensions in humans as well as on their impact on human health. This study investigated the transport and effects of 50nm and 0.5mum COOH-modified polystyrene (PS) particles, as representatives for NP and MP, in different biological models in vitro. Acute toxicity and potential translocation of the particles were studied at the human intestinal and placental barrier using advanced in vitro co-culture models. Furthermore, embryotoxicity and genotoxicity were investigated as highly sensitive endpoints. Polystyrene was not acutely toxic in both sizes (nano- and microparticles). No transport across the intestinal and placental barrier but a cellular uptake and intracellular accumulation of PS nano- and microparticles were determined. The particles were identified as weak embryotoxic and non-genotoxic. In contrast to single-organ studies, this multi-endpoint study is providing a data-set with the exact same type of particles to compare organ-specific outcomes. Our study clearly shows the need to investigate other types of plastics as well as towards long-term or chronic effects of plastic particles in different biological models in vitro.

Hess, R. D., et al. (1995). "Quantitative cytofluorimetric determination of cell membrane-associated large tumor antigen on SV40-transformed cells." Cytometry **20**(1): 81-85.

The aim of this study was to quantitate the number of cell membrane-located SV40 large tumor antigen (large T) molecules of SV40-transformed cell lines by cytofluorimetric analysis. Five different SV40-transformed cell lines were labelled by either a biotin- or a fluorescein-conjugated monoclonal antibody, PAb1605, which is specific for the large T carboxyterminus. The conjugated-antibody fluorescence signals of the stained large T molecules of transformed cells were measured via cytofluorimetry. Comparison of the fluorescence signals of calibrated beads bearing a known number of fluorescein molecules to the signals of conjugated PAb1605 antibodies bound on microbeads to a defined number of IgG binding sites made it possible to determine the number of antibody-accessible large T molecules per SV40-transformed cell. The numbers (x10(-4)) found per cell were 1.0 (ELONA, hamster), 3.0 (VLM, mouse), 3.5 (mKSA, mouse), 11 (C57SV, mouse), and 5.5 (SV80, human), respectively. Thus, the technique described allows a precise quantitation of surface-exposed, antibody-accessible viral antigen expression.

Hester-Reilly, H. J. and N. C. Shapley (2007). "Imaging contrast effects in alginate microbeads containing trapped emulsion droplets." Journal of Magnetic Resonance **188**(1): 168-175.

This study focuses on spherical microparticles made of cross-linked alginate gel and microcapsules composed of an oil-in-water emulsion where the continuous aqueous phase is cross-linked into an alginate gel matrix. We have investigated the use of these easily manufactured microbeads as contrast agents for the study of the flow properties of fluids using nuclear magnetic resonance imaging.

Heuchan, S. M., et al. (2019). "Development of Fertilizer Coatings from Polyglyoxylate-Polyester Blends Responsive to Root-Driven pH Change." Journal of Agricultural & Food Chemistry **67**(46): 12720-12729.

Many current controlled-release fertilizers (CRFs) are coated with nonbiodegradable polymers that can contribute to microplastic pollution. Here, coatings of self-immolative poly(ethyl glyoxylate) (PEtG) capped with a carbamate and blended with polycaprolactone (PCL) or poly(l-lactic acid) (PLA) were evaluated. They were designed to depolymerize and release fertilizers in the vicinity of plant roots, where the pH is lower than that in the surrounding environment. PEtG/PCL coatings exhibited significant temperature and pH effects, requiring 18 days at pH 5 and 30 degreeC, compared to 77 days at pH 7 and 22 degreeC, to reach 15% mass loss. Plant roots were also effective in triggering coating degradation. Spray-coating and melt-coating were explored, with the latter being more effective in providing pellets that retained urea prior to polymer degradation. Finally, PEtG/PCL-coated pellets promoted plant growth to a similar degree or better than currently available CRFs.

Heyward, S. and T. Williamson (2012). "Use of hepatocyte and kupffer cell co-culture models in assessment of cytochrome p450 metabolism." Drug Metabolism Reviews **1)**: 60.

Primary human hepatocyte cultures have long been the gold standard for assessment of liver metabolism of xenobiotic compounds. In the liver, the response to infection and inflammation by tissue-associated immune cells can alter gene expression, including cytochrome P450 (CYP) enzymes. Kupffer cells are macrophages which are part of the liver sinusoid and mediate many of these responses. Hepatocyte/Kupffer cell co-cultures offer a more comprehensive model to understand the effects of the liver inflammatory response and macrophage modulation of critical drug metabolizing enzymes for better in vivo correlation. Freshly isolated SD rat kupffer cells and hepatocytes were cultured as separate monolayers and in co-cultures at ratios ranging from physiological (1:16) to highly inflamed (1:2). Trypan blue exclusion was used to assess viability of isolated cells. The phagocytic properties of kupffer cells are retained in culture. The specific uptake of 1 mum fluorescently labeled latex microbeads was used to assess purity of the kupffer cells. Cells were cultured for 24 hours prior to initiating experiment. Bacterial endotoxin, lipopolysaccaride (LPS) was used to stimulate production of cytokine by kupffer cells. Kupffer/hepatocyte cocultures, at a ratio of 1:4 respectively, were exposed to increasing concentrations of LPS ranging from 0.1 mug/mL to 10 mug/mL. Samples were taken 24-hour post-LPS exposure and analyzed for levels of the pro-inflammatory cytokine IL-6 using ELISA. Following normal metabolism induction procedures, hepatocyte only cultures and 1:2, 1:4, and 1:8 kupffer/hepatocyte cocultures were exposed to know inducers of CYP1A, CYP2B, and CYP3A for 48 hours prior to substrate incubation and sample collection. Metabolite formation was determined using LCMS to measure enzyme activity and mRNA expression levels were quantified using Taqman Real-Time RT-PCR to measure protein synthesis. MTT was run in parallel to monitor viability of cultures throughout experiment. Specific uptake of 1 micron fluorescently labeled microbeads by freshly isolated kupffer cells showed >90% purity, as

indicated by flow cytometry. Cytokine quantitation using ELISA showed increased production of IL-6 (pg/mL) with increasing kupffer cell content, with the highly inflamed ratio 1:2 producing the highest levels of cytokine. ELISA results also showed a concentration dependent, linear increase in IL-6 production with increasing concentrations of LPS. Cultures were treated with and without LPS for 24 hours followed by induction for 48 hours with dexamethasone, phenabarbital and beta-napaflavone. Induction of CYP1A, 2B, and 3A were assessed by metabolism of protypical substrates and mRNA transcript levels. Both the substrate metabolism activity and mRNA results showed significant reduction in CYP gene induction in cultures of kupffers/hepatocytes at a ratio of 1:4. These data indicate that defined in vitro cultures of kupffer cells and hepatocytes can be obtained and used to better define the impact of immune mediators on liver metabolism.

Hick, P., et al. (2010). "Preparation of fish tissues for optimal detection of betanodavirus." Aquaculture **310**(1/2): 20-26.

Betanodaviruses, the causative agents of viral nervous necrosis (VNN) disease, cause significant production losses in aquaculture worldwide. To improve the detection of betanodavirus, methods of extraction of the virus and its RNA from the tissues of sub-clinically infected barramundi (Lates calcarifer) and Australian bass (Macquaria novemaculeata) were evaluated. Compared to crude manual processing, the yield of betanodavirus was increased by 3.5-fold when tissues were disrupted by micro-bead beating and 2-fold using an optimised manual pestle grinding method ($p<0.01$). Both of these methods produced a tissue homogenate which was compatible with virus isolation in SSN-1 cells. The quantity of betanodavirus detected was at least 5.6 times higher when nucleic acids were purified using an automated magnetic particle method compared to two commonly used silica-adsorption spin column products ($p<0.01$). When used together, tissue disruption by micro-bead beating and nucleic acid purification using a magnetic particle processor was predicted to result in a 15-fold increase in yield of virus from tissues, and increased the speed of sample preparation 10-fold compared to the use of manual tissue grinding and a silica-adsorption spin column. The mechanised and automated methods required less manual handling of samples, which may reduce the potential for false positive and false negative results arising through sample cross contamination, degradation and operator error. High-throughput preparation of tissue samples and detection of betanodavirus with greater sensitivity will enable improved control of VNN in aquaculture.

Hida, K., et al. (2013). "Development of a rapid total nucleic acid extraction method for the isolation of hepatitis A virus from fresh produce." International Journal of Food Microbiology **161**(3): 143-150.

Recently, there have been increasing reports of foodborne illnesses associated with the consumption of fresh produce. Among these, hepatitis A virus (HAV) remains epidemiologically important and has been continually implicated in several outbreaks. We describe a rapid method (<8h) for the isolation and subsequent detection with real-time quantitative PCR (RT-qPCR) of the HAV HM-175 cytopathic strain seeded onto baby spinach and sliced tomatoes using a total RNA extraction method, utilizing a high concentration (4M) guanidine thiocyanate buffer. Consistent detection of HAV genome from both produce items was achieved at an inoculation level of 3x103 PFU/25 g of food, with less consistent detection achieved at 3x102 PFU/25g. Initial studies revealed that a final precipitation of recovered RNA with potassium acetate to reduce carryover of polysaccharides and the addition of polyvinylpyrrolidone to remove polyphenolics in spinach were essential. For tomatoes, virus isolation was achieved with the incorporation of either an elution step with a high pH Tris-glycine-beef extract (TGBE) buffer or with an enzymatic digestion with pectinase. We also describe the development of a protocol for the detection of HAV from tomatoes utilizing a Luminex microbead-based suspension array. The results correlated well with the RT-qPCR assay suggesting the feasibility of the Bioplex as a detection platform for viruses isolated from foods.

Hidalgo, D., et al. (2014). "INTEGRATED AND SUSTAINABLE SYSTEM FOR MULTI-WASTE VALORIZATION." Environmental Engineering & Management Journal (EEMJ) **13**(10): 2467-2475.

The general aim of this paper is to demonstrate the sustainable management of a broad spectrum of wastes (livestock, industrial, agri-food, agricultural and non-recyclable fraction proceeding from waste treatment plants) in an integrated plant. The technological development and practical application of the "Mixed Plant" concept is used to achieve this objective. In order to valorize in a joint form all the above-mentioned categories of waste, two different processes have been integrated. The first one is an anaerobic digestion system for the transformation of biodegradable organic waste into biogas. The second one is a low-temperature pyrolysis (chemical) treatment for the valorization of the non-recyclable plastic waste fraction and other non-organic waste streams. Biogas together with pyrolysis gas fraction (syngas) will be used as fuel in an adapted co-generation engine. So as to close the recycling cycle with a minimum environmental impact, and as an added value, the digestate obtained in the anaerobic reactor will be valorized as a slow-release fertilizer (struvite), the liquid fraction obtained during the pyrolysis gas distillation process will be valorized as second generation biofuels and the solid fraction generated in the pyrolysis process (ashes) will be transformed into carbon pellets (biofuel). The ultimate aim of this model is to reduce costs associated with waste treatment processes, thereby optimizing waste management, not only from the environmental perspective, but also from the financial point of view. [ABSTRACT FROM AUTHOR]

Hidalgo, D., et al. (2019). "A multi-waste management concept as a basis towards a circular economy model." Renewable & Sustainable Energy Reviews **111**: 481-489.

This study proposes the use of a waste management procedure based on the technical development and practical implementation of a "Multi-Waste Plant" concept. A final point of this model is to reduce the costs related to waste treatment processes, thus optimizing its management, from the ecological viewpoint, as well as from the money related perspective. To this end, it is proposed: 1. Treatment, in the same facility, of various types of waste: municipal, industrial, biomass; 2. Energy and mass integration of individual waste treatment processes (anaerobic digestion and pyrolysis) to obtain a single integrated process more economical; 3. Complete recuperation of waste as energy (biogas, syngas and carbon pellets) and slow-release fertilizers (struvite). As a result, stable codigestion of a mix of poultry manure, pig manure, and vegetable waste (40/40/20 w/w) was achieved in a two-phase biodigester with production of biogas (65%CH 4, energy content 6.5kWhm−3) and non-harmful digestate with phytotoxicity less than 25 Equitoxm−3, later transformed in struvite fertilizer with up to 95,4% of nutrients recovery. In parallel, the pyrolysis of a mix of organic fraction, waste biomass, plastic waste and other industrial waste (15/15/50/20 w/w) at 420-450°C produced non-condensable gas (86.2%, LHV 8.5kWhm−3), char (9%) and a liquid phase (4.8%). A Pinch analysis reveals that an energy integration process in the plant will make possible to cover energy needs of the whole facility.

The "Multi-Waste Plant" concept along these lines turns into an unmistakable example of the circular economy model. Image 1 • Different waste streams treated in the same facility: the key of sustainability. • Energy integration leads to an optimization of global consumptions. • Flexibility of waste management is enhanced and process costs are reduced. • The "Multi-Waste Plant" concept is a clear exponent of the circular economy model. Hidalgo-Bastida, L. A., et al. (2011). "Lattice-Boltzmann mathematical model of cell attachment in a perfusion bioreactor: Validation using microCT." European Cells and Materials **3)**: 46.
INTRODUCTION : The optimisation of tissue engineering bioreactors is a lengthy and expensive experimental process. Mathematical modelling can reduce cost and time by providing a very close approximation of the operational parameters. Although different models have been used in bioengineering, only the lattice-Boltzmann code allows the simulation of multi-scale systems such as these. Cell attachment and subsequent proliferation and differentiation are determined by the cell (particle) behaviour in a given perfusion environment (flow rate, cell concentration, nutrients availability and waste removal). By using this mathematical tool we aim to optimise a perfusion bioreactor by developing a code that can simulate all these conditions and then conducting experimental work to validate it. METHOD(S): The lattice-Boltzmann model was developed to predict cell adhesion based on surface, perfusion rate (fluid velocity) and initial cell concentration parameters. The simulations were run for straight and bended channels to mimic the pattern of a single cell moving through a porous scaffold. For the validation, protein-coated and uncoated tygon tubing (1.02 mm diameter) was seeded at 0.0003 ml/min with hMSC previously labelled with superparamagnetic particles (CD105 Microbeads, Miltenyi Biotec Ltd, UK) and placed in a "U" holder. Samples were CT imaged at low voltage and high current using a Nikon Custom 320 kV bay. Reconstructed images were cropped into straight sections and 90 degrees section for the validation. RESULT(S): Mathematical modelling of 90 degrees sections revealed that when particles of different sizes are present in the perfusion system, large particles push the small particles to the edges; meanwhile, cells in straight sections always are concentrated in the centre of the channel. Validation data showed that cells seeded onto uncoated tygon tubing did not attach regardless of seeding time. Protein-coated tubing confirmed cell adhesion to the internal walls in the lowers region of the conduit. (Figure presented) Discussion & CONCLUSION(S): The cell attachment simulations produced by the lattice-Boltzmann code provided useful information on cell behaviour and attachment for our perfusion model. CT data of labelled cells showed specific adhesion patterns. Cells accumulated near the bend as suggested in the model, however the main deposition occurred in the bottom section. We hypothesise this was caused by gravity. Our model did not include that component, which would explain why the data did not match the simulation. Current work incorporates gravity to our lattice-Boltzmann model to confirm the influence of this element.

Hidalgo-Ruz, V., et al. (2012). "Microplastics in the marine environment: A review of the methods used for identification and quantification." Environmental Science and Technology **46**(6): 3060-3075.
This review of 68 studies compares the methodologies used for the identification and quantification of microplastics from the marine environment. Three main sampling strategies

were identified: selective, volume-reduced, and bulk sampling. Most sediment samples came from sandy beaches at the high tide line, and most seawater samples were taken at the sea surface using neuston nets. Four steps were distinguished during sample processing: density separation, filtration, sieving, and visual sorting of microplastics. Visual sorting was one of the most commonly used methods for the identification of microplastics (using type, shape, degradation stage, and color as criteria). Chemical and physical characteristics (e.g., specific density) were also used. The most reliable method to identify the chemical composition of microplastics is by infrared spectroscopy. Most studies reported that plastic fragments were polyethylene and polypropylene polymers. Units commonly used for abundance estimates are "items per m²" for sediment and sea surface studies and "items per m³" for water column studies. Mesh size of sieves and filters used during sampling or sample processing influence abundance estimates. Most studies reported two main size ranges of microplastics: (i) 500 mum-5 mm, which are retained by a 500 mum sieve/net, and (ii) 1-500 mum, or fractions thereof that are retained on filters. We recommend that future programs of monitoring continue to distinguish these size fractions, but we suggest standardized sampling procedures which allow the spatiotemporal comparison of microplastic abundance across marine environments. © 2012 American Chemical Society.

Hidayah, N. and Syafrudin (2018). A Review on Landfill Management in the Utilization of Plastic Waste as an Alternative Fuel. Les Ulis, EDP Sciences. **31**.

Wastes from landfills originate from many spheres of life. These are produces as a result of human activities either domestically or industrially. The global plastic production increased over years due to the vast applications of plastics in many sectors. The continuous demand of plastics caused the plastic wastes accumulation in the landfill consumed a lot of spaces that contributed to the environmental. In addition, economic growth and development also increased our demand and dependency on plastics which leads to its accumulation in landfills imposing risk on human health, animals and cause environmental pollution problems such as ground water contamination, sanitary related issues, etc. The management and disposal of plastic waste have become a major concern, especially in developing cities. The idea of waste to energy recovery is one of the promising techniques used for managing the waste of plastic. Hence, this paper aims review at utilizing of plastic as an alternative fuel.

Hidayaturrahman, H. and T. G. Lee (2019). "A study on characteristics of microplastic in wastewater of South Korea: Identification, quantification, and fate of microplastics during treatment process." Marine Pollution Bulletin **146**: 696-702.

This study investigated the removal of microplastics from different treatment stages in three WWTPs and examined the performance of tertiary treatment that was done by coagulation and different technologies such as ozone (WWTP-A), membrane disc-filter (WWTP-B), and rapid sand filtration (WWTP-C). The results showed that the primary and secondary treatment processes effectively remove microplastics from wastewater with efficiencies ranging between 75% and 91.9%. The removal efficiency increased further to >98% after tertiary treatment. Microbeads and fragments were the major types of microplastics found in all wastewater sampling points. Microbeads found in the wastewater samples were classified as primary microplastics, that mainly came from personal care products, whereas secondary microplastics consisted of fragments, fibers, and sheets that were generated mainly due to fragmentation of larger plastics. Microplastics were still found in a high concentration in the final effluent, especially from WWTP-B, which is discharged into the Geumho river.

Hieu, N. M., et al. (2017). "Synthesis of SiO2-Coated Fe3O4 Nanoparticles Using Ultrasound and Its Application in DNA Extraction from Formalin-Fixed, Paraffin-Embedded Human Cancer Tissues." Journal of Electronic Materials **46**(6): 3738-3747.

SiO2-coated Fe3O4 nanoparticles (Fe3O4@SiO2 NPs) were successfully synthesized using ultrasound in order to extract DNA from cancer tissues for application in diagnostics. The core 10.7-nm-diameter Fe3O4 nanoparticles were synthesized by co-precipitation of Fe3+ and Fe2+ as reaction substrates and NH4OH as precipitant, then coated with a thin layer of amorphous silica by a modified Stober method. Further SiO2 coating using alkaline hydrolysis of tetraethyl orthosilicate in ethanol and water mixture was accelerated in the presence of a 37-kHz ultrasound, resulting in the NPs having different sizes of 14.5 nm (version M1), 24.4 nm (version M2), and 34.9 nm (version M3) with saturation magnetization values of 50.2 emu/g, 18.6 emu/g, 10.3 emu/g, respectively. Among the three Fe3O4@SiO2 NPs versions, the M1 NPs allowed extraction of DNAs from 10 mg formalin-fixed and paraffin-embedded (FFPE) tissues of nasopharyngeal carcinoma patients with the highest recovery of about 100–500 ng/µl and good purity (A260/A280: 1.8–1.9). The extracted DNAs could be used as templates for downstream amplification of 252-bp sequencing specifically for the Braf cancer biomarker gene using polymerase chain reaction (PCR), as well as detection of the pathogenic Epstein–Barr virus (EBV) and the human papilloma-virus (HPV) using real-time PCR. DNA extraction recoveries of both EBV and HPV using Fe3O4@SiO2 NPs M1 were significantly better that those using commercialized Fe3O4@SiO2 microbeads, as indicated by lower threshold cycles of all fluorescent signals including fluorescein amidite (FAM) dye representative for EBV infection, hexachlorofluorescein (HEX) dye representative for β-globin (internal control), and SYBR Green dye representative for HPV infection in tested clinical samples from patients with nasopharyngeal carcinoma (NPC). © 2017, The Minerals, Metals & Materials Society.

Higashi, T., et al. (2004). "A novel transfection method for mammalian cells using calcium alginate microbeads." Journal of Bioscience & Bioengineering **97**(3): 191-195.

The direct transfer of genetic materials into mammalian cells is an indispensable technique. We have developed calcium alginate (CA) microbeads which can deliver plasmid DNAs and yeast artificial chromosomes into plant and yeast cells. In this paper, we demonstrate the effective transfection of mammalian cells by CA microbeads immobilizing plasmid DNAs. The transfection was performed using the pEGFP-C1 plasmid containing the cytomegalovirus (CMV) promoter and enhanced green fluorescent protein (EGFP) gene. The transient expression of EGFP was observed 24 h after transfection. The expression efficiency was maximum when the concentration of sodium alginate was 1% and the amount of plasmid DNA was increased to 100 microg. The expression efficiency of our method using CA microbeads is 2-10 times higher than that of the polyethylene glycol (PEG) method. Our results suggest that the CA microbead mediated transfection of mammalian cells effectively delivers genetic materials into mammalian suspension cells.

Higgins, R., et al. (2011). "National registry of ABO and HLA antibody incompatible renal transplantation." American Journal of Transplantation **2)**: 109.

Introduction: Antibody incompatible renal transplantation (AIT) is widely practiced, but the most outcome reports are from single centres. The UK Registry is the first comprehensive national registry for HLA and ABO AIT. Method(s): Data for all UK transplants are already collected. An additional AIT dataset was introduced in 2008, collecting data on transplants since 2001 with ABO incompatibility (ABOi), or donor specific HLA antibodies (HLAi) detectable in the immediate pre-transplant period. Result(s): The Registry is aware of 381 AIT transplants; 213 HLAi, 150

ABOi, and 18 were both HLAi and ABOi. In 2009, of the 972 living donor transplants performed in the UK, 49 (5%) were HLAi, and 64 (7%) were ABOi. Fourteen centres reported HLAi transplants, range per unit 1-76. Pre-treatment complement dependent cytotoxic (CDC) crossmatch (XM) was +ve in 29%. Flow cytometric (FC) XM was +ve but CDC XM -ve in 49%, and 22% had donor specific antibodies (DSA) detectable only by microbead or other solid phase assay. 179 (77%) were from a living donor grafts and 52 (23%) deceased donor. Centres used different combinations of IVIg and CD20 as well as plasmapheresis prior to transplantation. For ABOi, excluding the HLAi and ABOi cases, 146 were planned ABOi in living transplants, 3 were deceased donor transplants in a planned programme of A2 donor into selected B recipients at a single centre. ABO antibodies were removed with plasmapheresis in 76% of cases, antigen-specific absorption in 18%, and 6% had no antibody removal. Three year graft survival (death and graft loss) was 84 (95% CI 69-92)% in ABOi, and 84 (69-92)% in HLAi, compared with 92 (91-93)% for all other living donor transplants, and 84 (83-85)% for all other deceased donor transplants. Discussion. 12% of living donor renal transplants in 2009 were antibody incompatible, and over three quarters of the transplant units in the UK have reported AIT transplants. Overall three year graft survival rates were comparable with the Results: of 'antibody compatible' deceased donor transplantation.

Higgins, R., et al. (2010). "UK registry of antibody incompatible kidney transplantation 2001-2010." Transplantation **1)**: 189.

Introduction. Antibody incompatible renal transplantation (AIT) is now widely practiced, but there remain uncertainties about outcomes. The UK Registry is the first comprehensive national registry for HLA and ABO AIT. Methods. Comprehensive data for all UK transplants are already collected. An additional AIT dataset was introduced in 2008, collecting data on transplants since 2001 with ABO incompatibility (ABOi), or donor specific HLA antibodies (HLAi) detectable in the immediate pre-transplant period. Those with historic positive, current negative DSA were not included. Results. 381 AIT transplants have been performed; 213 HLAi, 150 ABOi (37 full reports to registry awaited), and 18 were both HLAi and ABOi. In 2009, of the 972 living donor transplants performed in the UK, 49 (5%) were HLAi, and 64 (7%) were ABOi. Fourteen centres reported HLAi transplants, number per unit ranging from 1-76. The pre-treatment complement dependent cytotoxic (CDC) crossmatch (XM) (non AHG enhanced) was +ve in 29% of cases. Flow cytometric (FC) XM was +ve but CDC XM -ve in 49%, and 22% had donor specific antibodies (DSA) detectable only by microbead or other solid phase assay. 106 (46%) were first grafts; 94 (41%) were second; 23 (10%) were third and 8 (3%) were fourth grafts. 179 (77%) grafts used kidneys from a living donor while 52 (23%) used kidneys from a deceased donor. Centres used different combinations of IVIg and CD20 as well as plasmapheresis prior to transplantation. For ABOi cases, excluding the HLAi and ABOi cases, 146 were planned ABOi in living transplants, 3 were deceased donor transplants in a planned programme of A2 donor into selected B recipients at a single centre, and there was 1 other O recipient who received an A donor kidney. ABO antibodies were removed with plasmapheresis in 76% of cases, antigen-specific absorption in 18%, and 6% had no antibody removal. Three year graft survival (death and graft loss) was 84 (95% CI 69-92)% in ABOi transplant, and 82 (73-88)% in HLAi transplants, compared with 92 (91-93)% for all other living donor transplants, and 84 (83-85)% for all other deceased donor transplants. Conclusion. 12% of living donor renal transplants performed in the UK in 2009 were antibody incompatible, and over three quarters of the transplant units in the UK have reported AIT transplants to the Registry. Overall three year graft survival rates were comparable with the results of 'antibody compatible' deceased donor transplantation. The dataset will allow further analysis by specificity and level of donor specific HLA antibody transplants, and outcomes

according to blood group mismatch and prior HLA sensitisation in ABOi transplants.

Higgins, R., et al. (2009). "Rises and falls in donor-specific and third-party HLA antibody levels after antibody incompatible transplantation." Transplantation **87**(6): 882-888.

BACKGROUND: After human leukocyte antigen (HLA) antibody-incompatible transplantation, donor specific and third party HLA antibodies may be found, and their levels fall in a donor-specific manner during the first month. However, these changes have not been previously described in detail.

METHODS: Donor-specific HLA antibody (DSA) and third-party HLA antibody (TPA) levels were measured using the microbead method in 44 presensitized patients who had renal transplantation.

RESULTS: DSA+TPA fell in the first 4 days after transplantation, and greater falls in DSA indicated absorption by the graft. This occurred for class I (57.8% fall compared with 20.2% for TPA, P<0.0005), HLA DR (63.0% vs. 24.3%, P<0.0004), and for HLA DP/DQ/DRB3-4 (34% vs. 17.5%, P=0.014). Peak DSA levels occurred at a mean of 13 days posttransplant, and they were higher than pretreatment in 25 (57%) patients and lower in 19 (43%) patients (P=ns). The risk of rejection was associated with peak DSA levels; 15 of 25 (60%) patients with DSA at median fluorescence intensity (MFI) more than 7000U experienced rejection, compared with 4 of 7 (57%) patients with peak DSA MFI 2000 to 7000U, and 2 of 12 (17%) patients with peak DSA MFI less than 2000U (P<0.02). DSA levels subsequently fell in a donor specific manner compared to TPA.

CONCLUSION: DSA levels may change markedly in the first month after antibody incompatible transplantation, and the risk of rejection was associated with higher pretreatment and peak levels.

Higgins, R., et al. (2014). "Refining the prediction of early antibody mediated rejection after antibody incompatible renal transplantation; importance of pregnancy-induced sensitisation." Transplantation **1)**: 103.

