Recent advances in microfluidic technologies have created a demand for a simple and efficient separation intended for various applications such as food industries, biological preparation, and medical diagnostic. In this paper, we report a tapered microfluidic device for passive continuous separation of microparticles by using hydrodynamic separation. By exploiting the hydrodynamic properties of the fluid flow and physical characteristics of micro particles, effective size based separation is demonstrated. The tapered microfluidic device has widening geometries with respect to specific taper angle which amplify the sedimentation effect experienced by particles of different sizes. A mixture of 3-µm and 10-µm polystyrene microbeads are successfully separated using 20° and 25° taper angles. The results obtained are in agreement with three-dimensional finite element simulation conducted using Abaqus 6.12. Moreover, the feasibility of this mechanism for biological separation is demonstrated by using polydisperse samples consists of 3-µm polystyrene microbeads and human epithelial cervical carcinoma (HeLa) cells. 98% of samples purity is recovered at outlet 1 and outlet 3 with flow rate of 0.5-3.0 µl/min. Our device is interesting despite adopting passive separation approach. This method enables straightforward, label-free, and continuous separation of multiparticles in a stand-alone device without the need for bulky apparatus. Therefore, this device may become an enabling technology for point of care diagnosis tools and may hold potential for micrototal analysis system applications.

Iemma, F., et al. (2008). "Removal of metal ions from aqueous solution by chelating polymeric microspheres bearing phytic acid derivatives." European Polymer Journal **44**(4): 1183-1190.

The aim of this study was to investigate the possibility to synthesize new chelating polymeric microspheres owing immobilized biocompatible agent as chelating functional groups and to evaluate their performance in metal ions removal from aqueous solution. The microparticles were synthesized via precipitation polymerization of 4-O-(4-vinylbenzyl)-myo-inositol 1,3,5-orthoformate with ethylene glycol dimethacrylate (EGDMA) and subsequent exhaustive phosphorylation of myo-inositol groups using phosphoric acid. Spherical geometry with monodisperse nature of the polymeric microparticles was confirmed by scanning electron micrographs (SEM) and dimensional analysis. A large surface area of the microspheres provided a maximum interaction of metal ions and the chelating functional groups on the surface. Absorption capacity of the beads for the selected metal ions, i.e., Cu(II), Ni(II), Fe(III), was investigated in detail in aqueous solution at pH 5.0 utilizing UV /Vis spectroscopy. This study showed that the macromolecular systems are very effective in chelating these metal ions and the affinity order of the microbeads toward metal ions is: Fe(III)>Ni(II)>Cu(II). The chelating beads can be easily regenerated by 1.0M HNO sub(3) with high effectiveness. These features make the synthesized beads a potential candidate for metal ions removal at high capacity.

Igoli, J. O., et al. (2015). "Chromatographic and spectroscopic analysis of the components present in the phenanthridinium trypanocidal agent isometamidium." Analytical and bioanalytical chemistry **407**(4): 1171-1180.

Issue Title: A different way of looking at vibrational hyperspectral data/Micellar extraction for

the analysis of Alzheimer's disease brain proteome/Quantification of polyolefin microplastics in personal-care products/Removal of Triton X-100 by microdialysis The chromatographic isolation and characterisation of the four compounds present in the quaternary phenanthridine veterinary trypanocidal agent, isometamidium chloride hydrochloride (ISM), is reported. The isolated compounds were unambiguously characterised using spectroscopic (NMR, UV, IR and MS) methods as 3-amino-8-[3-(3-carbamimidoyl-phenyl)-triazenyl]-5-ethyl-6-phenylethidium (1a) and related isomers,
8-amino-3-[3-(3-carbamimidoyl-phenyl)-triazenyl]-5-ethyl-6-phenylethidium,
3,-8-diamino-7-[3-(3-carbamimidoyl-phenyl)-triazenyl]-5-ethyl-6-phenylethidium and
3,-8-bis[3-(3-carbamimidoyl-phenyl)-triazenyl]-5-ethyl-6-phenylethidium. During the course of this study, it was realised that the nature of the solvent used in the NMR study was critical as in DMSO-d^sub 6^ the quaternary group in the compounds was reduced to dihydro forms (e.g. 2a).

Ilagan, B. G. (2008). The development of an elastomeric scaffold for small diameter blood vessel tissue engineering.

In coronary artery bypass surgery the autologous saphenous vein is the most commonly used vascular graft. However, in a growing number of patients this vein is not available due to disease or availability. To date, there are no commercially available vascular grafts to replace the autologous saphenous vein. Nevertheless, it is widely accepted that a successful small diameter blood vessel alternative will be found using a tissue engineering approach. A photo-cross-linked biodegradable elastomer of acrylated star-poly(e-caprolactone-co-D,L-lactide) (ASCP) has recently been developed. The elastomer possesses many desirable properties, such as manufacturability and mechanical properties, making it an interesting scaffolding material candidate for this application. To test the feasibility of the ASCP elastomer as a scaffolding material, a porous scaffold with 90% porosity was constructed using paraffin microbeads combined with an emulsion of ASCP prepolymer and water. Native arterial mechanical properties were matched with an 1800 Da ASCP elastomeric scaffold (ELAS 1800) having 85% porosity. In vitro degradation of scaffolds prepared with two different ASCP M sub(n) (1800 and 4500 Da) was investigated for 8 weeks. Bulk hydrolysis was the mode of degradation regardless of configuration, with the porous scaffold degrading slower than the nonporous control. In addition, the ELAS 4500 scaffold also degraded faster than the ELAS 1800 scaffold with the same porosity. In order to promote the cellular response to this potential vascular scaffold, the surface of the elastomer was modified to enhance bovine coronary artery smooth muscle cell (SMC) attachment and proliferation. Base etching the surface was not as effective as adding a small peptide sequence Gly-Arg-Gly-Asp-Ser (GRGDS) known to enhance cell adhesion. The surface modifications did not change SMC phenotype as all surfaces expressed the contractile marker proteins smooth muscle a-actin and h-caldesmon. The SMCs also expressed these marker proteins when seeded on porous scaffolds. Finally, it was possible to integrate the porous scaffold into a biomimetic blood vessel design. With this initial testing, it appears that the ASCP elastomer is a feasible scaffolding material for small diameter blood vessel tissue engineering. Nevertheless, more detailed testing of mechanical properties and cell behaviour must be conducted to ascertain that the ASCP elastomer and the proposed biomimetic blood vessel design can be appropriate replacements for the autologous saphenous vein.

Ileana, S., et al. (2010). "Characterization of some composites ALG-HA potentially used as bone regeneration scaffolds." European Cells and Materials **1)**: 42.

INTRODUCTION: Sodium alginate (ALG) is extracted with a diluted alkali solution from marine

brown algae and is not a random polysaccharide, but depending on the algae source, consists of blocs of similar and strictly alternating residue (i.e. MMM, GGG, GMGMGM), each of which has different conformational preferences and behaviours. ALG is soluble in aqueous solutions and forms stable gels at room temperature in the presence of non-cytotoxic concentrations of certain bivalent cations (i.e., Ca²⁺) through ionic interaction between G acid groups. This leads to 3D structures, often with viable cells embedded in the gel by cross-linking in non-cytotoxic conditions. Nafcillin, is a semi-synthetic antistaphylococcal penicillin, highly effective in penicillinase-producing staphylococcal infections, in which the activity is mainly created through steric hindrance. Unlike penicillin, ampicillin, or the extended-spectrum penicillins, nafcillin resists hydrolysis by penicillinase; therefore, along with other agents in the same group (e.g., oxacillin, dicloxacillin), this antibiotic is active against penicillinase-producing Staphylococcus aureus. In the present work, ALG-hydroxyapatite composites have been created as cross-linkable materials physically loaded with nafcillin. The drug-release efficiency was explored by UV-VIS spectroscopy. These materials are intended as bone fillers presenting, besides the incorporated drug, the advantage of low-invasive delivery in the bone-defect through injection, followed by an improvement of the mechanical strength due to in vivo Ca²⁺ cross-linking. METHOD(S): ALG solution (2% wt%) in physiologic saline (0.9% NaCl) was mixed with different concentrations of hydroxyapatite (HA) powder: 5%, 10%, 50%, 200% and 500% (wt%). The phase distribution of the inorganic filler in the organic matrix was evaluated through scanning electron microscopy (SEM). The rheograms have been drawn to control the injectability of the formulations. The drug release has been performed using cross-linked composites microbeads loaded with 10 and, respectively, 20% (wt%) antibiotic. The beads have been cross-linked in CaCl2 (50mM in saline). They have been rinsed with saline and then suspended in saline. The supernatant has been systematically analysed with respect to nafcillin release in time; this was monitored as specific absorbance at 330 nm over time. The end of the release, as obtained through UV-VIS, was confirmed through FT-IR. RESULT(S): Five composites formulations have been prepared and then loaded with nafcillin (two different ratios: 10 and 20% wt). The HA has been homogeneously distributed in the composites, as shown in figure 1. Increasing the inorganic filler ratios has lead to increasing viscosity of the composites, the formulations remaining injectable. (Figure presented) The inorganic filler content has proved to play an important role in the drug release enhancing the phenomenon. DISCUSSION & CONCLUSION(S): This work reports the potential of ALG-HA composites to be used as in situ cross-linkable bone regeneration scaffolds deliverable through minimally invasive surgery (injection). Nevertheless, the bone healing process could be sustained through progressive localized antibiotic release. The release kinetics as well as the mechanical properties of the resulting scaffolds are controllable through the balance organic/inorganic. Nevertheless, the in situ cross-linking of the ALG improves the stability of the materials and the biomechanical performance.

Illhardt, T., et al. (2015). "T-and B-cell depleted haploidentical stem cell transplantation in relapsed metastatic high-risk neuroblastoma." Bone Marrow Transplantation **1)**: S468.

Introduction: Outcome in patients with relapsed metastatic neuroblastoma is still very poor despite advances in chemotherapy and surgery. There is growing evidence for Graftversus-tumor effects in solid tumors after haploidentical stem cell transplantation. We present an analysis of 2 prospective trials with 31 patients who received T- and B-cell depleted haploidentical stem cells Materials (or patients) and methods: All donors were >=2 HLA loci mismatched parents. G-CSF mobilized peripheral stem cells were T-cell depleted by using CD3-coated microbeads. B-cell depletion was done by either using CD19-coated microbeads or by in vivo depletion with antiCD20-mAb (Rituximab). 14 Patients received MIBG-therapy during 4 weeks prior to transplantation. The myeloablative conditioning consisted of fludarabine (40 mg/m²), thiotepa (2 x 5 mg/kg) and melphalan (2x70 mg/m²). One patient was treated without melphalan and fludarabine was replaced by clorafabine (4x50 mg/m²) in one patient. OKT3 was given as graft rejection prophylaxis (0- 1 mg/kg per day for 10 days) and was replaced in 2012 by ATG-F (30 mg/kg total dose, n=4 patients). Short course Mycophenolate mofetil was given as prophylactic immune suppression, if residual T cells in the graft exceeded 2-5 x 104/ kg BW.G-CSF was routinely started on day +4 in 20/31 patients. Remission status before transplantation after salvage therapy was: CR (n=4 patients), PR (n= 20 patients), non-response/ progression (n=7 patients). 19 patients have been transplanted in first and 6 patients in second or subsequent relapse. 6 patients never reached remission before SCT. Result(s): 8/31 patients are alive after a median follow-up of 5.24 years (0.92-9.28). 5-year overall and event-free survival was 22% and 20% respectively. Primary engraftment was observed in 28/31 (91%) patients, 3 (9%) patients rejected and were rescued with an autologeous backup. No transplant related mortality was observed. 23 Patients relapsed in the first year after transplantation. Relapse was very unlikely after 1 year. ANC was reached after a median of 11 days (9-33). We observed a rapid increase of natural killer cells in the early posttransplant period, reaching 230 cells/mul in the mean (SD=113) on day 21. Regeneration of T- and B-cells started around day 30 and reached 110/ml (SD=193) and 38/ml (SD=43) in the mean at day 90 and 292/ml (SD=285) and 177/ml (SD=172) at day 180. Toxicity was tolerable. 26 patients (84%) suffered from degreeIII-IV gastrointestinal toxicity including mucositis, nausea and diarrhoea. 3-fold elevated liver enzymes were found in 10 patients (32%). Hypoxia requiring O<inf>2</inf>-Substitution occurred in 3 patients. No cardiac, neurological, renal or dermatological degreeIII-IV toxicities were observed. No veno-occlusive disease occurred. Acute degreeI-II GvHD was observed in 21 and degreeIII in 3 patients. No degreeIV aGvHD was observed. Chronic degreeI-II GvHD occurred in 11 patients. No degreeIII-IV cGvHD was observed. Conclusion(s): Haploidentical stem cell transplantation is feasible for treatment of patients with relapsed neuroblastoma with acceptable toxicity and morbidity. Incidence of GvH was low. However, NK cell mediated GvT effects still have to be evaluated and seem to be not sufficient in the majority of patients since 80% relapsed. Thus, additional post transplant means to increase GvT effects on the basis of the new established immune system like use of anti-GD2 mAbs, DLI and cytokine stimulation need to be urgently investigated.

Im, H., et al. (2015). "Digital diffraction analysis enables low-cost molecular diagnostics on a smartphone." Proceedings of the National Academy of Sciences of the United States of America **112**(18): 5613-5618.

The widespread distribution of smartphones, with their integrated sensors and communication capabilities, makes them an ideal platform for point-of-care (POC) diagnosis, especially in resource-limited settings. Molecular diagnostics, however, have been difficult to implement in smartphones. We herein report a diffraction-based approach that enables molecular and cellular diagnostics. The D3 (digital diffraction diagnosis) system uses microbeads to generate unique diffraction patterns which can be acquired by smartphones and processed by a remote server. We applied the D3 platform to screen for precancerous or cancerous cells in cervical specimens and to detect human papillomavirus (HPV) DNA. The D3 assay generated readouts within 45 min and showed excellent agreement with gold-standard pathology or HPV testing, respectively. This approach could have favorable global health applications where medical access is limited or when pathology bottlenecks challenge prompt diagnostic readouts.

Im, J. S., et al. (2016). "The use of ex vivo expanded human invariant natural killer T cells as a novel cell therapy to modulate graft-versus-host-disease." Biology of Blood and Marrow Transplantation **1)**: S399.