Background. Acute antibody mediated rejection (AMR) after HLA antibody incompatible renal transplantation is related to donor specific HLA antibody (DSA) levels. However, pre-treatment DSA levels have a low predictive value for AMR, partly because of rapid changes in DSA levels post-transplant. This study examined changes in DSA according to the primary sensitising event. Methods. Responses to 220 HLA specificities in 64 patients over the first 30 days after transplantation were evaluated using single antigen microbead assays. The primary sensitising event for each specificity was assigned according to the time of appearance of antibody in relation to pregnancy, transfusion or transplantation, taking into account the HLA type of the sensitisor and HLA epitope maps. Results. The greatest increase from pre-treatment to peak DSA level was seen in those stimulated by pregnancy, median (IQR) increase in MFI of 1981 (94-5870) u. The next highest increase was for those sensitised by transplant with repeat HLA epitope mismatch, at 546u (-308u-2698u) (p<0.01). Time to peak level was shorter in the pregnancy group, median 13 (9-19.75) days, compared to 15.5 (11-21) days in the transfusion group and 16 (12-23) days in the transplant group (p<0.01). For specificities with pre-treatment MFI <5000u, peak level of >5,000u occurred in 24/58 (41%) stimulated by pregnancy, compared to 8/119 (7%) in all other specificities (p<0.0001). With pre-treatment total DSA MFI <5000u, AMR occurred after primary sensitisation by pregnancy in 7/9 (78%) patients, compared to 2/5 (40%) for transfusion and 1/7 (14%) for transplantation. Conclusion. After transplantation rises in DSA were greatest, fastest and most likely to be associated with rejection for specificities where pregnancy was the primary sensitising event. In contrast, there were lower rises DSA corresponding to HLA exposure from previous transplants, at both antigen and epitope levels.

Greater insight into the antibody response post-transplantation will enable better risk stratification and cost-effective tailoring of therapy.

Higgins, R., et al. (2011). "Human leukocyte antigen antibody-incompatible renal transplantation: excellent medium-term outcomes with negative cytotoxic crossmatch." Transplantation **92**(8): 900-906.
BACKGROUND: Human leukocyte antigen (HLA) antibody-incompatible renal transplantation has been increasingly performed since 2000 but with few data on the medium-term outcomes.
METHODS: Between 2003 and 2011, 84 patients received renal transplants with a pretreatment donor-specific antibody (DSA) level of more than 500 in a microbead assay. Seventeen patients had positive complement-dependent cytotoxic (CDC) crossmatch (XM), 44 had negative CDC XM and positive flow cytometric XM, and 23 had DSA detectable by microbead only. We also reviewed 28 patients with HLA antibodies but no DSA at transplant. DSAs were removed with plasmapheresis pretransplant, and patients did not routinely receive antithymocyte globulin posttransplant.
RESULTS: Mean follow-up posttransplantation was 39.6 (range 2-91) months. Patient survival after the first year was 93.8%. Death-censored graft survival at 1, 3, and 5 years was 97.5%, 94.2%, and 80.4%, respectively, in all DSA+ve patients, worse at 5 years in the CDC+ve than in the CDC-ve/DSA+ve group at 45.6% and 88.6%, respectively (P<0.03). Five-year graft survival in the DSA-ve group was 82.1%. Rejection occurred in 53.1% of DSA+ve patients in the first year compared with 22% in the DSA-ve patients (P<0.003).
CONCLUSIONS: HLA antibody-incompatible renal transplantation had a high success rate if the CDC XM was negative. Further work is required to predict which CDC+ve XM grafts will be successful and to treat slowly progressive graft damage because of DSA in the first few years after transplantation.

Higgins, R., et al. (2012). "From median fluorescence intensity to microgrammes per millilitre; quantification of hla antibody levels." American Journal of Transplantation **3)**: 310.
Introduction. Recent advances in anti-HLA antibody detection methodologies has provided the clinical laboratory with a valuable tool to rapidly and accurately monitor the changes in antibody levels through the course of a kidney transplant. This is of particular importance in HLA antibody incompatible transplantation (HLAiTx) where daily monitoring of antibody status is often neccessary and clinical intervention can be heavily influenced by these results. However antibody data is given only as units of detectable fluorescence and no insight into the serum concentration of HLA specific antibody can be inferred. We describe a simple method for estimating serum concentration of HLA specific antibody using standard curves derived from human monoclonal HLA specific antibody. Methods. HLA epitope specific monoclonal antibodies of IgG isoform were quantified and 'spiked' into HLA antibody negative AB serum and standard curves for single antigen bead binding were constructed in the dynamic range of 0.1-200ug/ ml. Patient sera with the same single epitope reactivity as determined by inhibition analysis were then analysed using the concentration curve as reference. Results. One transplant waiting list patient demonstrated a 142T epitope specific antibody (HLA-A2,28) at a consistent concentration of between 30-40ug/ml between three-monthly samples. The second patient underwent HLAiTX at our centre and had a pre-treatment serum antibody concentration of 12.8ug/ml which rose to a peak of 185ug/ml at day 17 post-transplant during a period of antibody mediated rejection. The base/peak ratio of absolute concentration was 14.5, compared to base/peak values of microbead MFI of 2984 u and 12000 u, giving a ratio of 4.1. Discussion. This pilot study provides a valuable insight into the concentrations at which anti-HLA antibody is found in the general circulation and the dynamic ranges of antibody concentration

that can be observed during the early post-transplant period in HLAiTx. Knowledge of circulating HLA-specific antibody levels is of fundamental importance if designing more specific antibody reduction strategies.

Higgins, R., et al. (2010). "The histological development of acute antibody-mediated rejection in HLA antibody-incompatible renal transplantation." Nephrology Dialysis Transplantation **25**(4): 1306-1312.
BACKGROUND: The aim of this study was to examine the development of acute antibody-mediated rejection in HLA antibody-incompatible renal transplantation in relation to the Banff 07 histological classification.
METHODS: Renal biopsies were scored using the Banff 07 diagnostic criteria, and paraffin-embedded sections were stained with the pan-leucocyte marker CD45.
RESULTS: Thirty-six patients had 72 renal biopsies. In biopsies performed 30 min after graft reperfusion, the mean number of CD45+ cells per glomerulus was higher than in control grafts ($P < 0.04$) and was associated with the donor-specific antibody (DSA) level at transplantation measured by microbeads ($P < 0.01$), and eight out of nine patients with greater than five CD45+ cells per glomerulus had early post-transplant rejection or oliguria, compared to 11 out of 20 with less than five cells per glomerulus ($P < 0.01$). In the first 10 days post-transplant, although peritubular capillary (PTC) leucocyte margination grade 3 and C4d deposition were specific for rejection, their sensitivities were low. PTC C4d staining was only seen in two out of 11 biopsies taken in the first 5 days after transplant, even in the presence of rejection, but was present in the majority of later biopsies with rejection. In biopsies stained for CD3, CD68 and CD20, it was notable that CD20+ cells were not seen during acute rejection, the infiltrates comprising CD3+ and CD68+ leucocytes.
CONCLUSIONS: Glomerular margination of leucocytes occurred early after transplantation and was associated with DSA level and early graft dysfunction. The Banff 07 PTC margination scoring system was easy to apply, especially when CD45 staining was used, and PTC margination grade 3 was always associated with clinical rejection.

Higgs, R. (1997). "Europe recycling more plastics, APME says." Plastics News **9**(12): 7.
Reports that according to figures released by the Association of Plastics Manufacturers in Europe (APME), recovery of post-consumer plastic waste through recycling or waste-to-energy incineration in Europe improved in 1995. What is cited for the improvement; Comments from Fred Mader, APME's deputy director; Other findings by APME; What the statistics show.

Hiki, K. and F. Nakajima (2015). "Effect of salinity on the toxicity of road dust in an estuarine amphipod Grandidierella japonica." Water Science and Technology **72**(6): 1022-1028.
Urban runoff can reach coastal aquatic environments; however, little is known about the effect of salinity on road runoff toxicity. The objective of this study is to investigate the toxicity of highway road dust over a salinity gradient from 5 to 35 per mil, in an estuarine benthic amphipod, Grandidierella japonica. Road dust toxicity was evaluated by assessing mortality after 10 days of exposure and short-term microbead ingestion activity of the amphipod. For all road dust samples considered, amphipod mortality increased with increasing salinity, whereas no significant difference in mortality was observed among test salinities in the reference river sediment. Ingestion activity during exposure to road dust decreased with increasing salinity. In fact, none of the individuals ingested any microbeads at salinity of 35 per mil. If assumed microbead ingestion is a proxy for feeding activity, high mortality at 35 per mil could be attributed to aquatic exposure and not to dietary exposure. These findings suggest that road dust may have considerable impact on benthic organisms at high salinity levels.

Hildebrand, M., et al. (1992). "Comparison of bioanalytical determinations of Iloprost, a chemically stable PGI<inf>2</inf> mimetic, by conventional radioimmunoassay (RIA) and scintillation proximity assay (SPA)." Eicosanoids **5**(1): 5-8.

The scintillation proximity assay is a novel variant of classical radioimmunoassay. It can be performed as a single tube measurement because the separation of bound and unbound tracer fraction is avoided. In principle, microbeads are coated with anti-species antibodies that can couple with the respective antiserum used for RIA. By means of special cores, light emission takes place if labelled, antiserum-bound tracer is coupled to the anti-species antibody on the fluomicrosphere surface. In the present report, the novel assay was compared to a validated RIA for the bioanalysis of the PGI<inf>2</inf> mimetic, Iloprost. Extraction recovery of Iloprost was ~ 90% at pH <=4. The detection limit of the novel assay was 2-4 pg/sample, corresponding to 10-20 pg/ml plasma (if 0.2 ml plasma was used). Coefficients of variations were 9, 7 and 6% (within-day, n = 5) and 30, 11 and 10% (day-to-day, n = 10) at 50, 100 and 200 pg/ml. RIA and SPA levels of Iloprost measured in human plasma samples (n = 428) were similar. The SPA method exhibits both a similar specificity and detection limit to RIA and will be used for further analyses.

Hildebrandt, L., et al. (2019). "Evaluation of continuous flow centrifugation as an alternative technique to sample microplastic from water bodies." Marine Environmental Research **151**: 104768.

The scientific and public interest regarding environmental pollution with microplastic has considerably increased within the last 15 years. Nevertheless, up to now there is no widely applied standard operation procedure for microplastic sampling, resulting in a lack of inter-study comparability. In addition, many studies on microplastic occurrences do not indicate a sound methodological validation of the applied methods and procedures. This study presents an alternative volume-reduced sampling technique to sample the entire load of suspended particulate matter including microplastic particles in natural waters, based on continuous flow centrifugation. For the lab-scale validation of the proposed instrumental setup, six different microplastic types (PE, PET, PS, PVDC, EPS and PP) were used. The particles covered a size range from 1mum to 1mm and a density range from 0.94gmL⁻¹ to 1.63gmL⁻¹. Recoveries ranged from 95.0%+/-2.3% - 99.1%+/-0.3% for virgin powders and from 96.1%+/-0.6% - 99.4%+/-0.2% (1 SD, n=2 - 3) for microplastic suspended in river water for 40 days. Gravimetric and microscopic analysis of the effluent indicates efficient removal of microplastic from the suspensions. Static light scattering analysis of the microplastic suspensions prior to and after centrifugation confirmed that no change of the particle size distribution has occurred - neither through aggregation nor through size-discrimination during centrifugation. Moreover, the system was tested in the field and used twice to sample suspended particulate matter from the Elbe estuary directly on site. Based on these first lab-scale experiments, continuous flow centrifugation proves a promising technique bearing potential to alleviate drawbacks such as contamination, filter clogging and particle size-discrimination of commonly used volume-reduced microplastic sampling approaches.

Hilder, P. E., et al. (2019). "Retinal adaptations of southern bluefin tuna larvae: implications for culture." Aquaculture **507**: 222-232.

We examined Southern bluefin tuna, Thunnus maccoyii, larvae to identify specific retinal adaptations that would indicate both important parameters for culture and larval ecology in the wild. Plastic resin histology, microspectrophotometry and behavioural feeding responses were used to describe visual development. Thunnus maccoyii larvae reflected the visual morphogenesis template commonly observed in many other marine fish species exhibiting indirect development. First-feeding (3 days post-hatching, [dph], 3.4 mm standard length [SL]) larvae possessed tightly packed single cone photoreceptors. Rods and twin cones were present in the retina in post-flexion larvae (21 dph, 8.39 mm fork length [FL]) with cone mosaic patterns observed in juveniles (30 dph, 21 mm FL). Based on the spacing of adjacent photoreceptors and focal length, first feeding larvae had a maximum theoretical visual acuity of 1.23+or-0.11 degrees that decreased to 0.14+or-0.02 degrees at 30 dph. Thunnus maccoyii displayed high cell density in the ventral retinal region (cones, bipolar and horizontal cells), a low convergence of cone cells to ganglion cells throughout the retina during larval development (1.1+or-0.2 to 1.4+or-0.3 at 3 dph and 30 dph, respectively), and early development of retinal pigment epithelium (RPE) migration. Microspectrophotometry showed twin cone visual pigments maximally sensitive to light in the blue-green part of the visual spectrum (wavelength of maximum absorption [lambda _{max}] of 494 nm, 507 nm and 524 nm), and behavioural experiments showed they fed preferentially at these wavelengths. Increased retinal cone densities in the ventral region indicated a localized region specialized for acute vision for prey and predator detection in the upward direction (dorsal plane) at an early age, representing a possible adaptation to life in deeper oceanic waters. The apparent high acuity and photopic sensitivity observed in T. maccoyii is hypothesised to be associated with the ability to feed in low light conditions. This has important practical considerations in determining lighting regimes for culture of T. maccoyii and possibly for other tuna species.

Hill, D., et al. (2018). "The relative effects of concentration and PH on mucus rheology." American Journal of Respiratory and Critical Care Medicine. Conference: American Thoracic Society International Conference, ATS **197**(MeetingAbstracts).

RATIONAL Cystic fibrosis (CF) airway disease is characterized by thickened, sticky mucus with increase viscosity and elasticity. Currently, there are two competing hypotheses as to the underlying cause of abnormal CF l mucus: The first is that dehydration of the airway surface layer (ASL) due to improper chloride secretion and sodium hyper absorption draws water out of the ASL and results in hyper-concentrated mucus; The second is that acidification of the ASL by impaired bicarbonate secretion by Cystic fibrosis transmembrane conductance regulator (CFTR) increases mucus viscosity. This study evaluates the relative contributions of concentration and pH to the rheological properties of mucus to determine the dominate contributor to abnormal CF mucus rheology. METHODS Our study employs two isolated mucin solutions, porcine gastric mucin (PGM) and bovine submaxillary mucin (BSM) at concentrations of 20mg/ml and 50 mg/ml and physiologically relevant pHs of 6, 7, and 8. We additionally studied mucus harvest from human bronchial epithelial (HBE) cell cultures prepare to concentration of 2 and 4% solids, mimicking healthy and pathological mucus, as well as CF sputum. The buffer capacity of each solution was measured by titration 100mM hydrochloric acid. The biophysical properties of each mucin / mucus specimen were measured across length scales that range from the nano to macroscopic by fluorescents recovery after photobleaching (FRAP), thermal microbead rheology (TMR), and macroscopic cone and plate rheology (C&PR) respectively. Finally, mucociliary transport (MCT) rates were measured on HBE cultures at healthy and pathological concentration across the same pH range. RESULTS Mucins and mucus display a concentration dependent buffer capacity, needing more protons added at higher concentration to achieve the same pH changes. TMR showed that concentration effects the diffusion of 1um microsphere a factor of 10 ($p < 0.001$) across all specimen types, while changing pH between 6 and 8 did not significantly affect the motion of tracer particles. Similar results were found in C&PR studies. FRAP studies showed both concentration and pH dependent changes in the nanoscopic rheology of mucus.

Studies on the non-mucin component (small protein) of sputum showed that the majority of FRAP signal arises from small proteins, and not the gel forming mucins. Like rheology, transport was significantly reduced by dehydration, while pH did not have a measureable effect. CONCLUSIONS Concentration affects the biophysical properties of mucus across multiple length scales and model systems, while pH has a limited effect across physiologically relevant scales of 6 - 8.

Hill, D. B., et al. (2016). "Biophysical analysis of pediatric CF bal: Defining biomarkers of the onset of CF airway disease." Pediatric Pulmonology **51 (Supplement 45)**: 239.

The AREST CF project represents a unique opportunity to document the early onset of airways disease in cystic fibrosis. In this ongoing study, bronchoalveolar lavage (BAL) samples are being collected from pediatric patients at regular intervals over the first 6 years of life. The goal of our analysis is to investigate changes in the rheological properties of mucus brought on by CF airway disease. We have previously shown that CF sputum is characterized by significantly increased mucin concentration [1], resulting in modified biophysical properties such as viscoelasticity and osmotic pressure [2, 3]. Due to the dilute nature of BAL samples, determining the native concentration of mucus along the airways from BAL samples has proven impossible. While small flecks of concentrated, viscoelastic mucus are present in the pediatric CF BALs, the samples also contain highly diluted mucus that is rheologically identical to saline. By combining sophisticated microbead rheological measurements of BAL samples with advanced data analytics, we are able to determine a diversity of rheological microenvironments in which tracer particles are sampling. Specifically, we embed 1 micron diameter tracer particles into the sample volume and analyze their diffusive fluctuations. Analytically, we firstly determine which particle tracked paths are consistent with normal saline and exclude those from further analysis. For non-excluded particles, anomalous sub-diffusion parameters of each particle path are calculated [4], reflecting motilities from a range of diluted to pure mucus sample. We compare our results to adult CF and normal BALs, finding that the samples collected from the pediatric AREST participants display a rheology that lies between that of healthy adults and adult CF patients. We additionally compare the results of over 150,000 particle tracks from 64 patients and 12 non-CF pediatric disease patients with traditional clinical biomarkers such as CT scan scoring and cell counts.

Hill, D. B., et al. (2018). "The relative effects of concentration and ph on the biophysical properties of airway mucus and its clearance from the lung." Pediatric Pulmonology **53 (Supplement 2)**: 173.

Background: Currently, there are two competing hypotheses that seek to explain the underlying cause of abnormally viscous CF mucus. The first is that dehydration of the airway surface layer (ASL) as a result of defective CFTR-mediated chloride secretion coupled with sodium hyperabsorption results in a hyper-concentrated mucus layer; the second is that acidification of the ASL resulting from impaired bicarbonate secretion by CFTR increases mucus viscosity. This study evaluated the relative contributions of concentration and pH to the rheological properties of mucus to determine the dominant contributor to abnormal CF mucus rheology and mucus clearance. Method(s): Our study examined the effects of mucus concentration and pH in 1) commercially available mucins, 2) mucus harvested from normal and CF human bronchial epithelium (HBE) cell cultures, and 3) sputum from CF patients. Porcine gastric mucin (PGM) and bovine submaxillary mucin (BSM) was prepared at concentrations of 20 mg/mL and 50 mg/ mL and physiologically relevant pHs of 6, 7, and 8. Normal and CF HBE mucus was prepared at concentrations of 2% and 4% solids, mimicking healthy and pathological CF mucus. The buffer capacity of each solution was measured by titration with 100 mM hydrochloric acid. The

biophysical properties of each mucin/mucus specimen were measured across length scales that range from the nano to macroscopic by fluorescent recovery after photobleaching (FRAP), thermal microbead rheology (TMR), and macroscopic cone and plate rheology (C&PR) respectively. Finally, mucociliary transport (MCT) rates, mucus osmotic pressure, and pericilary layer (PCL) heights were measured on HBE cultures at healthy and pathological concentrations across a range of pHs from 6 to 8. Result(s): Mucins and mucus display a concentration-dependent buffer capacity, needing more protons added at higher mucus concentrations to achieve the same change in pH. TMR showed that concentration affects the diffusion of 1mum microspheres a factor of 10 ($p < 0.001$) across all specimen types while changing pH between 6 and 8 did not significantly affect the motion of tracer particles. Similar results were found in C&PR studies. FRAP studies showed both concentration and pH-dependent changes in the nanoscopic rheology of mucus. However, further studies on the non-mucin component (small protein) of sputum showed that the majority of the FRAP signal arises from small proteins, and not the large gel-forming mucins. Osmotic pressure was increased by mucus dehydration and not by pH. Like rheology, the PCL height and MCT rates were all significantly reduced by dehydration, while pH did not have a measurable effect. Conclusion(s): Concentration affects the biophysical properties of mucus across multiple length scales and model systems, while pH has a negligible effect across physiologically relevant scales of 6 - 8.

Hill, D. B., et al. (2010). "Force generation and dynamics of individual cilia under external loading." Biophysical Journal **98**(1): 57-66.

Motile cilia are unique multimotor systems that display coordination and periodicity while imparting forces to biological fluids. They play important roles in normal physiology, and ciliopathies are implicated in a growing number of human diseases. In this work we measure the response of individual human airway cilia to calibrated forces transmitted via spot-labeled magnetic microbeads. Cilia respond to applied forces by 1), a reduction in beat amplitude (up to an 85% reduction by 160-170 pN of force); 2), a decreased tip velocity proportionate to applied force; and 3), no significant change in beat frequency. Tip velocity reduction occurred in each beat direction, independently of the direction of applied force, indicating that the cilium is "driven" in both directions at all times. By applying a quasistatic force model, we deduce that axoneme stiffness is dominated by the rigidity of the microtubules, and that cilia can exert 62 +/- 18 pN of force at the tip via the generation of 5.6 +/- 1.6 pN/dynein head.

Hill, D. B., et al. (2015). "Defining successful mucus: Marrying biochemistry and biophysics." American Journal of Respiratory and Critical Care Medicine. Conference: American Thoracic Society International Conference, ATS **191**(MeetingAbstracts).

Rationale In human airways diseases, including cystic fibrosis (CF) and chronic obstructive pulmonary disease (COPD), host defense is compromised and airways inflammation and infection often result. Mucus clearance and trapping of inhaled pathogens constitute key elements of host defense. Clearance rates are governed by mucus viscous and elastic moduli at physiological driving frequencies, whereas transport of trapped pathogens in mucus layers is governed by diffusivity. There is a clear need for simple and effective clinical biomarkers of airways disease that correlate with these properties. Methods We tested the hypothesis that mucus solids concentration, indexed as weight percent solids (wt%), is such a biomarker. Passive microbead rheology was employed using 1micron diameter embedded tracer particles to determine both diffusive and viscoelastic properties of mucus harvested from human bronchial epithelial (HBE) cultures. The range of concentrations explored in these studies was guided by sputum from healthy (1.5-2.5 wt%) and diseased (COPD, CF; 5 wt%) subjects to represent disease progression and severity. Results Analyses of microbead datasets showed mucus diffusive properties and viscoelastic moduli scale robustly with wt%. Importantly, prominent changes in both biophysical properties arose at 4 wt%, consistent with a gel transition (from a more viscous- dominated solution to a more elastic-dominated gel). These findings have significant implications for: (1) penetration of cilia into the mucus layer and effectiveness of mucus transport; and (2) diffusion vs. immobilization of micro-scale particles relevant to mucus barrier properties. Conclusions These data provide compelling evidence for mucus solids concentration as a baseline clinical biomarker of mucus barrier and clearance functions.

Hill, D. B., et al. (2014). "A biophysical basis for mucus solids concentration as a candidate biomarker for airways disease." PLoS ONE [Electronic Resource] **9**(2): e87681.

In human airways diseases, including cystic fibrosis (CF) and chronic obstructive pulmonary disease (COPD), host defense is compromised and airways inflammation and infection often result. Mucus clearance and trapping of inhaled pathogens constitute key elements of host defense. Clearance rates are governed by mucus viscous and elastic moduli at physiological driving frequencies, whereas transport of trapped pathogens in mucus layers is governed by diffusivity. There is a clear need for simple and effective clinical biomarkers of airways disease that correlate with these properties. We tested the hypothesis that mucus solids concentration, indexed as weight percent solids (wt%), is such a biomarker. Passive microbead rheology was employed to determine both diffusive and viscoelastic properties of mucus harvested from human bronchial epithelial (HBE) cultures. Guided by sputum from healthy (1.5-2.5 wt%) and diseased (COPD, CF; 5 wt%) subjects, mucus samples were generated in vitro to mimic in vivo physiology, including intermediate range wt% to represent disease progression. Analyses of microbead datasets showed mucus diffusive properties and viscoelastic moduli scale robustly with wt%. Importantly, prominent changes in both biophysical properties arose at ~4 wt%, consistent with a gel transition (from a more viscous-dominated solution to a more elastic-dominated gel). These findings have significant implications for: (1) penetration of cilia into the mucus layer and effectiveness of mucus transport; and (2) diffusion vs. immobilization of micro-scale particles relevant to mucus barrier properties. These data provide compelling evidence for mucus solids concentration as a baseline clinical biomarker of mucus barrier and clearance functions.

Hilton, J. P. (2013). Microfluidic Selection and Applications of Aptamers.

BioMEMS technology has the potential to increase the efficiency of conventional biological and medical protocols, by reducing their consumption of time and resources. Through more efficient surface-based chemical reactions and automation of tedious manual processes, orders of magnitude increases in efficiency across a number of metrics can be achieved by shifting conventional medical and biological protocols to the microscale domain. The SELEX process, by which aptamer sequences are selected via isolation from randomized libraries, is a time-consuming and resource-intensive protocol which is being performed with increasing frequency in both academic and private sector laboratories. Conventional approaches using macroscale technology cannot meet the current demand for selection of new aptamer sequences, as they require months of work and liters of expensive reagents. Microscale approaches to the SELEX process have been receiving attention in recent years due to their initial successes in reducing the time and reagents necessary to find aptamers. In particular, microscale "selection" or partitioning of weakly bound sequences from aptamer candidates, and on-chip integration of the protocol have separately been explored as approaches to scaling and improving SELEX. Initial results have shown that this technology can reduce resource requirements for SELEX by at least an order of magnitude. In this dissertation, a new approach to on-chip SELEX is developed which integrates highly efficient microfluidic selection and on-chip integration of the entire protocol. As a result, further reductions in processing time and reagent requirements can be realized. A demonstration of aptamer capabilities is first achieved via the development of a microfluidic aptasensor for cocaine, which utilizes aptamer-coated microbeads and fluorescent detection. Secondly, a technology necessary for on-chip integration of SELEX is developed: a novel bead-based polymerase chain reaction (PCR) protocol which vastly simplifies procedures for the capture and resuspension of ssDNA in solution. This protocol is then integrated on-chip with bead-based partitioning of weakly bound sequences to develop a microchip which performs temperature-specific isolation of aptamer sequences from a randomized library. Finally, this approach is further developed into a microfluidic SELEX chip which is capable of performing multiple rounds of temperature-specific SELEX. The novel bead-based protocol is shown to efficiently isolate target-binding sequences from a random library in a fraction of the time previously reported. As a result, this research provides a schematic for the development of highly efficient, integrated microfluidic SELEX devices. Such devices have the potential to impact a variety of fields including medical diagnostics, drug detection, and aptamer-based therapeutics.

Hintersteiner, I., et al. (2015). "Characterization and quantitation of polyolefin microplastics in personal-care products using high-temperature gel-permeation chromatography." Analytical & Bioanalytical Chemistry **407**(4): 1253-1259.

In recent years, the development of reliable methods for the quantitation of microplastics in different samples, including evaluating the particles' adverse effects in the marine environment, has become a great concern. Because polyolefins are the most prevalent type of polymer in personal-care products containing microplastics, this study presents a novel approach for their quantitation. The method is suitable for aqueous and hydrocarbon-based products, and includes a rapid sample clean-up involving twofold density separation and a subsequent quantitation with high-temperature gel-permeation chromatography. In contrast with previous procedures, both errors caused by weighing after insufficient separation of plastics and matrix and time-consuming visual sorting are avoided. In addition to reliable quantitative results, in this investigation a comprehensive characterization of the polymer particles isolated from the product matrix, covering size, shape, molecular weight distribution and stabilization, is provided.

Hipfner, J. M., et al. (2018). "Two forage fishes as potential conduits for the vertical transfer of microfibres in Northeastern Pacific Ocean food webs." Environmental Pollution **239**: 215-222.

We assessed the potential role played by two vital Northeastern Pacific Ocean forage fishes, the Pacific sand lance (Ammodytes personatus) and Pacific herring (Clupea pallasii), as conduits for the vertical transfer of microfibres in food webs. We quantified the number of microfibres found in the stomachs of 734 sand lance and 205 herring that had been captured by an abundant seabird, the rhinoceros auklet (Cerorhinca monocerata). Sampling took place on six widely-dispersed breeding colonies in British Columbia, Canada, and Washington State, USA, over one to eight years. The North Pacific Ocean is a global hotspot for pollution, yet few sand lance (1.5%) or herring (2.0%) had ingested microfibres. In addition, there was no systematic relationship between the prevalence of microplastics in the fish stomachs vs. in waters around three of our study colonies (measured in an earlier study). Sampling at a single site (Protection Island, WA) in a single year (2016) yielded most (sand lance) or all (herring) of the microfibres recovered over the 30 colony-years of sampling involved in this study, yet no microfibres had been recovered there, in either species, in the previous year. We thus found no evidence that sand lance and herring currently act as major food-web conduits for microfibres along British Columbia's outer coast, nor that the local at-sea density of plastic necessarily determines how much plastic enters marine food webs via zooplanktivores. Extensive urban development around the Salish Sea probably explains the elevated microfibre loads in fishes collected on Protection Island, but we cannot account for the between-year variation. Nonetheless, the existence of such marked interannual variation indicates the importance of measuring year-to-year variation in microfibre pollution both at sea and in marine biota.

Hipfner, J. M., et al. (2017). "Low incidence of plastics in food loads delivered to nestlings by a zooplanktivorous seabird over a 21-year period." Marine Pollution Bulletin **121**(1/2): 320.

We quantified the amount of plastic found in food loads delivered to nestlings in Cassin's Auklet (Ptychoramphus aleuticus), a small, zooplanktivorous seabird, on Triangle Island, British Columbia, in 1996-2016. The density of plastic in surrounding waters is moderately high, yet few food loads contained any plastic (3 of 850), and none more than two pieces. That result accords well with previous observations on the other four North Pacific auklets (Aethia spp.), leading us to conclude that true auklets rarely transfer plastic to nestlings. However, many hatch-year Cassin's Auklets found dead in coastal British Columbia, Washington and Oregon during the mass mortality event of fall and winter 2014-15 had plastic in their ventriculi. We suggest that these plastic particles would have been obtained at sea after fledging, perhaps while the birds transited south through a region of high plastic density off the west coast of Vancouver Island, Washington and Oregon.

Hirakawa, K., et al. (2006). "Electrochemical immunoassay for vitellogenin based on sequential injection using antigen-immobilized magnetic microbeads." Analytical Sciences **22**(1): 81-86.

A rapid and sensitive immunoassay for the determination of vitellogenin (Vg) is described. The method involves a sequential injection analysis (SIA) system equipped with an amperometric detector and a neodymium magnet. Magnetic beads, onto which an antigen (Vg) was immobilized, were used as a solid support in an immunoassay. The introduction, trapping and release of magnetic beads in an immunoreaction cell were controlled by means of the neodymium magnet and by adjusting the flow of the carrier solution. The immunoassay was based on an indirect competitive immunoreaction of an alkaline phosphatase (ALP) labeled anti-Vg monoclonal antibody between the fraction of Vg immobilized on the magnetic beads and Vg in the sample solution. The immobilization of Vg on the beads involved coupling an amino group moiety of Vg with the magnetic beads after activation of a carboxylate moiety on the surface of magnetic beads that had been coated with a polylactate film. The Vg-immobilized magnetic beads were introduced and trapped in the immunoreaction cell equipped with the neodymium magnet; a Vg sample solution containing an ALP labeled anti-Vg antibody at a constant concentration and a p-aminophenyl phosphate (PAPP) solution were sequentially introduced into the immunoreaction cell. The product of the enzyme reaction of PAPP with ALP on the antibody, paminophenol, was transported to an amperometric detector, the applied voltage of which was set at +0.2 V vs. an Ag/AgCl reference electrode. A sigmoid calibration curve was obtained when the logarithm of the concentration of Vg was plotted against the peak current of the amperometric detector using various concentrations of standard Vg sample solutions (0-500 ppb). The time required for the analysis is less than 15 min.

Hirata-Koizumi, M., et al. (2009). "Disappearance of gender-related difference in the toxicity of benzotriazole ultraviolet absorber in juvenile rats." Congenital Anomalies **49**(4): 247-252.

2-(2'-hydroxy-3',5'-di-tert-butylphenyl)benzotriazole (HDBB) is an ultraviolet absorber used in plastic resin products, such as building materials and automobile components. In oral repeated dose toxicity studies using 5- or 6-week-old rats, this chemical induced hepatic histopathological changes, such as hypertrophy accompanied with eosinophilic granular changes and focal necrosis of hepatocytes, and male rats showed nearly 25 times higher susceptibility to the toxic effects than females. Castration at approximately 4 weeks of age markedly reduced the sex-related variation in HDBB toxicity, but some difference, less than five times, remained between male and female castrated rats. Following oral HDBB administration to male and female juvenile rats from postnatal days 4-21, such gender-related difference in toxic susceptibility was not detected; therefore, it is speculated that the determinants of susceptibility to HDBB toxicity are differentiated between sexes after weaning. In young rats given HDBB, there was no gender-related difference in plasma HDBB concentration, and no metabolites were detected in the plasma of either sex. HDBB induced lauric acid 12-hydroxylase activity in the liver and this change was more pronounced in males than in females. These findings indicate that HDBB could show hepatic peroxisome proliferation activity, and the difference in the susceptibility of male and female rats to this effect might lead to marked gender-related differences in toxicity.

Hirayama, T., et al. (2004). "Effects of heat exposure on nutrient digestibility, rumen contraction and hormone secretion of goats." Animal Science Journal **75**(3): 237-243.

The present study investigated the changes in nutrient digestibility, rumen fermentation, behaviour and hormone (growth hormone (GH), insulin and insulin-like growth factor-1 (IGF-1)) secretion of goats (three male goats) in a hot (H, 35+or-1.2 degrees C; relative humidity (RH), 80+or-7.2%; 13 days), thermoneutral (T, 20+or-0.6 degrees C; RH, 80+or-3.4%; 20 days), and in a thermoneutral environment accompanied by the same restricted diet as provided in the hot environment (TR, 20+or-0.6 degrees C; RH, 80+or-3.4%; 20 days). The following results were obtained: rectal temperature and water intake were higher in the H treatment than in the T or TR treatment while hay consumption was lower. Crude protein, neutral detergent fibre and acid detergent fibre digestibility were highest in H treatment. The concentrations of acetic acid and butyric acid in the rumen were also highest in the H treatment. The time spent during eating was also highest in the H treatment, followed in order by T then TR treatment. Ruminating time was lower in H treatment than in T or TR treatment and reposing time was highest in the TR treatment. When eating and ruminating, the amplitude values of the rumen contraction were lowest in the H treatment as was the frequency of rumen contraction. Excretion of plastic particles were faster in T and TR treatments than H treatment. Heat exposure was associated with lowered concentrations of total volatile fatty acids and acetic acid in the plasma. The plasma glucose concentration was highest in the T treatment, followed in order by the TR then H treatment. The H treatment had the lowest plasma GH concentration but with the highest plasma insulin. The IGF-1 concentration was highest in the H treatment, followed in order by T then TR treatment. It is concluded that heat exposure of goats decreased the feed intake and rumen contraction but increased digestibility. However, when goats in a thermoneutral environment received the same restricted feeding as they received in the hot environment, digestibility increased without a change in rumen contraction. Between H and TR treatments, the changes in digestibility are accomplished by coordinate changes in hormone secretion in order to maintain body homeostasis.

Hiskakis, M., et al. (2008). "Agricultural plastic waste mapping in Greece." Acta Horticulturae **801**(Vol 1): 351-358.

A detailed geographical mapping of the agricultural plastic use in Greece was conducted in the framework of a European project focusing in the areas of high concentration. Quantitative data and analysis of the agricultural plastic waste generation by category (films, bags etc), the geographical distribution, the compositional range and physical characteristics of the agricultural plastic waste per use, the temporal distribution of removal, the current agricultural plastic waste management practices and disposal methods available are presented. Reported information on the agricultural plastic use in Greece is sporadic and unreliable. Data from the Ministry of Agriculture and the Statistical Organization of Greece were combined with the information from the services of the prefectures, local agronomists and farmers, site visits and interviews with the sales departments of major producers and importers of agricultural plastics. The temporal distribution of the agricultural plastic waste generation within each zone is important for the logistics of the consolidation operation. The composition and physical characteristics of the agricultural plastic waste streams were mapped by category and by application. These characteristics may delimit some of the disposal options of the streams (i.e. recycling, energy recovery) and guide the consolidation methodology. This work represents the first systematic effort to completely map the agricultural plastic waste generation and consolidation in Greece. The structured information and the reliable data provided in this work are expected to stimulate the design of an optimized waste management system for the agricultural plastic wastes chain in Greece. It is also expected to facilitate the implementation of the labelling scheme to be developed in the framework of the European project Labelagriwaste.

Hitchcock, J. N. and S. M. Mitrovic (2019). "Microplastic pollution in estuaries across a gradient of human impact." Environmental Pollution **247**: 457-466.

Microplastic (MP) pollution is an emerging issue in aquatic sciences. Little comparative information currently exists about the problem in coastal systems exposed to different levels of human impact. Here we report a year-long study on the abundance of MP in the water column of three estuaries on the east-coast of Australia. The estuaries are subject to different scales of human impact; the Clyde estuary has little human modification, the Bega estuary has a small township and single wastewater treatment works discharging to its waters, and the Hunter estuary which has multiple townships, multiple wastewater treatment plants, and heavy industry. MP abundance followed an expected pattern with the lowest abundance in the low-impact Clyde estuary (98 part. m³), moderate levels of MP in the moderately impacted Bega estuary (246 part. m³), and high MP abundance in the highly impacted Hunter estuary (1032 part. m³). The majority of particles were <200mum and fragment-like rather than fiber-like. MP abundance was positively related to maximum antecedent rainfall in the Bega estuary, however there are no clear environmental factors that could explain MP variation in the other systems. MP were generally higher in summer and following freshwater inflow events. On the Hunter estuary MP abundance was at times as high as zooplankton abundance, and within the range of numbers reported in other highly impacted systems globally. The results confirm that higher levels of human impact lead to greater plastic pollution and highlight the need to examine aquatic ecosystems under a range of conditions in order to adequately characterize the extent of MP pollution in rivers and coastal systems.

Hitchings, L. (2014). "Plastic crackdown." New Scientist **222**(2975): 7-7.

The article reports on the ban of cosmetics that contain plastic microbeads that has been implemented in Illinois in an effort to reduce pollution in the state.

Ho, H. O., et al. (1994). "Fibrin-based drug delivery systems. II: The preparation and characterization of

microbeads." Drug Development and Industrial Pharmacy **20**(4): 535-546.
An emulsion method was employed to prepare fibrin beads having different sizes in this study. The oil phase of emulsion system was consisted of mineral oil with various amount of oleic acid as surfactant. Fibrin was converted from fibrinogen with thrombin in Tris buffer solution, then the mixture was emulsified into the oil phase forming droplets. After curing for one hour, 400 ul of glutaraldehyde solution (0.5% v/v) was added to minimize coagulation. The recovery of fibrin beads was simply done by decanting the oil phase and washing the residual with diethyl ether once and then with a mixture of isopropanol and n-hexane (1:3) containing 0.2% w/v Tween 80 twice. As expected, increasing the amount of oleic acid in the oil phase decreased the size of fibrin beads. It is due to the decrease of interfacial tension with increasing oleic acid amount. The presence of macromolecules showed no interference on the formation of fibrin beads except lysozyme. The diffusion characteristics of fibrin beads was evaluated using macromolecules of different molecular weight as model. The size of fibrin beads affected the penetration rate, whereas the effect of molecular weight of macromolecules was inconclusive. An exponential equation was able to approximate the penetration of macromolecules into fibrin beads during the late-time period. The possibility of using fibrin beads as the carrier to deliver protein drugs was appreciated.

Ho, L. T. and P. L. M. Goethals (2019). "Opportunities and challenges for the sustainability of lakes and reservoirs in relation to the Sustainable Development Goals (SDGs)." Water **11**(7).
Emerging global threats, such as biological invasions, climate change, land use intensification, and water depletion, endanger the sustainable future of lakes and reservoirs. To deal with these threats, a multidimensional view on the protection and exploitation of lakes and reservoirs is needed. The holistic approach needs to contain not just the development of economy and society but also take into account the negative impacts of this growth on the environment, from that, the balance between the three dimensions can be sustained to reach a sustainable future. As such, this paper provides a comprehensive review on future opportunities and challenges for the sustainable development of lakes and reservoirs via a critical analysis on their contribution to individual and subsets of the Sustainable Development Goals (SDGs). Currently, lakes and reservoirs are key freshwater resources. They play crucial roles in human societies for drinking water provision, food production (via fisheries, aquaculture, and the irrigation of agricultural lands), recreation, energy provision (via hydropower dams), wastewater treatment, and flood and drought control. Because of the (mostly) recent intensive exploitations, many lakes and reservoirs are severely deteriorated. In recent years, physical (habitat) degradation has become very important while eutrophication remains the main issue for many lakes and ponds worldwide. Besides constant threats from anthropogenic activities, such as urbanization, industry, aquaculture, and watercourse alterations, climate change and emerging contaminants, such as microplastics and antimicrobial resistance, can generate a global problem for the sustainability of lakes and reservoirs. In relation to the SDGs, the actions for achieving the sustainability of lakes and reservoirs have positive links with the SDGs related to environmental dimensions (Goals 6, 13, 14, and 15) as they are mutually reinforcing each other. On the other hand, these actions have direct potential conflicts with the SDGs related to social and economic dimensions (Goals 1, 2, 3 and 8). From these interlinkages, we propose 22 indicators that can be used by decision makers for monitoring and assessing the sustainable development of lakes and reservoirs.

Ho, S., et al. (2006). "Study of recycled polyethylene materials as asphalt modifiers." Canadian Journal of Civil Engineering **33**(8): 968-981.

There has been interest in modifying asphalt with polyethylene materials, which are a major plastic waste substance, especially low-density polyethylene (LDPE). In this study, combinations of three low molecular weight polyethylene (PE) wax materials and three recycled LDPE materials were used as asphalt modifiers. The modified asphalts were studied using the SuperpaveTM MP1 and MP1a specifications, 1% direct tension test (DTT) failure strain criteria, phase separation, and microscopy. When the molecular weight distribution of the polyethylene modifiers was widened, the bending beam rheometer thermal stress curve of the modified asphalt shifted to the low-temperature end, giving a better critical cracking temperature. Not all recycled LDPE are the same. When using recycled LDPE in asphalt modification, we have to consider the LDPE properties, such as molecular weight and molecular weight distribution, which have been found to play important roles in asphalt's low-temperature properties, hot storage stability, and polymer phase distribution. This study showed that LDPE with lower molecular weight and wider molecular weight distribution are more suitable materials for asphalt modification, compared with high molecular weight LDPE with very narrow molecular weight distribution. (English) [ABSTRACT FROM AUTHOR]

Il se développe un intérêt envers la modification de l'asphalte par des polyéthylènes, des déchets de plastiques importants, surtout le polyéthylène à faible densité (LDPE). Dans la présente étude, des combinaisons de trois composés de cire de polyéthylène (PE) de faible poids moléculaire et de trois matériaux en LDPE recyclés ont été utilisées comme agents modificateurs de l'asphalte. Les asphaltes modifiés ont été étudiés selon les spécifications MP1 et MP1a SuperpaveTM, des critères de contrainte de défaillance par essai en traction pure (DTT) de 1 %, la séparation des phases et la microscopie. Lorsque la répartition des poids moléculaires des agents modificateurs du polyéthylène a été élargie, la courbe de contrainte thermique du rhéomètre de flexion de poutre Bending Beam Rheometer de l'asphalte modifié s'est déplacée vers l'extrémité de basse température, donnant une meilleure température critique de fissuration. Les LDPE recyclés ne sont pas tous les mêmes. Lors de l'utilisation de LDPE recyclés dans l'asphalte modifié, nous avons dû tenir compte des propriétés des LDPE telles que le poids moléculaire et la répartition du poids moléculaire, ce qui s'est avéré jouer un rôle important dans les propriétés de l'asphalte à basse température, la stabilité d'entreposage à chaud et la répartition des phases du polymère. La présente étude montre que les LDPE ayant un poids moléculaire plus faible et une répartition plus large du poids moléculaire sont de meilleurs matériaux pour la modification de l'asphalte par rapport aux LDPE de poids moléculaire plus élevé ayant une répartition très étroite du poids moléculaire.Mots clés : superpave, LDPE, polyéthylène, asphalte, recyclé, rhéomètre à flexion de poutre (« bending beam rheometer (BBR) »), essais en traction pure, répartition des poids moléculaires, régalage à basse température.[Traduit par la Rédaction] (French) [ABSTRACT FROM AUTHOR]

Ho, W. K. and K. S. Leung (2019). "Sorption and desorption of organic UV filters onto microplastics in single and multi-solute systems." Environmental Pollution **254**(Pt B): 113066.

Sorption studies of organic pollutants by microplastics (MPs) in single-solute systems are well established in the literature. However, actual aquatic environments always contain a mixture of contaminants. Prediction of the fate and biological effects of MPs-mediated chemical exposure

requires a better understanding of sorption-desorption processes of multiple organic contaminants by MPs. In this study, the altered sorption and desorption behaviors of individual organic UV filters (BP-3 and 4-MBC) in the presence of cosolutes (BP-3, 4-MBC, EHMC and OC) on two types of MPs (LDPE and PS) were examined. In most cases, co-occurrence of other organic UV filters appeared to have an antagonistic effect on the sorption of primary solute, which was consistent with trends found in previous studies. Nevertheless, the sorption uptake of 4-MBC as primary solute on PS was enhanced in the presence of cosolute(s), arising presumably from solute multilayer formation caused by laterally attractive pi-pi interactions between adsorbed cosolute(s) and 4-MBC molecules. Such formation of multilayer sorption in multi-solute systems depends on the solute hydrophobicity and concentration as well as inherent sorptivity of MPs. Our further desorption experiments revealed that the bioaccessibility of primary solute was significantly elevated with cosolutes, even though competitive sorption was observed under the same experimental conditions. These findings supplement the current knowledge on sorption mechanisms and interactions of multiple organic contaminants on MPs, which are critical for a comprehensive environmental risk assessment of both MPs and hazardous anthropogenic contaminants in natural environments.

Hoai, N. T., et al. (2010). "Batch and column separation characteristics of copper-imprinted porous polymer micro-beads synthesized by a direct imprinting method." Journal of Hazardous Materials **173**(1-3): 462-467.

Copper (II) ion-imprinted porous polymethacrylate micro-particles were prepared. Two functional monomers, methacrylic acid and vinyl pyridine, formed a complex with the template copper ion through ionic interactions. The self-assembled copper/monomer complex was polymerized in the presence of an ethylene glycol dimethacrylate cross-linker by a suspension method. After the imprinting sites were provided through removal of the template, the micro-porous particles, of approximate size 200 microm, were obtained for batch and column separation applications. The chemical structure and morphology of the Cu(II)-imprinted micro-porous particles were analyzed using FTIR, SEM, and BET. The adsorption capacity and adsorption kinetics of the imprinted beads for the template Cu(II) ion were significantly affected by particle size, copper ion concentration, pH, and flow rate of the feed solution. The imprinted particles showed high selectivity for the copper ion over other metal ions such as Ni and Zn. The selectivity of the present imprinted polymers for the copper ion was at least 10 times as high as those from commercial sources.

Hoang, T. C. and M. Felix-Kim (2020). "Microplastic consumption and excretion by fathead minnows (Pimephales promelas): Influence of particles size and body shape of fish." Science of the Total Environment **704**: 135433.

The present study characterizes the dependence of microplastic consumption and excretion on particle size and body shape of fathead minnow (Pimephales promelas) over time that has not been studied. Specifically, the study is to answer four important questions: 1) how do P. promelas consume microplastic particles at different size ranges over time? 2) how long does it take for P. promelas to excrete microplastic particles after consumption? 3) do P. promelas reconsume microplastic particles after excretion? 4) are microplastic consumption and excretion by P. promelas dependent on the body shape? To answer these questions, larval P. promelas were exposed to polyethylene microbeads (PMBs) at two different consumable size ranges of 63-75 micro m and 125-150 micro m in moderately hard water. The experiments were designed to allow and to not allow fish to reconsume the particles they excreted.

Hodge, S., et al. (2003). "Alveolar macrophages from subjects with chronic obstructive pulmonary disease are deficient in their ability to phagocytose apoptotic airway epithelial cells." Immunology & Cell Biology **81**(4): 289-296.

Chronic obstructive pulmonary disease is a highly prevalent, complex disease, usually caused by cigarette smoke. It causes serious morbidity and mortality and costs the global community billions of dollars per year. While chronic inflammation, extracellular matrix destruction and increased airway epithelial cell apoptosis are reported in chronic obstructive pulmonary disease, the understanding of the basic pathogenesis of the disease is limited and there are no effective treatments. We hypothesized that the accumulation of apoptotic airway epithelial cells chronic obstructive pulmonary disease in could be due to defective phagocytic clearance by alveolar macrophages. There have been no previous studies of the phagocytic capacity of alveolar macrophages in chronic obstructive pulmonary disease using physiologically relevant apoptotic airway epithelial cells as phagocytic targets. We developed a phagocytosis assay whereby cultured 16HBE airway epithelial cells were induced to apoptosis with ultraviolet radiation and stained with mitotracker green. Alveolar macrophages from bronchoalveolar lavage from eight control and six chronic obstructive pulmonary disease subjects were analysed following 1.5 h incubation with apoptotic airway epithelial cells, then staining with macrophage marker anti CD33. CD33+/mitotracker green + events (i.e., alveolar macrophages which had phagocytosed apoptotic airway epithelial cells) were analysed using flow cytometry. Phagocytosis of polystyrene microbeads was investigated in parallel. A significantly reduced proportion of alveolar macrophages from chronic obstructive pulmonary disease subjects ingested apoptotic airway epithelial cells compared with controls (11.6 +/- 4.1% for chronic obstructive pulmonary disease versus 25.6 +/- 9.2% for control group). Importantly, the deficiency was not observed using polystyrene beads, suggesting that the failure to resolve epithelial damage in chronic obstructive pulmonary disease may result, at least partially, from specific defects in phagocytic ability of alveolar macrophages to ingest apoptotic airway epithelial cells.

Hodgson, D. J., et al. (2018). "Ingestion and fragmentation of plastic carrier bags by the amphipod Orchestia gammarellus: effects of plastic type and fouling load." Marine Pollution Bulletin **127**: 154-159.

Inappropriate disposal of plastic debris has led to the contamination of marine habitats worldwide. This debris can be ingested by organisms; however, the extent to which chewing and gut transit modifies plastic debris is unclear. Detritivores, such as amphipods, ingest and shred natural organic matter and are fundamental to its breakdown. Here we examine ingestion and shredding of plastic carrier bags by Orchestia gammarellus. A laboratory experiment showed these amphipods shredded plastic carrier bags, generating numerous microplastic fragments (average diameter 488.59 micro m). The presence of a biofilm significantly increased the amount of shredding, but plastic type (conventional, degradable and biodegradable) had no effect. Subsequent field observations confirmed similar shredding occurred on the strandline. Rates of shredding will vary according to amphipod density; however, our data indicates that shredding by organisms could substantially accelerate the formation microplastics in the environment.

Hodson, M. E., et al. (2017). "Plastic bag derived-microplastics as a vector for metal exposure in terrestrial invertebrates." Environmental Science & Technology **51**(8): 4714-4721.

Microplastics are widespread contaminants in terrestrial environments but comparatively little is known about interactions between microplastics and common terrestrial contaminants such as zinc (Zn). In adsorption experiments fragmented HDPE bags c. one mm² in size showed similar sorption characteristics to soil. However, when present in combination with soil, concentrations of adsorbed Zn on a per mass basis were over an order of magnitude lower on microplastics. Desorption of the Zn was minimal from both microplastics and soil in synthetic soil solution (0.01 M CaCl₂), but in synthetic earthworm guts desorption was higher from microplastics (40-60%) than soil (2-15%), suggesting microplastics could increase Zn bioavailability. Individual Lumbricus terrestris earthworms exposed for 28 days in mesocosms of 260 g moist soil containing 0.35 wt% of Zn-bearing microplastic (236-4505 mg kg⁻¹) ingested the microplastics, but there was no evidence of Zn accumulation, mortality, or weight change. Digestion of the earthworms showed that they did not retain microplastics in their gut. These findings indicate that microplastics could act as vectors to increase metal exposure in earthworms, but that the associated risk is unlikely to be significant for essential metals such as Zn that are well regulated by metabolic processes.

Hoellein, T. J., et al. (2017). "Longitudinal patterns of microplastic concentration and bacterial assemblages in surface and benthic habitats of an urban river." Freshwater Science **36**(3): 491-507.

Rivers are a major source of microplastic particles (<5 mm) to oceans, but empirical measurements of microplastic movement in freshwater ecosystems are rare. The hard, buoyant surface of microplastic is a novel habitat that selects for unique microbial assemblages in rivers, especially downstream of wastewater treatment plant (WWTP) point sources. We measured microplastic in surface water and benthic habitats 50 m upstream and 50, 305, 1115, and 1900 m downstream of the effluent outfall from a large WWTP in an urban river. We used high-throughput sequencing to measure bacterial assemblages on microplastic from surface and benthic habitats and compared them to bacterial assemblages from seston, water, and sediment. Concentrations of total microplastic and microplastic types (fragment, pellet) in surface water did not change with distance downstream of the WWTP. Thus, microplastic transport showed no net deposition or resuspension. Microplastic concentrations were much higher in the benthic zone than surface water. Benthic deposition appears to be a plastic sink over longer time scales, but subsequent studies are needed to resolve microplastic transport dynamics by particle type, size, and habitat. Composition of microplastic-attached bacterial assemblages differed from that of assemblages in water, seston, and sediment and supports domestic wastewater as a point source of microplastic (e.g., gastrointestinal taxa). Shifts in microplastic assemblages with distance from the WWTP suggest succession toward a 'stream-like' bacterial assemblage. Future studies are required to quantify the metabolic capacity of microplastic-associated bacteria. Estimates of transport distance, microplastic storage, and microbial interactions are critical to include lotic ecosystems in accountings of global plastic budgets.

Hohmann-Jeddi, C. (2019). "Microplastics in drinking water: WHO calls for more research on risks. [German]." Pharmazeutische Zeitung **164**(35): 46.

Holland, E. R., et al. (2016). "Plastics and other anthropogenic debris in freshwater birds from Canada." Science of the Total Environment **571**: 251-258.

Plastics in marine environments are a global environmental issue. Plastic ingestion is associated with a variety of deleterious health effects in marine wildlife, and is a focus of much international research and monitoring. However, little research has focused on ramifications of plastic debris for freshwater organisms, despite marine and freshwater environments often having comparable plastic concentrations. We quantified plastic and other anthropogenic debris in 350 individuals of 17 freshwater and one marine bird species collected across Canada. We determined freshwater birds' anthropogenic debris ingestion rates to be 11.1% across all species studied. This work establishes that plastics and other anthropogenic debris are a genuine concern for management of the health of freshwater ecosystems, and provides a baseline for the prevalence of plastic and other anthropogenic debris ingestion in freshwater birds in Canada, with relevance for many other locations. Holland, T. (2009). "Market Watch." Materials Recycling Week **194**(14): 35-38.
The article offers information on the materials markets in Great Britain. The world's lightest screwcap wine bottle is expected to be available for Christmas by the lightweight glass project GlassRite, which is led by the Waste and Resources Action Pogramme (WRAP). The WRAP-funded scheme, which subsidised composting bins for local authorities, has ended in September 2009 because many authorities are already doing the action for themselves. The Recoup organization which advocates plastic recycling, released its annual report on plastics packaging collection, exposing that 40% of plastic bottles were collected for recycling in 2008.

Holland, T. (2011). "Party time heralds bumper volumes." Materials Recycling Week **197**(17): 10-10.
The article reports that as of May 2011, recyclers in England are expecting a windfall of extra material to work with. It states that in light of more drinking due to the hot weather, extra banking holidays, as well as celebrations to honor the Royal Wedding, more waste was produced. It is expected therefore, that more aluminum, plastic and glass will be collected for reprocessing, a change from February when waste material becomes scarce. Some claim to have seen an increase in waste by as much as 50%, considered a good sign for the industry.

Holloway, J., et al. (2003). "Assessment of white blood cell phagocytosis as an immunological indicator of methylmercury exposure in birds." Archives of Environmental Contamination and Toxicology **44**(4): 493-501.
White blood cell (WBC) phagocytosis was investigated as a potential immunological indicator of methylmercury (MeHg) exposure in birds. The assay was first assessed using chicken WBCs dosed with MeHg in vitro either in whole blood or as isolated cells and later using blood of wild common loons exposed in vivo to a range of dietary MeHg and having a range of blood-Hg concentrations. Whole blood and isolated WBCs from captive chickens were exposed to a range of MeHg concentrations for 3 h. After MeHg exposure, cells were incubated with fluorescent latex microbeads (diameter=1.75 micro m), fixed, and analyzed for size, complexity, and fluorescent intensity by flow cytometry. MeHg significantly depressed phagocytic activity when added to isolated WBCs at concentrations >0.01 micro g/ml, but not when added to whole blood up to 50 micro g/ml. Similarly, no significant relationship between the concentration of Hg in whole blood and phagocytic capacity of WBCs in free-living loons was observed. Our results suggest that the phagocytosis assay, although rapid and convenient for use in field studies with wildlife species, is not a responsive immunological indicator of MeHg exposure at environmentally realistic concentrations of blood-Hg in wild loons. Assays that measure other immunologic endpoints (e.g., bacterial killing assay, PHA skin test, and mitogen-induced lymphocyte proliferation) should be assessed with respect to their ability to detect MeHg immunotoxicity in wild birds.