CD1d-restricted invariant Natural Killer (iNK) T cells are powerful innate cells that can influence adaptive immunity either toward inflammation or immune-suppression via production of Th1-type (IFNg and TNFa) or Th2-type (IL-4, Il- 5, IL-13) cytokines, respectively. Several studies suggest that iNK T cells may play a role in preventing graft versus host disease (GVHD) in allogeneic stem cell transplantation (ASCT). Moreover, iNK T cells may mediate additional antileukemia effects through NK-like effector function. Thus, iNK T cells can be the ideal cells for novel therapy to prevent GVHD and promote graft versus leukemia (GVL) effects in ASCT. Here, we sought to compare phenotypic and functional differences of expanded iNK T cells from cord blood (CB) and adult PBMC, and evaluated the modulatory property in a murine xenograft GVHD model. Because iNK T cells are rare cells consisting of only less than 0.1% of T cells, we first enriched iNK T cells using anti-iNKT MicroBead and MiniMacsTM Separator, prior to expansion with dendritic cells plus iNKT ligand, a-galactosyl ceramide and IL-2. After 2 weeks, we obtained up to 107 iNK T cells with >= 90% purity from single CB unit or 2x10⁸ adult PBMC. Expanded CB iNK T cells were mostly CD4⁺CD25⁺ CD127^{low}, while expanded adult iNK T cells consisted of varying percentages of CD4⁺ iNK T cells comparable to phenotypic distribution of unmanipulated adult iNK T cells. Unlike CB iNK T cells, CD4⁻CD8a⁺ iNK T cells from adult PBMC were disproportionally expanded, constituting up to 40% of iNK T cells. Compared to expanded CB iNK T cells, expanded adult iNK T cells expressed higher levels of NK receptors such as NKG2C, NKG2D, NKR-P1A, CD16 and CD56. In addition, expanded CB iNK T cells preferentially produced Th2-cytokines, while adult iNK T cells preferentially produced Th1- cytokines. Despite predisposition to polarize towards Th1, the expanded adult iNK T cells tend to decrease GVHDrelated mortality at 28 days but not statistically significant (HR 0.3921, p=0.0712), when 5x10⁵ iNK T cells were coinfused with 3x10⁶ human PBMC in irradiated NOD-SCID IL2gamma^{-/-} mice. In summary, we demonstrated it is feasible to selectively expand iNK T cells from CB and adult PBMC. The expanded CB iNK T cells maintained regulatory phenotype and were polarized toward Th2-response, while iNK T cells from adult PBMC exhibited a phenotype consistent with greater effector and were polarized toward Th1 responses, suggesting that CB might be a preferred source for iNK T cell therapy to modulate GVHD. Nonetheless, adult iNK T cells showed a decrease in GVHD related mortality in a murine xenograft GVHD model although not statistically significant, supporting a potential role for immune-modulation post transplantation. Further investigation is ongoing to delineate unique regulator-effector function of CD4⁺ vs CD4⁻ vs CD8a⁺ iNK T cells in modulating GVHD.

Im, P., et al. (2017). "Fabrication of cell-benign inverse opal hydrogels for three-dimensional cell culture." Journal of Colloid & Interface Science **494**: 389-396.

Inverse opal hydrogels (IOHs) for cell culture were fabricated and optimized using calcium-crosslinked alginate microbeads as sacrificial template and gelatin as a matrix. In contrast to traditional three-dimensional (3D) scaffolds, the gelatin IOHs allowed the utilization of both the macropore surface and inner matrix for cell co-culture. In order to remove templates efficiently for the construction of 3D interconnected macropores and to maintain high cell viability during the template removal process using EDTA solution, various factors in fabrication, including alginate viscosity, alginate concentration, alginate microbeads size, crosslinking calcium concentration, and gelatin network density were investigated. Low viscosity alginate, lower crosslinking calcium ion concentration, and lower concentration of alginate and gelatin

were found to obtain high viability of cells encapsulated in the gelatin matrix after removal of the alginate template by EDTA treatment by allowing rapid dissociation and diffusion of alginate polymers. Based on the optimized fabrication conditions, gelatin IOHs showed good potential as a cell co-culture system, applicable to tissue engineering and cancer research.

Imai, T., et al. (2003). "Comparison of the Recyclability of Flame-Retarded Plastics." Environmental Science & Technology **37**(3): 652.

Mechanical recycling of plastics from waste from electrical and electronical equipment (WEEE) is increasingly expected by regulators and demanded by original equipment manufacturers (OEMs); however, mechanical recycling is generally recognized to be the most economically costly and technically challenging method of recovering WEEE plastics. With 12% of WEEE plastics requiring the use of flameretardants in order to ensure appropriate levels of consumer fire safety, there is a distinct need for data from comparative tests on recyclability of various flameretarded plastics. Ten commercially available flame-retarded plastic grades commonly used in electronic equipment (eight "halogen-free" grades and two grades containing brominated flame-retardants (BFRs)) were subjected to two different recycling scenarios. A standard recycling scenario was carried out by repeatedly extruding the materials and an accelerated hydrolysis scenario was carried out to study the influence of humidity from air during use on the process. Both, virgin and recycled materials were tested for a potential formation of polybrominated dibenzodioxins/furans (PBDD/Fs), their mechanical properties were assessed and the fire safety rating was determined. Results indicate that none of the tested materials showed a potential to form the PBDD/Fs regulated by the German Chemicals Banning Ordinance. The halogen-free plastic grades showed a significant deterioration of mechanical properties after recycling, whereas those plastics containing BFRs were able to pass all test criteria, thus maintaining their original properties. With respect to the fire safety rating, none of the eight tested halogen-free plastic grades could maintain their fire safety rating after five recycling loops, whereas both BFR plastics continued to achieve their fire safety ratings. Therefore the tested BFR containing plastic materials showed superior recycling properties compared to the tested halogen-free plastic grades with... [ABSTRACT FROM AUTHOR]

Imber, M. J. (1996). "The food of Cook's petrel Pterodroma cookii during its breeding season on Little Barrier Island, New Zealand." Emu **96**(3): 189-194.

Food samples were obtained from 69 Cook's Petrels Pterodroma cookii on Little Barrier Island. New Zealand, during the breeding seasons (October-March) of 1972 to 1977. Food comprised Cephalopoda, fish, Crustacea and Tunicata in that order of importance by volume. Dietary oil formed about 38% by volume of food fed to chicks. The main cephalopods (of 26 species) preyed on were members of the Cranchiidae, Spurilidae (entirely Spirula spirula) and Histioteuthidae (37, 24 and 22% respectively by mass). About 90% by mass of fishes taken were lantern-fishes (Myctiophidae), and about 50% by mass of crustaceans were decapod prawns. Seasonal variation was found in the proportion only of the cephalopods Argonauta and Leachia in the diet. Pumice and plastic particles were ingested. The diet revealed by these samples showed extensive reliance on small, mesopelagic, bioluminescent prey, most of which could

have been taken by active feeding at night. Selection of prey was related to the petrel's small size: over half of the cephalopods eaten were juvenile or immature.

Imhof, H. K., et al. (2013). "Contamination of beach sediments of a subalpine lake with microplastic particles." Current Biology **23**(19): R867-868.

Imhof, H. K. and C. Laforsch (2016). "Hazardous or not - are adult and juvenile individuals of Potamopyrgus antipodarum affected by non-buoyant microplastic particles?" Environmental Pollution **218**: 383-391.

Microplastic has been ubiquitously detected in freshwater ecosystems. A variety of freshwater organisms were shown to ingest microplastic particles, while a high potential for adverse effects are expected. However, studies addressing the effect of microplastic in freshwater species are still scarce compared to studies on marine organisms. In order to gain further insights into possible adverse effects of microplastic particles on freshwater invertebrates and to set the base for further experiments we exposed the mud snail (Potampoyrgus antipodarum) to a large range of common and environmentally relevant non-buoyant polymers (polyamide, polyethylene terephthalate, polycarbonate, polystyrene, polyvinylchloride). The impact of these polymers was tested by performing two exposure experiments with irregular shaped microplastic particles with a broad size distribution in a low (30%) and a high microplastic dose (70%) in the food. First, possible effects on adult P. antipodarum were assessed by morphological and life-history parameters. Second, the effect of the same mixture on the development of juvenile P. antipodarum until maturity was analyzed. Adult P. antipodarum showed no morphological changes after the exposure to the microplastic particles, even if supplied in a high dose. Moreover, although P. antipodarum is an established model organism and reacts especially sensitive to endocrine active substances no effects on embryogenesis were detected. Similarly, the juvenile development until maturity was not affected. Considering, that most studies showing effects on marine and freshwater invertebrates mostly exposed their experimental organisms to very small (<=20 micro m) polystyrene microbeads, we anticipate that these effects may be highly dependent on the chemical composition of the polymer itself and the size and shape of the particles. Therefore, more studies are necessary to enable the identification of harmful synthetic polymers as some of them may be problematic and should be declared as hazardous whereas others may have relatively moderate or no effects.

Imhof, H. K., et al. (2016). "Pigments and plastic in limnetic ecosystems: A qualitative and quantitative study on microparticles of different size classes." Water Research **98**: 64-74.

Recently, macroplastic (>5 mm) and especially microplastic (<5 mm) particles have been reported as emerging contaminants in marine and limnetic ecosystems. Their coloration is gained by the addition of pigments to the polymer blend which is the major component of the respective product. However, color is also a feature of paint and coatings whereby the pigment is the major component. Once abraded from a surface, paint particles may enter the environment via similar pathways as microplastic particles. So far no detailed studies of microplastic particles (pigmented and non-pigmented) as well as paint particles have been performed focusing on very small microparticles (1-50 mum), in either marine or limnetic ecosystems. Using Raman microspectroscopy with a spatial resolution down to 1 mum, we report a remarkable increase in the occurrence of (pigmented) microplastic particles below 500 mum. Among those, most particles were found at a size of ~130 mum in a freshwater ecosystem (subalpine Lake Garda, Italy). Moreover, our qualitative and quantitative analyses revealed that the number of paint microparticles significantly increased below the size range of 50 mum due

to their brittleness (the smallest detected paint particle had a size of 4 mum). Inductively coupled plasma mass spectrometry measurements showed that both colored particles found in nature as well as virgin particles contain a high variety of metals such as cadmium, lead and copper. These additives may elicit adverse effects in biota ingesting these microparticles, thus paints and associated compounds may act as formerly overlooked contaminants in freshwater ecosystems.

Imhof, H. K., et al. (2017). "Do microplastic particles affect Daphnia magna at the morphological, life history and molecular level?" PLoS ONE **12**(11).

Microplastic particles are ubiquitous not only in marine but also in freshwater ecosystems. However, the impacts of microplastics, consisting of a large variety of synthetic polymers, on freshwater organisms remains poorly understood. We examined the effects of two polymer mixtures on the morphology, life history and on the molecular level of the waterflea Daphnia magna (three different clones). Microplastic particles of ~40 µm were supplied at a low concentration (1% of the food particles) leading to an average of ~30 particles in the digestive tract which reflects a high microplastic contamination but still resembles a natural situation. Neither increased mortality nor changes on the morphological (body length, width and tail spine length) or reproductive parameters were observed for adult Daphnia. The analyses of juvenile Daphnia revealed a variety of small and rather subtle responses of morphological traits (body length, width and tail spine length). For adult Daphnia, alterations in expression of genes related to stress responses (i.e. HSP60, HSP70 & GST) as well as of other genes involved in body function and body composition (i.e. SERCA) were observed already 48h after exposure. We anticipate that the adverse effects of microplastic might be influenced by many additional factors like size, shape, type and even age of the particles and that the rather weak effects, as detected in a laboratory, may lead to reduced fitness in a natural multi-stressor environment.

Imhof, H. K., et al. (2012). "A novel, highly efficient method for the separation and quantification of plastic particles in sediments of aquatic environments." Limnology and Oceanography: Methods **10**(7): 524-537.

Although plastic debris is constantly accumulating in aquatic environments, the impact on aquatic ecosystems is not yet fully understood. A first important step to assess the consequences of plastic debris in aquatic ecosystems is the establishment of a reliable, verified, and standardized method to quantify the amount of plastic particles in the environment. We improved the density separation approach by the construction of the so called Munich Plastic Sediment Separator (MPSS). It enables a reliable separation of different ecologically relevant size classes of plastic particles from sediment samples. A ZnCl sub(2)-solution (1.6-1.7 kg/L) as separation fluid allows for an extraction of plastic particles ranging from large fragments to small microplastic particles (S-MPP, <1 mm). Subsequent identification and quantification of the particles with spatial resolution down to 1 mu m can be performed using Raman microspectroscopy. Our study is the first providing validated recovery rates of 100% for large microplastic particles (L-MPP, 1-5 mm) and 95.5% for S-MPP. The recovery rate for S-MPP, using the MPSS, was significantly higher than the value obtained by application of classical density separation setup (39.8%). Moreover, our recovery rates were significantly higher than those based on froth flotation (55.0% for L-MPP) commonly used in recycling industries. Hence, our improved method can be used for a reliable and time-efficient separation, identification and quantification of plastic fragments down to S-MPP. This will help foster studies quantifying the increasing contamination of aquatic environments with microplastic particles, which is a crucial prerequisite for future risk assessment and management strategies.

Immerseel, F. v., et al. (2004). "Microencapsulated short-chain fatty acids in feed modify colonization and invasion early after infection with Salmonella Enteritidis in young chickens." Poultry Science **83**(1): 69-74.

Short-chain fatty acids (SCFA) are widely used as feed additives in poultry for the control of pathogenic bacteria, such as Salmonella enteritidis. Recently, a new range of products was developed in which SCFA are encapsulated in mineral carriers, resulting in a slow release during the transport of these carriers through the intestinal tract. To test the efficacy of this type of products against early colonization after Salmonella infection in poultry, a challenge experiment with S. enteritidis was performed. Five groups of 20 chickens were given feed with no supplement or feed supplemented with acetic acid (0.24%), formic acid (0.22%), or propionic acid (0.27%) as film-coated microbeads or butyric acid (0.15%) as spray-cooled microcapsules. The 5 groups were challenged with 5.10³ cfu S. enteritidis at d 5 and 6 posthatch, and samples of ceca, liver, and spleen were taken at d 8 and analysed for the number of colony-forming units of Salmonella per gram of tissue. Feed supplementation with acetic acid, and to a lesser extent formic acid, resulted in an increase of colonization of ceca and internal organs. Birds receiving propionic acid-coated microbeads as feed supplement were colonized with Salmonella to the same extent as controls. Butyric acid-impregnated microbeads in the feed, however, resulted in a significant decrease of colonization by S. enteritidis in the ceca but not in liver and spleen.

Imparato, G., et al. (2013). "Bottom-up strategy to build up functional 3D dermis equivalent in vitro by tuning microscaffold degradation rate." Regenerative Medicine **1)**: 19.