Holmes, C. M., et al. (2020). "A National-Scale Framework for Visualizing Riverine Concentrations of Microplastics Released from Municipal Wastewater Treatment Incorporating Generalized Instream Losses." Environmental Toxicology & Chemistry **39**(1): 210-219.
Down-the-drain exposure models provide a valuable tool for estimating environmental exposure to substances which are treated and discharged by municipal wastewater-treatment plants

(WWTPs). Microplastics may enter WWTPs from consumer activities and disposal. An exposure framework was developed using the iSTREEM R model, which estimates spatially explicit concentrations of substances in riverine systems across the United States and portions of Ontario, Canada. One hundred simulations covering a range of WWTP removal and instream loss rates (proxy for net sedimentation) were incorporated into a Web-based visualization tool for user exploration of relative concentrations across simulations. Surface water concentrations specific to user-supplied tonnage were examined via interactive heat maps and cumulative distributions. Exploring the spatial aspect of iSTREEM results showed that modeling 90% WWTP removal and no instream loss resulted in 8.5% of the mass entering WWTPs discharged to marine estuaries (7.4%) or Great Lakes (1.1%) environments, with the remainder of the mass discharged (1.5%) in inland sinks or exiting the United States via rivers. Modeling an example instream loss of k = 0.1 d⁻¹ (i.e., half-life = 7 d), terminal river segments contained 3.3% of influent mass (2.3% marine estuaries, 1.0% Great Lakes). Varying instream loss rates had substantial impacts on the total mass exported. The Web-based tool provided a user-based mechanism to visualize relative freshwater concentrations of microplastics across a large geographic area by varying simplified particle fate assumptions. Environ Toxicol Chem 2019;39:210-219. © 2019 SETAC.

Holmes, L. A., et al. (2012). "Adsorption of trace metals to plastic resin pellets in the marine environment." Environmental Pollution **160**(1): 42-48.

Plastic production pellets collected from beaches of south west England contain variable concentrations of trace metals (Cr, Co, Ni, Cu, Zn, Cd and Pb) that, in some cases, exceed concentrations reported for local estuarine sediments. The rates and mechanisms by which metals associate with virgin and beached polyethylene pellets were studied by adding a cocktail of 5 mug L ⁻¹ of trace metals to 10 g L⁻¹ pellet suspensions in filtered seawater. Kinetic profiles were modelled using a pseudo-first-order equation and yielded response times of less than about 100 h and equilibrium partition coefficients of up to about 225 ml g⁻¹ that were consistently higher for beached pellets than virgin pellets. Adsorption isotherms conformed to both the Langmuir and Freundlich equations and adsorption capacities were greater for beached pellets than for virgin pellets. Results suggest that plastics may represent an important vehicle for the transport of metals in the marine environment. © 2011 Elsevier Ltd. All rights reserved.

Holt, N. and S. Sanjay (2016). "Transforming the plasticulture production system through novel bed geometry design." Transactions of the ASABE **59**(3): 993-1003.

Raised-bed plasticulture with drip irrigation is used worldwide for growing high-value crops, especially vegetables. This high-input, intensive system must become more efficient to meet food demands while reducing its environmental footprint. Futuristic tall and narrow compact beds were designed with an aim to improve the plasticulture system by increasing or maintaining yield while decreasing system input requirements. Using a whole-systems approach, compact geometries were evaluated on an example crop, eggplant (L.), in the ecologically sensitive but highly productive sub-tropical Everglades region of Florida. Two compact beds, 61 cm (width) x25 cm (height) and 45 cm x 30 cm, were evaluated against a conventional short and wide bed, 91 cm x 15 cm. The conventional bed used two drip tapes for irrigation and fertigation. The compact beds needed only one tape but produced equivalent yields as the conventional bed. Irrigation, nitrogen, and phosphorus application rates were respectively reduced by 50%, 14%, and 19% in the compact beds. Water and nutrient productivities with the compact beds increased by at least $43 per 10 kL irrigation, $6 per kg nitrogen, and $8 per kg phosphorus applied, representing respective gains of 92%, 11%, and 8% over the conventional bed. Productivity increases highlight how compact beds can make plasticulture more efficient. Shifting to compact beds also brings non-water co-benefits, including reductions in the system's production costs by $560 to $670 ha⁻¹, carbon footprint by 5% to 10% (reduced fumigant and plastic usage), agricultural plastic waste, and potential detrimental impacts from changed climate. Compact beds provide flood and disease protection by decreasing impervious (mulched) surface area and having extra bed height above the ground. Use of compact beds at the study farm would decrease rainfall intensity in the row middles by 34% and increase the farm's soil water storage capacity by 52% (1.4 cm). Increased storage and infiltration of rainfall will decrease flooding frequency and runoff volume, thereby reducing peak flows in downstream environments. Compact beds also have an added economic benefit for farmers who pay to lease land, as production can be increased through a higher plant population density without changing total mulched surface area. A cultural shift to taller and narrower compact beds makes plasticulture more sustainable as water, nutrient, cost, and energy inputs are reduced without sacrificing yields. Compact beds provide the impetus to transform plasticulture to a futuristic, further-optimized system that is more automated (e.g., chemigation), less labor intensive, and better adapted to climate change for continued economic and environmental viability.

Holt, N., et al. (2017). "Transforming the food-water-energy-land-economic nexus of plasticulture production through compact bed geometries. (Special Section: The challenge of understanding the water-food nexus complexity.)." Advances in Water Resources **110**: 515-527.

Raised-bed plasticulture, an intensive production system used around the world for growing high-value crops (e.g., fresh market vegetables), faces a water-food nexus that is actually a food-water-energy-land-economic nexus. Plasticulture represents a multibillion dollar facet of the United States crop production value annually and must become more efficient to be able to produce more on less land, reduce water demands, decrease impacts on surrounding environments, and be economically-competitive. Taller and narrower futuristic beds were designed with the goal of making plasticulture more sustainable by reducing input requirements and associated wastes (e.g., water, nutrients, pesticides, costs, plastics, energy), facilitating usage of modern technologies (e.g., drip-based fumigation), improving adaptability to a changing climate (e.g., flood protection), and increasing yield per unit area. Compact low-input beds were analyzed against conventional beds for the plasticulture production of tomato (Solanum lycopersicum), an economically-important crop, using a systems approach involving field measurements, vadose-zone modeling (HYDRUS), and production analysis. Three compact bed geometries, 61 cm (width) x25 cm (height), 45 cm x30 cm, 41 cm x30 cm, were designed and evaluated against a conventional 76 cm x20 cm bed. A two-season field study was conducted for tomato in the ecologically-sensitive and productive Everglades region of Florida. Compact beds did not statistically impact yield and were found to reduce: (1) production costs by $150-$450/ha; (2) leaching losses by up to 5% (1 cm/ha water, 0.33 kg/ha total nitrogen, 0.05 kg/ha total phosphorus); (3) fumigant by up to 47% (48 kg/ha); (4) plasticulture's carbon footprint by up to 10% (1711 kg CO₂-eq/ha) and plastic waste stream by up to 13% (27 kg/ha); (5) flood risks and disease pressure by increasing field's soil water storage capacity by up to 33% (~1 cm); and (6) field runoff by 0.48-1.40 cm (51-76%) based on HYDRUS model simulations of 10-year, 2-h storm events in other major tomato production regions of California and Virginia. Re-designing the bed geometries in plasticulture production systems to be more compact is an example of win-win production optimization not only for traditional farms in rural areas but also for urban and peri-urban farms which are located closer to city centers. Compact beds could enable more plants per unit area, thus requiring less land area for the same production. Needing less area facilitates urban and peri-urban farming where land values can be high. Urban and peri-urban farming has several benefits, including reductions in transportation energy as production is closer to market and the ability for city wastewater to be reused for irrigation instead of freshwater withdrawals. Compact beds allow plasticulture to have smaller water, chemical, energy, carbon, waste, and economic footprints without impacting production. Improving agricultural systems in this way could enhance economic and environmental viability, which is essential for a sustainable food-water-energy-land-economic nexus.

A two-season field study was conducted for tomato in the ecologically- sensitive and productive Everglades region of Florida. Compact beds did not statistically impact yield and were found to reduce: 1) production costs by \$150-\$450/ha; 2) leaching losses by up to 5% (1 cm/ha water, 0.33 kg/ha total nitrogen, 0.05 kg/ha total phosphorus); 3) fumigant by up to 47% (48 kg/ha); 4) plasticulture's carbon footprint by up to 10% (1711 kg C02-eq/ha) and plastic waste stream by up to 13% (27 kg/ha); 5) flood risks and disease pressure by increasing field's soil water storage capacity by up to 33% (≈1 cm); and 6) field runoffby 0.48-1.40cm (51-76%) based on HYDRUS model simulations of 10- year, 2-h storm events in other major tomato production regions of California and Virginia. Re-designing the bed geometries in plasticulture production systems to be more compact is an example of win-win production optimization not only for traditional farms in rural areas but also for urban and pen-urban farms which are located closer to city centers. Compact beds could enable more plants per unit area, thus requiring less land area for the same production. Needing less area facilitates urban and pen-urban farming where land values can be high. Urban and pen-urban farming has several benefits, including reductions in transportation energy as production is closer to market and the ability for city wastewater to be reused for irrigation instead of freshwater withdrawals. Compact beds allow plasticulture to have smaller water, chemical, energy, carbon, waste, and economic footprints without impacting production. Improving agricultural systems in this way could enhance economic and environmental viability, which is essential for a sustainable food-water-energy-land-economic nexus.

Homsy, A., et al. (2007). "Magnetohydrodynamic pumping in nuclear magnetic resonance environments." Sensors and Actuators B: Chemical **123**(1): 636-646.

We present a DC magnetohydrodynamic (MHD) pump as component of a nuclear magnetic resonance (NMR) microfluidic chip. This is the first time that MHD pumping in an NMR environment was observed and demonstrated. This chip generates a maximum flow rate of 1.5kLmin super(-) super(1) (2.8mms super(-) super(1) in the microchannel) for an applied voltage of 19V with only 38mW of power consumption in a 7T superconductive magnet. We developed a simple method of flow rate measurement inside the bulky NMR magnet by monitoring the displacement of a liquid-liquid interface of two immiscible liquids in an off-chip capillary. We compared and validated this flow measurement technique with another established technique for microfluidics based on the displacement of microbeads. This allowed us to characterize and compare the flow rate generated by the micropump on top of a permanent magnet (B sub(1)=0.33T) with the superconductive magnet (B sub(0)=7.05T). We observed a 21-fold increase in flow rate corresponding to the ratio of the magnetic field intensities (B sub(0)/B sub(1)=21) in accordance with the theoretical flow dependence on the magnetic field intensity. The final aim is to integrate MHD pumps together with planar coils in a microfluidic system for NMR analysis. The high performance of MHD pumps at relatively low flow rates is seen as an asset for NMR and MRI applications.

Homsy, E., et al. (2019). "Characterization of microparticle Gasdermin-D in patients in the medical intensive care unit." American Journal of Respiratory and Critical Care Medicine. Conference **199**(9).

Rationale: The inflammasome is a multimeric complex that is responsible for the activation of protein mediators of inflammation. Gasdermin-D (GSDM-D) is a protein with membrane pore forming properties that assists with intercellular transference of the inflammasome by microparticle vectors. In vitro studies have shown that activated caspase-1 cleaves inactive p52 GSDM-D into its active p30 subunit which then encapsulates both proteins into microparticles. These microparticles are then able to induce pyroptosis in healthy cells¹. We therefore hypothesized that GSDM-D plays an important role in sepsis and ARDS among other inflammatory conditions, and sought to better characterize GSDM-D in the much more complicated clinical setting. Method(s): Thirty seven patients were enrolled. Day 1 blood samples were drawn from the patients early into their admission to the medical intensive care unit. Eight healthy volunteers were also enrolled to serve as controls. Microparticles were isolated by ultracentrifugation. Monocytes were isolated using CD14 coated microbeads. Active and inactive forms of GSDM-D were analyzed in both fractions using immunoblot. Quantification was carried out using densitometry with ImageJ software. Researchers were kept blinded to patients' clinical conditions. Diagnoses and markers of severity of illness were collected and correlated with active GSDM-D values. Result(s): Active GSDM-D was detected in the microparticle and monocyte lysates and there was notable heterogeneity in band signal. Inactive p52 GSDM-D was detected only in the cell lysates. Only septic patients had elevated active GSDM-D levels in the microparticle fraction. Conversely, active GSDM-D levels in the monocyte fractions were lower in the septic patients compared to the non-septic critically ill patients. This suggests that there is release of active GSDM-D from monocytes in the inflammatory state. There were too few cases of ARDS in the cohort to make any generalizations. Conclusion(s): Our finding of elevated active GSDM-D levels only in the microparticle fraction of septic patients supports the hypothesis that GSDM-D plays an important role in sepsis. Our data also supports the hypothesis that active GSDM-D is formed in stimulated monocytes and then packaged into microparticles leading to its depletion in the cell lysates.

Hong, C. S., et al. (2014). "Isolation and characterization of CD34+ blast-derived exosomes in acute myeloid leukemia." PLoS ONE [Electronic Resource] **9**(8): e103310.

Exosomes are membrane-bound vesicles found in all biological fluids. AML patients' plasma collected at diagnosis contains elevated exosome levels relative to normal donor (ND) plasma. The molecular profile of AML exosomes changes in the course of therapy and may serve as a measure of disease progression or response to therapy. However, plasma contains a mix of exosomes derived from various cell types. To be able to utilize blast-derived exosomes as biomarkers for AML, we have developed an immunoaffinity-based capture method utilizing magnetic microbeads coated with anti-CD34 antibody (Ab). This Ab is specific for CD34, a unique marker of AML blasts. The capture procedure was developed using CD34+ exosomes derived from Kasumi-1 AML cell culture supernatants. The capture capacity of CD34microbeads was shown to linearly correlate with the input exosomes. A 10 uL aliquot of CD34 microbeads was able to capture all of CD34+ exosomes present in 100-1,000 uL of AML plasma. The levels of immunocaptured CD34+ exosomes correlated with the percentages of CD34+ blasts in the AML patients' peripheral blood. The immunocaptured exosomes had a typical cup-shaped morphology by transmission electron microscopy, and their molecular cargo was similar to that of parental blasts. These exosomes were biologically-active. Upon co-incubation with natural killer (NK) cells, captured blast-derived exosomes down-regulated surface NKG2D expression, while non-captured exosomes reduced expression levels of NKp46. Our data provide a proof-of-principle that blast-derived exosomes can be quantitatively recovered from AML patients' plasma, their molecular profile recapitulates that of autologous blasts and they retain

the ability to mediate immune suppression. These data suggest that immunocaptured blast-derived exosomes might be useful in diagnosis and/or prognosis of AML in the future.

Hong, G., et al. (2014). "Near-infrared II fluorescence for imaging hindlimb vessel regeneration with dynamic tissue perfusion measurement." Circulation: Cardiovascular Imaging **7**(3): 517-525.

Background-Real-time vascular imaging that provides both anatomic and hemodynamic information could greatly facilitate the diagnosis of vascular diseases and provide accurate assessment of therapeutic effects. Here, we have developed a novel fuorescence-based all-optical method, named near-infrared II (NIR-II) fuorescence imaging, to image murine hindlimb vasculature and blood fow in an experimental model of peripheral arterial disease, by exploiting fuorescence in the NIR-II region (1000-1400 nm) of photon wavelengths. Methods and Results-Because of the reduced photon scattering of NIR-II fuorescence compared with traditional NIR fuorescence imaging and thus much deeper penetration depth into the body, we demonstrated that the mouse hindlimb vasculature could be imaged with higher spatial resolution than in vivo microscopic computed tomography. Furthermore, imaging during 26 days revealed a signifcant increase in hindlimb microvascular density in response to experimentally induced ischemia within the frst 8 days of the surgery (P<0.005), which was confrmed by histological analysis of microvascular density. Moreover, the tissue perfusion in the ischemic hindlimb could be quantitatively measured by the dynamic NIR-II method, revealing the temporal kinetics of blood fow recovery that resembled microbead-based blood fowmetry and laser Doppler blood spectroscopy. Conclusions-The penetration depth of millimeters, high spatial resolution, and fast acquisition rate of NIR-II imaging make it a useful imaging tool for murine models of vascular disease. © 2014 American Heart Association, Inc.

Hong, X., et al. (2014). "Research progress of AlphaLISA technology in food safety detection." Journal of Food Safety and Quality **5**(1): 198-202.

Homogeneous time-resolved fluoroimmunoassay (AlphaLISA) is a new homogeneous detection technology based on light stimulating of the chemiluminescence of nano micro-bead. Compared with the traditional ELISA, the AlphaLISA has characteristics of homogeneity, free of cleaning, high sensitivity and specificity. This paper introduced the principles and characteristics of AlphaLISA, briefly summarized the application research of AlphaLISA technology at home and abroad in recent years, reviewed the research progress of food safety field (including biological toxins and drug residues), and the future development of this technology was also prospected.

Hopkins, A. M., et al. (2017). "Intracellular CD3+ T Lymphocyte Teriflunomide Concentration Is Poorly Correlated with and Has Greater Variability Than Unbound Plasma Teriflunomide Concentration." Drug Metabolism & Disposition **45**(1): 8-16.

Leflunomide's active metabolite teriflunomide inhibits dihydro-oroate dehydrogenase, an enzyme essential to proliferation of T lymphocytes. As teriflunomide must reach the target site to have this effect, this study assessed the distribution of teriflunomide into T lymphocytes, as intracellular concentrations may be a superior response biomarker to plasma concentrations. CD3 MicroBeads (Miltenyi Biotec, Bergisch Gladbach, Germany) were used to extract CD3⁺ T cells from the peripheral blood of patients with rheumatoid arthritis who were taking a stable dose of leflunomide. Unbound plasma and intra-CD3⁺ T cell teriflunomide concentrations were quantified using liquid chromatography-mass spectrometry. Concentration (log transformed) and partition differences were assessed through paired Student t tests. Sixteen patients provided plasma steady-state teriflunomide samples, and eight provided a sample 6-12 weeks later. At time-point one, the geometric mean teriflunomide

concentration (range) in CD3⁺ T cells was 18.12 mug/L (6.15-42.26 mug/L) compared with 69.75 mug/L (32.89-263.1 mug/L) unbound in plasma (P < 0.001). The mean partition coefficient (range) for unbound plasma teriflunomide into CD3⁺ T cells was 0.295 (0.092-0.632), which was significantly different from unity (P < 0.001). The median (range) change in teriflunomide concentration between the two time points was 14% (-10% to 40%) in unbound plasma and -29% (-69 to 138%) for CD3⁺ T cells. Because teriflunomide concentrations in CD3⁺ T cells were lower and displayed a higher intraindividual variability than the unbound plasma concentrations, its applicability as a therapeutic drug-monitoring marker may be limited.

Hopkins, A. M., et al. (2017). "Intracellular CD3⁺ T lymphocyte teriflunomide concentration is poorly correlated with and has greater variability than unbound plasma teriflunomide concentration." Drug Metabolism and Disposition **45**(1): 8-16.

Leflunomide's active metabolite teriflunomide inhibits dihydro-oroate dehydrogenase, an enzyme essential to proliferation of T lymphocytes. As teriflunomide must reach the target site to have this effect, this study assessed the distribution of teriflunomide into T lymphocytes, as intracellular concentrations may be a superior response biomarker to plasma concentrations. Sixteen patients provided plasma steady-state teriflunomide samples, and eight provided a sample 6-12 weeks later. At time-point one, the geometric mean teriflunomide concentration (range) inCD3⁺ T cellswas 18.12mug/L (6.15-42.26mug/L) comparedwith 69.75 mug/L (32.89-263.1mug/L) unbound in plasma (P < 0.001). The mean partition coefficient (range) for unbound plasma teriflunomide into CD3⁺ T cells was 0.295 (0.092-0.632), which was significantly different from unity (P < 0.001). The median (range) change in teriflunomide concentration between the two time pointswas 14% (210% to 40%) in unbound plasma and 229% (269 to 138%) for CD3⁺ T cells. Because teriflunomide concentrations in CD3⁺ T cells were lower and displayed a higher intraindividual variability than the unbound plasma concentrations, its applicability as a therapeutic drug-monitoring marker may be limited.

Horcajo-Berná, E., et al. (2019). "Necropsy of a Green Turtle (Chelonia mydas) and the Impacts of Plastic Pollution in Tioman Island, Malaysia." Marine Turtle Newsletter(158): 14-15.

Hori, T., et al. (2020). "Fuel cell and electrolyzer using plastic waste directly as fuel." Waste Management **102**: 30-39.

The effective utilization of plastic waste, including its use as an energy or chemical resource, has attracted much attention. Nevertheless, energy recovery from plastics via incineration generates air pollutants and toxic compounds, while chemical conversion requires significant energy inputs, especially in the case of gasification. Herein, we report the electrochemical conversion of plastics into electricity or hydrogen without the use of special procedures. When a mixture of plastic solid combined with an acidic solution was fed into an electrochemical cell, the solid was found to dissolve in the solution at 100degreeC or higher, followed by the release of protons from the anode to the cathode according to a multi-electron oxidation reaction. This oxidation reaction required an anode that was sufficiently porous so as to allow transport of the

reactants. Taking the sponge sample as an example, the dissolved polyurethane had a molecular weight of 2000 or higher, the transport of which was facilitated using a carbon support with a pore diameter of approximately 10nm. In addition, carbon black having an ordered porous structure exhibited better reagent transport compared to a disordered porous carbon black with similar pore diameters. As a consequence, this cell continuously provided power densities on the order of mW cm⁻² in the fuel cell mode and generated hydrogen at a low cell voltage of 0.55V in the electrolyzer mode, using plastics as fuels at an operational temperature of 200degreeC.

Horikawa, S., et al. (2011). "Effects of surface functionalization on the surface phage coverage and the subsequent performance of phage-immobilized magnetoelastic biosensors." Biosensors and Bioelectronics **26**(5): 2361-2367.

One of the important applications for which phage-immobilized magnetoelastic (ME) biosensors are being developed is the wireless, on-site detection of pathogenic bacteria for food safety and bio-security. Until now, such biosensors have been constructed by immobilizing a landscape phage probe on gold-coated ME resonators via physical adsorption. Although the physical adsorption method is simple, the immobilization stability and surface coverage of phage probes on differently functionalized sensor surfaces need to be evaluated as a potential way to enhance the detection capabilities of the biosensors. As a model study, a filamentous fd-tet phage that specifically binds streptavidin was adsorbed on either bare or surface-functionalized gold-coated ME resonators. The surface functionalization was performed through the formation of three self-assembled monolayers with a different terminator, based on the sulfur-gold chemistry: AC (activated carboxy-terminated), ALD (aldehyde-terminated), and MT (methyl-terminated). The results, obtained by atomic force microscopy, showed that surface functionalization has a large effect on the surface phage coverage (46.8%, 49.4%, 4.2%, and 5.2% for bare, AC-, ALD-, and MT-functionalized resonators, respectively). In addition, a direct correlation of the observed surface phage coverage with the quantity of subsequently captured streptavidin-coated microbeads was found by scanning electron microscopy and by resonance frequency measurements of the biosensors. The differences in surface phage coverage on the differently functionalized surfaces may then be used to pattern the phage probe layer onto desired parts of the sensor surface to enhance the detection capabilities of ME biosensors.

Horn, D., et al. (2019). "Microplastics are ubiquitous on California beaches and enter the coastal food web through consumption by Pacific mole crabs." Marine Pollution Bulletin **139**: 231-237.

Microplastics are commonly found in marine ecosystems, but their distribution, prevalence, and impacts on resident fauna are still not well understood. Microplastics in coastal sediments expose invertebrate infauna to the risk of ingestion of plastic debris and associated toxicants. We assessed the prevalence of microplastics in beach sediments and ingested by Pacific mole crabs (Emerita analoga) at sandy beaches spanning >900 km of the California coast. Microplastics were present in sediments of every one of 51 beaches sampled. At a subset of 38 beaches Pacific mole crabs were collected and crabs at every beach had ingested microplastics. Across all beaches sampled, an average of 35% of Pacific mole crabs examined had microplastics in their guts. Our study demonstrates that microplastics are ubiquitous in sediments on California beaches and they are frequently consumed by a filter-feeding crustacean that is a common prey item in the diet of a wide variety of taxa, including fishes and birds.

Horrocks, A. R. (1996). "RECYCLING AND RECOVERY STRATEGIES." Recycling Textile & Plastic Waste: 3-15.

The article discusses the recycling and recovery strategies of the textile industries in Europe. It is stated that the complexity and value of many technical and industrial textiles had created opportunities for their effective recovering and recycling practices. It is noted that the recycling strategies of the textiles industries which are observed during the coming of the 21st century focus on the ecological perspectives and economic forces. It is concluded that the movement towards recycling requires consumer education, local authority cooperation and conceptualization of legislation.

Horrocks, J. A. (1996). "RECYCLING OF PLASTIC FIBRE AND PACKAGING WASTE." Recycling Textile & Plastic Waste: 61-76.

The article offers methods of recycling plastic fibers and packaging wasts from three sources including the in-house, post industrial and post consumer. It is stated that the simplest method of recycling is by granulating and producing a product which is impossible to reuse directly. The standard method of extrusion is by melting, filtering and pelletizing. It highlights the Erema process which was introduced by three Austrian engineers in 1982. The Erema process is an in-line extrusion process that is dust free, low noise level, occupies small space, low energy usage and low maintenance cost.

Horstmann, J. P., et al. (2013). "NLRP3 inflammasome recovery improves monocyte function after major trauma." Shock **2)**: 38.

Objectives: Suppressed function of monocytes in the early posttraumatic response plays a key role in the initiation of the inflammatory response by inflammasome activation and subsequent IL-1beta release. NLRP3 inflammasome deficiency is associated with several inflammatory diseases. We analyzed the monocyte function in a 5-day time course after trauma and their capacity to recover by NLRP3 gene insertion in isolated cells from trauma patients. Method(s): Twenty seven severely injured trauma patients [ISSQ16] and ten healthy volunteers were enrolled. Monocytes were isolated by CD14+ microbeads daily up to day 5 after trauma and assayed for their ex vivo in vitro IL-1beta production after LPS-stimulation (10mug/ml, 24h) by ELISA. Fresh monocyte RNA was analyzed for IL-1beta daily. In parallel, isolated monocytes were transfected with an expression plasmid encoding NLRP3 and 48 h later they were stimulated with LPS to uncover their functionality. Result(s): LPS-stimulation increased markedly the IL-1beta release in healthy volunteers compared to unstimulated controls (p<0.05) and the LPS-response early after trauma. IL-1beta mRNA in samples from trauma patients was significantly enhanced compared to healthy volunteers early after trauma declining on day 3 and 4. Transfecting monocytes obtained from trauma patients after admission and on day 3 after trauma with NLRP3 significantly increased IL-1beta release after LPSstimulation compared to corresponding unstimulated samples. The IL- 1beta release in NLRP3-transfected and LPS-stimulated monocytes from patients was comparable to IL-1beta release in healthy volunteers. Conclusion(s): Reduced IL-1beta release from monocytes early after trauma is paralleled by enhanced IL-1beta gene expression. This monocyte dysbalance can be partly counterbalanced by NLRP3 gene insertion, suggesting potential new targets and strategies for immunorecovery after trauma.

Horton, A. A. and S. J. Dixon (2018). "Microplastics: An introduction to environmental transport processes." Wiley Interdisciplinary Reviews **5**(2).

Microplastic pollution is widespread across the globe, pervading land, water, and air. These environments are commonly considered independently, however, in reality these are closely linked. This review gives an overview of the background knowledge surrounding sources, fate and transport of microplastics within the environment. We introduce a new "Plastic Cycle" concept in order to better understand the processes influencing flux and retention of microplastics between and across the wide range of environmental matrices. As microplastics are a pervasive, persistent and potentially harmful pollutant, an understanding of these processes will allow for assessment of exposure to better determine the likely long-term ecological and human health implications of microplastic pollution. WIREs Water 2018, 5:e1268. doi: 10.1002/wat2.1268 This article is categorized under: Engineering Water > Water, Health, and Sanitation Science of Water > Water and Environmental Change Water and Life > Stresses and Pressures on Ecosystems

Horton, A. A., et al. (2018). "The influence of exposure and physiology on microplastic ingestion by the freshwater fish Rutilus rutilus (roach) in the River Thames, UK." Environmental Pollution **236**: 188-194.

Microplastics are widespread throughout aquatic environments. However, there is currently insufficient understanding of the factors influencing ingestion of microplastics by organisms, especially higher predators such as fish. In this study we link ingestion of microplastics by the roach Rutilus rutilus, within the non-tidal part of the River Thames, to exposure and physiological factors. Microplastics were found within the gut contents of roach from six out of seven sampling sites. Of sampled fish, 33% contained at least one microplastic particle. The majority of particles were fibres (75%), with fragments and films also seen (22.7% and 2.3% respectively). Polymers identified were polyethylene, polypropylene and polyester, in addition to a synthetic dye. The maximum number of ingested microplastic particles for individual fish was strongly correlated to exposure (based on distance from the source of the river). Additionally, at a given exposure, the size of fish correlated with the actual quantity of microplastics in the gut. Larger (mainly female) fish were more likely to ingest the maximum possible number of particles than smaller (mainly male) fish. This study is the first to show microplastic ingestion within freshwater fish in the UK and provides valuable new evidence of the factors influencing ingestion that can be used to inform future studies on exposure and hazard of microplastics to fish.

Horton, A. A., et al. (2020). "Accumulation of polybrominated diphenyl ethers and microbiome response in the great pond snail Lymnaea stagnalis with exposure to nylon (polyamide) microplastics." Ecotoxicology & Environmental Safety **188**: 109882.

Microplastics attract widespread attention, including for their potential to transport toxic chemicals in the form of plasticisers and associated hydrophobic organic chemicals, such as polybrominated diphenyl ethers (PBDEs). The aims of this study were to investigate how nylon (polyamide) microplastics may affect PBDE accumulation in snails, and the acute effects of nylon particles and PBDEs on survival, weight change and inherent microbiome diversity and community composition of the pond snail Lymnaea stagnalis. Snails were exposed for 96h to BDEs-47, 99, 100 and 153 in the presence and absence of 1% w/w nylon microplastics in quartz sand sediment. No mortality was observed over the exposure period. Snails not exposed to microplastics lost significantly more weight compared to those exposed to microplastics. Increasing PBDE concentration in the sediment resulted in an increased PBDE body burden in the snails, however microplastics did not significantly influence total PBDE uptake. Based on individual congeners, uptake of BDE 47 by snails was significantly reduced in the presence of microplastics. The diversity and composition of the snail microbiome was not significantly altered by the presence of PBDEs nor by the microplastics, singly or combined. Significant effects on a few individual operational taxonomic units (OTUs) occurred when comparing the highest PBDE concentration with the control treatment, but in the absence of microplastics only. Overall within these acute experiments, only subtle effects on weight loss and slight microbiome alterations occurred. These results therefore highlight that L. stagnalis are resilient to acute exposures to microplastics and PBDEs, and that microplastics are unlikely to influence HOC accumulation or the microbiome of this species over short timescales.

Horton, A. A., et al. (2018). "Acute toxicity of organic pesticides to Daphnia magna is unchanged by co-exposure to polystyrene microplastics." Ecotoxicology and Environmental Safety **166**: 26-34.

Daphnia magna were exposed to two pesticides in the presence or absence of microplastics (300 000 particles ml⁻¹ 1 micro m polystyrene spheres) and to microplastics alone. The pesticides were dimethoate, an organophosphate insecticide with a low log Kow, and deltamethrin, a pyrethroid insecticide with a high log Kow. Daphnia were exposed to a nominal concentration range of 0.15, 0.31, 0.63, 1.25, 2.5, 5 mg l⁻¹ dimethoate and 0.016, 0.08, 0.4, 2, 5 and 10 micro g l⁻¹ deltamethrin. Exposure to polystyrene microplastics alone showed no effects on Daphnia magna survival and mobility over a 72 h exposure. In the dimethoate exposures, mobility and survival were both affected from a concentration of 1.25 mg l⁻¹, with effects were seen on mobility from 28 h and survival from 48 h, with greater effects seen with increasing concentration and exposure time. In deltamethrin exposures, survival was affected from a concentration of 0.4 micro g l⁻¹ and mobility from a concentration of 0.08 micro g l⁻¹. Effects of deltamethrin on mobility were seen from 5 h and on survival from 28 h, with greater effects on survival and mobility seen with increasing concentration and exposure time. Contrary to expectations, pesticide toxicity to Daphnia magna was not affected by the presence of microplastics, regardless of chemical binding affinity (log Kow). This therefore suggests that polystyrene microplastics are unlikely to act as a significant sink, nor as a vector for increased uptake of pesticides by aquatic organisms. Capsule: Polystyrene microplastics are unlikely to act as vector for increased uptake of pesticides by aquatic organisms.

Horton, A. A., et al. (2017). "Microplastics in freshwater and terrestrial environments: Evaluating the current understanding to identify the knowledge gaps and future research priorities." Science of the Total Environment **586**: 127-141.

Plastic debris is an environmentally persistent and complex contaminant of increasing concern. Understanding the sources, abundance and composition of microplastics present in the environment is a huge challenge due to the fact that hundreds of millions of tonnes of plastic material is manufactured for societal use annually, some of which is released to the environment. The majority of microplastics research to date has focussed on the marine environment. Although freshwater and terrestrial environments are recognised as origins and transport pathways of plastics to the oceans, there is still a comparative lack of knowledge about these environmental compartments. It is highly likely that microplastics will accumulate within continental environments, especially in areas of high anthropogenic influence such as agricultural or urban areas. This review critically evaluates the current literature on the presence, behaviour and fate of microplastics in freshwater and terrestrial environments and, where appropriate, also draws on relevant studies from other fields including nanotechnology, agriculture and waste management. Furthermore, we evaluate the relevant biological and chemical information from the substantial body of marine microplastic literature, determining the applicability and comparability of this data to freshwater and terrestrial systems. With the evidence presented, the authors have set out the current state of the knowledge, and identified the key gaps. These include the volume and composition of microplastics entering the environment, behaviour and fate of microplastics under a variety of environmental conditions and how characteristics of microplastics influence their toxicity. Given the technical challenges surrounding microplastics research, it is especially important that future studies develop standardised techniques to allow for comparability of data. The identification of these research needs will help inform the design of future studies, to determine both the extent and potential ecological impacts of microplastic pollution in freshwater and terrestrial environments.

Horvath, B., et al. (2018). "Designing Business Solutions for Plastic Waste Management to Enhance Circular Transitions in Kenya." Sustainability **10**(5).

Least-developed countries face many challenges regarding their plastic waste management systems. In 2017, Kenya imposed a selective ban targeting manufacturers and consumers of plastic carrier bags. However, this selectivity does not avoid the continuous use of other plastic products. The present paper states that circular priorities, which have been defined to advanced economies, would not be entirely valid for the rest of the world. While high-income countries face only the impacts of their own consumption, developing nations must endure the externalities of these developed economies. Thus, the focus of the least developed part of the world must not be on reducing its relatively normal (or even low) consumption, but to manage its surplus material flow. According to the employed circular evaluation methodology (CEV—Circular Economic Value), the circularity level in Kenya's plastic material flow stands on a rather low stage with 32.72%. This result outlines the linear deficiencies of the plastic waste management system and urges the prevention of further material leakage (such as energy use). Through the Business Model Canvas (BMC) approach this study offers a holistic business solution which can improve the system's sustainability.

Hosoda, J., et al. (2014). "Monitoring of organic micropollutants in Ghana by combination of pellet watch with sediment analysis: e-waste as a source of PCBs." Marine Pollution Bulletin **86**(1-2): 575-581.

Plastic resin pellets collected at 11 beaches covering the whole Ghanaian coastline were analyzed for polychlorinated biphenyls (PCBs). PCB concentrations (13 congeners) were higher in Accra, capital city, and Tema (39-69 ng/g-pellets) than those in rural coastal towns (1-15 ng/g-pellets) which are close to global background, indicating local inputs of PCBs. River sediments were also analyzed for PCBs together with molecular markers. Sedimentary PCBs concentrations were highest at a site (AR02) downstream of an electronic waste (e-waste) scrapyard. At the site (AR02), concentration of linear alkylbenzenes (LABs), a marker of municipal wastewater, was lower than another site (AR03) which is located at the downstream of downtown Accra. This result suggests that PCBs are introduced more to the river from the e-waste site than from activities in downtown Accra. PAHs concentrations were relatively higher in urban areas with strong petrogenic signature. Abundance of triphenylbenzenes suggested plastic combustion near e-waste scrapyard.

Hosoki, K., et al. (2013). "Differential activation of eosinophils by bacteria associated with asthma." International Archives of Allergy & Immunology **161 Suppl 2**: 16-22.

BACKGROUND: It has been suggested that there is a complex interaction between microbiota and various human diseases. Some bacteria have been reported to be involved in the inception and progression of asthma, and others in the protection against asthma. We know very little about the mechanisms by which bacteria do harm or good with regard to asthma. This study investigated whether bacteria exert differential effects on the functions of eosinophils, major effector cells in airway inflammation in asthma.

METHODS: Eosinophils were purified from healthy adult volunteers by Percoll density gradient centrifugation and negative immunomagnetic bead selection using anti-CD16 microbeads. Three

kinds of heat-killed bacteria that have been implicated in asthma, namely Staphylococcus aureus (SA), Haemophilus influenzae (HI) and a Prevotella sp. (PS), were tested for their effects on the secretion of eosinophil-derived neurotoxin (EDN), the generation of superoxides and the production of cytokines/chemokines.

RESULTS: SA, but not HI or PS, induced significant EDN release in a dose-dependent manner. Superoxide generation was significantly enhanced by each of the bacterial species, but most strongly by SA, which induced significantly greater TNF-alpha production by eosinophils than either HI or PS. Conversely, interleukin 10, an anti-inflammatory cytokine, was more strongly induced by HI and PS than by SA.

CONCLUSIONS: Bacteria exert differential effects on eosinophils. Based on these results, SA may be involved in the exacerbation of, and HI and PS in the inhibition of, eosinophilic inflammation in asthma.

Hosoki, K., et al. (2011). "Differential effects of GAS6 and protein S in human eosinophils." Journal of Thrombosis and Haemostasis **2)**: 824-825.

Background: GAS6 and protein S belong to vitamin K-dependent protein family; their amino acid sequence homology is 43%. They bind to the TAM receptor tyrosine kinases (Tyro3, Axl and Mer). TAM receptors are expressed by cells of the immune, nervous, reproductive, and vascular systems. Some reports have shown that they can inhibit inflammation. However, there is little information about the role of TAM receptors in allergy. Objective(s): To assess the function of TAM receptors in eosinophils, the cardinal effector cells in allergic inflammation. Method(s): Eosinophils were purified from healthy adult volunteers with percoll density gradient centrifugation and negative immunomagnetic beads selection using anti-CD16 microbeads. The presence of TAM receptors in human peripheral blood eosinophils was evaluated by PCR. Eosinophils were stimulated with ligands of TAM receptors (GAS 6 or protein S) and their effects on survival, secretion of eosinophil-derived neurotoxin (EDN), and cytokine production were examined. Result(s): PCR showed that Tyro3 and Mertk, but not Axl, are expressed in human peripheral eosinophils. Protein S significantly prolonged eosinophil survival and this effect was comparable to the effect of granulocyte/macrophage-colony stimulating factor (GMCSF). Protein S had no effect on EDN release from eosinophils in the presence or absence of GM-CSF. In contrast, GAS 6 significantly induced EDN release and this effect was comparable to that induced by GM-CSF, but it had no effect on survival. Protein S, but not GAS6, inhibited IL-1beta secretion from eosinophils. Conclusion(s): Although both GAS 6 and protein S bind to TAM receptors, they had differential effects in human eosinophils. GAS 6 and protein S may be involved in the pathogenesis of eosinophilrelated inflammatory diseases such as bronchial asthma.

Hossain, M. S., et al. (2019). "Microplastics in fishes from the Northern Bay of Bengal." Science of the Total Environment **690**: 821-830.

Microplastics were determined in pink Bombay-duck (Harpadon nehereus), white Bombay-duck (H. translucens) and gold-stripe sardine (Sardinella gibbosa) collected from the Northern Bay of Bengal at Bangladesh. Gastrointestinal tracts of fishes (n=25 per species) were examined for microplastics following alkali digestion protocol, microscopic observations and chemical analysis by micro-Fourier Transformed Infrared Spectroscope (micro -FTIR). A total of 443 microplastic items were found in the intestines of H. nehereus, H. translucens and S. gibbosa, averaging in the range of 3.20-8.72 items per species. Among various shapes, colours and types of microplastics, irregular (37-43%), white/transparent (26-68%) and fiber (50-55%) were dominant. The size fraction of microplastics ranging between 1 micro m and 5 mm was 6884 items/kg biomass, and micro -FTIR analysis identified 13 particles of polyethylene terephthalate and 66 particles of polyamide. The study findings raised concern that microplastics in marine fish could be a threat to public health via the food chain.

Hossain, M. S., et al. (2020). "Microplastic contamination in Penaeid shrimp from the Northern Bay of Bengal." Chemosphere **238**: N.PAG-N.PAG.

Microplastic pollution has received increased attention recently due to potential threat to marine biota and human health. This study reports microplastic (MP) content in brown shrimp (Metapenaeus monocerous) and tiger shrimp (Penaeus monodon) inhabiting in the shallow and offshore waters of the Northern Bay of Bengal, Bangladesh. Gastrointestinal tract (GT) of shrimps (n = 150) were examined for MPs following alkali digestion, microscopic observation and chemical analysis by micro-Fourier Transformed Infrared Spectroscope (μFTIR). A total of 33 and 39 MP items were found in P. monodon and M. monocerous , averaging 3.40 ± 1.23 and 3.87 ± 1.05 items/g GT, respectively. Among various shapes, types and colours of MP, filament (57–58%), fiber (32–57%) and black (48–51%) were dominant amongst the various particles identified. Tiger shrimp had high numbers (23 items) of larger size fractions of MPs (1–5 mm) but brown shrimp had high numbers (15 items) of smaller MPs (250–500 μm), and μ-FTIR data confirmed 13 particles of polyamide-6 and 6 particles of rayon polymers. These results provide a baseline of MP contamination in seafood from Bangladesh that should be useful for future monitoring efforts. Image 1 • MP items in two shrimps were ranged 33–39 with a mean abundance 3.40–3.87 items/g GT. • MP particles were dominated by black fibers and filament. • MPs were composed of polyamide-6 and rayon polymers. • MPs may transfer to humans as shrimps are often eaten without removing the intestines. [ABSTRACT FROM AUTHOR]

Houtman, M., et al. (2018). "T-cell transcriptomics from peripheral blood highlights differences between polymyositis and dermatomyositis patients." Arthritis Research & Therapy **20**(1): 188.

BACKGROUND: Polymyositis (PM) and dermatomyositis (DM) are two distinct subgroups of idiopathic inflammatory myopathies, a chronic inflammatory disorder clinically characterized by muscle weakness and inflammatory cell infiltrates in muscle tissue. In PM, a major component of inflammatory cell infiltrates is CD8+ T cells, whereas in DM, CD4+ T cells, plasmacytoid dendritic cells, and B cells predominate. In this study, with the aim to differentiate involvement of CD4+ and CD8+ T-cell subpopulations in myositis subgroups, we investigated transcriptomic profiles of T cells from peripheral blood of patients with myositis.

METHODS: Total RNA was extracted from CD4+ T cells (PM = 8 and DM = 7) and CD8+ T cells (PM = 4 and DM = 5) that were isolated from peripheral blood mononuclear cells via positive selection using microbeads. Sequencing libraries were generated using the Illumina TruSeq Stranded Total RNA Kit and sequenced on an Illumina HiSeq 2500 platform, yielding about 50 million paired-end reads per sample. Differential gene expression analyses were conducted using DESeq2.

RESULTS: In CD4+ T cells, only two genes, ANKRD55 and S100B, were expressed significantly higher in patients with PM than in patients with DM (false discovery rate [FDR] < 0.05, model adjusted for age, sex, HLA-DRB1*03 status, and RNA integrity number [RIN]). On the contrary, in CD8+ T cells, 176 genes were differentially expressed in patients with PM compared with patients with DM.

Of these, 44 genes were expressed significantly higher in CD8+ T cells from patients with PM, and 132 genes were expressed significantly higher in CD8+ T cells from patients with DM (FDR < 0.05, model adjusted for age, sex, and RIN). Gene Ontology analysis showed that genes differentially expressed in CD8+ T cells are involved in lymphocyte migration and regulation of T-cell differentiation.

CONCLUSIONS: Our data strongly suggest that CD8+ T cells represent a major divergence between PM and DM patients compared with CD4+ T cells. These alterations in the gene expression in T cells from PM and DM patients might advocate for distinct immune mechanisms in these subphenotypes of myositis.

Howard, B. (2003). "Message in a Bottle: Despite the Hype, Bottled Water is Neither Cleaner nor Greener Than Tap Water." E Magazine **14**(5): 26.

Bottled water has captured a large share of the beverage market, and many consumers prefer it over tap water. The bottled water industry has successfully created a marketing strategy based on vilifying public water sources, and glorifying the benefits of bottled water. Consumers also associate bottled water with higher social status. In fact, tap water is far more closely regulated than bottled water. Tests of bottled water have revealed numerous incidents of both biological and chemical contaminants, including carcinogenic agents. Consumers also complain about misleading labeling with regard to both source and purity of the bottled water. Another complaint is leveled by environmentalists, who note the vast amount of plastic waste generated by the bottled water market.

Howell, R. R. and M. A. Lloyd-Puryear (2016). "Implementation of newborn screening for Duchenne muscular dystrophy and spinal muscular atrophy." Journal of Inherited Metabolic Disease **39 (Supplement 1)**: S77.

Background: To be considered by theACHDNC for a newborn screening (NBS) panel in the US, pilot data at a state laboratory level, information on what drugs and treatments are available, how individuals with Duchennemuscular dystrophy (DMD) or Spinal muscular atrophy (SMA) could benefit from early administration of drugs and treatments are needed. This presentation will focus on the efforts for establishing NBS programs for DMD and SMA in the U.S. and will present a summary of a plan for the development of the DMD pilot for NBS in the U.S.A., current efforts for establishing NBS for SMA and activities accomplished to date. Method(s): Both SMA and DMD cause significant mortality in infants and children. DMD is one of the ten most severe pediatric genetic diseases and affects an estimated 1 in every 3,500-5000 male births. SMA is the leading genetic cause of infant mortality. Recent very promising clinical trials for treatments for DMD and SMA will require NBS, in order to be lifesaving. The treatments for DMD are based on the various genetic mutations causing DMD and include atalauren and eteplirsen. SMA treatments include nusinersen, olesoxime and a gene therapy trial. Result(s): In 2015, a DMD-NBS initiative was formed in partnership with the NBSTRN. DMD will screened using an immunoassay. Screens for SMA have employed liquid microbead suspensions assays; HRMA has been used to evaluate individuals with SMA for screening and diagnosis. Results from HRMA have been reported from a pilot study in 3 states. PCR has been developed for SMA diagnosis and also applied to DBS specimens. Studies show 100 % concordance with clinical status, identifying affected individuals and excluding carriers and unaffected individuals. Discussion(s): Issues raised within the work groups include a multitude of ethical issues that include screening universally vs. targeting males; reporting carrier status; identifying secondary conditions for which there are no treatments and absorption of costs associated with treatments.

Hrabina, M., et al. (2009). "Development of multiparametric immunoassays for the quantification of major allergens in grass pollen and house dust mite extracts." Allergy: European Journal of Allergy and Clinical Immunology **90)**: 105.

Background: The aim of the study was to develop and validate two multiparametric immunoassays based on Luminex technology, allowing to quantify (i) Der p 1, Der f 1 and group 2 allergens in mixtures of Dermatophagoides pteronyssinus (Dp) and Dermatophagoides farinae (Df) extracts, (ii) group 1 and 5 allergens in grass pollen extracts. Both multiparametric assays were compared to corresponding ELISA sandwich assays. Method(s): Color-coded panels of beads were coated with various capture monoclonal antibodies specific for either Der p 1, Der f 1, HDM group 2 allergens, grass pollen group 1 or 5 allergens (Stallergenes, France and Indoors Biotechnologies, UK). ELISA assays were conducted in comparison with Luminex immunoassays on 20 mixtures of Dp and Df extracts and 25 grass pollen extracts, using an universal standard (Indoors Biotechnologies, UK) for HDM allergens or a five grass pollen in house reference preparation. Fluorescence of labelled revealing monoclonal antibodies directed to each of the allergens and of micro-beads was detected using a two laser excitation system (Bio-plex array reader - Bio-Rad). Result(s): Two distinct multiparametric immunoassays based on Luminex technology were successfully established to quantify Der p 1/Der f 1/Group 2 allergens in mixtures of Dp and Df allergenic extracts, or group 1/group 5 allergens in grass pollen extracts, respectively. Repeat abilities (interassay variations) varied between 1.8% and 3.3% for all allergens tested. Intermediate precisions (intra-assay variations) were around 5% for HDM allergens and in the range of 15% for grass pollen allergens. Lower and upper limits of quantification (LLOQ and ULOQ, respectively) were 0.12-7.8 ng/ml for both Der p 1 and Der f 1, 0.04-1.56 ng/ml for HDM group 2 allergens, 0.057-58 ng/ml for grass pollen group 1, 1.06-34ng/ml for grass pollen group 5. Correlations between allergen levels assayed using Elisa and Luminex on 25 Dpt and Df mixtures and 20 grass pollen extracts were R = 0.94 for Der p 1, R = 0.98 for HDM group 2, R = 0.97 for Der f 1, and R = 0.99 for both grass pollen group 1 and group 5 allergens. Conclusion(s): LLOQ, repeatability and intermediate precision characteristics associated with Luminex were equal or better to the ones obtained with ELISA assays. Correlations between Luminex and ELISA simplex method were excellent for the 5 assays.

Hristov, M., et al. (2003). "Endothelial progenitor cells: Isolation and characterization." Trends in Cardiovascular Medicine **13**(5): 201-206.

Bone marrow of adults contains a subtype of progenitor cells that have the capacity to differentiate into mature endothelial cells and have therefore been termed endothelial progenitor cells (EPCs). Of the three cell markers (CD133, CD34, and the vascular endothelial growth factor receptor 2) that characterize the early functional EPCs, located predominantly in the bone marrow, EPCs obviously lose CD133/CD34 and start to express CD31, vascular endothelial cadherin, and von Willebrand factor when migrating to the circulation. Various isolation procedures of EPCs from different sources by using adherence culture or magnetic microbeads have been described, but published findings with regard to the number of EPCs in the peripheral circulation of healthy adults are scanty and no data regarding the lifetime of EPCs in vivo exist. Clinical studies employing EPCs for neovascularization of is-chemic organs have just been started; however, the mechanisms stimulating or inhibiting the differentiation of bone marrow-derived EPCs in vivo and the signals causing their adhesion, migration, and homing to sites of injured tissue are largely unknown at present. © 2003, Elsevier Inc.

Hruby, M., et al. (2016). "Biodegradable system for drug delivery of hydrolytically labile azanucleoside drugs." Biomedical Papers of the Medical Faculty of Palacky University in Olomouc, Czech Republic

160(2): 222-230.
BACKGROUND: The archetypal DNA methyltransferase inhibitors, 5-azacytidine (AZA) and 5-aza-2'-deoxycytidine (DAC) are potent antineoplastic agents used in the treatment of mainly, blood malignancies. However, the administration of these drugs is confounded by their hydrolytic lability which decreases plasma circulation time. Here, we describe a new biodegradable, polyanhydride formulation for drug delivery that circumvents this drawback.
METHODS: Injectable/implantable polymeric microbeads containing dispersed microcrystals of hydrophilic AZA or DAC packed in a dry environment are protected from hydrolysis, until the hydrolytic zone reaches the core. Diclofenac is embedded into the formulation to decrease any local inflammation. The efficacy of the formulations was confirmed by monitoring the induced demethylation, and cytostatic/cytotoxic effects of continuous drug release from the time-course dissolution of the microbeads, using an in vitro developed cell based reporter system.
RESULTS: Poly(sebaccic acid-co-1,4-cyclohexanedicarboxylic acid) containing 30 wt. % drug showed zero-order release (R(2) = 0.984 for linear regression), and release rate of 10.0 %/h within the first 5 h, and subsequent slower release of the remaining drug, thus maintaining the level of drugs in the outer environment considerably longer than the typical plasma half-life of free azanucleosides. At lower concentrations, the differences between powder drug formulations and microbeads were very low or negligible, however, at higher concentrations, we discovered equivalent or increasing effects of the drugs loaded in microbeads.
CONCLUSIONS: The study provides evidence that microbead formulations of the hydrolytically labile azanucleoside drugs could prevent their chemical decomposition in aqueous solution, and effectively increase plasma circulation time.

Hsiao, A. P. (2012). Methods and devices for comprehensive molecular analysis of single cells.
Typical analytical methods for evaluating the protein and gene expression of cells rely on the molecular analysis of analytes from a large number of cells. These methods, however, do not reveal insight into the heterogeneous nature of cells and instead only provide average results of the bulk population. Moreover, these methods are insensitive to low copy number proteins or mRNA that may in fact play a significant role in a cell's phenotypic state. The ability to discern the true distributions of protein and gene expression in a cell population will give rise to the effective identification of unique subpopulations. This allows for a deeper understanding of disease progression, molecular pathways, and cellular differentiation by revealing previously undetectable states of cells. Therefore, it is essential that technologies capable of isolating and comprehensively analyzing many single cells in parallel be developed. In this dissertation, I present new methods and technologies for integrating the capture and isolation of single cells with comprehensive, quantitative on-chip molecular analysis within a single microfluidic platform. I first present the design, development, and function of polymethyldisiloxane (PDMS) microfluidic devices capable of trapping and fully isolating many single cells along a series of compartments. Additionally, I discuss various methods for trapping (dielectrophoretic or hydrodynamic) and lysing (electric-field or chemical) of the cells directly in individual, nanoliter-sized compartments. Subsequently, I present methods for the fabrication, assembly, and application of high-density antibody-conjugated microbead arrays for single-cell proteome analysis. I then discuss how such arrays can be integrated directly into the PDMS devices using a protective patterning scheme to overcome current challenges in producing patterned, modified surfaces in PDMS devices. I also present methods we have developed which could enable analysis of single-cell gene expression by directly sequencing the mRNA transcripts captured from each single cell on the device. Finally, I present my work on electric field-directed assembly of enzyme-nanoparticle layers for biosensor applications. Together, these methods and devices

constitute key advancements towards the development of a technology capable of fully integrating single-cell capture and comprehensive molecular analysis.

Hsiao, L. L., et al. (1991). "Modification of host cell membrane lipid composition by the intra-erythrocytic human malaria parasite Plasmodium falciparum." Biochemical Journal **274**(Pt 1): 121-132.

The phospholipid and fatty acid compositions of the host infected erythrocyte plasma membrane (IEPM) have been determined for erythrocytes infected with the human malaria parasite Plasmodium falciparum. IEPM were prepared by selective lysis of the host erythrocyte (but not of the parasite membranes) with 0.1% saponin, followed by differential centrifugation. The purity of the IEPM was determined by measuring the membrane-specific enzyme markers acetylcholinesterase, glutamate dehydrogenase and lactate dehydrogenase, and by immunoelectron microscopy using monoclonal antibodies specific for human erythrocyte glycophorin A (4E7) and for a 195 kDa parasite membrane glycoprotein (Pf6 3B10.1). Both approaches demonstrated that the host erythrocyte plasma membrane preparation was free from contamination by parasite membranes. During intra-erythrocytic development of the parasite, the phospholipid composition of the erythrocyte membrane was strikingly altered. IEPM contained more phosphatidylcholine (38.7% versus 31.7%) and phosphatidylinositol (2.1% versus 0.8%) and less sphingomyelin (14.6% versus 28.0%) than normal uninfected erythrocytes. Similar alterations in phospholipid composition were determined for erythrocyte membranes of parasitized cells isolated by an alternative method utilizing polycationic polyacrylamide microbeads (Affigel 731). The total fatty acid compositions of the major phospholipids in IEPM were determined by g.l.c. The percentage of polyunsaturated fatty acids in normal erythrocyte phospholipids (39.4%) was much higher than in phospholipids from purified parasites (23.3%) or IEPM (24.0%). The unsaturation index of phospholipids in IEPM was considerably lower than in uninfected erythrocytes (107.5 versus 161.0) and was very similar to that in purified parasites (107.5 versus 98.5). Large increases in palmitic acid (C16:0) (from 21.88% to 31.21%) and in oleic acid (C18:1) (from 14.64% to 24.60%), and major decreases in arachidonic acid (C20:4) (from 17.36% to 7.85%) and in docosahexaenoic acid (C22:6) (from 4.34% to 1.8%) occurred as a result of infection. The fatty acid profiles of individual phospholipid classes from IEPM resembled in many instances the fatty acid profiles of parasite phospholipids rather than those of uninfected erythrocytes. Analysis of IEPM from P. falciparum-infected erythrocytes (trophozoite stage) revealed that, during intra-erythrocytic maturation of the parasite, the host erythrocyte phospholipid composition was markedly refashioned. These alterations were not dependent on the method used to isolate the IEPM, with similar results obtained using either a saponin-lysis method or binding to Affigel beads. Since mature erythrocytes have negligible lipid synthesis and metabolism, these alterations must occur as a result of parasite-directed metabolism of erythrocyte lipids and/or trafficking of lipids between the parasite and erythrocyte membranes.