One of the most challenging issues of in vitro tissue engineering is the implementation of strategies to successfully culture large and viable constructs in vitro, mimicking the natural tissue organization. Most of the natural tissues are often a combination of small repeating units assembled over several scales. As a consequence, from an engineering point of view, it was proposed to build tissues by assembling blocks mimicking those units in a bottom-up or modular approach. We proposed a versatile strategy yielding 3D dermis tissue constructs of defined size and geometry by means of the biological sintering of cell seeded microscaffold so-called microtissue precursors (muTPs). In the present study we produce 3D dermis equivalent exploiting muTPs assembling strategy, and investigate the role of microscaffold properties in guiding ECM organization and assembly towards the realization of the 3D final tissue. To this end we tuned the stiffness and degradation rate of the gelatin microscaffold by varying its crosslinking extent and realizing muTP with each kind of microscaffold type. We hypothesized that microscaffold properties strongly affect the collagen deposition in the extracellular space as well as its assembly and composition, resulting in 3D dermal-like tissue having different final properties. Gelatin porous microcarriers (GPM) were prepared according to a modified double emulsion technique (O/W/O) and then chemically crosslinked by means of glyceraldeide at 3%, 4% and 5% w/w of the microbeads in order to obtain microscaffolds characterized by different degradation rate. Building blocks for bottom-up tissue applications, such as muTPs were obtained by dynamic cell seeding of human dermal fibroblasts on the realized GPM by means of a spinner flask bioreactor. Dynamic culture lasts nine days during which muTPs samples were withdrawn for morphological and histological analyses. At end of spinner culture muTPs were transferred to a maturation chamber where under optimized culture conditions are induced to assembling generating a 3D dermal equivalent tissue. Time and space evolution of de novo synthesized collagen within the 3D growing tissue was monitored by means of histological analyses (staining with Picro sirius Red, hematoxylin eosin and masson's trichrome), second harmonic generation imaging (SHG) and ultra-structure analyses. Results showed that dynamic seeding performed on GPM at each crosslinking extents led to generation of muTP able to sustain the successively formation of 3D dermal equivalents tissues (Figure 1A). Endogenous ECM was present in the 3D tissues equivalent realized as highlighted by hystology, polarization microscopy with picrosirius red (Figure 1B) and SHG imaging (Figure 1C). Imaging analysis performed on picro sirius red staining images of 3D tissue equivalents allowed to discern between thck/mature fiber of collagen and thin/immature fiber of collagen. This quantitative analysis was exploited to monitor collagen maturation confirming that ECM's time evolution, organization and collagen assembly kinetics strongly depended upon the microscaffold's crosslinking extent. In particular, the increase of the crosslinking extent sped up collagen assembly kinetic obtaining stiffer ECM able to balance both scaffold's mass loss and cell traction. The results reached in this study demonstrate that muTP precursor assembly approach can be exploited to build-up human dermal tissue equivalent in vitro completely made up by endogenous ECM components. Due to the fundamental role played by microscaffol's degradation rate in the collagen maturation, it emerges the importance of controlling initial microscaffold properties in order to obtain 3D tissue having desired final features. (Figure Presented).

Imran, M., et al. (2019). "Co-selection of multi-antibiotic resistance in bacterial pathogens in metal and microplastic contaminated environments: An emerging health threat." Chemosphere **215**: 846-857.

Misuse/over use of antibiotics increases the threats to human health since this is a main reason behind evolution of antibiotic resistant bacterial pathogens. However, metals such as mercury, lead, zinc, copper and cadmium are accumulating to critical concentration in the environment and triggering co-selection of antibiotic resistance in bacteria. The co-selection of metal driven antibiotic resistance in bacteria is achieved through co-resistance or cross resistance. Metal driven antibiotic resistant determinants evolved in bacteria and present on same mobile genetic elements are horizontally transferred to distantly related bacterial human pathogens. Additionally, in marine environment persistent pollutants like microplastics is recognized as a vector for the proliferation of metal/antibiotics and human pathogens. Recently published research confirmed that horizontal gene transfer between phylogenetically distinct microbes present on microplastics is much faster than free living microbes. Therefore, microplastics act as an emerging hotspot for metal driven co-selection of multidrug resistant human pathogens and pose serious threat to humans which do recreational activities in marine environment and ingest marine derived foods. Therefore, marine environment co-polluted with metal, antibiotics, human pathogens and microplastics pose an emerging health threat globally.

Imre, L., et al. (2011). "Detection of mutations by flow cytometric melting point analysis of PCR products." Cytometry Part A: The Journal of the International Society for Analytical Cytology **79**(9): 720-726.

Exploring the possibilities offered by flow cytometric microbead analyses for the detection of genetic alterations, an assay based on the dependence of the melting point of double-stranded DNA molecules on their length has been developed, making use of PCR products carrying biotin and fluorescent moiety on their two ends. The samples of different length PCR products immobilized on streptavidine coated microbeads are heat-treated in the presence of formamide at temperatures between the melting point of the longer and that of the shorter PCR product, when the mean fluorescence intensity of the beads carrying the shorter molecules decreases as a result of denaturation, as opposed to the sample containing the longer product. The efficacy and sensitivity of the method is demonstrated in the case of the assessment of the degree of triplet expansion in Huntington's disease. Its utility for the detection of point mutations in heterozygous clinical samples is shown in the case of the BRCA1 gene. The assay is simple and may be offered for the purposes of clinical diagnostics of a number of genetic conditions. These include screening of samples for triplet expansions and SNPs predisposing for particular pathological or pharmacogenomic conditions. In general, the method described herein is offered for the diagnosis of any pathological condition where the length of a genomic or cDNA sequence is expected to be different from that of the normal allele.

Ings, S. (2017). "Animal or mineral?" New Scientist **234**(3122): 26-27.
The article reports on the photograph of Copeopod langisticus taken by the Mandy Barker and also talks about the small, immotile organism known as plankton who ingest plastic particles by mistaking them for food and because many larger creatures depend on plankton as a crucial source of food. Mandy Barker has been selected for this years Prix Pictet photography prize.

Iniguez, M. E., et al. (2017). "Microplastics in Spanish Table Salt." Scientific Reports **7**(1): 8620.
Marine debris is widely recognized as a global environmental problem. One of its main components, microplastics, has been found in several sea salt samples from different countries, indicating that sea products are irremediably contaminated by microplastics. Previous studies show very confusing results, reporting amounts of microparticles (MPs) in salt ranging from zero to 680 MPs/kg, with no mention of the possible causes of such differences. Several errors in the experimental procedures used were found and are reported in the present work. Likewise, 21 different samples of commercial table salt from Spain have been analyzed for MPs content and nature. The samples comprise sea salts and well salts, before and after packing. The microplastic content found was of 50-280 MPs/kg salt, being polyethylene-terephthalate (PET) the most frequently found polymer, followed by polypropylene (PP) and polyethylene (PE), with no significant differences among all the samples. The results indicate that even though the micro-particles might originate from multiple sources, there is a background presence of microplastics in the environment.

Inoue, T., et al. (2008). "Interleukin-8 as an independent predictor of long-term clinical outcome in patients with coronary artery disease." International Journal of Cardiology **124**(3): 319-325.
BACKGROUND: Accumulating evidence suggests that inflammation plays an essential role in the pathogenesis of atherosclerosis and that circulating inflammatory markers predict future cardiovascular events. However, previous studies evaluated the predictive value of only a single cytokine at a time.
AIMS: This study was designed to simultaneously measure plasma levels of multiple cytokines in patients with coronary artery disease and to evaluate their ability to predict long-term prognosis.
METHODS: The study enrolled 158 consecutive patients with angiographically identified stable coronary artery disease. Using the Luminex micro-beads array system, we simultaneously measured plasma levels of the following 10 cytokines: interleukin (IL)-1beta, IL-2, IL-4, IL-5, IL-6, IL-8, IL-10, tumor necrosis factor (TNF)-alpha, granulocyte-macrophage colony stimulating factor (GM-CSF) and gamma-interferon (IFN-gamma).
RESULTS: None of the 10 cytokine levels as well as high-sensitive C reactive protein (hs-CRP) was correlated with the severity of coronary artery disease. During a 7-year follow-up period, cardiovascular events occurred in 56 patients (35%). Multi-vessel disease, diabetes, and high levels of all of the 10 measured cytokines and hs-CRP were significant predictors of cardiovascular events in univariate analysis. However, multivariate analysis using multi-vessel disease, diabetes and the levels of all of 10 cytokines and hs-CRP showed that the only

independent predictor was IL-8 (RR, 2.98; 95%CI, 1.64-7.24; P=0.0001).
CONCLUSION: IL-8 was the only cytokine that predicted cardiovascular events independent of the other 9 cytokines and hs-CRP. Since IL-8 is a neutrophil chemokine, these results suggest that neutrophil activation may be related to the occurrence of cardiovascular events.

Inui, T. A., et al. (2018). "Daidzein-Stimulated Increase in the Ciliary Beating Amplitude via an [Cl⁻]_i Decrease in Ciliated Human Nasal Epithelial Cells." International Journal of Molecular Sciences **19**(12): 26.

The effects of the isoflavone daidzein on the ciliary beat distance (CBD, which is a parameter assessing the amplitude of ciliary beating) and the ciliary beat frequency (CBF) were examined in ciliated human nasal epithelial cells (cHNECs) in primary culture. Daidzein decreased [Cl⁻]_i and enhanced CBD in cHNECs. The CBD increase that was stimulated by daidzein was mimicked by Cl⁻-free NO3⁻ solution and bumetanide (an inhibitor of Na+/K+/2Cl⁻ cotransport), both of which decreased [Cl⁻]_{i.} Moreover, the CBD increase was inhibited by 5-Nitro-2-(3-phenylpropylamino)benzoic acid (NPPB, a Cl⁻ channel blocker), which increased [Cl⁻]_i. CBF was also decreased by NPPB. The rate of [Cl⁻]_i decrease evoked by Cl⁻-free NO3⁻ solution was enhanced by daidzein. These results suggest that daidzein activates Cl⁻ channels in cHNECs. Moreover, daidzein enhanced the microbead transport driven by beating cilia in the cell sheet of cHNECs, suggesting that an increase in CBD enhances ciliary transport. An [Cl⁻]_i decrease enhanced CBD, but not CBF, in cHNECs at 37 degreeC, although it enhanced both at 25 degreeC. Intracellular Cl⁻ affects both CBD and CBF in a temperature-dependent manner. In conclusion, daidzein, which activates Cl⁻ channels to decrease [Cl⁻]_i, stimulated CBD increase in cHNECs at 37 degreeC. CBD is a crucial factor that can increase ciliary transport in the airways under physiological conditions.

Inui, T. A., et al. (2019). "Enhancement of ciliary beat amplitude by carbocisteine in ciliated human nasal epithelial cells." Laryngoscope **11**: 11.

OBJECTIVE: Carbocisteine (CCis), a mucoactive agent, is used to improve the symptoms of sinonasal diseases. However, the effect of CCis on nasal ciliary beating remains uncertain. We examined the effects of CCis on ciliary beat distance (CBD, an index of amplitude), and ciliary beat frequency (CBF) in ciliated human nasal epithelial cells (cHNECs) in primary culture.
METHODS: The cHNECs were prepared from the nasal tissue resected from patients required surgery for chronic sinusitis (CS) or allergic rhinitis (AR). CBD and CBF were measured using videomicroscopy equipped with a high-speed camera.
RESULTS: CCis increased CBD by 30%, but not CBF, and decreased intracellular Cl⁻ concentration ([Cl⁻]_i) in cHNECs. The CCis' actions were mimicked by the Cl⁻ -free NO₃ ⁻ solution. In contrast, prior treatment of NPPB (20 muM) or CFTR(inh)-172 (1 muM), which increased [Cl⁻]_i by 20%, decreased CBF by 10% and CBD by 25% and inhibited the CCis' actions. However, prior treatment of T16Ainh-A01 (10 muM) did not inhibit the CCis' actions, although it decreased [Cl⁻]_i by 10% and CBD by 15%. Thus, CCis stimulates Cl⁻ channels including cystic fibrosis transmembrane conductance regulator (CFTR). Moreover, CCis enhanced the transport of microbeads driven by the beating cilia in cHNECs. The CCis actions were similar in cHNECs from both types of pateints.
CONCLUSION: CCis increased CBD by 30% in cHNECs via an [Cl⁻]_i decrease

stimulated by activation of Cl⁻ channels, including CFTR. CCis may stimulate nasal mucociliary clearance by increasing CBD in patients contracting CS or AR.
LEVEL OF EVIDENCE: NA. Laryngoscope, 2019.

Ionescu, S., et al. (2011). "RISK OF EXPOSURE TO ASBESTOS IN CASE OF THE MECHANICAL DEGRADATION OF SOME ASBOCEMENT COMPOSITES." Environmental Engineering & Management Journal (EEMJ) **10**(11): 1773-1777.

The hereby article presents a part of the results of the research made by the author during his PhD degree preparation with respect to asbestos and plastics wastes recycling in the form of composite with polymeric matrix, respectively the toxicological tests performed on the new product. In this respect, three categories of tests were made based on complex and modern analysis methodologies, with high results accuracy: spectral analysis of the wear wastes, morphological analysis of the wear wastes and analysis of other air samples from the impact area. The results of the investigations performed have denied the supposed toxicity of asbestos in the conditions of its embedding in a polymeric mass and could thus represent important arguments in the direction of making the applicable legislation flexible in the sense of allowing unrestricted sale of the resulted product. [ABSTRACT FROM AUTHOR]

Iqbal, R., et al. (2019). "In-vitro GIT Tolerance of Microencapsulated Bifidobacterium bifidum ATCC 35914 Using Polysaccharide-Protein Matrix." Probiotics & Antimicrobial Proteins **11**(3): 830-839.

Longevity of probiotic is the main concern for getting maximum benefits when added in food product. Bifidobacterium, a probiotic, tends to lose its viability during gastrointestinal track (GIT) transit and storage of food. Their viability can be enhanced through microencapsulation technology. In this study, Bifidobacterium bifidum (B. bifidum) ATCC 35914 was encapsulated by using two experimental plans. In the first plan, chitosan (CH) at 0.6, 0.8, and 1.0% and sodium alginate (SA) at 4, 5, and 6% were used. Based on encapsulation efficiency, 6% sodium alginate and 0.8% chitosan were selected for single coating of the bacteria, and the resulting micro beads were double coated with different concentrations (5, 7.5, and 10%) of whey protein concentrate (WPC) in the second plan. Encapsulation efficiency and GIT tolerance were determined by incubating the micro beads in simulated gastrointestinal juices (SIJ) at variable pH and exposure times, and their release (liberation of bacterial cells) profile was also observed in SIJ. The microencapsulated bacterial cells showed significantly (P < 0.01) higher viability as compared to the unencapsulated (free) cells during GIT assay. The double-coated micro beads SA 6%-WPC 5% and CH 0.8%-WPC 5% were proven to have the higher survival at pH 3.0 after 90 min of incubation time and at pH 7.0 after 3-h exposure in comparison to free cells in simulated conditions of the stomach and intestine, respectively. Moreover, double coating with whey protein concentrate played a significant role in the targeted (10⁶⁻⁹ CFU/mL) delivery under simulated intestinal conditions.

Ira, T. and S. Mukta (2012). "Awareness and interpretation of the symbols and codes by housewives used in plastic packaging." Asian Journal of Home Science **7**(1): 59-63.