Hsu, F.-Y., et al. (2018). "Macroporous microbeads containing apatite-modified mesoporous bioactive glass nanofibres for bone tissue engineering applications." Materials Science & Engineering. C, Biomimetic Materials, Sensors and Systems **89**: 346.

Mesoporous bioactive glass (MBG) has a greater surface area and pore volume than conventional BG. Hence, MBG is useful as a drug delivery carrier. Previously, MBG has been fabricated as dense or porous blocks. Compared to blocks, microbeads have a greater flexibility to fill different-shaped cavities with close packing. Moreover, fibrous materials have proven to increase cell attachment and differentiation because they mimic the three-dimensional structure of the natural extracellular matrix (ECM). Macroporous materials possess porous structures with interconnecting channels that allow the invasive growth of cells and capillaries.

Hence, the aim of this study was to fabricate macroporous microbeads containing MBG nanofibres (MMBs). We used poly(methyl methacrylate) (PMMA) microspheres as the macroporous template in the process and removed the PMMA microspheres after the calcination treatment. Scanning electron microscopy imaging showed multiple pores on the surface of the MMBs, and a micro-computed tomography image showed the presence of pores throughout the entire microbead. The cellular attachment of MG63 osteoblast-like cells was considerably higher on the MMBs than on glass beads after culturing for 4 h. However, the cell viability greatly decreased after culturing for 1 day. We speculated that the release of a high concentration of calcium ions from the MMBs decreased the cell viability. To improve the cell viability, we modified the MMBs by immersing the MMBs in a simulated body fluid to fabricate a thin apatite layer on the surface of the MMBs. The apatite-modified MMBs (Ap-MMB) decreased the release of calcium ions and improved the cell viability. In an animal study, the bone defect in the control group did not recover. In contrast to the control group, the Ap-MMBs in the defect were nearly filled with new bone. The results show that the Ap-MMBs have great potential in osteogenesis for bone tissue engineering.

Hu, B., et al. (2019). "All-Natural Food-Grade Hydrophilic-Hydrophobic Core-Shell Microparticles: Facile Fabrication Based on Gel-Network-Restricted Antisolvent Method." Acs Applied Materials & Interfaces **11**(12): 11936-11946.

Hydrophilic-hydrophobic core-shell microparticles are highly appealing for a variety of industrial applications (foods, pharmaceutics, cosmetics, biomedicines, etc.) owing to their unique properties of moisture resistance and controlled release. However, the fabrication of such structured microparticles proves to be nontrivial due to the difficulty in assembling two materials of distinctly different hydrophilicities and hydrophobicities. This paper reports a facile method to fabricate hydrophilic-hydrophobic core-shell microparticles using all-natural food-grade polysaccharides and proteins, based on a novel principle of gel-network-restricted antisolvent precipitation. Immersion of microgel beads prepared from hydrophilic polysaccharides (i.e., alginates, kappa-carrageenan, agarose) into a hydrophobic protein solution (i.e., zein in 70% aqueous ethanol) enables slow and controllable antisolvent precipitation of a protein layer around the microbead surface, leading to the formation of a hydrophilic-hydrophobic core-shell structure. The method applies to various gelling systems and can easily tailor the particle size and shell thickness. The resulting freeze-dried microparticles demonstrate restricted swelling in water, improved moisture resistance, and sustained release of encapsulants, with great potential in applications such as protection of unstable and/or hygroscopic compounds and delivery and controlled release of drugs, bioactives, flavors, etc. The method is rather universal and can be extended to prepare more versatile core-shell structures using a large variety of hydrophilic and hydrophobic materials.

Hu, D., et al. (2019). "Microplastics and nanoplastics: would they affect global biodiversity change?" Environmental Science & Pollution Research **26**(19): 19997-20002.

Micro(nano)plastics, new emerging contaminants, are ubiquitously found in the environment due to continuous release and accumulation. Widespread micro(nano)plastics can increase their exposure to organisms, pose threats to the ecological environment and human health, and potentially result in global biodiversity changes. Research has been started on micro(nano)plastics regarding their environmental distribution, contamination sources, and methods and technologies for analysis, as well as the environmental impacts and ecological effects on organisms ingesting micro(nano)plastics. However, limited information focused on the consequences of global biodiversity has been reported and the research approaches on

biodiversity change caused by micro(nano)plastics are still seldom developed. Recently, researchers in environmental and ecological groups have begun to be conscious of the relationship between micro(nano)plastics and biodiversity. Even so, more efforts are needed to assess the impacts of micro(nano)plastics on this subject, as well as the interactions between organisms and micro(nano)plastics.

Hu, D., et al. (2019). "Micro(nano)plastics: An un-ignorable carbon source?" Science of the Total Environment **657**: 108-110.

Micro(nano)plastics, new emerging contaminants, are widely found in the environment due to continuous release. Massive and widespread presence of micro(nano)plastics may have a significant impact on the calculation of total organic carbon, and potentially result in misunderstanding of the overall environmental pollution level. Previous studies typically paid attention to the environmental distribution, source, analysis methods and technologies, as well as the environmental and ecological effects of micro(nano)plastics. However, little was aware of the total organic carbon consequences. There are few evidences for the contribution of micro(nano)plastics to total organic carbon. Accordingly, more efforts need to be taken to explore the contribution of micro(nano)plastics to total organic carbon. Copyright © 2018

Hu, E., et al. (2019). "Cotransport of naphthalene with polystyrene nanoplastics (PSNP) in saturated porous media: Effects of PSNP/naphthalene ratio and ionic strength." Chemosphere **245**: 125602.

As emerging contaminants of global concern, nanoplastics are significantly potential carriers of hydrophobic organic compounds in aquatic and soil environment. However, little is known about the interactions between the transports of nanoplastics and organic contaminants in porous media. In this study, the cotransport of naphthalene with polystyrene nanoplastics (PSNP) in saturated sand columns as influenced by the PSNP/naphthalene ratio and ionic strength (IS) was investigated. The presence of PSNP dramatically enhanced the mobility of naphthalene at low IS (0.5 mM), but such effect was prohibited at high IS (5 mM and 50 mM). The mobility of PSNP in the sand column was higher when it was solely exist in the pore-water than that when in the presence of naphthalene, because of the charge-shielding effect. This work showed that the coexistence of PSNP and naphthalene would influence the mobility of each other in the saturated porous media, which highly related to their concentration ratio and IS levels.

Hu, L., et al. (2018). "Microplastics in small waterbodies and tadpoles from Yangtze River Delta, China." Environmental Science & Technology **52**(15): 8885-8893.

Although microplastic (MP) pollution in freshwater systems is gaining attention, our knowledge of its distribution in small waterbodies is scarce. Small waterbodies are freshwater habitats to many species, including amphibians, that are vulnerable to MP pollution. This study analyzed the distribution and characteristics of MPs in 25 small waterbodies from the Yangtze River Delta, China. MPs were detected in surface water, sediment, and tadpoles with abundances ranging from 0.48 to 21.52 items L⁻¹, 35.76 to 3185.33 items kg⁻¹, and 0 to 2.73 items individual⁻¹ (0 to 168.48 items g⁻¹), respectively. The dominant shape and polymer of MPs in water and tadpole samples were polyester (PES) fibers, and polypropylene (PP) fibers and fragments were dominant in sediment samples. In addition, MPs were primarily <0.5 mm in length in all samples. Tadpole length was positively correlated to the number of MPs detected. The abundance, shape, and polymer distribution of MPs in tadpoles resembled that of water rather than sediment, suggesting that tadpoles likely take up MPs from the surrounding water. This study demonstrated that MPs are abundant in these small waterbodies and are ingested by resident tadpoles. This may suggest a pathway of MP entry into aquatic and terrestrial food webs.

Hu, L., et al. (2017). "Preparation and optimization of a novel microbead formulation to improve solubility and stability of curcumin." Particulate Science and Technology **35**(4): 448-454.

Curcumin is an active ingredient which is poorly water-soluble, leading to a low oral bioavailability. The aim of this research was to prepare a novel microbead formulation, and to solubilize, solidify, and improve storage stability of curcumin. Firstly, curcumin was solubilized with Kolliphor^{TM} RH40 and then microencapsulated by cross linking of sodium alginate with calcium chloride. A three-factor, three-level Box-Behnken design was employed to acquire the optimum microbead formulation, namely the best entrapment efficiency and in vitro curcumin release. The independent variables were sodium alginate concentration, calcium chloride concentration, and the weight of curcumin solution, while the dependent variables were entrapment efficiency and in vitro curcumin release. The optimized microbead formulation was 2.06% sodium alginate, 24.33% calcium chloride, and 1.28 g curcumin solution (containing curcumin and RH40 with a ratio of 1:22, g/g). Results showed that high concentrations of sodium alginate and calcium chloride could increase the entrapment efficiency. In vitro curcumin release decreased with increasing of sodium alginate as well as decreasing of calcium chloride. In conclusion, the optimum microbead formulation increased the solubility of curcumin and enhanced its stability, and achieved a high entrapment efficiency and in vitro curcumin release. Hu, L., et al. (2016). "Uptake, accumulation and elimination of polystyrene microspheres in tadpoles of Xenopus tropicalis." Chemosphere **164**: 611-617.

Microplastic is an emerging contaminant affecting freshwater and marine ecosystem across the globe. In the present study, the filter feeding tadpoles of Xenopus tropicalis were exposed to polystyrene microspheres (1 and 10 micro m) for 48 h. Microspheres were observed in gills and digestive tract of tadpoles within 1 h after exposure as well as in feces 6 h after exposure. The accumulation of microspheres in the tadpoles were concentration dependent (Univariate ANOVA, $p<0.001$), but no time dependent accumulation of microspheres was observed in tadpoles 48 h after exposure (Univariate ANOVA, $p>0.05$). After the exposed tadpoles were transferred to clean water, the number of microspheres in the tadpoles decreased dramatically after 1 d and continued to decrease gradually afterwards. The absorbed polystyrene particles in unfed tadpoles was significantly higher than those in the fed tadpoles at 12 and 24 h after exposure. After transfer to clean water, the fed tadpoles showed a significant decrease in the amount of absorbed polystyrene particles, while the unfed tadpoles showed no significant change in the amount of absorbed polystyrene particles. Our results suggested that microspheres were likely to be ingested and egested relatively fast by tadpoles. Our results indicated that aquatic vertebrate organisms might ingest more microplastics if the abundance of microplastics continues to increase while the available food becomes less.

Hu, S., et al. (2004). "Cell spreading controls balance of prestress by microtubules and extracellular matrix." Frontiers in Bioscience **9**: 2177-2182.

The controversy surrounds the cellular tensegrity model. Some suggest that microtubules (MTs) must bear a significant portion of cell contractile stress (prestress) if tensegrity is a useful model. Previously we have shown that for highly spread airway smooth muscle cells (areas>2500 microm2) MTs balance a significant but small potion (average 14%) of the prestress. To further explore if controlling the degree of cell spreading could modulate the portion of the prestress balanced by MTs, we utilized a recent method by which tractions are quantified in cells that are constrained within micropatterned adhesive islands of defined sizes on the surface of flexible polyacrylamide gels containing fluorescent microbeads. The prediction is that if MTs balance a portion of the contractile stress, then, upon their disruption, the portion of the stress balanced by MTs would shift to the substrate, causing an increase in traction and strain energy. We first activated the cells maximally with histamine and then disrupted the MTs with colchicine. Histamine resulted in an increase in intracellular calcium whereas ensuing colchicine addition in the presence of histamine did not change intracellular calcium concentration, suggesting there was no additional net increase in contractile stress inside the cell. We found that following disruption of MTs the increase in traction and strain energy varied with the degree of cell spreading: as the cell projected areas increased from 500 micrometer 2 to about 1800 micrometer 2, the percent increase in tractions decreased from 80% to about a few percent and the percent increase in strain energy decreased from 200% to almost zero percent, indicating the portion of the prestress balanced by MTs decreased as the cells increased spreading. These findings demonstrate that complementary role of the extracellular matrix and the MTs in balancing the prestress is controlled by the degree of cell spreading.

Hu, X. and J. M. Calo (2005). "Enhancement of liquid-fluidized bed classification (LFBC) of plastic particle mixtures via selective thermal particle modification." Powder Technology **151**(1-3): 44-53.

A novel method, based on temperature programming of the fluidizing medium, is investigated to improve the separation of complex plastic mixtures via liquid-fluidized bed classification (LFBC). Experiments were performed in a liquid-fluidized bed apparatus that was designed to operate in both upflow and downflow modes, for "heavier-than-water" and "lighter-than-water" plastic particle species, respectively. Temperature programming was achieved by using heated or cooled fluidizing feed water from two different reservoirs controlled at the desired temperatures. Binary beds of plastic mixtures of typical consumer/industrial plastics (PVC, PET, PS PC, LDPE, HDPE, and PP) were used. Due to differences in the thermal properties of the various plastic types, namely thermal diffusivities and glass transition temperatures, the experimental results show that the separation performance of LFBC can be significantly improved by selective modification of particle size/density via temperature programming of the fluidizing medium, water.

Hu, X., et al. (2016). "Development of a multiple immunoaffinity column for simultaneous determination of multiple mycotoxins in feeds using UPLC-MS/MS. (Special Section: Immunoanalysis for environmental monitoring and human health.)." Analytical and bioanalytical chemistry **408**(22): 6027-6036.

A sensitive and specific immunoaffinity column to clean up and isolate multiple mycotoxins was developed along with a rapid one-step sample preparation procedure for ultra-performance liquid chromatography-tandem mass spectrometry analysis. Monoclonal antibodies against aflatoxin B1, aflatoxin B2, aflatoxin G1, aflatoxin G2, zearalenone, ochratoxin A, sterigmatocystin, and T-2 toxin were coupled to microbeads for mycotoxin purification. We optimized a homogenization and extraction procedure as well as column loading and elution conditions to maximize recoveries from complex feed matrices. This method allowed rapid, simple, and simultaneous determination of mycotoxins in feeds with a single chromatographic run. Detection limits for these toxins ranged from 0.006 to 0.12 ng mL⁻¹, and quantitation limits ranged from 0.06 to 0.75 ng mL⁻¹. Concentration curves were linear from 0.12 to 40 micro g kg⁻¹ with correlation coefficients of R²>0.99. Intra-assay and inter-assay comparisons indicated excellent repeatability and reproducibility of the multiple immunoaffinity columns. As a proof of principle, 80 feed

samples were tested and several contained multiple mycotoxins. This method is sensitive, rapid, and durable enough for multiple mycotoxin determinations that fulfill European Union and Chinese testing criteria.

Hu, X., et al. (2012). "Epidermal cells delivered for cutaneous wound healing." Journal of Dermatological Treatment **23**(3): 224-237.

Re-epithelialization is the first and most important step in cutaneous wound healing. The vital role of epidermal cells, or keratinocytes, in accelerating wound healing has long been established. The technique of delivering the cultured and uncultured epidermal cells to the wound bed takes a variety of forms including cultured epithelial autografts (CEAs), tissue-engineered skin equivalent, epidermal suspension and microbead-loaded composite. These techniques, together with the keratinocyte culturing method and scaling up equipment, are still the ongoing research. Application of these techniques also bears direct impact on the outcome of the wounded patients. Best understanding of the delivery technique and its relationship with the culturing method and delivery vehicle could benefit not only the wounded patient but also the development of tissue-engineered skin equivalent.

Hu, Y., et al. (2019). "Current research trends on microplastic pollution from wastewater systems: a critical review." Reviews in Environmental Science and Bio/Technology **18**(2): 207-230.

Microplastics have been widely considered as contaminants for the environment and biota. Till now, most previous studies have focused on the identification and characterization of microplastics in freshwater, sea water, and the terrestrial environment. Although microplastics have been extensively detected in the wastewater, research in this area is still lacking and not thoroughly understood. To fill this knowledge gap, the current review article covers the analytical methods of microplastics originating from wastewater streams and describes their sources and occurrences in wastewater treatment plants (WWTPs). Studies indicated that microplastic pollution caused by domestic washing of synthetic fibers could be detected in the effluent; however, most microplastics from personal care and cosmetic products (PCCPs) can be efficiently removed during wastewater treatment. Moreover, various techniques for sampling and analyzing microplastics from wastewater systems are reviewed; while, the implementation of standardized protocols for microplastics is required. Finally, the fate of microplastics during wastewater treatments and the environmental contamination of effluent to environment are presented. Previous studies reported that the advanced wastewater treatment (e.g., membrane bioreactor) is needed for improving the removal efficiency of small-sized microplastics (<100 micro m). Although the role of microplastics as transport vectors for persistent organic pollutants (POPs) is still under debate, they have demonstrated abilities to absorb harmful agents like pharmaceuticals.

Hua, M., et al. (2018). "Aberrant expression of microRNAs in CD4 cells may contribute to the imbalance of Th17/Treg cells in primary immune thrombocytopenia." Blood. Conference: 60th Annual Meeting of the American Society of Hematology, ASH **132**(Suppl. 1).

Backgrounds:Primary immune thrombocytopenia (ITP) is an acquired autoimmune disease characterized by reduced platelet count and an increased risk of bleeding. The imbalance of Treg/Th17 cells has been demonstrated in ITP, but the mechanism of Th17/Treg cells imbalance is still not clear. In this study, we aimed to investigate whether the expression of helper T (Th) or Treg cell-related microRNAs, such as miR-183-96-182 cluster, miR-17-5p, miR-99a, miR-146-5p, miR-155-5p, miR-181-5p, and miR-326, regulates the ratio of Th17/Treg in CD4 T cells and could be used to evaluate the clinical implications of ITP patients. Method(s): Peripheral blood was

obtained from 54 patients with active ITP and 34 healthy controls. Peripheral blood mononuclear cells (PBMCs) were isolated using Ficoll density-gradient centrifugation and the CD4 cells were separated by immuno-magnetic microbeads selection. Amplification technique of RT-PCR using stem-loop primers was applied to detect the relative expression of microRNAs (miR-17-5p, miR-99a, miR-96-5p, miR- 146a-5p, miR-155-5p, miR-181a-5p, miR-182-5p, miR-183-5, miR-326) and U6 was normalized as control for miRNA quantification. The frequencies of Th17 and Treg cells in peripheral blood were analyzed by flow cytometry. The mRNA expression levels of Il-6, Il-10, Il-17, Rorgamma-t and Foxp-3 in CD4 cells were determined by RT-PCR. Platelet autoantibodies specific for GPIIb/IIIaor GPIb/IX were measured using MAIPA method. CD4+ cells were transfected with miRNAs (miR-99a, miR-182-5p, miR-183-5), mimics or inhibitors, which were used to detect the function of miRNAs. Cytokines in culture medium were determined by ELISA. Result(s): Our results showed that the relative expression of miR-182-5p and miR-183-5p in CD4 cells was significantly increased in active ITP patients, compared to healthy controls (miR-182-5p, median 9.2678 vs 5.2723, $p < 0.05$, Fig. 1a; miR-183-5p, median 5.4435 vs 2.009, $p < 0.05$, Fig. 1b). In addition, the relative expression of miR-99a in ITP patients was lower than that of healthy controls (median 3.4214 vs 7.9648, $p < 0.05$; Fig. 1c). Moreover, the frequency of Treg cells decreased significantly in ITP patients compared to those in controls (1.89+/-1.59% vs 4.12+/-1.42%, $p < 0.05$; Fig. 2a), and the percentage of Treg cells was positively correlated with the relative expression of miR-99a in ITP patients(r=0.461, p< 0.05; Fig. 2c) and health controls(r=0.729, p< 0.05; Fig. 2d). Though the percentage of Th17 cells increased in ITP patients compared to the health controls (3.51+/-2.13%vs 1.85+/-0.63%, $p < 0.05$; Fig. 2b), there was no correlation between the percentage of Th17 and the relative expression of microRNAs in ITP patients or health controls. Besides, there was no correlation between the expression of mRNAs (Il-10, Il-17, Rorgamma-t and Foxp-3) and microRNAs (miR-99a, miRNA-182-5p or miR-183-5p). No significant correlation was found between the microRNAs expression and platelets counts or different autoantibody subsets in ITP patients. The relative expression of other microRNAs (miR-17-5p, miR-96-5p, miR-146a-5p, miR- 155-5p, miR-181-5p, miR-326) revealed no difference in CD4 cells between ITP patients and health controls. Furthermore, the down-regulated expression of miR-183-5p with inhibitors promoted to the differentiation of Th17 cells(Fig. 3a), while up-regulated expression of miR-99a with mimics contributed to Treg cells in CD4 cells from ITP patients (Fig. 3b). Meanwhile, the IL-17A in culture medium decreased in inhibitor group of miR-183-5p or miR-183-5p. However, miR-182-5p inhibitor had no effect on the differentiation of Th17 cells. Conclusion(s): Our results show the abnormal expression of microRNAs (miR-99a, miRNA-182-5p and miR-183-5p) in CD4 cells and the miR-99a was closely correlated with the Treg cells. The aberrant expression of microRNAs may contribute to the imbalance of Th17/Treg cells in the development of ITP patients and potentially constitute a novel therapeutic target. (Figure Presented).

Hua, M., et al. (2018). "NLRP3 inflammsome activation in pbmcs controls the T cell response in adult patients with chronic immune thrombocytopenia." HemaSphere **2 (Supplement 2)**: 393.

Background: Immune thrombocytopenia (ITP) is an acquired autoimmune disorder, which is characterized by imbalanced adaptive immunity of T cells. NLRP3 inflammasome has recently been reported to be involved in diverse inflammatory or immune diseases. However, NLRP3 inflammasome activation in the pathophysiology of ITP remains unclear. Aim(s): To explore the effects of NLRP3 inflammsome activation on the T cells in adult patients with chronic ITP. Method(s): Peripheral blood was obtained from 28 adult patients with chronic ITP. PBMCs were isolated using Ficoll density-gradient centrifugation and the CD4+ cells were purified by positive immuno-magnetic microbeads selection. The PBMCs, CD4+ or CD8+ cells were primed with LPS, then stimulated with ATP and finally cultured in plate-bound anti-human CD3 and soluble anti-human CD28 plus IL-2. After four days, the percentage of CD4+ cells and CD8+ cells, the T helper cell subsets (Th cells) of Th1, Th2, Th17 and T-reg cells, the inhibitory molecules, PD1 and CTLA4, and the CFSE-labeled cells were analyzed by flow cytometry. IFN-gamma, IL-4, IL-17 and TGF-beta in cultured supernatants were assayed by ELISA. The mRNA expression level of cytokines associated with Th cells (Ifn-gamma, Il-6, IL-10, Il-17), the key transcription factors of Th cells (T-bet, Gata3, Foxp3, Ror-gammat) and the inhibitory molecules (Ctla-4, Btla, Tim3, Lag3, Pd1 and Vista) was determined by Real-Time PCR. Result(s):We found that NLRP3 inflammasome activation in PBMCs initiated caspase-1-dependent IL-1beta secretion, and thereby weakened the Th1 cell differentiation (unstimulated control 13.3% vs. stimulation 5.3%; p=0.015), which can be restored, at least in part, by caspase-1 inhibitor Z-YVADFMK (Figure 1). The production of IFN-gamma and the expression of Ifn-gamma, were significantly down-regulated after NLRP3 inflammsome activation. However, the percentage of Th2 or Th17 was not significantly different between the stimulated and unstimulated groups. Meanwhile, the percentage of Treg cells was also decreased after stimulation by LPS plus ATP in PBMCs (unstimulated control 6.67% vs. stimulation 4.39%; p=0.033). More importantly, NLRP3 inflammasome activation significantly suppressed the proliferation but didn't induce the apoptosis of CD4+ cells and CD8+ cells (Figure 2). Accordingly, the mRNA expression of inhibitory molecules (Ctla-4, Btla, Tim3, Pd1 and Vista) of T cells and the PD1 or CTLA4 (Figure 3) on the membrane surface of CD4+ and CD8+ cells were up-regulated after the activation of NLRP3 inflammasome in PBMCs. Furthermore, the percentage of CD8+ cells significantly decreased after NLRP3 inflammasome activation in PBMCs. However, LPS plus ATP took no effect on purified CD4+ or CD8+ cells in contrast with PBMCs. Summary/Conclusion: NLRP3 inflammsome-mediated innate immune reaction may play an important role in controlling the T cell responses of adaptive immunity by the inhibitory molecules and might prevent disease progression in adult chronic ITP. (Figure Presented).

Huang, D., et al. (2011). "Losartan inhibits oxidized-low density lipoprotein induced immune maturation of dendritic cells." European Heart Journal **1)**: 511.

Purpose: The angiotensin II receptor blocker (ARB) has generally been shown to have anti-inflammatory effects and dendritic cells (DCs) are the most efficient antigen presenting cells that play an active role in the development of atherosclerosis through inflammatory-immune responses. The effects of ARB on DCs maturation and immune function remain unknown and we, therefore, studied the influence of ARB losartan on the maturation and immune function of DCs. Method(s): Peripheral blood mononuclear cells were obtained from healthy volunteers by density gradient centrifugation. Human monocytes were purified using CD14+ immunomagnetic micro beads and incubated in RPMI-1640 medium supplemented with GM-CSF (100ng/mL) and IL-4 (50ng/mL). After 5 days, immature DCs were derived. Losartan (1, 10 and 100mumol/L) was added to the medium for 24 hours. Ox-LDL (50mug/ml) was then added to the medium for another 24 hours. The immunophenotypic expressions (CD1a, CD40, CD83, CD86 and HLADR) were analyzed by FACS. The capacity of DCs to stimulate T-cell proliferation was measured by allogenic mixed lymphocyte reaction (MLR). To understand the anti-inflammatory mechanisms of losartan, the angiotensin II secretions of culture supernatants of ox-LDL (10, 50 and 100mug/ml) were measured with ELISA. We also studied the effects of ox-LDL and angiotensin II (0.1, 1 and 10mumol/L) on the maturation of DCs and the expressions of scavenger receptors (SR-A, CD36 and LOX-1) on DCs. Result(s): (1) Ox-LDL and angiotensin IIinduced DCs maturation accompanied with increased expressions of CD1a, CD40, CD83, CD86 and HLA-DR. The capacity of DCs to stimulate T-cell proliferation was also enhanced by ox-LDL and angiotensin II. (2)

Ox-LDL enhanced the secretion of angiotensin IIof DCs in a concentration-dependent manner. (3) Losartan reduced ox-LDL-induced immunophenotypic expressions and capacity to stimulate T-cell proliferation of DCs. (4) Ox-LDL and angiotensin II significantly upregulated SR-A and LOX-1, other than CD36, expression on DCs and the upregulation was attenuated by losartan. (5) Ox-LDL-induced immunophenotypic expression was partly inhibited by either an anti-LOX-1 or anti-SR-A neutralizing antibody. Conclusion(s): Losartan could inhibit the ox-LDL-induced maturation and immune function of DCs partly through attenuated the effect of angiotensin II secreted by DCs which was enhanced by ox-LDL. SR-A and LOX-1 played an important role in the ox-LDL- or angiotensin II- induced DCs maturation. These findings might explain in part the interactive roles of ox-LDL, renin-angiotensin system (RAS) and DCs in the processes of atherosclerosis.

Huang, D. Y., et al. (2013). "Pollution characteristics of volatile organic compounds, polycyclic aromatic hydrocarbons and phthalate esters emitted from plastic wastes recycling granulation plants in Xingtan Town, South China." Atmospheric Environment **71**: 327-334.

With the aim to investigate the main pollution characteristics of exhaust gases emitted from plastic waste recycling granulation plants, mainly volatile organic compounds (VOCs), polycyclic aromatic hydrocarbons (PAHs) and phthalate esters (PAEs) were analyzed in Xingtan Town, the largest distribution center of plastic waste recycling in China. Both inside and outside the plants, the total concentrations of volatile monocyclic aromatic hydrocarbons (MAHs), PAHs and PAEs ranged from 2000 to 3000 mug m⁻³, 450 to 1200 ng m⁻³, and 200 to 1200 ng m⁻³, respectively. Their concentration levels inside the plants were higher than those outside the plants, and PAHs and PAEs were mainly distributed in the gas-phase. Notably, highly toxic benzo[a]pyrene (BaP) could be detected inside the plants, and harmful PAEs could be detected not only inside but also outside the plants, although PAEs are non-volatile. The exhaust gas composition and concentration were related to the plastic feedstock and granulation temperature. © 2013 Elsevier Ltd.

Huang, F. Y., et al. (2019). "[Effects of Microplastics on Antibiotic Resistance Genes in Estuarine Sediments]." Huanjing Kexue/Environmental Science **40**(5): 2234-2239.

Microplastics and antibiotic resistance genes (ARGs) are emerging pollutants/contaminants, and are also the research hotspots concerning environmental health in the past few years. To explore the effects of microplastics on ARGs in estuarine sediment, three different microplastics were added to microcosm incubation experiments of sediments. Then, we investigated the persistence, abundance, diversity, and shifts of the ARGs in estuarine sediments by high-throughput quantitative polymerase chain reaction (PCR). The results showed that the microplastics significantly changed the structure of ARGs in the sediments. PVC and PE, which are hard to degrade, had significant effects on the structures and types of ARGs. However, the PVA, which is soluble, reduced the types and persistence of ARGs significantly. The abundance of ARGs in S_PVC, S_PE, and S_PVA were 4.1x10⁹, 8.1x10⁹, and 2.0x10⁹ copies.g⁻¹, respectively. The abundance of ARGs in sediments with added PE almost increased by one order of magnitude, implying that microplastics could significantly increase the abundance of ARGs in sediments. Furthermore, OLS regression analysis showed that ARGs are significantly correlated with transposon and integron, suggesting that mobile genetic elements (MGEs) may promote the transfer and dissemination of ARGs.

Huang, H., et al. (2017). "Hexabromocyclododecanes in soils and plants from a plastic waste treatment area in North China: occurrence, diastereomer- and enantiomer-specific profiles, and metabolization."

Environmental Science & Pollution Research **24**(27): 21625-21635.

Plastic waste is a source of organic contaminants such as hexabromocyclododecanes (HBCDs). HBCDs have been found to cause developmental and reproductive toxicity; it is important to investigate the occurrence and metabolization of HBCDs in the soil environments with plastic waste contamination. This work analyzed HBCDs and their metabolites in soil and plant samples collected from Xinle and Dingzhou-the major plastic waste recycling centers in North China.

Huang, H., et al. (2019). "Biodegradation of Structurally Diverse Phthalate Esters by a Newly Identified Esterase with Catalytic Activity toward Di(2-ethylhexyl) Phthalate." Journal of Agricultural & Food Chemistry **67**(31): 8548-8558.

Herein, we report a double enzyme system to degrade 12 phthalate esters (PAEs), particularly bulky PAEs, such as the widely used bis(2-ethylhexyl) phthalate (DEHP), in a one-pot cascade process. A PAE-degrading bacterium, Gordonia sp. strain 5F, was isolated from soil polluted with plastic waste. From this strain, a novel esterase (GoEst15) and a mono(2-ethylhexyl) phthalate hydrolase (GoEstM1) were identified by homology-based cloning. GoEst15 showed broad substrate specificity, hydrolyzing DEHP and 10 other PAEs to monoalkyl phthalates, which were further degraded by GoEstM1 to phthalic acid. GoEst15 and GoEstM1 were heterologously coexpressed in Escherichia coli BL21 (DE3), which could then completely degrade 12 PAEs (5 mM), within 1 and 24 h for small and bulky substrates, respectively. To our knowledge, GoEst15 is the first DEHP hydrolase with a known protein sequence, which will enable protein engineering to enhance its catalytic performance in the future.

Huang, H., et al. (2009). "Rapid analysis of alpha-fetoprotein by chemiluminescence microfluidic immunoassay system based on super-paramagnetic microbeads." Biomedical Microdevices **11**(1): 213-216.

A rapid and sensitive chemiluminescence microfluidic immunoassay system based on super-paramagnetic microbeads for determination of alpha-fetoprotein (AFP) is described. In this system we use CO(2) laser to fabricate microfluidic chip, and use super-paramagnetic microbeads as solid carrier of antibody, chemiluminescence as detection signal. With this system we can perform AFP analysis within 20 min, and the linear range of AFP concentration is 1 approximately 800 ng/mL, the detection limit is 0.23 ng/mL. By this method no separation or preconcentration steps are needed. Most of all, the chip can be reused.

Huang, J. S., et al. (2020). "Microplastic accumulation in fish from Zhanjiang mangrove wetland, South China." Science of the Total Environment **708**: 134839.

Microplastics (MPs) are widespread in marine and estuarine environments, but the contamination of MPs in mangrove wetlands is relatively unknown. Here, we quantify the presence of MPs in fish collected from Zhanjiang mangrove wetland, the largest mangrove in South China, which provide baseline data on MPs accumulation in fish in mangrove environment as the first evidence in China. MPs were found in 30 out of 32 fish species at an average abundance of 2.83+/-1.84items individual⁻¹, ranged from 0.6 to 8.0items individual⁻¹ in each species. MPs were detected in gills, stomach and intestine, and not found in muscles and livers. Positive relationship was found between MPs abundance and body length or weight of mangrove fish. The dominant polymers identified by micro-FTIR were polyethylene, polyethylene terephthalate, polypropylene and cellophane. MPs consisted primarily of fibers and with the prominent size range of 0.02-1mm. The body sizes, living habitats and feeding habits of fish are important factors affecting MPs accumulation in different fish species. This study revealed the wide presences of MPs in fish species within a mangrove wetland.

Huang, L. and X. Fang (2008). "Immunoaffinity fractionation of plasma proteins by chicken IgY antibodies." Methods in Molecular Biology **425**: 41-51.

Separation of complex mixtures having a wide dynamic range of protein concentration, such as plasma or serum, presents a significant challenge for proteomic analysis. Immunoaffinity fractionation is one of the most effective methods used during sample preparation to improve the ability to detect low-abundant proteins (LAP), enhancing biomarker discovery. Avian IgY (Immunoglobulin Yolk) antibodies have unique and advantageous features, which include strong avidity, high specificity, low nonspecific binding, and accumulative production. Polyclonal IgY antibodies covalently coupled to microbeads are particularly effective in specifically removing high-abundant proteins (HAP) from plasma, serum, CSF, urine, and other body fluid or cellular sources. IgY-12 is a composition of IgY microbeads designed for one-step removal of the 12 most abundant proteins in human serum or plasma: albumin, IgG, transferrin, fibrinogen, alpha1-antitrypsin, IgA, IgM, alpha2-macroglobulin, haptoglobin, apolipoproteins A-I and A-II, and orosomucoid (alpha1-acid glycoprotein). Removal of the 12 HAPs enables improved resolution and dynamic range for one-dimensional gel electrophoresis (1DGE), two-dimensional gel electrophoresis (2DGE), and liquid chromatography/mass spectrometry (LC/MS).

Huang, L., et al. (2005). "Immunoaffinity separation of plasma proteins by IgY microbeads: meeting the needs of proteomic sample preparation and analysis." Proteomics **5**(13): 3314-3328.

Separation of complex protein mixtures that have a wide dynamic range of concentration, such as plasma or serum, is a challenge for proteomic analysis. Sample preparation to remove high-abundant proteins is essential for proteomics analysis. Immunoglobulin yolk (IgY) antibodies have unique and advantageous features that enable specific protein removal to aid in the detection of low-abundant proteins and biomarker discovery. This report describes the efficiency and effectiveness of IgY microbeads in separating 12 abundant proteins from plasma with an immunoaffinity spin column or LC column. The protein separation and sample preparation process was monitored via SDS-PAGE, 2-DE, LC-MS/MS, or clinical protein assays. The data demonstrate the high specificity of the protein separation, with removal of 95-99.5% of the abundant proteins. IgY microbeads against human proteins can also selectively remove orthologous proteins of other mammals such as mouse, rat, etc. Besides the specificity and reproducibility of the IgY microbeads, the report discusses the factors that may cause potential variations in protein separation such as protein-protein interactions (known as "Interactome"), binding and washing conditions of immunoaffinity reagents, etc. A novel concept of Seppromics is introduced to address methodologies and science of protein separation in a context of proteomics.

Huang, M. C. and J. J. Lin (2008). "Characteristics and management of infectious industrial waste in Taiwan." Waste Management **28**(11): 2220-2228.

Infectious industrial waste management in Taiwan is based on the specific waste production unit. In other countries, management is based simply on whether the producer may lead to infectious disease. Thus, Taiwan has a more detailed classification of infectious waste. The advantage of this classification is that it is easy to identify the sources, while the disadvantage lies in the fact that it is not flexible and hence increases cost. This study presents an overview of current management practices for handling infectious industrial waste in Taiwan, and addresses the current waste disposal methods. The number of small clinics in Taiwan increased from 18,183 to 18,877 between 2003 and 2005. Analysis of the data between 2003 and 2005 showed

that the majority of medical waste was general industrial waste, which accounted for 76.9%-79.4% of total medical waste. Infectious industrial waste accounted for 19.3%-21.9% of total medical waste. After the SARS event in Taiwan, the amount of infectious waste reached 19,350 tons in 2004, an increase over the previous year of 4000 tons. Waste minimization was a common consideration for all types of waste treatment. In this study, we summarize the percentage of plastic waste in flammable infectious industrial waste generated by medical units, which, in Taiwan was about 30%. The EPA and Taiwan Department of Health have actively promoted different recycling and waste reduction measures. However, the wide adoption of disposable materials made recycling and waste reduction difficult for some hospitals. It has been suggested that enhancing the education of and promoting communication between medical units and recycling industries must be implemented to prevent recyclable waste from entering the incinerator.

Huang, Q., et al. (2020). "Modelling the global impact of China's ban on plastic waste imports." Resources, Conservation and Recycling **154 (no pagination)**(104607).

China has long been the world's leading plastic waste importer. However, in January 2018 the Chinese Government enacted a new policy to permanently ban the import of most plastic waste into the country. This raises an important question: what will the impact of this policy be both domestically and globally? It is argued that the answer to this question can in part be systematically revealed by employing three methods of analysis. (1) A combined multiregional input-output model with structural path analysis (SPA) to understand how consumption patterns domestically and globally drive China's plastic waste imports. (2) An ecological network analysis to identify which region is the dominant controller of the global plastic waste trade network. Lastly, (3) a hypothetical extraction method to investigate the value-added change for China and the increased requirement of waste treatment capacity for other economies. The results indicate that the imported plastic waste was mainly driven by China's domestic consumption of products containing recycled plastic. Given this demand, it is recommended that the Chinese Government undertake various actions to increase local plastic waste recycling to compensate for the loss of recycled plastic material since the import ban took place. China is a dominant controller, along with the US, the European Union and Germany of the global plastic waste trade network. At this stage it is not possible for other large economies to replace the role of China in the short term. China's waste import ban caused a minor economic loss for China, however, it has resulted in the need for other economies to increase their waste treatment capacity. As well as increasing local plastic waste recycling, it is recommended the Chinese Government consider reopening imports for high quality recycled material and to seek global collaboration, which would not only ease the shortage of recycled plastic material but also buy time for other economies to build new waste treatment plants. Huang, Q., et al. (2018). "Gelatin Nanoparticle-Coated Silicon Beads for Density-Selective Capture and Release of Heterogeneous Circulating Tumor Cells with High Purity." Theranostics **8**(6): 1624-1635.

Background: Circulating tumor cells (CTCs) are a burgeoning topic in cancer biomarker discovery research with minimal invasive blood draws. CTCs can be used as potential biomarkers for disease prognosis, early cancer diagnosis and pharmacodynamics. However, the extremely low abundance of CTCs limits their clinical utility because of technical challenges such as the isolation and subsequent detailed molecular and functional characterization of rare CTCs from patient blood samples. Methods: In this study, we present a novel density gradient centrifugation method employing biodegradable gelatin nanoparticles coated on silicon beads for the isolation, release, and downstream analysis of CTCs from colorectal and breast cancer

patients. Results: Using clinical patient/spiked samples, we demonstrate that this method has significant CTC-capture efficiency (>80%) and purity (>85%), high CTC release efficiency (94%) and viability (92.5%). We also demonstrate the unparalleled robustness of our method in downstream CTC analyses such as the detection of PIK3CA mutations. Conclusion: The efficiency and versatility of the multifunctional density microbeads approach provides new opportunities for personalized cancer diagnostics and treatments.

Huang, X., et al. (2015). "A Dual-Mode Large-Arrayed CMOS ISFET Sensor for Accurate and High-Throughput pH Sensing in Biomedical Diagnosis." IEEE Transactions on Biomedical Engineering **62**(9): 2224-2233.

GOAL: The existing ISFET-based DNA sequencing detects hydrogen ions released during the polymerization of DNA strands on microbeads, which are scattered into microwell array above the ISFET sensor with unknown distribution. However, false pH detection happens at empty microwells due to crosstalk from neighboring microbeads. In this paper, a dual-mode CMOS ISFET sensor is proposed to have accurate pH detection toward DNA sequencing.

METHODS: Dual-mode sensing, optical and chemical modes, is realized by integrating a CMOS image sensor (CIS) with ISFET pH sensor, and is fabricated in a standard 0.18-mum CIS process. With accurate determination of microbead physical locations with CIS pixel by contact imaging, the dual-mode sensor can correlate local pH for one DNA slice at one location-determined microbead, which can result in improved pH detection accuracy. Moreover, toward a high-throughput DNA sequencing, a correlated-double-sampling readout that supports large array for both modes is deployed to reduce pixel-to-pixel nonuniformity such as threshold voltage mismatch.

RESULTS: The proposed CMOS dual-mode sensor is experimentally examined to show a well correlated pH map and optical image for microbeads with a pH sensitivity of 26.2 mV/pH, a fixed pattern noise (FPN) reduction from 4% to 0.3%, and a readout speed of 1200 frames/s.

CONCLUSION: A dual-mode CMOS ISFET sensor with suppressed FPN for accurate large-arrayed pH sensing is proposed and demonstrated with state-of-the-art measured results toward accurate and high-throughput DNA sequencing.

SIGNIFICANCE: The developed dual-mode CMOS ISFET sensor has great potential for future personal genome diagnostics with high accuracy and low cost.

Huang, Y., et al. (2019). "Distribution characteristics of microplastics in Zhubi Reef from South China Sea." Environmental Pollution **Part 1. 255 (no pagination)**(113133).

As a new type of emerging pollutant in the ocean, microplastics have received global attention in recent years. Considering the increasing amount of human activities around the South China Sea, it is important to determine the current status of microplastic pollution in this region. In this study, we analyzed the abundance and distribution of microplastics at Zhubi Reef in the South China Sea. Microplastic abundance ranged from 1400 to 8100 items/m³ of surface water, which was much higher than the values reported from other ocean areas. About 80% of the microplastics were smaller than 0.5 mm in size. Fibers and pellets comprised the most common microplastic types. The dominant microplastics were transparent or blue in color. The main polymer types were polypropylene (25%) and polyamide (18%). In general, our results revealed Zhubi Reef was contaminated with microplastics, which were likely derived from the intensive fisheries in the area and emissions from coastal cities. This study also provides baseline data that are useful for additional studies of microplastics in the South China Sea. Microplastics pollution in South China Sea. Copyright © 2019 Elsevier Ltd

Huang, Y., et al. (2019). "LDPE microplastic films alter microbial community composition and enzymatic activities in soil." Environmental Pollution **254**(Pt A): 112983.

Concerns regarding microplastic contamination have spread from aquatic environments to terrestrial systems with a growing number of studies have been reported. Notwithstanding, the potential effects on soil ecosystems remain largely unexplored. In this study, the effects of polyethylene microplastics on soil enzymatic activities and the bacterial community were evaluated, and the microbiota colonizing on microplastics were also investigated. Microplastic amendment (2000 fragments per kg soil) significantly increased the urease and catalase activities in soil after 15 days, and no discernible alteration of invertase activities was detected.

Huang, Z., et al. (2019). "Sustainable, Reshapable Surfactant-Polyelectrolyte Plastics Employing Water as a Plasticizer." Acs Applied Materials & Interfaces **11**(34): 31311-31316.

Natural polymers such as those present in foods contain abundant noncovalent intra- and intermolecular interactions, notably hydrogen bonds, which make them rigid when dry, but on exposure to water soften, due to disruption of these interactions. This softening process allows them to be reshaped. Food-derived materials, however, have limited practical use due to their high brittleness and gradual degradation. Nevertheless, inspired by such properties, surfactant-polyelectrolyte-based polymers that contain abundant ionic interactions and can be repeatedly reshaped using water as plasticizer are described. The polymers, on the basis of main chain anionic poly(styrene sulfonates) combined with phosphonium surfactant, are readily synthesized with well-defined lamellar domains through interfacial metathesis reactions. The polymers present typical stress-strain characteristics of plastics, and their modulus undergoes a decrease of ca. 3 orders of magnitude upon shear and stretch forces after plasticizing with water. Since recycling of plastics generally involves complicated and energy-intensive processes (that leads to the majority of plastics being land-filled or incinerated), it is envisaged that reshapable polymers, such as those described here, could reduce the amount of plastic waste as they can be remolded as and when required, thus reducing pollution and the depletion of resources, ultimately contributing to a more sustainable society.

Hua-Shan, T. and C. You-Shen (2007). "Mixing Recovered Waste Fiber-Reinforced Plastic with Polyethylene Plastic Waste." Practice Periodical of Hazardous, Toxic & Radioactive Waste Management **11**(3): 158-163.

Polyblending was applied to mix waste fiber-reinforced plastic (FRP) and polyethylene (PE) plastic waste in various proportions and particle sizes. Compatibility, morphology, mechanical properties, and dynamical mechanical analyses of the matrix composites were used as indices to justify the physical behaviors of composites. Differential scanning calorimetry measurements and scanning electron microscopy observations showed that PE and FRP in the blends were incompatible. The mechanical strengths of blends were decreased if the FRP ratio or particle size increased. Results of tensile and impact strength tests indicated that the blends had a brittle property. The loss tangent (tan δ) of dynamical mechanical analysis also increased with the increase of the FRP ratio and particle size. These results reveal a weakening interaction between the FRP and plastic matrix. As PE lost ability to cover FRP, external forces were unable to be transferred or dispersed properly across the composite matrix. This increased the tendency of the blends to fracture. [ABSTRACT FROM AUTHOR]

Hübner, M., et al. (2019). "Myeloid-Derived Suppressor Cells Mediate Immunosuppression After Cardiopulmonary Bypass." Critical Care Medicine **47**(8): e700-e709.

OBJECTIVESCardiopulmonary bypass is associated with severe immune dysfunctions. Particularly, a cardiopulmonary bypass-related long-lasting immunosuppressive state predisposes patients to a higher risk of postoperative complications, such as persistent bacterial infections. This study was conducted to elucidate mechanisms of post-cardiopulmonary bypass immunosuppression.DESIGNIn vitro studies with human peripheral blood mononuclear cells.SETTINGCardiosurgical ICU, University Research Laboratory.PATIENTSSeventy-one patients undergoing cardiac surgery with cardiopulmonary bypass (enrolled May 2017 to August 2018).INTERVENTIONSPeripheral blood mononuclear cells before and after cardiopulmonary bypass were analyzed for the expression of immunomodulatory cell markers by real-time quantitative reverse transcription polymerase chain reaction. T cell effector functions were determined by enzyme-linked immunosorbent assay, carboxyfluorescein succinimidyl ester staining, and cytotoxicity assays. Expression of cell surface markers was assessed by flow cytometry. CD15 cells were depleted by microbead separation. Serum arginine was measured by mass spectrometry. Patient peripheral blood mononuclear cells were incubated in different arginine concentrations, and T cell functions were tested.MEASUREMENTS AND MAIN RESULTSAfter cardiopulmonary bypass, peripheral blood mononuclear cells exhibited significantly reduced levels of costimulatory receptors (inducible T-cell costimulator, interleukin 7 receptor), whereas inhibitory receptors (programmed cell death protein 1 and programmed cell death 1 ligand 1) were induced. T cell effector functions (interferon γ secretion, proliferation, and CD8-specific cell lysis) were markedly repressed. In 66 of 71 patients, a not yet described cell population was found, which could be characterized as myeloid-derived suppressor cells. Myeloid-derived suppressor cells are known to impair immune cell functions by expression of the arginine-degrading enzyme arginase-1. Accordingly, we found dramatically increased arginase-1 levels in post-cardiopulmonary bypass peripheral blood mononuclear cells, whereas serum arginine levels were significantly reduced. Depletion of myeloid-derived suppressor cells from post-cardiopulmonary bypass peripheral blood mononuclear cells remarkably improved T cell effector function in vitro. Additionally, in vitro supplementation of arginine enhanced T cell immunocompetence.CONCLUSIONSCardiopulmonary bypass strongly impairs the adaptive immune system by triggering the accumulation of myeloid-derived suppressor cells. These myeloid-derived suppressor cells induce an immunosuppressive T cell phenotype by increasing serum arginine breakdown. Supplementation with L-arginine may be an effective measure to counteract the onset of immunoparalysis in the setting of cardiopulmonary bypass.

Huerta Lwanga, E., et al. (2017). "Field evidence for transfer of plastic debris along a terrestrial food chain." Scientific Reports **7**(1).

Although plastic pollution happens globally, the micro- (<5 mm) and macroplastic (5-150 mm) transfer of plastic to terrestrial species relevant to human consumption has not been examined. We provide first-time evidence for micro- and macroplastic transfer from soil to chickens in traditional Mayan home gardens in Southeast Mexico where waste mismanagement is common. We assessed micro- and macroplastic in soil, earthworm casts, chicken feces, crops and gizzards (used for human consumption). Microplastic concentrations increased from soil (0.87+or-1.9 particles g⁻¹), to earthworm casts (14.8+or-28.8 particles g⁻¹), to chicken feces (129.8+or-82.3 particles g⁻¹). Chicken gizzards contained 10.2+or-13.8 microplastic particles, while no microplastic was found in crops. An average of 45.82+or-42.6 macroplastic particles were found per gizzard and 11+or-15.3 macroplastic particles per crop, with 1-10 mm particles being significantly more abundant per gizzard (31.8+or-27.27 particles) compared to the crop (1+or-2.2 particles). The data show that micro- and macroplastic are capable of entering terrestrial food webs.

Huffer, T. and T. Hofmann (2016). "Sorption of non-polar organic compounds by micro-sized plastic particles in aqueous solution." Environmental Pollution **214**: 194-201.

The presence of microscale polymer particles (i.e., microplastics) in the environment has become a major concern in recent years. Sorption of organic compounds by microplastics may affect the phase distribution within both sediments and aqueous phases. To investigate this process, isotherms were determined for the sorption of seven aliphatic and aromatic organic probe sorbates by four polymers with different physico-chemical properties. Sorption increased in the order polyamide < polyethylene < polyvinylchloride < polystyrene. This order does not reflect the particle sizes of the investigated microplastics within the aqueous dispersions, indicating the influence of additional factors (e.g., pi-pi-interactions) on the sorption of aromatic compounds by polystyrene. Linear isotherms by polyethylene suggested that sorbate uptake was due to absorption into the bulk polymer. In contrast, non-linear isotherms for sorption by PS, PA, and PVC suggest a predominance of adsorption onto the polymer surface, which is supported by the best fit of these isotherms using the Polanyi-Manes model. A strong relationship between the sorption coefficients of the microplastics and the hydrophobicity of the sorbates suggests that hydrophobic interactions are of major importance.

Huffer, T., et al. (2019). "Polyethylene microplastics influence the transport of organic contaminants in soil." Science of the Total Environment **657**: 242-247.

Plastics are now found in all natural environments including soil. The effects of microplastics in terrestrial systems, however, remain largely unexplored. Polyethylene is one of the mass-manufactured polymers found in terrestrial environments. It is used in many different sectors, for example in agricultural mulches, composite materials, and packaging. The presence of microplastics in soil, including polyethylene, can affect the transport of hydrophobic organic pollutants including pesticides. The objective of this study was to investigate the influence of polyethylene microplastics (<250mum) on the transport of two selected organic plant-protection agents (atrazine and 4-(2,4-dichlorophenoxy) butyric acid) in soil under different aqueous conditions, using inverse liquid chromatography. The distribution coefficients for the sorbates that were sorbed to pure polyethylene microplastic were found to be significantly smaller than those for the sorbates sorbed to pure soil. The addition of 10% (w/w) polyethylene to the soil therefore led to an overall reduction in sorption, but the sorption trends due to variations in pH and ionic strength were not affected. The results imply that the presence of polyethylene microplastics in soil may therefore increase the mobility of organic contaminants by reducing the sorption capacity of natural soils, which must be validated by further research.

Huffer, T., et al. (2017). "Microplastic Exposure Assessment in Aquatic Environments: Learning from Similarities and Differences to Engineered Nanoparticles." Environmental Science & Technology **51**(5): 2499-2507.

Microplastics (MPs) have been identified as contaminants of emerging concern in aquatic environments and research into their behavior and fate has been sharply increasing in recent

years. Nevertheless, significant gaps remain in our understanding of several crucial aspects of MP exposure and risk assessment, including the quantification of emissions, dominant fate processes, types of analytical tools required for characterization and monitoring, and adequate laboratory protocols for analysis and hazard testing. This Feature aims at identifying transferrable knowledge and experience from engineered nanoparticle (ENP) exposure assessment. This is achieved by comparing ENP and MPs based on their similarities as particulate contaminants, whereas critically discussing specific differences. We also highlight the most pressing research priorities to support an efficient development of tools and methods for MPs environmental risk assessment.

Huffer, T., et al. (2019). "The molecular interactions of organic compounds with tire crumb materials differ substantially from those with other microplastics." Environmental Science. Processes & Impacts **06**: 06.

Tire materials are the most commonly found elastomers in the environment and they account for a significant fraction of microplastic pollution. In the discussions on the environmental impact of microplastics tire materials and their sorption properties have been largely overlooked. In this study we used experimental sorption data from six organic probe sorbates sorbing to two tire materials and their major components, styrene butadiene rubber and carbon black, to gain a better understanding of the underlying sorption processes of tire materials. Commonly applied models used to describe non-linear sorption processes were unable to fully explain sorption to tire materials but showed that absorption into the rubber fraction dominated the sorption process. Hydrophobicity was approximated using the hexadecane-water partitioning constant, which correlated very well with the distribution data obtained for styrene rubber, whereas the correlations between hydrophobicity of sorbates and the sorption data to the tire materials were poor. Although hydrophobicity plays an important role in sorption to tire materials, additional interactions must be taken into account. Overall, the processes involved in sorption to tire materials differed significantly from those governing sorption to other microplastics.

Huffer, T., et al. (2018). "Sorption of organic compounds by aged polystyrene microplastic particles." Environmental Pollution **236**: 218-225.

Microplastics that are released into the environment undergo aging and interact with other substances such as organic contaminants. Understanding the sorption interactions between aged microplastics and organic contaminants is therefore essential for evaluating the impact of microplastics on the environment. There is little information available on how the aging of microplastics affects their sorption behavior and other properties. We have therefore investigated the effects of an accelerated UV-aging procedure on polystyrene microplastics, which are used in products such as skin cleaners and foams. Physical and chemical particle characterizations showed that aging led to significant surface oxidation and minor localized microcrack formation. Sorption coefficients of organic compounds by polystyrene microplastics following aging were up to one order of magnitude lower than for pristine particles. Sorption isotherms were experimentally determined using a diverse set of probe sorbates covering a variety of substance classes allowing an in-depth evaluation of the poly-parameter linear free-energy relationship (ppLFER) modelling used to investigate the contribution of individual molecular interactions to overall sorption. The ppLFER modelling was validated using internal cross-validation, which confirmed its robustness. This approach therefore yields improved estimates of the interactions between aged polystyrene microplastics and organic contaminants.

Hufnagl, B., et al. (2019). "A methodology for the fast identification and monitoring of microplastics in environmental samples using random decision forest classifiers (A short video showing the application of the RDF model using the datasets 'Microplastic' and 'RefEnv1' is available through DOI: 10.5281/zenodo.2541745) (Electronic supplementary information (ESI) available: Classification results of the datasets 'Microplastic', 'RefEnv1' and 'RefEnv2' (data not shown) are provided as *.png and MATLAB*.mat files. See DOI: 10.1039/c9ay00252a)." Analytical Methods **11**(17): 2277-2285.

A new yet little understood threat to our ecosystems is microplastics. These microscopic particles accumulate in our oceans and in the end may find their way into the food chain. Even though their origin and the laws governing their formation have become ever more clear fast and reliable methodologies for their analysis and identification are still lacking or at an early stage of development. The first automatic approaches to analyze µFTIR images of microplastics which have been enriched on membrane filters are promising and provide the impetus to put further effort into their development. In this paper we present a methodology which allows discrimination between different polymer types and measurement of their abundance and their size distributions with high accuracy. In particular we apply random decision forest classifiers and compute a multiclass model for the polymers polyethylene, polypropylene, poly(methyl methacrylate), polyacrylonitrile and polystyrene. Further classification results of the analyzed µFTIR images are given for comparability. The study also briefly discusses common issues that can arise in classification such as the curse of dimensionality and label noise.