Food packaging has played an important role in the life of consumers. Packaging is best tool for

transportation, protection and in preservation of food. Packaging phenomenon has grown from plant leaves to polymeric chemical compound plastic and thus continuously replacing its other counterparts, its various properties e.g. lightweight, strength, moisture resistance and durability has made it favorite for packaging industry so causing an increase in plastic production at a rate of about 5 per cent per year since 1973 (IWMB, 2003). The Indian polymer industry continues to show a growth rate of 15 per cent per annum. Studies have reported that plastics polymers pose potential hazards on human ecology, they have tendency of migrating the toxic chemicals as well as plastic's economical and environmental impact. Chemical additives used in plastics like phthalates or phthalic acid esters (PAE's), bisphenol A (BPA) could be transferred to human directly from plastics, via food and drink that is packaged in plastics. Plastics can be identified by the resin type code given from American Plastics Council. The picture and codes printed on plastics packaging can play an important role in spreading awareness regarding plastic produce toxicity for health and environment. Therefore, in this paper an attempt has been made to study the awareness and interpretation of symbols and codes printed on plastic packages among house wives. Data were collected by interview-cum-questionnaire method. It was found that awareness level was very less regarding plastic resin code though they knew about recycling symbols.

Iribarren, D., et al. (2012). "Preliminary assessment of plastic waste valorization via sequential pyrolysis and catalytic reforming." Journal of Material Cycles and Waste Management **14**(4): 301-307.

In this article, a life cycle assessment approach is used to carry out a preliminary assessment of the environmental and energy performance of a specific chemical recycling and recovery system that supplies a variety of petrochemical blendstocks through the sequential pyrolysis and catalytic reforming of plastic wastes. Characterization results are presented for a selection of seven impact categories: abiotic depletion, global warming, acidification, eutrophication, ozone layer depletion, photochemical oxidant formation and cumulative non-renewable energy demand. From a combined environmental and energy perspective, the results suggest the suitability of this system for plastic waste valorization. However, improvement actions aimed at reducing the thermal energy demand and mitigating direct emissions to the air should be undertaken. Furthermore, the environmental profiles of the proposed petrochemical blendstocks are compared with those of conventional energy products. A comparison among this chemical recycling and recovery system and two conventional management practices (municipal incineration and landfilling) is also addressed. The results show that the considered system could entail relevant environmental and energy benefits when compared to conventional energy systems and waste management strategies.

Ishii, K., et al. (2018). "Pemphigus foliaceus IgG autoantibodies block heterophilic trans-interaction of desmoglein 1 and desmocollin 1 without intracellular signaling." Journal of Investigative Dermatology **138 (5 Supplement 1)**: S145.

Pemphigus foliaceus (PF) is an autoimmune blistering disease caused by autoantibodies against desmoglein 1 (Dsg1). It is controversial whether blister formation is due to direct inhibition of Dsg interaction or intracellular signaling events that cause desmosome destabilization or both. A recent study showed that heterophilic binding of Dsg and desmocollin (Dsc) is important for adhesive unit of desmosomes. Here we analyzed that PF autoantibodies can block the trans-interaction of Dsg1 and Dsc1. Ectodomains of Dsg1 and Dsc1 were produced by a mammalian expression system and then coated on microbeads. Beads coated with Dsg1 alone or Dsc1 alone showed minimal aggregation while a mixture of Dsg1 beads and Dsc1 beads formed large aggregates after 30 min incubation, confirming that the heterophilic binding of

Dsg1 and Dsc1 is dominant. The aggregation required a mature form of Dsg1 and Dsc1, consistent with adhesion being a property only of mature, not proprotein. To determine if PF Abs can directly block Dsg/Dsc adhesion, we tested anti-Dsg1 mAbs isolated from a PF patient by phage display. A pathogenic anti-Dsg1 IgG or scFv mAb which binds putative trans-adhesive interface of Dsg1 could block the aggregation of Dsg1 and Dsc1 beads. On the other hand, non-pathogenic Dsg1 IgG or scFv mAbs did not inhibit aggregation. These findings indicated that this in vitro aggregation bead assay can discriminate pathogenic vs. non-pathogenic PF Abs. Furthermore, sera from 8 PF patients with active disease all inhibited the aggregation of Dsg1 and Dsc1 beads. When paired sera obtained from 3 PF patients in active stage and in remission were compared, the former inhibited aggregation much better than the latter, as determined by aggregate size. These findings show direct evidence that PF autoantibodies cause steric hindrance of the heterophilic transinteraction of Dsg and Dsc that provide adhesion to desmosomes. Furthermore, this assay will be a valuable and simple tool to assess pathogenic strength of PF autoantibodies.

Ishimatsu, R., et al. (2013). "An organic thin film photodiode as a portable photodetector for the detection of alkylphenol polyethoxylates by a flow fluorescence-immunoassay on magnetic microbeads in a microchannel." Talanta **117**: 139-145.

An organic thin film photodiode (OPD) was successfully employed as a portable photodetector in a competitive enzyme-linked immunosorbent assay (ELISA) of a class of nonionic surfactants, namely alkylphenol polyethoxylates (APnEOs) which are an environmental pollutant. Microbeads that were chemically immobilized with an anti-APnEOs antibody were used in the assay. The OPD consisted of a layer of copper phthalocyanine (CuPc), C60 and a second layer of bathocuproine (BCP) with a bulk heterojunction composed of CuPc and C60 prepared by a vapor deposition method on an indium-tin oxide coated glass substrate. The OPD showed an incident photon-current efficiency (IPCE) of approximately 19% for light at a wavelength of 585 nm. This relatively high IPCE at 585 nm makes it suitable for detecting the fluorescence of resorufin (lambdaem=585 nm), the product of the competitive ELISA, produced through the enzymatic reaction of Amplex Red with horseradish peroxidase (HRP) and H2O2. A fluorometric detector was assembled on a microchip by combining the fabricated OPD and a commercial LED as a photodetector and a light source, respectively. The photocurrent of the OPD due to the fluorescence of resorufin was proportional to the concentration of resorufin in the concentration range from 0 to 8 muM. When the fabricated OPD was used as a portable photodetector, the competitive ELISA of APnEOs using HRP labeled APnEOs (HRP-APnEOs) was performed on magnetic microbeads on which surface an anti-APnEOs antibody had been immobilized. A typical sigmoidal calibration curve was obtained and the data were in good agreement with a numerical simulation, where the photocurrent of the OPD was plotted against the concentration of APnEOs, determined via the competitive ELISA. The detection limit of the immunoassay for APnEOs was approximately 2 and 4 ppb in batch and flow system, respectively.

Ishioka, E., et al. (2016). "Elevated proportion of cd38highigd+ b cells in peripheral blood is related to disease activity in patients with primary sjogren's syndrome." Arthritis and Rheumatology **68 (Supplement 10)**: 1408-1409.

Background/Purpose: Primary Sjogren's syndrome (pSS) is well recognized as an autoimmune disease accompanied by hypergammaglobulinemia and production of autoantibodies such as anti-Ro/SSA and anti-La/SSB antibodies. Although these serological aberrations suggest that abnormally activated B cells play a key role in the pathogenesis of pSS, the possible involvement of hyperactivated B cells in the development of pSS has not been fully understood. In this study, we tried to identify B cell subsets in peripheral blood which may be responsible for disease activities of pSS. Method(s): Peripheral blood was collected from pSS patients (n = 34) and gender- matched healthy controls (HC, n = 20), and the proportion of B cell subsets characterized by anti-CD19, anti-IgD and anti-CD38 antibodies was analyzed by flow cytometry. CD19⁺B cells prepared from pSS patients and HC by using CD19-microbeads were stimulated in vitro with a mixture of an anti-IgM antibody, recombinant human CD40 ligand, recombinant human IL-4 and recombinant human soluble BAFF (B cell stimulation). IgG production by the cells was measured by ELISA. Disease activities of the pSS patients were quantified based on the European League against Rheumatism (EULAR) Primary Sjogren's syndrome disease activity index (ESSDAI). The serological data of the patients were collected by clinical records. Result(s): The proportion of CD19⁺ B cells was significantly increased in pSS patients as compared with HC. In addition, IgG production by CD19⁺ B cells in vitro upon B cell stimulation was also significantly increased in pSS patients. Moreover, the IgG production was positively and significantly correlated with serum IgG levels of the patients. Interestingly, FACS analysis of whole blood samples revealed that both CD38^{high}IgD⁺ and CD38^{high}IgD⁻ B cells were significantly increased in pSS patients compared with HC. Moreover, the number of CD38^{high}IgD⁺ B cells was significantly higher than that of CD38^{high}IgD⁻ B cells in the patients. In addition, the proportion of CD38^{high}IgD⁺ B cells to CD19⁺B cells was positively and significantly correlated with ESSDAI, serum levels of IgG, anti-Ro/SSA and anti-La/SSB antibodies. Conclusion(s): Our results suggest that CD38^{high}IgD⁺ B cells, which are known as activated B cells, are involved in overproduction of IgG and associated with disease activity of pSS. Our findings may shed light on the mechanism of pathogenesis of pSS.

Islam, A., et al. (2018). "Numerical simulation of gas injection in vertical water saturated porous media." Environmental Modeling & Assessment **23**(4): 459-469.

We present numerical simulations of drainage induced by air injection in a vertical water-saturated Hele-Shaw cell filled with glass microbeads. We use the macroscale Subsurface Transport Over Multiple Phases (STOMP) simulator developed by the Pacific Northwest National Laboratory's Hydrology Group. To trigger fingering, we use random permeability fields consistent to capillary entry pressure fields. We compare the numerical results to our own experimental results shown in a previous study. We analyze the effects of the microheterogeneity degree as well as the macroscopic parameters on the gas saturation results. The main objective of the work is to investigate how microscopic effects could be accounted for by macroscopic variables during drainage.

Islam, S., et al. (2019). "Targeting microplastic particles in the void of diluted suspensions." Environment International **123**: 428-435.

Accumulation of microplastic in the environment and food chain will be a grand challenge for our society. Polyurethanes are widely used synthetic polymers in medical (e.g. catheters) and industrial products (especially as foams). Polyurethane is not abundant in nature and only a few microbial strains (fungi and bacteria) and enzymes (polyurethaneases and cutinases) have been reported to efficiently degrade polyurethane. Notably, in nature a long period of time (from 50 to >100 years depending on the literature) is required for degradation of plastics. Material binding peptides (e.g. anchor peptides) bind strongly to polymers such as polypropylene, polyethylene terephthalate, and polyurethane and can target specifically polymers. In this study we report the fusion of the anchor peptide Tachystatin A2 to the bacterial cutinase Tcur1278 which accelerated the degradation of polyester-polyurethane nanoparticles by a factor of 6.6 in comparison to wild-type Tcur1278. Additionally, degradation half-lives of polyester-polyurethane nanoparticles were reduced from 41.8 h to 6.2 h (6.7-fold) in a diluted polyester-polyurethane suspension (0.04% w/v). Graphical abstract Unlabelled Image Highlights • Material binding peptides such as anchor peptides strongly bind synthetic polymers. • The anchor peptide Tachystatin A2 served as adhesion promoter for cutinase Tcur1278. • Tachystatin A2 enhanced enzymatic degradation of polyester-polyurethane by 6.6-fold. • Tachystatin A2 reduced half-life of polyester-polyurethane nanoparticles by 6.7-fold. • Prominent anchoring effect of adhesion promoter in highly diluted nanoparticles. [ABSTRACT FROM AUTHOR]

Isobe, A. (2016). "Percentage of microbeads in pelagic microplastics within Japanese coastal waters." Marine Pollution Bulletin **110**(1): 432-437.

To compare the quantity of microbeads with the quantity of pelagic microplastics potentially degraded in the marine environment, samples were collected in coastal waters of Japan using neuston nets. Pelagic spherical microbeads were collected in the size range below 0.8mm at 9 of the 26 stations surveyed. The number of pelagic microbeads smaller than 0.8mm accounted for 9.7% of all microplastics collected at these 9 stations. This relatively large percentage results from a decrease in the abundance of microplastics smaller than 0.8mm in the upper ocean, as well as the regular loading of new microbeads from land areas, in this size range. In general, microbeads in personal care and cosmetic products are not always spherical, but rather are often a variety of irregular shapes. It is thus likely that this percentage is a conservative estimate, because of the irregular shapes of the remaining pelagic microbeads.

Isobe, A., et al. (2019). "Abundance of non-conservative microplastics in the upper ocean from 1957 to 2066." Nature communications **10**(1): 417.

Laboratory-based studies have suggested that marine organisms can be harmed by ingesting microplastics. However, unless the current and future microplastic abundance in the ocean environment is quantified, these experimental studies could be criticized for using an unrealistic density or sparsity of microplastics. Here we show the secular variations of pelagic microplastic abundance in the Pacific Ocean from 1957 to 2066, based on a combination of numerical modeling and transoceanic surveys conducted meridionally from Antarctica to Japan. Marine plastic pollution is an ongoing concern especially in the North Pacific, and pelagic microplastics are regarded as non-conservative matter due to the removal processes that operate in the upper ocean. The results of our numerical model incorporating removal processes on a 3-year timescale suggested that the weight concentrations of pelagic microplastics around the subtropical convergence zone would increase approximately twofold (fourfold) by 2030 (2060) from the present condition.

Isobe, A., et al. (2014). "Selective transport of microplastics and mesoplastics by drifting in coastal waters." Marine Pollution Bulletin **89**(1/2): 324-330.

The quantity and size distributions of small plastic fragments in the Seto Inland Sea, Japan were

investigated using field surveys and a numerical particle-tracking model. The model was used to interpret the distributions of small plastic fragments and the possible transport processes in coastal waters. Of note, the size and quantity of mesoplastics (approximately >5 mm) gradually increased close to the coast irrespective of the existence of river mouths, which probably act as a major source of anthropogenic marine debris. Additionally, microplastics were more dominant as we moved further offshore. The numerical model reproduced the near-shore trapping of mesoplastics, suggesting that mesoplastics are selectively conveyed onshore by a combination of Stokes drift and terminal velocity, dependent on fragment sizes. It is suggested that mesoplastics washed ashore on beaches degrade into microplastics, and that the microplastics, which are free from near-shore trapping, are thereafter spread offshore in coastal waters.

Isobe, A., et al. (2015). "East Asian seas: A hot spot of pelagic microplastics." Marine Pollution Bulletin **101**(2): 618-623.

To investigate concentrations of pelagic micro- (5mm) in the East Asian seas around Japan, field surveys using two vessels were conducted concurrently in summer 2014. The total particle count (pieceskm-2) was computed based on observed concentrations (piecesm-3) of small plastic fragments (both micro- and mesoplastics) collected using neuston nets. The total particle count of microplastics within the study area was 1,720,000pieceskm-2, 16 times greater than in the North Pacific and 27 times greater than in the world oceans. The proportion of mesoplastics increased upstream of the northeastward ocean currents, such that the small plastic fragments collected in the present surveys were considered to have originated in the Yellow Sea and East China Sea southwest of the study area.

Isobe, A., et al. (2017). "Microplastics in the Southern Ocean." Marine Pollution Bulletin **114**(1): 623-626.

A field survey to collect microplastics with sizes <5mm was conducted in the Southern Ocean in 2016. We performed five net-tows and collected 44 pieces of plastic. Total particle counts of the entire water column, which is free of vertical mixing, were computed using the surface concentration (particle count per unit seawater volume) of microplastics, wind speed, and significant wave height during the observation period. Total particle counts at two stations near Antarctica were estimated to be in the order of 100,000pieceskm⁻².