Hug, H. and R. Schuler (2003). "Measurement of the number of molecules of a single mRNA species in a complex mRNA preparation." Journal of Theoretical Biology **221**(4): 615-624.

The normalization of data obtained from hybridization experiments with DNA chips to determine mRNA expression and concentration (gene expression profiling) is an unsolved problem. Furthermore, slight changes in mRNA expression or small numbers of mRNA molecules which may be relevant to disease cannot be detected so far. We have designed a method to calculate the number of molecules of a single mRNA species in a complex mRNA preparation. The basic concept is the transformation of a quantitative problem into a qualitative problem. Individual molecules pertaining to the same molecular species (IMPSMS) are transformed to a mixture of new different molecular species (DMS) and amplified. We propose two implementations of the method. The first procedure is based on a method for cloning tagged nucleic acid molecules onto the surface of micro-beads. It should be possible to transform and determine up to 10(6) IMPSMS into new DMS. The second strategy uses multimeric linkers, a method frequently used in DNA computing to assemble random DNA. The second strategy should be easier to implement but is limited to a few hundred IMPSMS.

Hughes, A., et al. (2000). "Studies with natural rapeseed and microbially derived polyhydroxybutyrate to simulate extraction of plastic from transgenic material." Bioprocess Engineering **23**(3): 257-263.

The creation of transgenic plants with high levels of products such as plastic particles, takes a number of seasons to scale-up. In the interim, studies of natural plant material with microbially derived product, in this case polyhydroxybutyrate (PHB), can indicate what may be possible and where difficulties are likely. Large scale processes exist for the removal of oil from rapeseed, and an earlier study examined their applicability prior to the recovery of PHB. The present study examined the subsequent separation of PHB from protein meal. In particular, the density and size characteristics of PHB in a single particle and aggregate form and of the meal were examined. These were used to predict separation by sedimentation with and without the use of a densifying material (52% w/w sucrose). Sedimentation did not yield a full separation but densification of the medium allowed an almost complete separation. As an alternative approach, the selective dissolution of the protein meal was examined and 2 M sodium hydroxide was found to be the most effective agent. It did not cause a molecular weight change of the PHB provided the pH was lower than 11. The protein was precipitated subsequent to separation of the PHB by the use of acids with phosphoric acid being the most effective (80% recovery). The relationship of this approach to the use of a second solvent for PHB dissolution is briefly discussed.

Hugues-Ayala, A. M., et al. (2020). "Airbrush encapsulation of Lactobacillus rhamnosus GG in dry microbeads of alginate coated with regular buttermilk proteins." LWT Food Science and Technology **117**(108639).

Lactobacillus rhamnosus GG (L. rhamnosus GG) loaded calcium alginate microbeads were prepared via an airbrush system and subsequently coated with regular butter milk proteins (RBMP). Scanning electron micrographs and changes in zeta potential demonstrated the presence of RBMP on microbeads surface. Survivability of probiotics after microbead lyophilization was higher in coated microbeads (8.91+or-0.03 log cfu) than in the uncoated ones (7.67+or-0.09 log cfu). After storage at -20 degrees C for 30 d, the coated and uncoated microbeads showed 0.4 log and 0.8 log cfu/g loss in cell number, respectively. RBMP also enhance the survival of L. rhamnosus GG after exposure to sequential simulated gastrointestinal conditions. These results suggest that coating alginate capsules with RBMP is an effective strategy for the survival of L. rhamnosus GG when encapsulated with an airbrush system.

Humar, M., et al. (2017). "Biomaterial microlasers implantable in the cornea, skin, and blood." Optica **4**(9): 1080-1085.

Stand-alone laser particles that are implantable into biological tissues have potential to enable novel optical imaging, diagnosis and therapy. Here we demonstrate several types of biocompatible microlasers and their lasing action within biological systems. Dye-doped polystyrene beads were embedded in the cornea and optically pumped to generate narrowband emission. We fabricated microbeads with poly(lactic-co-glycolic acid) and poly(lactic acid)-substances approved for medical use-and demonstrate lasing from within tissues and whole blood. Furthermore, we demonstrate biocompatible cholesterol-derivative microdroplet lasers via self-assembly to an onion-like radially-resonant photonic crystal structure.

Hung, K. Y., et al. (2001). "Dipyridamole inhibits human peritoneal mesothelial cell proliferation in vitro and attenuates rat peritoneal fibrosis in vivo." Kidney International **59**(6): 2316-2324.

BACKGROUND: Peritoneal fibrosis (PF) is one of the most serious complications after long-term continuous ambulatory peritoneal dialysis (CAPD). Proliferation of human peritoneal mesothelial cells (HPMC) and matrix over-production are regarded as the main processes predisposing to PF. Dipyridamole (DP) has been reported to have potential as an antiproliferative and antifibrotic agent. We thus investigated the effect of DP in inhibiting proliferation and collagen synthesis of HPMC. A rat model of peritonitis-induced PF was also established to demonstrate the in vivo preventive effect of DP.

METHODS: HPMC was cultured from human omentum by an enzyme digestion

METHOD: Cell proliferation was measured by the methyltetrazolium assay. Intracellular cAMP was measured using an enzyme immunoassay (EIA) kit. Total collagen synthesis was measured by (3)H-proline incorporation assay. Expression of collagen alpha1 (I) and collagen alpha 1 (III) mRNAs was determined by Northern blotting. The rat model of peritonitis-induced PF was developed by adding dextran microbeads (Cytodex, 8 mg/1 mL volume) to a standardized

suspension (3 x 10(9)) of Staphylococcus aureus. DP was administrated via intravenous infusion (4 mg in 1 h) daily for seven days. Macroscopic grading of intraperitoneal adhesions and histological analyses of peritoneal thickness and collagen expression were performed.
RESULTS: Addition of DP to HPMC cultures suppressed serum-stimulated cell proliferation and collagen synthesis. The antimitogenic and antifibrotic effects of DP appear to be predominantly mediated through the cAMP pathway, as DP increased intracellular cAMP in a dose-dependent manner. The macroscopic grade of intraperitoneal adhesion and peritoneal thickness were both significantly increased in animals treated with Cytodex plus S. aureus; on the other hand, DP attenuated these fibrotic changes with statistical significance (P < 0.01). Analysis of gene expression of collagen alpha 1 (I) and alpha1 (III) in the peritoneal tissue of experimental animals yielded similar results.
CONCLUSIONS: This study suggests that dipyridamole may have therapeutic potential in treating peritoneal fibrosis.

Huq, T., et al. (2017). "Alginate based nanocomposite for microencapsulation of probiotic: Effect of cellulose nanocrystal (CNC) and lecithin." Carbohydrate Polymers **168**: 61-69.
Probiotic (Lactobacillus rhamnosus ATCC 9595) was encapsulated in alginate-CNC-lecithin microbeads to produce nutraceutical microcapsules. Addition of CNC and lecithin in alginate microbeads (ACL-1) improved the viability of L. rhamnosus during gastric passage and storage. The compression strength of the freeze-dried ACL-1 microbeads improved 40% compared to alginate microbeads alone. Swelling studies revealed that addition of CNC and lecithin in alginate microbeads decreased (around 47%) the gastric fluid absorption but increased the dissolution time by 20min compared to alginate microbeads (A-0). During transition through the gastric passage, the viability of L. rhamnosus in dried ACL-1 microbeads was increased 37% as compared to A-0 based beads. At 25 and 4degreeC storage conditions, the viability of L. rhamnosus encapsulated in ACL-1 microbeads decreased by 1.23 and 1.08 log respectively, whereas the encapsulation with A-0 microbeads exhibited a 3.17 and 1.93 log reduction respectively.

Huq, T., et al. (2014). "Microencapsulation of nisin in alginate-cellulose nanocrystal (CNC) microbeads for prolonged efficacy against Listeria monocytogenes." Cellulose **21**(6): 4309-4321.
The present study was undertaken to develop edible nisin-microencapsulated beads in order to inhibit growth of Listeria monocytogenes in ready-to-eat (RTE) ham. Different concentrations of nisin (16, 31, and 63 mu g/ml) were microencapsulated into alginate-cellulose nanocrystal beads. Microencapsulation kept the available nisin (63 mu g/ml) content 20 times greater compared with free nisin (63 mu g/ml) during 28 days of storage at 4 degree C. Results showed that 63 mu g/ml microencapsulated nisin exhibited 31.26 mu g/ml available nisin content after 28 days of storage at 4 degree C, whereas there was no available nisin content left for free nisin. Cooked ham slices were then coated by the microencapsulated nisin beads, inoculated with L. monocytogenes [~3 log colony-forming units (CFU)/g], and stored at 4 degree C under vacuum packaging for 28 days. The beads containing 16, 31, and 63 mu g/ml nisin significantly (P less than or equal to 0.05) reduced the L. monocytogenes counts by 2.65, 1.50, and 3.04 log CFU/g after 28 days of storage compared with free nisin. Furthermore, microencapsulated nisin beads did not change the physicochemical properties (pH and color) of RTE ham during storage.

Hurley, R., et al. (2018). "Microplastic contamination of river beds significantly reduced by catchment-wide flooding." Nature Geoscience **11**(4): 251-257.
Microplastic contamination of the oceans is one of the world's most pressing environmental

concerns. The terrestrial component of the global microplastic budget is not well understood because sources, stores and fluxes are poorly quantified. We report catchment-wide patterns of microplastic contamination, classified by type, size and density, in channel bed sediments at 40 sites across urban, suburban and rural river catchments in northwest England. Microplastic contamination was pervasive on all river channel beds. We found multiple urban contamination hotspots with a maximum microplastic concentration of approximately 517,000 particlesm⁻². After a period of severe flooding in winter 2015/16, all sites were resampled. Microplastic concentrations had fallen at 28 sites and 18 saw a decrease of one order of magnitude. The flooding exported approximately 70% of the microplastic load stored on these river beds (equivalent to 0.85+or-0.27 tonnes or 43+or-14 billion particles) and eradicated microbead contamination at 7 sites. We conclude that microplastic contamination is efficiently flushed from river catchments during flooding.

Hurley, R. R., et al. (2018). "Validation of a Method for Extracting Microplastics from Complex, Organic-Rich, Environmental Matrices." Environmental Science & Technology **52**(13): 7409-7417.

Complex and organic-rich solid substrates such as sludge and soil have been shown to be contaminated by microplastics; however, methods for extracting plastic particles have not yet been systemically tested or standardized. This study investigated four main protocols for the removal of organic material during analysis of microplastics from complex solid matrices: oxidation using H₂O₂, Fenton's reagent, and alkaline digestion with NaOH and KOH. Eight common polymer types were used to assess the influence of reagent exposure on particle integrity. Organic matter removal efficiencies were established for test sludge and soil samples. Fenton's reagent was identified as the optimum protocol. All other methods showed signs of particle degradation or resulted in an insufficient reduction in organic matter content. A further validation procedure revealed high microplastic extraction efficiencies for particles with different morphologies. This confirmed the suitability of Fenton's reagent for use in conjunction with density separation for extracting microplastics. This approach affords greater comparability with existing studies that utilize a density-based technique. Recommendations for further method optimization were also identified to improve the recovery of microplastic from complex, organic-rich environmental samples.

Hurley, R. R., et al. (2017). "Ingestion of Microplastics by Freshwater Tubifex Worms." Environmental Science and Technology **51**(21): 12844-12851.

Microplastic contamination of the aquatic environment is a global issue. Microplastics can be ingested by organisms leading to negative physiological impacts. The ingestion of microplastics by freshwater invertebrates has not been reported outside the laboratory. Here we demonstrate the ingestion of microplastic particles by Tubifex tubifex from bottom sediments in a major urban waterbody fed by the River Irwell, Manchester, UK. The host sediments had microplastic concentrations ranging from 56 to 2543 particles kg⁻¹. 87% of the Tubifex-ingested microplastic particles were microfibers (55-4100 mum in length), while the remaining 13% were microplastic fragments (50-4500 mum in length). FT-IR analysis revealed ingestion of a range of polymers, including polyester and acrylic fibers. While microbeads were present in the host sediment matrix, they were not detected in Tubifex worm tissue. The mean concentration of ingested microplastics was 129 +/- 65.4 particles g⁻¹ tissue. We also show that Tubifex worms retain microplastics for longer than they retain other particulate components of the ingested sediment matrix. Microplastic ingestion by Tubifex worms poses a significant risk for trophic transfer and biomagnification of microplastics up the aquatic food chain. Copyright © 2017 American Chemical Society.

Hurst, G. B., et al. (1999). "Analysis for TNF- using solid-phase affinity capture with radiolabel and MALDI-MS detection." Analytical Chemistry **71**(20): 4727-4733.

Screening of mutant mice for subtle phenotypes requires sensitive, high-throughput analyses of sentinel proteins in functional pathways. The cytokine TNF- is upregulated during inflammatory reactions associated with auto-immune diseases. We have developed a method to monitor the concentration of TNF- under physiological conditions. TNF- is captured, purified, and concentrated using monoclonal antibody-coated microbeads. The capture is efficient (gt;80%) and can be used in the concentration range 100 pg/mL to gt;50 ng/mL, as determined by detection of 125I-labeled TNF-. The bead capture of TNF- can be combined with direct detection by MALDI-MS for sample concentrations of gt;10 ng/mL. TNF- can be captured and detected from diluted mouse serum, with minimal interferences observed in the MALDI spectrum. This method is adaptable to high-throughput sample handling with microfluidic devices and automated mass spectrometric analysis.

Husain, B., et al. (2019). "Extracellular Protein Microarray Technology for High Throughput Detection of Low Affinity Receptor-Ligand Interactions." Journal of Visualized Experiments **143**(01): 07.

Secreted factors, membrane-tethered receptors, and their interacting partners are main regulators of cellular communication and initiation of signaling cascades during homeostasis and disease, and as such represent prime therapeutic targets. Despite their relevance, these interaction networks remain significantly underrepresented in current databases; therefore, most extracellular proteins have no documented binding partner. This discrepancy is primarily due to the challenges associated with the study of the extracellular proteins, including expression of functional proteins, and the weak, low affinity, protein interactions often established between cell surface receptors. The purpose of this method is to describe the printing of a library of extracellular proteins in a microarray format for screening of protein-protein interactions. To enable detection of weak interactions, a method based on multimerization of the query protein under study is described. Coupled to this microbead-based multimerization approach for increased multivalency, the protein microarray allows robust detection of transient protein-protein interactions in high throughput. This method offers a rapid and low sample consuming-approach for identification of new interactions applicable to any extracellular protein. Protein microarray printing and screening protocol are described. This technology will be useful for investigators seeking a robust method for discovery of protein interactions in the extracellular space.

Hussein, A. K. and G. Fetih (2006). "Novel optimization of shape, swelling and release behaviors of tolmetin sodium loaded alginate microbeads." Asian Journal of Andrology **8**(3): 165-174.

In the design of oral delivery, alginates (Alg) have attracted increasing attention. However, due to their hydrophilic character incorporation of small hydrophilic drugs such as tolmetin sodium (TOL) into Alg beads will not provide the desired regular shape as well as delayed drug release. There is no study investigating the effect of methylcellulose (MC) and dual cross-linking (CaCl sub(2) and glutaraldehyde, GA) on their shape, swelling and release behaviors. Hence this study aimed to evaluate the influence of MC and cross-linking agents on these behaviors of Alg microbeads prepared using the ionotropic gelation method compared with Alg microspheres prepared with wlo emulsion method. The results obtained display some interesting information. Both concentration of MC and type of cross-linking agent had dramatic effects on shape as well as swelling, erosion and release behaviors of the prepared microbeads. Swelling through ion-exchange process of Alg/MC blend single cross-linked microbeads was hindered in the case of dual cross-linked microbeads. The release of the drug from Alg/MC dual cross-linked microbeads was extended for up to 12 h and the release mechanism was shifted from erosion type release to time-independent release process. Analgesic activity study indicated significantly different response patterns compared with plain TOL solution.

Huttinger, K. J., et al. (1987). "Influence of surface chemistry of the substrate on the adsorption of Escherichia coli." Zentralblatt fur Bakteriologie, Mikrobiologie und Hygiene - Serie B, Umwelthygiene, Krankenhaushygiene, Arbeitshygiene, Praventive Medizin **184**(6): 538-547.

The adsorption of Escherichia coli as influenced by the surface chemistry of different absorbents was studied with microbeads of (1) polystyrene, hydroxymethylated, chloromethylated and aminomethylated polystyrene, (2) cation and anion exchange resins, (3) glass and siliconized glass using a shake test. The adsorption kinetics can be described by a first order rate law for all materials. The specific surface free energy is not even a rough correlation parameter for the adsorption effect. Polar groups with the exception of those with a negative charge (cation exchange resin) favour adsorption of Escherichia coli, but the type of the polar surface group plays a dominating role. Adsorption was maximum with protonated aminomethylated polystyrene which is attributed to the interaction of the positive charge with the negatively charged bacterial surface.

Huysman, S., et al. (2017). "Performance indicators for a circular economy: A case study on post-industrial plastic waste." Resources, Conservation and Recycling **120**: 46-54.

A linear economy approach results in many environmental challenges: resources become depleted and end up as waste and emissions. One of the key strategies to overcome these problems is using waste as a resource, i.e. evolving toward a circular economy. To monitor this transition, suitable indicators are needed that focus on sustainability issues whilst taking into account the technical reality. In this paper, we develop such an indicator to quantify the circular economy performance of different plastic waste treatment options. This indicator is based on the technical quality of the plastic waste stream and evaluates resource consumption by using the Cumulative Exergy Extraction from the Natural Environment (CEENE) method. To illustrate the use of this new indicator, it was applied in a case study on post-industrial plastic waste treatment. The results show that the indicator can be a very useful approach to guide waste streams towards their optimal valorization option, based on quality of the waste flow and the environmental benefit of the different options. Huysman, S., et al. (2015). "The recyclability benefit rate of closed-loop and open-loop systems: A case study on plastic recycling in Flanders." Resources, Conservation and Recycling **101**: 53-60.

Over the last few years, waste management strategies are shifting from waste disposal to recycling and recovery and are considering waste as a potential new resource. To monitor the progress in these waste management strategies, governmental policies have developed a wide range of indicators. In this study, we analyzed the concept of the recyclability benefit rate indicator, which expresses the potential environmental savings that can be achieved from recycling the product over the environmental burdens of virgin production followed by disposal. This indicator is therefore, based on estimated environmental impact values obtained through Life Cycle Assessment (LCA) practices. We quantify the environmental impact in terms of resource consumption using the Cumulative Exergy Extraction from the Natural Environment method. This research applied this indicator to two cases of plastic waste recycling in Flanders: closed-loop recycling (case A) and open-loop recycling (case B). Each case is compared to an incineration scenario and a landfilling scenario. The considered plastic waste originates from small domestic appliances and household waste other than plastic bottles. However, the existing recyclability benefit rate indicator does not consider the potential substitution of different materials occurring in open-loop recycling. To address this issue, we further developed the indicator for open-loop recycling and cascaded use. Overall, the results show that both closed-loop and open-loop recycling are more resource efficient than landfilling and incineration with energy recovery. Copyright © 2015 The Authors. Hwang, J., et al. (2019). "An assessment of the toxicity of polypropylene microplastics in human derived cells." Science of the Total Environment **684**: 657-669.

Environmental pollution caused by plastic waste is a growing global problem. Discarded plastic products and debris (microplastic particles) in the oceans detrimentally affect marine ecosystems and may impact human. Humans are exposed to plastic debris via the consumption of seafood and drinking water, contact with food packaging, or inhalation of particles. The accumulation of microplastic particles in humans has potential health risks such as cytotoxicity, hypersensitivity, unwanted immune response, and acute response like hemolysis. We investigated the cellular responses of secondary polypropylene microplastics (PP particles) of approximately ~20mum and 25-200mum in different condition and size to normal cells, immune cells, blood cells, and murine immune cells by cytokine analysis, ROS assay, polarization assay and proliferation assay. We found that PP particles showed low cytotoxicity effect in size and concentration manner, however, a high concentration, small sized, DMSO method of PP particles stimulated the immune system and enhanced potential hypersensitivity to PP particles via an increase in the levels of cytokines and histamines in PBMCs, Raw 264.7 and HMC-1 cells.

Hwang, J. Y., et al. (2014). "Cell membrane deformation induced by a fibronectin-coated polystyrene microbead in a 200-MHz acoustic trap." IEEE Transactions on Ultrasonics Ferroelectrics & Frequency Control **61**(3): 399-406.

The measurement of cell mechanics is crucial for a better understanding of cellular responses during the progression of certain diseases and for the identification of the cell's nature. Many techniques using optical tweezers, atomic force microscopy, and micro-pipettes have been developed to probe and manipulate cells in the spatial domain. In particular, we recently proposed a two-dimensional acoustic trapping method as an alternative technique for small particle manipulation. Although the proposed method may have advantages over optical tweezers, its applications to cellular mechanics have not yet been vigorously investigated. This study represents an initial attempt to use acoustic tweezers as a tool in the field of cellular mechanics in which cancer cell membrane deformability is studied. A press-focused 193-MHz single-element lithium niobate ($LiNbO_3$) transducer was designed and fabricated to trap a 5-mum polystyrene microbead near the ultrasound beam focus. The microbeads were coated with fibronectin, and trapped before being attached to the surface of a human breast cancer cell (MCF-7). The cell membrane was then stretched by remotely pulling a cell-attached microbead with the acoustic trap. The maximum cell membrane stretched lengths were measured to be 0.15, 0.54, and 1.41 mum at input voltages to the transducer of 6.3, 9.5, and 12.6 Vpp, respectively. The stretched length was found to increase nonlinearly as a function of the voltage input. No significant cytotoxicity was observed to result from the bead or the trapping force on the cell during or after the deformation procedure. Hence, the results convincingly demonstrated the possible application of the acoustic trapping technique as a tool for cell manipulation.

Hwang, S. M., et al. (2011). "Thrombomodulin phenotype of a distinct monocyte subtype is an

independent prognostic marker for disseminated intravascular coagulation." Critical Care **15 (2) (no pagination)**(R113).

Introduction: Thrombomodulin, which is expressed solely on monocytes, along with tissue factor (TF), takes part in coagulation and inflammation. Circulating blood monocytes can be divided into 3 major subtypes on the basis of their receptor phenotype: classical (CD14^{bright}CD16^{negative}, CMs), inflammatory (CD14^{bright}CD16^{positive}; IMs), and dendritic cell-like (CD14^{dim}CD16^{positive}DMs). Monocyte subtype is strongly regulated, and the balance may influence the clinical outcomes of disseminated intravascular coagulation (DIC). Therefore, we investigated the phenotypic difference in thrombomodulin and TF expression between different monocyte subtypes in coagulopathy severity and prognosis in patients suspected of having DIC. Method(s): In total, 98 patients suspected of having DIC were enrolled. The subtypes of circulating monocytes were identified using CD14 and CD16 and the thrombomodulin and TF expression in each subtype, expressed as mean fluorescence intensity, was measured by flow cytometry. Plasma level of tissue factor was measured by ELISA. In cultures of microbead-selected, CD14-positive peripheral monocytes, lipopolysaccharide (LPS)- or interleukin-10-induced expression profiles were analyzed, using flow cytometry. Result(s): The proportion of monocyte subtypes did not significantly differ between the overt and non-overt DIC groups. The IM thrombomodulin expression level was prominent in the overt DIC group and was well correlated with other coagulation markers. Of note, IM thrombomodulin expression was found to be an independent prognostic marker in multivariate Cox regression analysis. In addition, in vitro culture of peripheral monocytes showed that LPS stimulation upregulated thrombomodulin expression and TF expression in distinct populations of monocytes. Conclusion(s): These findings suggest that the IM thrombomodulin phenotype is a potential independent prognostic marker for DIC, and that thrombomodulin-induced upregulation of monocytes is a vestige of the physiological defense mechanism against hypercoagulopathy. © 2011 Hwang et al.; licensee BioMed Central Ltd.

Hylton, L., et al. (2018). "Microplastic pollution in Indiana's White River: an exploratory study." Proceedings of the Indiana Academy of Science **127**(1): 72-81.

Plastic material is now a ubiquitous source of aquatic pollution. Microplastics, tiny plastic pieces often not visible to the naked eye, are a growing environmental concern in both marine and freshwater ecosystems. While many studies have documented the abundance and danger of microplastics in global oceans, little research is available on microplastic presence and impact in riverine ecosystems. This exploratory study aims to build on the findings of recent freshwater microplastic studies by reporting on the occurrence and types of microplastic pollution found in the West Fork White River in central Indiana. Fifteen surface water samples were collected from three bridge sites along the river over a four-month period (August-November 2015) and analyzed using established NOAA laboratory methods. Analysis revealed various microplastic particle types in the White River, with synthetic fibers being the predominant type collected. A total of 146 plastic pieces were collected across all sites and collection periods, with an average microplastic concentration of 0.71 items m⁻³. Surprisingly, there were no significant differences in microplastic concentrations among sites of differing population density. Further, a local wastewater treatment plant had no effect on particle type or abundance. These findings contribute to current gaps in microplastic research on freshwater, especially fluvial, environments. This contribution may guide researchers in better understanding the extent to which these synthetic particles are polluting U.S. surface waters as a whole.

Iannilli, V., et al. (2018). "Microplastics in <i>Talitrus saltator</i> (Crustacea, Amphipoda): new evidence of ingestion from natural contexts." Environmental science and pollution research international **25**(28): 28725-28729.

Using Fourier transform infrared spectroscopy (FT-IR) measurements and comparing the spectrum peaks (range 4000–600 cm−1) with reference spectra database and instrument libraries, we observed new evidence of the ingestion of microplastic particles analyzing the digestive tracts of Talitrus saltator. Specimens, sampled in central Italy, probably ingested the particles with natural detritus. Since worldwide many species of invertebrates and vertebrates (e.g., birds) feed on Amphipoda along coastal ecosystems, we hypothesized that microplastic in these crustaceans can be accumulated along the food chain.

Using Fourier transform infrared spectroscopy (FT-IR) measurements and comparing the spectrum peaks (range 4000-600 cm⁻¹) with reference spectra database and instrument libraries, we observed new evidence of the ingestion of microplastic particles analyzing the digestive tracts of Talitrus saltator. Specimens, sampled in central Italy, probably ingested the particles with natural detritus. Since worldwide many species of invertebrates and vertebrates (e.g., birds) feed on Amphipoda along coastal ecosystems, we hypothesized that microplastic in these crustaceans can be accumulated along the food chain.

Iannilli, V., et al. (2019). "First evidence of microplastics ingestion in benthic amphipods from Svalbard." Environmental Research **179**(Pt A): 108811.

The present paper provides the first record of ingestion of microplastics in natural context by Gammarus setosus from Svalbard Archipelago. The plastic particles were identified both by Nile Red staining and Micro FT-IR spectroscopy. The species studied ingests microplastic particles in natural conditions if present in its habitat, probably mistaking them as food. The microplastic particles ingested may be available for uptake to predators that consume this Arctic amphipod, producing consequences to the food web.

Iansante, V., et al. (2018). "A New High Throughput Screening Platform for Cell Encapsulation in Alginate Hydrogel Shows Improved Hepatocyte Functions by Mesenchymal Stromal Cells Co-encapsulation." Frontiers in Medicine **5**: 216.

Hepatocyte transplantation has emerged as an alternative to liver transplant for liver disease. Hepatocytes encapsulated in alginate microbeads have been proposed for the treatment of acute liver failure, as they are able to provide hepatic functions while the liver regenerates. Furthermore, they do not require immunosuppression, as the alginate protects the hepatocytes from the recipient's immune cells. Mesenchymal stromal cells are very attractive candidates for regenerative medicine, being able to differentiate into cells of the mesenchymal lineages and having extensive proliferative ability. When co-cultured with hepatocytes in two-dimensional cultures, they exert a trophic role, drastically improving hepatocytes survival and functions. In this study we aimed to (i) devise a high throughput system (HTS) to allow testing of a variety of different parameters for cell encapsulation and (ii) using this HTS, investigate whether mesenchymal stromal cells could have beneficial effects on the hepatocytes when co-encapsulated in alginate microbeads. Using our HTS platform, we observed some improvement of hepatocyte behavior with MSCs, subsequently confirmed in the low throughput analysis of cell function in alginate microbeads. Therefore, our study shows that mesenchymal stromal cells may be a good option to improve the function of hepatocytes microbeads. Furthermore, the platform developed may be used for HTS studies on cell encapsulation, in which several conditions (e.g., number of cells, combinations of cells, alginate modifications) could be easily compared at the same time.