Istamboulie, G., et al. (2007). "Highly sensitive detection of organophosphorus insecticides using magnetic microbeads and genetically engineered acetylcholinesterase." Biosensors & Bioelectronics **23**(4): 506-512.

This work presents a biosensor for organophosphorus pesticides based on immobilisation of a highly sensitive genetically engineered acetylcholinesterase (B394) by affinity interactions on metal chelate-functionalised magnetic microbeads. The developed sensor has been compared with those based on the widely used Electric eel cholinesterase and a classical entrapment procedure in a polyvinylalcohol-based matrix. The use of the B394 enzyme allowed lowering both IC50 and LOD by a factor of 100 when compared with Electric eel enzyme sensor. The oriented and site-specific immobilisation combined with the high specificity of the B349 mutant allows a more sensitive detection of insecticides, concentrations as low as 1.31(-11)M (IC10) being detected for both pesticides chlorpyriphos-oxon and chlorfenvinphos.

Ito, T., et al. (2009). "Preliminary study of a microbeads based histamine detection for food analysis using thermostable recombinant histamine oxidase from Arthrobacter crystallopoietes KAIT-B-007." Talanta **77**(3): 1185-1190.

We designed and prepared a micro biosensing system consisting of a flow through system with a

sub-micro liter injection valve and a sub-micro liter volume bioreactor. An electrochemical detector was combined with the reactor for immediate detections. The volumes of the reactor and the sample loop for the injection were 850 nl and 320 nl, respectively. This paper described about the characteristics of the sensing system in the case of histamine detection for food analysis. Histamine oxidase from KAIT-B-007 was prepared by using a gene recombination technique and they were immobilized with chitosan beads (phi -70-105 micro m). The detection less than one minute after injection made possible fast analysis for histamine. The biosensing system also showed a high performance for histamine detection in wide range of 1 micro M-1 mM. In addition, we practically measured histamine content in raw tuna stored at room temperature and 35 degrees C up to 96 h. As a result of the comparison between our sensing system and HPLC method, there was good agreement. These results show that our microfluidic biosensing system has the potential to assist miniaturization with small sample volume and short determination time for a sequential food analysis.

Ito, T., et al. (1991). "Preclinical assessment of ⁹⁰Y-labeled C110 anti-carcinoembryonic antigen immunotoxin: A therapeutic immunoconjugate for human colon cancer." Cancer Research **51**(1): 255-260.

We have synthesized ⁹⁰Y-labeled immunotoxin (IT) containing ricin A chain and C110 anti-carcinoembryonic antigen monoclonal antibody (MAb) to produce a therapeutic immunoconjugate for human colon cancer. The C110 IT was labeled with ⁹⁰Y via a benzylisothiocyanate derivative of diethylenetriaminepentaacetic acid. The efficiency of ⁹⁰Y labeling was consistently 90 to 98%, with a specific activity of about 1 muCi/mug. In in vitro stability studies, more than 80% of ⁹⁰Y remained bound to the C110 IT for up to 5 days after incubation. The percentage of binding of ⁹⁰Y-labeled C110 IT to carcinoembryonic antigen-coated microbeads was 86%, indicating good retention of the initial immunoreactivity of the C110 MAb. In in vitro protein synthesis inhibition assays, ⁹⁰Y-labeled C110 IT was approximately 3.7-fold more toxic to the LS174T human colon carcinoma cell line than unmodified C110 IT and 1380-fold more toxic than ⁹⁰Y-labeled C110 MAb. Biodistribution studies of ⁹⁰Y-labeled C110 IT in LS174T tumor-bearing mice showed that, at 24 h following i.p. injection, high accumulation of radioactivity was seen in the i.p. tumor and liver and, thereafter, high accumulation in these tissues remained almost unchanged until up to 168 h, with percentage of injected dose/g ranging from 15 to 18% in the tumor and 10 to 15% in the liver. The radioactivity in the spleen and bone gradually increased with time and reached their highest levels (approximately 8% of injected dose/g) at 168 h. Estimation of absorbed radiation doses to the tissues showed that i.p. tumor would have received an approximately 1.5 to 7 times higher radiation dose than normal organs. In in vivo therapeutic trials, ⁹⁰Y-labeled C110 IT provided survival prolongation of LS174T tumor-bearing mice superior to that with either unmodified C110 IT or ⁹⁰Y-labeled C110 MAb (4 < 0.01; Mann-Whitney U test). These results indicate that ⁹⁰Y labeled C110 anti-carcinoembryonic antigen IT may be a potent therapeutic immunoconjugate for human colon cancer and that it may have direct relevance for i.p. treatment of peritoneal carcinomatosis from colon cancers.

Ito, Y. A., et al. (2016). "A Magnetic Microbead Occlusion Model to Induce Ocular Hypertension-Dependent Glaucoma in Mice." Journal of Visualized Experiments(109): e53731.

The use of rodent models of glaucoma has been essential to understand the molecular mechanisms that underlie the pathophysiology of this multifactorial neurodegenerative disease.

With the advent of numerous transgenic mouse lines, there is increasing interest in inducible murine models of ocular hypertension. Here, we present an occlusion model of glaucoma based on the injection of magnetic microbeads into the anterior chamber of the eye using a modified microneedle with a facetted bevel. The magnetic microbeads are attracted to the iridocorneal angle using a handheld magnet to block the drainage of aqueous humour from the anterior chamber. This disruption in aqueous dynamics results in a steady elevation of intraocular pressure, which subsequently leads to the loss of retinal ganglion cells, as observed in human glaucoma patients. The microbead occlusion model presented in this manuscript is simple compared to other inducible models of glaucoma and also highly effective and reproducible. Importantly, the modifications presented here minimize common issues that often arise in occlusion models. First, the use of a bevelled glass microneedle prevents backflow of microbeads and ensures that minimal damage occurs to the cornea during the injection, thus reducing injury-related effects. Second, the use of magnetic microbeads ensures the ability to attract most beads to the iridocorneal angle, effectively reducing the number of beads floating in the anterior chamber avoiding contact with other structures (e.g., iris, lens). Lastly, the use of a handheld magnet allows flexibility when handling the small mouse eye to efficiently direct the magnetic microbeads and ensure that there is little reflux of the microbeads from the eye when the microneedle is withdrawn. In summary, the microbead occlusion mouse model presented here is a powerful investigative tool to study neurodegenerative changes that occur during the onset and progression of glaucoma.

Ivanidze, J., et al. (2016). "Assessment of cerebrospinal fluid leukotactin-1 (CCL-15) levels and blood-brainbarrier-permeability in the clinical setting." Journal of Cerebral Blood Flow and Metabolism **36 (Supplement 1)**: 258-259.

Objectives: Disruption of the Blood-Brain-Barrier (BBB) has been implicated in the pathophysiology of numerous conditions featuring an activated inflammatory milieu such as CNS malignancy, meningitis and autoimmune disorders, however, to date, there is limited clinical data on BBB permeability (BBBP). Recent studies demonstrated correlation of increase in BBBP with poor outcomes in patients with aneurysmal subarachnoid hemorrhage (SAH). CT Perfusion (CTP) allows assessment of quantitative parameters used to describe BBBP, including KEP, PS, Ktrans, and VE. KEP represents the washout rate constant of contrast agent from the EES (extravascular extracellular space) to the IVS (intravascular space), and is inversely related to BBBP. PS, the permeability surface area product, and represents the flow across the blood vessel wall. Ktrans equals plasma flow and VE represents EES volume per unit volume of tissue, respectively. Assessment of these parameters offers a promising technique to evaluate BBBP in the clinical setting. On the molecular level, increase in BBBP is thought to be mediated by inflammatory chemokines. The matrix metalloproteinase MMP-9 is inducible by chemokines, and plays a key role in the opening of the BBB. Leukotactin-1 (CCL15) is known to modulate MMP-9 release from macrophages in cardiovascular disease, however, the potential role of CCL15 in BBBP modulation has not been examined to date. The objective of this study is to correlate CCL15 protein levels in cerebrospinal fluid (CSF) with BBBP measured by CTP. Method(s): SAH patients underwent CTP in the early phase after aneurysmal rupture. CTP data were post-processed into BBBP quantitative maps of PS, K-trans, KEP, and VE using Olea Sphere software (Olea Medical, La Ciotat, France). Global cortically based ROI mean values were calculated for each patient. CSF was collected via indwelling ventriculostomy catheter (placed for intracranial pressure management) within 24 hours of CTP. CCL15 levels were measured in CSF supernatant using multiplex microbead immunoassay technology (Luminex Corp, Austin, TX). Result(s): In this preliminary study, BBBP parameters and CSF CCL15 levels were prospectively assessed in 7 patients with SAH admitted to the Neurological Intensive Care Unit at our institution. Spearman correlation analysis was performed to determine correlation between CCL15 and KEP, PS, Ktrans and VE, respectively. In the case of CCL15 and KEP, a statistically highly significant inverse correlation was found (r = - 0.96, p = 0.0028). Correlation results for PS, Ktrans, and VE were not statistically significant, however, there was a trend for positive correlation as demonstrated in Figure 1. Conclusion(s): Elevated BBBP, expressed as low KEP, correlated with elevated CSF levels of CCL15 in the clinical setting in patients with SAH, indicating a pathophysiological correlate for the presumed BBBP disruption via chemokine-induced MMP-9 upregulation. This study is limited due to its proof-of-concept character and small sample size, and future studies evaluating additional chemokines, as well as MMPs, are needed to improve understanding of BBBP disruption and to thereby improve clinical outcomes.

Ivanov, V., et al. (2004). "Removal of micro-particles by microbial granules used for aerobic wastewater treatment." Water Science & Technology **50**(12): 147-154.

Microbial granules with a diameter from 0.4 mm to 3.0 mm have been produced by fast sedimentation and retention of microbial aggregates in sequencing batch airlift reactors used for model wastewater treatment. The wastewater was with or without addition of calcium salt. The granules were able not only to degrade organic matter but to remove nano- and micro-particles from wastewater due to microchannels and pores in the matrix of the granules. To detect the removal of 0.1 microm, 0.6 pm, 4.2 microm fluorescent microspheres, and cells of Escherichia coli, stained by permeable nucleic acid stain SYTO9, the granules were incubated with these particles. The rate of particle removal and their accumulation in the granules was measured by a Fluoview300 confocal laser scanning microscope (CLSM) (Olympus, Japan); a FACSCalibur flow cytometer (Becton Dickinson, CA, USA), and a fluorescence spectrometer LS-50B (Perkin-Elmer, UK). The release or removal of biological and non-biological particles was analyzed by a flow cytometer after DNA staining. Total number of the particles bigger than 0.1 microm in the reactors was approximately 4 x 10(7) per ml, and 23% of these particles were bacterial cells. The 0.1 microm and 4.2. microm microbeads were accumulated within 250 microm in the upper layer of the microbial granule but externally added cells of Escherichia coli penetrated to the depth of approximately 800 microm in the granules without calcium addition. Microbial granules contained also attached ciliates but accumulation of the particles in protozoan cells was smaller than in the granule matrix. Kinetics of particle sorption was revealed by flow cytometry and fluorescence spectrometry. Almost half of the stained cells of E. coli can be removed by the granules for one hour. The ability of the microbial granules to remove the particles can enhance their function in aerobic treatment of wastewater.

Ivanova, M., et al. (2011). "A novel bead-based liquid assay as a platform for multiplex detection of mutations associated with myeloproliferative neoplasms." Tissue Antigens **77 (5)**: 472-473.

A plethora of aquired mutations, including JAK2 V617F, JAK2 exon 12 and MPL exon 10 mutations, have recently been reported to be associated with the pathogenesis of Philadelphia chromosome-negative myeloproliferative neoplasms (MPNs). Here we report the establishment and validation of a novel, rapid, cost-effective and high-throughput method for JAK2 and MPL mutations identification using a multiplexed bead-based suspension array platform - LuminexRxMAPTM and locked nucleic acid -modified oligonucleotide probes. The following 10 mutations relevant for diagnosis and therapy were selected: JAK2 exon 14 (V617F), 5 exon 12 mutations and deletions, 3 MPL exon 10 mutations. A 354 bp region of JAK2 exon 14, 180 bp region of exon 12 and 277 bp of MPL genes were amplified using biotinylated primers and genotyping was performed by direct hybridization with 2 oligonucleotide probes, specific for the

corresponding wild type and mutant alleles. The probes were modified with locked nucleic aicds and were synthesized with 5 amino group and 20 bases spacer oligonucleotides to allow covalent attachment to carboxylated microbeads (Luminex Corp). The method was validated by testing of on artificial plasmid constructs harboring the mutations and clinical samples from patients with MPNs, genotyped by direct DNA sequencing. Compared to previously described methods, our approach had a higher sensitivity- approximately 2% mutant DNA on a wild-type background. No discrepancies between the novel Luminex-based method and sequencing were observed. Thus, it could be successfully implemented in the diagnostic work-up for MPNs. Furthermore due to the multiplexing this system allowed simultaneous testing for the presence of various mutations associated with MPNs. Additionally, the assay allowed to quantify mutant alleles burden and therefore was applicable for assessment of minimal residual disease in patients following HSCT.

Ivanova, M., et al. (2010). "Detection of mutations associated with chronic myeloproliferative disorders using a bead-based liquid assay." Tissue Antigens **75 (5)**: 527-528.

The JAK2 V617F mutation has recently been reported to be associated with the pathogenesis of chronic myeloproliferative disorders (CMPDs). Several techniques such as restriction fragment length polymorphism, direct sequencing analysis, pyrosequencing, real-time AS-PCR6 and a denaturing high-performance liquid chromatography have been developed for the detection of this kind of mutation. Here we report the establishment and validation of a novel rapid, cost-effective and highthroughput method for JAK2 V617F mutation identification using a multiplexed microsphere-based suspension array platform - LuminexRxMAPTM. A 354 bp region of JAK2 gene was amplified using biotinilated primers and genotyping was performed by direct hybridization with 2 oligonucleotide probes, specific for the wiled type and mutant alleles. The probes were synthesized with 5' amino group and 20 bases spacer oligonucleotides to allow covalent attachment to carboxylated microbeads (Luminex Corp). The method was validated by testing of an artificial plasmid construct harboring the mutation and 80 clinical samples from patients with CMPDs, genotyped by DNA sequencing. The sensitivity of this novel assay was approximately 5% mutant DNA in a wild-type background. No discrepancies between the novel Luninex-based method and sequencing were observed. Thus, it could be successfully implemented in the diagnostic work-up for CMPDs. Additionally, the assay developed allowed to quantify mutant allele burden and therefore was applicable for assessment of minimal residual disease in patients following HSCT. Furthermore, this system would allow the design of multiplex assays for simultaneous testing for the presence of various mutations associated with CMPDs.

Ivar do Sul, J., et al. (2014). "Microplastics in the pelagic environment around oceanic islands of the Western Tropical Atlantic Ocean." Water, Air & Soil Pollution **225**(7): 1-13.

Recent evidence suggests that microplastic pollution is widespread in every oceanic basin; however, there is limited data available for the tropical South Atlantic Ocean. The purpose of this study was to examine the distribution, density and characteristics of plastic particles in plankton samples collected in the western tropical Atlantic Ocean. Neustonic tows (N = 160) were conducted near three important insular environments (Fernando de Noronha, Abrolhos and Trindade), and the presence of microplastics in the ocean surface of these areas was confirmed for the first time. The collected microplastic particles included hard plastic fragments, plastic films, paint chips and fibres and strands, which were classified as a secondary source of microplastics. The stock of plastic originates from both land-based and marine-based sources. This type of marine pollution in the tropical Atlantic Ocean is a potential threat to important

ecological species. [ABSTRACT FROM AUTHOR]

Ivar do Sul, J. A. and M. F. Costa (2014). "The present and future of microplastic pollution in the marine environment." Environmental Pollution **185**: 352-364.
Recently, research examining the occurrence of microplastics in the marine environment has substantially increased. Field and laboratory work regularly provide new evidence on the fate of microplastic debris. This debris has been observed within every marine habitat. In this study, at least 101 peer-reviewed papers investigating microplastic pollution were critically analysed (Supplementary material). Microplastics are commonly studied in relation to (1) plankton samples, (2) sandy and muddy sediments, (3) vertebrate and invertebrate ingestion, and (4) chemical pollutant interactions. All of the marine organism groups are at an eminent risk of interacting with microplastics according to the available literature. Dozens of works on other relevant issues (i.e., polymer decay at sea, new sampling and laboratory methods, emerging sources, externalities) were also analysed and discussed. This paper provides the first in-depth exploration of the effects of microplastics on the marine environment and biota. The number of scientific publications will increase in response to present and projected plastic uses and discard patterns. Therefore, new themes and important approaches for future work are proposed.

Ivar do Sul, J. A., et al. (2013). "Pelagic microplastics around an archipelago of the Equatorial Atlantic." Marine Pollution Bulletin **75**(1-2): 305-309.
Plastic marine debris is presently widely recognised as an important environmental pollutant. Such debris is reported in every habitat of the oceans, from urban tourist beaches to remote islands and from the ocean surface to submarine canyons, and is found buried and deposited on sandy and cobble beaches. Plastic marine debris varies from micrometres to several metres in length and is potentially ingested by animals of every level of the marine food web. Here, we show that synthetic polymers are present in subsurface plankton samples around Saint Peter and Saint Paul Archipelago in the Equatorial Atlantic Ocean. To explain the distribution of microplastics around the Archipelago, we proposed a generalised linear model (GLM) that suggests the existence of an outward gradient of mean plastic-particle densities. Plastic items can be autochthonous or transported over large oceanic distances. One probable source is the small but persistent fishing fleet using the area.

Ivarsen, A., et al. (2004). "Plastic particles at the LASIK interface." Ophthalmology **111**(1): 18-23.
PURPOSE: To investigate the origin, composition, and persistence of the interface particles that frequently are observed after LASIK.
DESIGN: Small case series and experimental animal study.
METHODS: Four patients received LASIK using a Schwind Supratome (Schwind, Kleinostheim, Germany) and a MEL 70 G-Scan excimer laser (Asclepion, Jena, Germany) and were examined over the course of 1 year using slit-lamp and in vivo confocal microscopy. Four rabbits received a monocular microkeratome incision and were examined immediately after surgery without lifting the flap. After monthly evaluation for 4 months using in vivo confocal microscopy, 2 corneas were processed for histologic analysis and were sectioned serially. To measure the iron content,

atomic absorption spectrometry was performed on 2 operated and 2 unoperated rabbit corneas. The chemical composition of the metal and plastic parts of the microkeratome blade was identified using energy dispersive x-ray fluorescence (metal part), and Raman and infrared spectroscopy (plastic part). Before and after oscillation in air, the microkeratome blade and motor-head were examined using light and fluorescence microscopy. In serial sections, interface particles were identified by fluorescence microscopy and their chemical composition was determined using Coherent Antistokes Raman Scattering microscopy.

RESULTS: In LASIK patients, thousands of brightly reflecting particles (up to 30 micro m) were observed throughout the interface. The highest particle density was detected where the microkeratome blade had first entered the cornea. Both in the center and at the flap edge, the morphologic features, distribution, and density of these particles remained unaltered throughout the 1-year observation period. In rabbit corneas, interface particles were observed immediately after the microkeratome incision, even though the flap had not been lifted. These particles were similar to those observed in humans and persisted unaltered throughout the study. The operated and unoperated rabbit corneas had comparable iron content, demonstrating that the particles were not fragments of the uncoated steel blade. Only a few particles were observed on the unused microkeratome motor head and blade, whereas numerous fluorescent particles were detected after oscillation in air, the amount of particles increasing with oscillation time. Interestingly, the only fluorescent part of the microkeratome was the plastic segment of the blade. This plastic (polyetherimide) emitted fluorescence identical to that of the observed particles, whereas all metal parts of the microkeratome blade and motor head were nonfluorescent. In serial sections, interface particles showed fluorescent properties equivalent to polyetherimide and exhibited molecular resonance at 1780 and 3100 cm(-1), in accordance with the Raman spectrum of polyetherimide.

CONCLUSIONS: Numerous plastic particles are generated during microkeratome oscillation and are deposited at the interface during LASIK. The particles persist unaltered for at least 1 year.

Ivleva, N. P., et al. (2017). "Microplastic in Aquatic Ecosystems." Angewandte Chemie. International Ed. in English **56**(7): 1720-1739.

The contamination of marine and freshwater ecosystems with plastic, and especially with microplastic (MP), is a global ecological problem of increasing scientific concern. This has stimulated a great deal of research on the occurrence of MP, interaction of MP with chemical pollutants, the uptake of MP by aquatic organisms, and the resulting (negative) impact of MP. Herein, we review the major issues of MP in aquatic environments, with the principal aims 1) to characterize the methods applied for MP analysis (including sampling, processing, identification and quantification), indicate the most reliable techniques, and discuss the required further improvements; 2) to estimate the abundance of MP in marine/freshwater ecosystems and clarify the problems that hamper the comparability of such results; and 3) to summarize the existing literature on the uptake of MP by living organisms. Finally, we identify knowledge gaps, suggest possible strategies to assess environmental risks arising from MP, and discuss prospects to minimize MP abundance in aquatic ecosystems.

Iwamoto, S., et al. (2002). "Preparation of gelatin microbeads with a narrow size distribution using microchannel emulsification." AAPS PharmSciTech **3**(3): E25.

The purpose of this study was to prepare monodisperse gelatin microcapsules containing an active agent using microchannel (MC) emulsification, a novel technique for preparing water-in-oil (W/O) and oil-in-water (O/W) emulsions. As the first step in applying MC emulsification to the preparation of monodisperse gelatin microcapsules, simple gelatin microbeads were prepared using this technique. A W/O emulsion with a narrow size distribution containing gelatin in the aqueous phase was created as follows. First, the aqueous disperse phase was fed into the continuous phase through the MCs at 40 degrees C (operating pressure: 3.9 kPa). The emulsion droplets had an average particle diameter of 40.7 microm and a relative standard deviation of 5.1%. The temperature of the collected emulsion was reduced and maintained at 25 degrees C overnight. The gelatin microbeads had a smooth surface after overnight gelation; the average particle diameter was calculated to be 31.6 microm, and the relative standard deviation, 7.3%. The temperature was then lowered to 5 degrees C by rapid air cooling and finally dried. The gelatin beads were dried and could be resuspended well in iso-octane. They had an average particle diameter of 15.6 microm, and a relative standard deviation of 5.9%. Using MC emulsification, we were able to prepare gelatin microbeads with a narrow size distribution. Since this emulsification technique requires only a low-energy input, it may create desirable experimental conditions for microencapsulation of unstable substances such as peptides and proteins. This method is promising for making monodisperse microbeads.

Iwasaki, K., et al. (2019). "Suppressive Effect of Everolimus on IL-2, IL-10, IL-21, and IFNgamma Levels: Implications for the Successful Minimization of Calcineurin Inhibitor Use in Transplantation." Therapeutic Drug Monitoring **41**(3): 371-375.

Background:Success with calcineurin inhibitors (CNIs) such as cyclosporine A (CSA) and tacrolimus (TAC) in organ transplantation has demonstrated that cytokine suppression is a key factor in patient management. However, the exact effects of recently introduced immunosuppressive agents other than CNI on cytokine expression remain unknown. In this study, the action of the mTOR-inhibitor everolimus (EVR) and that of the antimetabolite mycophenolic acid (MPA) on the transcription of several cytokines was investigated. Method(s):Peripheral blood mononuclear cells obtained from healthy volunteers were stimulated with anti-CD3/28 microbeads in the presence of CSA, TAC, EVR, and/or MPA for 8 hours. The mRNA levels of each cytokine were measured using quantitative real-time polymerase chain reaction. Result(s):MPA had no inhibitory effect on any of the cytokines tested. EVR showed moderate inhibition of IL-2, IL-10, IL-21, and IFNgamma levels. These cytokines were further analyzed to investigate the additive effect of EVR in combination with CNI. The beneficial effect of EVR addition was seen at low concentrations of CSA or TAC, while no additive effect was observed at high concentrations. Conclusion(s):EVR might effectively inhibit the activation of recipient immune cells in combination with a low dose of CNI, maximizing clinical benefit by preventing graft rejection and alleviating CNI-induced adverse effects. Iwasaki, S., et al. (2017). "Fate of microplastics and mesoplastics carried by surface currents and wind waves: a numerical model approach in the Sea of Japan." Marine Pollution Bulletin **121**(1/2): 85-96.

A numerical model was established to reproduce the oceanic transport processes of microplastics and mesoplastics in the Sea of Japan. A particle tracking model, where surface ocean currents were given by a combination of a reanalysis ocean current product and Stokes drift computed separately by a wave model, simulated particle movement. The model results corresponded with the field survey. Modeled results indicated the micro- and mesoplastics are moved northeastward by the Tsushima Current. Subsequently, Stokes drift selectively moves mesoplastics during winter toward the Japanese coast, resulting in increased contributions of mesoplastics south of 39 degrees N. Additionally, Stokes drift also transports micro- and mesoplastics out to the sea area south of the subpolar front where the northeastward Tsushima Current carries them into the open ocean via the Tsugaru and Soya straits. Average transit time of modeled particles in the Sea of Japan is drastically reduced when including Stokes drift in the model.

Iwata, H., et al. (1988). "Microencapsulation of Langerhans Islets in Agarose Microbeads and Their Application for a Bioartificial Pancreas." Journal of Bioactive and Compatible Polymers **3**(4): 356-369.

Microencapsulation of islets is considered to be a promising approach to the development of a bioartificial pancreas. In this study agarose was examined as a material to microencapsulate islets. By a low-temperature gelation tech nique, islets can be easily microencapsulated into agarose microbeads without any adverse effect on the functions of islets. Encapsulated islets in agarose microbeads maintained their intact round shapes during the entire period of culturing. They secreted 50-70 kU islet super(-1) day super(-1) insulin into the culture medium and regulated insulin secretion minute by minute in response to the change of glucose concentration even after 140 days of in vitro culture. The molecular weight permeability of agarose microbeads can be modulated by changing the agarose concentration. Agarose microbeads containing higher than 10 wt% can hinder the penetration of bovine serum albumin (M.W. = 67,000), and thus can protect islets from the attack of immunoglobulin. Hamster islets encapsulated in microbeads containing 11 wt% agarose were xenogenically transplanted into the peritoneal cavity of a diabetic mouse. Before the transplantation plasma glucose levels were higher than 400 mg dL super(-1). After transplantation plasma glucose levels were normalized within two days and the normoglycemic period was 29 days. Although more studies are needed to prolong this period for bioartificial pancreas function, agarose is a prominent basic material for en capsulating islets.

Iwata, H., et al. (1994). "Feasibility of agarose microbeads with xenogeneic islets as a bioartificial pancreas." Journal of Biomedical Materials Research, Part B: Applied Biomaterials **28**(9): 1003-1011.

A bioartificial pancreas, that is, transplantation of islets of Langerhans (islets) which are enclosed in a semipermeable membrane, has been proposed as a treatment for type I diabetes. The islets are immuno-isolated from the host by the semipermeable membrane preventing rejection while maintaining control of glucose metabolism for an extended period. The purpose of the current research is to evaluate the feasibility of preparing agarose microbeads with xenogeneic hamster islets as a bioartificial pancreas in streptozotocin induced diabetic mice. In the recipients with a low level of anti-hamster antibodies, the combination of encapsulation of hamster islets in 5% agarose microbeads and in vitro culture of them prolonged xenograft survivals. Four of 6 recipients were still normoglycemic at 100 days after implantation. However, the same procedure was not effective in the recipients which were sensitized in advance by transplantation of free hamster islets and thus had high levels of anti-hamster antibodies. The average normoglycemic period was 32 days. Antibodies permeated through the microbeads and activated complement on the cell surfaces. The network of agarose microbeads was rendered dense by increasing the concentration of agarose to restrict the diffusion of antibodies. Graft survivals were prolonged with increasing concentrations of agarose. As an analysis using diffusion equations predicted, the survivals were inversely proportional to the diffusion coefficient of IgG in each agarose gel. Islet xenotransplantation was enabled by the combination of the microbeads with a concentration of agarose higher than 7.5% and in vitro culture even in recipients having a high level of preformed antibodies.

Iwata, H., et al. (1999). "Control of complement activities for immunoisolation." Annals of the New York Academy of Sciences **875**: 7-23.

Immunoisolation of cells by semipermeable membranes is a most promising approach to transplant xenogeneic cells. Although membranes which allow xenotranplantation have been reported, ambiguity remains as to their long term effectiveness. In this review, we would like to reconsider the immuno-isolative effectiveness of membranes reported from the standpoint of permeability and present our strategy to prepare membranes that can realize long-term functioning of xenograft. There are distinct different types of semipermeable membranes, hydrogel membranes and ultrafiltration membranes. Studies on their permeability indicated that neither of these membranes effectively fractionate solutes on the basis of molecular size under a diffusion-controlled process, nor thus can they immuno isolate xenograft for a long time. Humoral immunity including antibodies and complement proteins is suspected of playing a major role in the rejection of xenografts. Control of complement cytolytic activities, not antibody permeation, may be a key factor determining the fate of the xenograft enclosed in membranes. We found that the microbead containing poly(styrene sulfonic acid) can consume complement cytolytic activities and thus can effectively protect xenogeneic islets of Langerhans in diabetic mice from the humoral immunity.

Iwata, H., et al. (1994). "Strategy for developing microbeads applicable to islet xenotransplantation into a spontaneous diabetic NOD mouse." Journal of Biomedical Materials Research **28**(10): 1201-1207.

A bioartificial pancreas (BAP) created through the encapsulation of islets of Langerhans (islets) in a semipermeable membrane has been proposed as a promising approach to treating insulin-dependent diabetes patients. A nonobese diabetic (NOD) mouse, which shares many features of human insulin-dependent diabetes mellitus, is an ideal model for evaluating the function of BAP. However, the functions of BAPs that have been developed have been limited in NOD mice. We propose novel microbeads that can realize long-term BAP function in NOD mice. The novel microbeads were composed of agarose and poly(styrene sulfonic acid) (PSSa) mixed gel. A polyion complex layer between PSSa and polycationic polybrene was formed on and just inside the microbead, and the microbead surfaces were further covered by polyanions to produce anionic surface charges. The islets in the novel microbeads were intraperitoneally implanted. Graft-functioning periods were dependent on both PSSa concentration and the kinds of polyanion. Islets in the microbeads composed of 5% agarose and 5% PSSa, which had an outermost surface covered by carboxymethyl cellulose, produced normoglycemic periods of more than 60 days in all five recipients. Control mice receiving either transplants of unenclosed islets or islets in agarose microbeads showed normoglycemic periods of less than 12 days. We believe that agarose/PSSa microbeads are promising for producing semipermeable membranes that enable xenotransplantation of islets in spontaneous diabetes mellitus.

Jabart, E., et al. (2015). "A microfluidic method for the selection of undifferentiated human embryonic stem cells and in situ analysis." Microfluidics and Nanofluidics **18**(5-6): 955-966.

Conventional cell-sorting methods such as fluorescence-activated cell sorting (FACS) or magnetic-activated cell sorting (MACS) can suffer from certain shortcomings such as lengthy sample preparation time, cell modification through antibody labeling, and cell damage due to exposure to high shear forces or to attachment of superparamagnetic Microbeads. In light of these drawbacks, we have recently developed a label-free, microfluidic platform that can not only select cells with minimal sample preparation but also enable analysis of cells in situ. We demonstrate the utility of our platform by successfully isolating undifferentiated human embryonic stem cells (hESCs) from a heterogeneous population based on the undifferentiated stem-cell marker SSEA-4. Importantly, we show that, in contrast to MACS or FACS, cells isolated by our method have very high viability (~90 %). Overall, our platform technology could likely be applied to other cell types beyond hESCs and to a variety of heterogeneous cell populations in order to select and analyze cells of interest.

Jabeen, K., et al. (2017). "Microplastics and mesoplastics in fish from coastal and fresh waters of China." Environmental Pollution **221**: 141-149.

Plastic pollution is a growing global concern. In the present study, we investigated plastic pollution in 21 species of sea fish and 6 species of freshwater fish from China. All of the species were found to ingest micro- or mesoplastics. The average abundance of microplastics varied from 1.1 to 7.2 items by individual and 0.2-17.2 items by gram. The average abundance of mesoplastics varied from 0.2 to 3.0 items by individual and 0.1-3.9 items by gram. Microplastics were abundant in 26 species, accounting for 55.9-92.3% of the total number of plastics items in each species. Thamnaconus septentrionalis contained the highest abundance of microplastics (7.2 items/individual). The average abundance of plastics in sea benthopelagic fishes was significantly higher than in freshwater benthopelagic fishes by items/individual. The plastics were dominated by fiber in shape, transparent in color and cellophane in composition. The proportion of plastics in the stomach to the intestines showed great variation in different species, ranging from 0.5 to 1.9 by items/individual. The stomach of Harpodon nehereus and intestines of Pampus cinereus contained the highest number of plastics, (3.3) and (2.7), respectively, by items/individual. Our results suggested that plastic pollution was widespread in the investigated fish species and showed higher abundance in comparison with worldwide studies. The ingestion of plastics in fish was closely related to the habitat and gastrointestinal tract structure. We highly recommend that the entire gastrointestinal tract and digestion process be used in future investigations of plastic pollution in fish.

Jabłońska, B., et al. (2019). "Physical and Chemical Properties of Waste from PET Bottles Washing as A Component of Solid Fuels." Energies **12**(11).

The latter causes air pollution due to emissions of oxides of hydrocarbons, ammonia, sulphur dioxide, corrosive organic acids, dioxins, furans and others [7]. [...]the most appropriate form of plastic waste management seems to be mechanical (material) and chemical (raw material) recycling, which results in the same products as the initial product or products for other purposes. [...]of processes preparing waste plastic for granulation in the washing process line, waste and sub-process waste are generated. According to [30], in the digestate sewage sludge, the content of combustible parts is ca. 60%, and in cotton stalks, 63%. Despite the small amount of heavy metal ions, the wastes tested do not meet the criteria determining the possibility of storing them in a landfill other than hazardous or inert wastes due to the over-normative content of PEE and TOC. [...]pursuant to Polish law [63], the waste cannot be disposed of via landfill of non-hazardous and inert waste, if TOC >5% d.m., loss on ignition >8% d.m. and the heat of combustion >6 MJ/kg d.m., which is the case. 5.

Jacassi, A., et al. (2017). "Scanning Probe Photonic Nanojet Lithography." Acs Applied Materials & Interfaces **9**(37): 32386-32393.

The use of nano/microspheres or beads for optical nanolithography is a consolidated technique for achieving subwavelength structures using a cost-effective approach; this method exploits the capability of the beads to focus electromagnetic waves into subwavelength beams called photonic nanojets, which are used to expose the photoresist on which the beads are placed. However, this technique has only been used to produce regular patterns based on the spatial arrangement of the beads on the substrate, thus considerably limiting the pool of applications. Here, we present a novel microsphere-based optical lithography technique that offers high subwavelength resolution and the possibility of generating any arbitrary pattern. The presented method consists of a single microsphere embedded in an AFM cantilever, which can be controlled using the AFM motors to write arbitrary patterns with subwavelength resolution (down to 290 nm with a 405 nm laser). The performance of the proposed technique can compete with those of commercial high-resolution standard instruments, with the advantage of a one-order-of-magnitude reduction in costs. This approach paves the way for direct integration of cost-effective, high-resolution optical lithography capabilities into several existing AFM systems.

Jack, R. M., et al. (2014). "Continuous isolation, labeling and collection of viable CTCs using an integrated microfluidic device." Cancer Research. Conference: 105th Annual Meeting of the American Association for Cancer Research, AACR **74**(19 SUPPL. 1).

The concept of studying tumor-derived circulating tumor cells (CTCs) from a simple blood-draw of a patient, has acquired significant attention in recent years. This relatively non-invasive approach opens many avenues in understanding and monitoring quite a number of cancers where correlations have since been made with CTCs and patient survival as well as patient response to therapeutics. Additionally, studies geared towards identifying genetic markers as well as gene profiling of CTCs are ongoing in efforts to develop early screening markers as well as gain a more holistic understanding of the various forms of the disease. Moreover, the concept of personalized medicine in treating several types of cancer is deemed indispensable due to the highly heterogeneous nature of the disease. Extensive studies involving genetic material of CTCs are expected to considerably develop effective therapeutics that are tailored to meet each patient's need. However, several challenges need to be overcome in order to harness the wealth of information that can be gained from CTC studies, such as the rarity of such cells among other blood cells, where CTCs occur as rarely as 1 to 1 million among other mononuclear blood cells. In this vein we discuss the development of an integrated, continuous microfluidic device designed to isolate and label CTCs disseminated from cancer tumors. The 3-part device initially exploits the size disparity of the majority of CTCs with other blood cells and couples this with the use of size-based inertial forces to presort CTCs from whole blood at 1.2mL/min. The CTC-rich fluid stream is then mixed passively, on-chip, with EpCAM coated micro-beads which allows the cells and beads to mix at the micron length scale. This is followed by a brief period of incubation which allows cells to be sufficiently labeled, where the majority of cells have experienced at least two-thirds magnetic bead coverage using this mixing-incubation approach. Thereafter on-chip magnetic sorting of CTCs from any remaining blood cells is achieved by application of an external magnet along the magnetic sorter of the integrated device. Cells with as little as one-third bead coverage experience magnetic deflection to the CTC collection stream. To identify CTCs, cells were stained positively for DAPI and CK-19, and CD45 was used to distinguish leukocytes. We demonstrate that the isolated CTCs are not only viable but that the range of WBC decontamination is the lowest yet reported in literature. Based on PANC-1 cell-line experiments with the device, an 80% recovery rate of cancer cells from other blood cells was consistently achieved. Testing of metastatic patient samples with the device has yielded high counts of CTCs, coupled with high purity rates. We believe that the use of this system in characterizing CTCs and studying cancer will contribute to understanding this aggressive disease in a non-invasive, efficient manner.

Jackson, D. A. and P. R. Cook (1985). "A general method for preparing chromatin containing intact DNA." EMBO Journal **4**(4): 913-918.

A simple and general method is described for preparing chromatin from eukaryotic cells using isotonic conditions. First, cells are encapsulated in agarose microbeads and then lysed using

Triton X-100 in the presence of a chelating agent and a physiological concentration of salt. Most cytoplasmic proteins and RNA diffuse rapidly out through pores in the beads to leave encapsulated chromatin which is nevertheless completely accessible to enzymes and other probes. This chromatin can be manipulated freely without aggregation in a variety of different salt and detergent concentrations. It also contains intact DNA since removal of the histones releases superhelical DNA. Conditions are described for incubating this chromatin at 37 degrees C in the presence of Mg2+ ions without any nicking of the DNA. We illustrate the usefulness of this chromatin in investigations on the attachment of nascent RNA to the nucleoskeleton, the accessibility of the ribosomal locus to EcoRI and the properties of the endogenous RNA polymerase II. This type of chromatin preparation should prove useful for both structural and functional studies.

Jackson, D. A. and P. R. Cook (1986). "A cell-cycle-dependent DNA polymerase activity that replicates intact DNA in chromatin." Journal of Molecular Biology **192**(1): 65-76.

An insoluble DNA polymerase activity that replicates the intact chromatin template at 85% of the rate found in vivo has been partially characterized. HeLa cells, encapsulated in agarose microbeads, are lysed using an isotonic salt concentration: the resulting encapsulated nuclei contain polymerase associated with a nucleoskeleton and the unbroken template. This preparation can be manipulated freely without aggregation or breaking the DNA and yet is accessible to enzymes and other probes. The major activity, which is sensitive to aphidicolin, is found only in S-phase nuclei and replicates DNA semi-conservatively, forming intermediates that are ligated efficiently into larger products.

Jackson, D. A., et al. (1990). "Attachment of DNA to the nucleoskeleton of HeLa cells examined using physiological conditions." Nucleic Acids Research **18**(15): 4385-4393.

Although it is widely believed that eukaryotic DNA is looped by attachment to a nucleoskeleton, there is controversy about its composition and which sequences are attached to it. As most nuclear derivatives are isolated using unphysiological conditions, the criticism that attachments seen in vitro are generated artifactually has been difficult to rebut. Therefore we have re-investigated attachments of chromatin to the skeleton using physiological conditions. HeLa cells are encapsulated in agarose microbeads and lysed using Triton in a 'physiological' buffer. Then, most chromatin can be electroeluted after treatment with a restriction enzyme to leave some at the base of the loops still attached. Analysis of the size and amounts of these residual fragments indicates that the loops are 80-90kbp long. The residual fragments are stably attached, with about 1kbp of each fragment protected from nuclease attack. This is very much longer than a typical protein-binding site of 10-20bp.

Jackson, D. A., et al. (1993). "Visualization of focal sites of transcription within human nuclei." EMBO Journal **12**(3): 1059-1065.

HeLa cells were encapsulated in agarose microbeads, permeabilized and incubated with Br-UTP in a 'physiological' buffer; then sites of RNA synthesis were immunolabelled using an antibody that reacts with Br-RNA. After extending nascent RNA chains by < 400 nucleotides in vitro, approximately 300-500 focal synthetic sites can be seen in each nucleus by fluorescence microscopy. Most foci also contain a component of the splicing apparatus detected by an anti-Sm antibody. alpha-amanitin, an inhibitor of RNA polymerase II, prevents incorporation into these foci; then, using a slightly higher salt concentration, approximately 25 nucleolar foci became clearly visible. Both nucleolar and extra-nucleolar foci remain after nucleolytic removal of approximately 90% chromatin. An underlying structure probably organizes groups of transcription units into 'factories' where transcripts are both synthesized and processed.

Jackson, G. D., et al. (2000). "Diet of the southern opah Lampris immaculatus on the Patagonian Shelf; the significance of the squid Moroteuthis ingens and anthropogenic plastic." Marine Ecology Progress Series **206**: 261-271.

The diet of the large pelagic fish, the southern opah Lampris immaculatus was examined along the Patagonian Shelf in the Falkland Islands region. Stomachs were available for 69 fish collected in 1993 and 1994. Surprisingly, this fish had a relatively narrow range of prey items. The single most frequent prey item was the onychoteuthid squid Moroteuthis ingens (predominantly juveniles) which was eaten by 93% of the fish. The other important prey were the loliginid squid Loligo gahi, the myctophid fish Gymnoscopelus nicholsi and the southern blue whiting Micromesistius australis. There was no evidence of larger individuals of L. immaculatus ingesting larger individuals of any of the 4 main prey species. An unexpected finding was the relatively high incidence of plastic ingestion (14% of fish). The plastic came from a variety of sources including food, napkin and cigarette wrappers and various pieces of plastic line and straps used in securing boxes. In several instances, there was evidence of feeding on fishing boat discards. The findings reveal a significant impact of plastic pollution in this region of the Southwest Atlantic.

Jacob, H., et al. (2019). "No effect of polystyrene microplastics on foraging activity and survival in a post-larvae coral-reef fish, Acanthurus triostegus." Bulletin of environmental contamination and toxicology **102**(4): 457-461.

Microplastics (MP) are ubiquitous in the marine environment and have been shown to alter the behaviour of some species due to potential neurotoxic effect. However, very little is known on the effect of this stressor on behavioural responses of early and more vulnerable life stages. This study explores the effects of polystyrene MP (90 micro m diameter) on the foraging activity of newly settled surgeonfish Acanthurus triostegus and on their survival facing predators. Exposure to a high concentration of 5 MP particles per mL (5 MP mL⁻¹) for 3, 5 and 8 days did not alter their foraging activity nor their susceptibility to predation. This suggests that short-term exposures to reportedly high MP concentrations have negligible effects on the behaviour of newly settled A. triostegus. Nevertheless, responses to MP can be highly variable, and further research is needed to determine potential ecological effects of MP on reef fish populations during early-life stages.

Jacob, H., et al. (2019). "No Effect of Polystyrene Microplastics on Foraging Activity and Survival in a Post-larvae Coral-Reef Fish, <i>Acanthurus triostegus</i>." Bulletin of environmental contamination and toxicology **102**(4): 457-461.

Microplastics (MP) are ubiquitous in the marine environment and have been shown to alter the behaviour of some species due to potential neurotoxic effect. However, very little is known on the effect of this stressor on behavioural responses of early and more vulnerable life stages. This study explores the effects of polystyrene MP (90 μm diameter) on the foraging activity of newly settled surgeonfish Acanthurus triostegus and on their survival facing predators. Exposure to a high concentration of 5 MP particles per mL (5 MP mL−1) for 3, 5 and 8 days did not alter their foraging activity nor their susceptibility to predation. This suggests that short-term exposures to reportedly high MP concentrations have negligible effects on the behaviour of newly settled A. triostegus. Nevertheless, responses to MP can be highly variable, and further research is needed to determine potential ecological effects of MP on reef fish populations during early-life stages.

Jacobsen, R., et al. (2018). "Increasing the quantity of separated post-consumer plastics for reducing combustible household waste: The case of rigid plastics in Flanders." Waste Management **78**: 708-716.

In Flanders, Belgium, rigid and soft plastics represent an interesting fraction of residual household waste as a potential 80 000 Gg a⁻¹ can be recycled instead of incinerated. Removing a large amount of rigid packaging and non-packaging plastics from the residual household waste fraction could contribute to the goal to reduce the amount of residual household waste to less than 150 kg capita⁻¹ a⁻¹ for the Flemish region, where currently only 20% of plastics are collected selectively in drop-off facilities. Given the wide range of plastic separation schemes across the region, it is the aim of this paper to identify whether the applied separation options have an impact on the quantity of separated plastics, and, moreover, which scheme is able to separate most plastics. Cross-sectional data for the period 2008-2012 were collected for all 308 Flemish municipalities to conduct a regression analysis. The results of the analysis show that the quantity of separated plastics differs significantly between the different separation schemes used. If municipalities change their separation schemes, Flanders as a whole would be able to collect more plastic waste to better comply with its own objectives and EU regulation on recycling. Improved separation-at-source recycling initiatives, by applying the appropriate separation scheme for plastics, may increase recycling growth. Copyright © 2018 Elsevier Ltd

Jacobsen, U. (1995). "Situation and perspectives relating to the agricultural utilization of sewage sludge in Lower Saxony." Korrespondenz Abwasser **42**(8): 1285-1290.

The principal findings of a sewage sludge utilization study commissioned in 1994 by the Lower Saxony Association of Municipal Authorities are presented. There were numerous problems encountered by the sewage undertakings in arranging for agricultural disposal of their sludge because of both legislative constraints and hostile public opinion. The problems of convincing both farmers and the general public of the benefits of using sludge as a fertilizer are considered. In certain cases crops grown under contract for food processing could not be grown on sludge-treated soils and even church lands were subject to a prohibition on the use of sludge by tenant farmers. Ways in which sludge recycling could be made more acceptable are discussed. Novel processes for sludge conversion to more acceptable forms were the use of bristle worms for volume reduction and dewatering of fluid sludge, partial drying of sludge by evapotranspiration from wetland plants in reed bed enclosures and gasification in conjunction with plastic waste to produce a combustible product used to generate heat and electricity. (English translation 265 pounds sterling, valid for 1996).

Jacquin, J., et al. (2019). "Microbial ecotoxicology of marine plastic debris: A review on colonization and biodegradation by the "plastisphere"." Frontiers in Microbiology **10 (APR) (no pagination)**(865).

Over the last decades, it has become clear that plastic pollution presents a global societal and environmental challenge given its increasing presence in the oceans. A growing literature has focused on the microbial life growing on the surfaces of these pollutants called the "plastisphere," but the general concepts of microbial ecotoxicology have only rarely been integrated. Microbial ecotoxicology deals with (i) the impact of pollutants on microbial communities and inversely (ii) how much microbes can influence their biodegradation. The goal of this review is to enlighten the growing literature of the last 15 years on microbial ecotoxicology related to plastic pollution in the oceans. First, we focus on the impact of plastic on marine microbial life and on the various functions it ensures in the ecosystems. In this part, we also discuss the driving factors influencing biofilm development on plastic surfaces and the potential role of plastic debris as vector for dispersal of harmful pathogen species. Second, we give a critical view of the extent to which marine microorganisms can participate in the decomposition of plastic in the oceans and of the relevance of current standard tests for plastic biodegradability at sea. We highlight some examples of metabolic pathways of polymer biodegradation. We conclude with several questions regarding gaps in current knowledge of plastic biodegradation by marine microorganisms and the identification of possible directions for future research. Jain, A., et al. (2018). "Utilization of shredded waste plastic bags to improve impact and abrasion resistance of concrete." Environment, Development and Sustainability: 1-26.

Plastic bags (PB) have become a requisite part of human beings in the present time. Hundreds of varieties of plastic bags are used for packing and protecting general things. The disposal of PB is a prime environmental problem which significantly threatens the environment, as its disposal affects fertility of land due to its non-biodegradable nature; it lowers useful land area and generates toxic gases on incineration. Hence, there is a requirement of useful applications for these increased quantities of wastes. The usage of waste plastic bags (WPB) in concrete not only solve dumping crisis of WPB but also yields cost-effective concrete, which is worthy to both plastic recycling and construction industry. In this study, the influence of shredded WPB as fine aggregate on the properties of concrete was evaluated. The replacement of WPB was maintained at 0, 5, 10, 15 and 20% by weight of fine aggregate. The finding of the tested samples showed that the workability, density, compressive strength, flexural strength, static and dynamic modulus of elasticity of concrete samples decreased with increase in the WPB content, while penetrability to water increased. Microstructural analysis of the plastic waste concrete (PWC) specimens was carried out using scanning electron microscope. The microstructural studies indicated the presence of voids and openings between mortar matrix and WPB which was the main reason for the inferior properties of PWC. However, there has been a significant improvement in abrasion resistance, impact resistance and energy absorption capacity of PWC.

Jain, S. and M. Datta (2016). "Montmorillonite-alginate microspheres as a delivery vehicle for oral extended release of Venlafaxine hydrochloride." Journal of Drug Delivery Science and Technology **33**: 149-156.

Extended release of drugs is extremely essential for patients who require medicinal treatment round the clock. Depressed patients are one of such patients who suffer from recurrent and chronic disorder requiring long-term treatment. The treatment for such disease lies in the use of anti-depressants. Venlafaxine hydrochloride (VF) is an effective third generation drug which is capable of inhibiting the reuptake of serotonin, norepinephrine and dopamine. This highly water soluble drug (534 mg/ml) has a short steady state elimination half-life of 4-5 h due to which this drug needs to be administrated 2 to 3 times in a day in order to maintain its required concentration in the blood plasma. The present study aimed at developing montmorillonite (Mt) alginate (ALG) biopolymeric composites as micro beads with 97% encapsulation efficiency for an oral extended release of VF. These micro beads were synthesized using in situ ion-exchange followed by ionotropic gelation technique. The in - vitro release profile of pure drug shows a rapid burst release followed by 100% cumulative release within 5.5 h and 3.5 h in the gastric and intestinal fluid respectively. Whereas, the in - vitro release profile of VF from Mt biopolymeric beads show substantially less burst release with cumulative release of 20% (over a period of 26 h) and 22% (over a period of 29 h) in the gastric and intestinal fluid respectively. The presence of clay not only reduces the burst effect but also results in extended release of drug. Thus, there is possibility of making a formulation for oral extended release dosage forms for Venlafaxine with better patient compliance as repeated intake (every 3-4 h) of drug will not be necessary. Jain, S. K., et al. (2016). "Development and in vitro characterization of a multiparticulate delivery system for acyclovir-resinate complex." Artificial Cells, Nanomedicine, & Biotechnology **44**(5): 1266-1275.

CONTEXT: Herpes viruses cause threatening infections in humans and stand second as causative agents for most human viral diseases, after influenza and cold viruses.

OBJECTIVE: A novel multiparticulate delivery system for acyclovir (ACV), based on ion-exchange resin, was developed to achieve a gastro-mucoadhesive effect in order to effectively combat the herpes simplex virus.

MATERIALS AND METHODS: A combination of ACV and cholestyramine resin was optimized and further entrapped within sodium alginate and Carbopol microbeads. The developed systems were evaluated for drug entrapment efficiency (DEE), percentage of mucoadhesion, and in vitro release characteristics in simulated gastric fluid (SGF, pH 1.2).

RESULTS: With the aid of scanning electron microscopy (SEM), differential scanning calorimetry (DSC), and Fourier-transform infrared spectroscopy (FTIR), the interaction of the resinate and polycations with alginate has been revealed, which consequently supports the formation of the membrane by the polyelectrolyte complex. The in vitro drug release studies demonstrate that formulations without the drug-resin complex (DRC) released the drug more rapidly than formulations containing DRC, which released the drug in a controlled manner, due the formation of a complex between drug and resin.

DISCUSSION AND CONCLUSION: Preliminary results from this study suggest that these DRC-entrapped microbeads may be used to incorporate other antiviral drugs and could be effective against infections caused by herpes viruses. Such formulations developed could be subjected to in vivo studies in future, in order to prove complete clearance of herpes infections.

Jalilian, I., et al. (2016). "Live multiplexed imaging of stem cell mechanotransduction and mechanoadaptation." Journal of Orthopaedic Research. Conference **34**(Supplement 1).

INTRODUCTION: The mechanical milieu of the stem cell modulates its lineage commitment.¹³ At the same time, stem cells modulate their environment directly through secretion of extracellular matrix proteins, and indirectly through growth and adaptation including shape and volume changes as well as modulation of cell-cell and cell-matrix junctions, where persistence of structure for function over time represents the final 'seal of fate'.⁴ Given the role of cytoskeleton in sensing extracellular forces and in mechanotransduction, it is crucial to test causality and elucidate mechanisms by which stem cells adapt to mechanical stress through cytoskeletal remodeling, changes in gene transcription, expression of extracellular matrix and cell junctional proteins, and ultimately lineage commitment. Live imaging methods allow for precise measurement of changes in volume and shape as well as spatiotemporal tracking of cytoskeletal dynamics in stem cells as lineage commitment unfolds. However, until recently, it has not been possible to measure these processes in concert. Here we describe a novel method for live cell multiplexed fluorescent imaging enabling quantification of spatiotemporal changes in the cell nucleus, membrane and cytoskeleton concomitant to application of controlled stresses and measurement of the

resulting subcellular strains. METHOD(S): To image the cell nucleus, membrane and cytoskeleton at the same time and to measure their spatiotemporal distribution, these respective cellular compartments were stained simultaneously with specific fluorescent dyes during exposure to controlled mechanical stress and/or strains, in embryonic murine mesenchymal stem cells (C3H1T1/2). The nucleus and membrane of the cells were stained using Hoechst and wheat germ agglutinin, respectively. In addition, to track cell membrane displacement for strain mapping using digital image correlation, live cells were tagged at time zero with Concavalin A (Con A) conjugated microbeads, which bind noncovalently to the glycoproteins of the cell glycocalyx. The cytoskeleton structures (actin filaments and tubulin) were tagged using BacMam fluorescent probes during transcription. Robustness of the approach was tested by applying the techniques successfully to other cell types including tumor cells (rat neuroblastoma B35 cells). RESULT(S): Through this multiplexed approach, the displacement and spatiotemporal distribution of each individual cellular compartment was tracked independently under the controlled mechanical stress. Finally, by pairing a multiphysics computational model with the live cell experimental mechanics approach, stem cell mechanoadaptation was mapped as a function of specific mechanical cue libraries (referred to as 'mapping the mechanome'). This novel imaging technique enabled us to image and track the changes in the cell membrane, nucleus and cytoskeleton in real time. Furthermore, by using the multiplexed imaging fluorescence technique and different fluorescent dyes, it is now possible to separate and study each cellular compartment individually and simultaneously at different time points (Fig. 1). DISCUSSION: In the current study we developed a novel method for live cell multiplexed fluorescent imaging for the spatiotemporal changes of the cell nucleus, membrane and cytoskeleton concomitant to measurement of the subcellular strains under controlled mechanical stress. Given the significant role of cytoskeleton in stem cell mechanoadaptation, mechanotransduction and differentiation, live multiplexed imaging, in combination with multiphysics computational modelling, provided an unprecedented means to quantify spatiotemporal dynamics of stem cell mechanotransduction and mechanoadaptation. Our results also showed that the specific spatiotemporal organisation of the cytoskeleton in these cells resulted in the over- or down-regulation of specific genes, providing more insights towards the critical role of cytoskeleton in stem cell differentiation. SIGNIFICANCE: For the first time to our knowledge, it is now possible to carry out controlled mechanical testing on live stem cells during the process of lineage commitment. Understanding the mechanisms underlying these processes in real time will enable prospective guidance of targeted tissue genesis and healing by stem cells.

Jamdade, S. M. and R. H. Kasliwal (2013). "Design fabrication and evaluation of microbeads for controlled release using natural polymers." International Journal of Pharma and Bio Sciences **4**(4): P644-P660.

Diclofenac sodium is an Non-steroidal anti-inflammatory drugs, having an elimination half-life of 1-2 hrs. The objective of the study is to prepare Diclofenac sodium Microbeaads using Natural Polymers in different concentrations. For this purpose calcium ions were used as cross linking agents in formulation of alginate-guar gumpectin, alginate-guar gum-lecithin and alginate-pectin-lecithin Microbeads by ionotropic gelation method. The Microbeads were investigated for swelling index, dynamic water uptake, entrapment efficiency, particle size, SEM and in-vitro release studies. The Microbeads formulations showed acceptable properties and complied with in-house specifications for tested parameters. The results of in-vitro dissolution studies indicated that formulation DF4, DF6 and DF7 could extend the drug release up to 12 hours. While an increase in the concentration of sodium alginate and other polymer dispersions

increased sphericity, size distribution, mean particle size. The successful formulation of the study, exhibited satisfactory drug release (DF4, DF6 and DF7) which suggests sustained/controlled release profile.

Jamero, M. L., et al. (2018). "Community-based adaptation in low-lying islands in the Philippines: challenges and lessons learned. (Special Issue: 1.5 degrees C and small island Developing States.)." Regional Environmental Change **18**(8): 2249-2260.

Community-based adaptation (CBA) seeks to address climate risks and socio-economic drivers of vulnerability simultaneously. However, as CBA activities appear very similar to standard development work, difficulties in identifying good practices arise. To clarify the role of CBA, this study elucidated how climate change can impact pre-existing development problems by investigating the experiences of four low-lying island communities in central Philippines. The islands currently suffer from frequent and extreme tidal flooding (following an earthquake-induced land subsidence in 2013, with a magnitude that is broadly similar to sea-level rise projections under a 1.5 to 2 degrees C global warming scenario), and endured a dry spell in 2016. The study also identified various publicly and privately initiated adaptation strategies, and evaluated their resilience against actual biophysical events. The study conducted focus group discussions with local leaders and in-depth interviews with government officials and residents in March 2016. Results show that tidal flooding impacted almost all aspects of daily life on the islands, while the dry spell completely depleted their limited water supplies. The strategies implemented by governments and NGOs (e.g., seawalls, rainwater collectors) were found to be inadequate in preventing tidal flooding and compensating for the dry spell. Also, communities used coral stones and plastic waste for raising the floors of their homes, which have an erosive effect on their capacity to adapt in the long term. Lack of community participation in publicly initiated projects and lack of adaptation funding for community-based strategies were the greatest obstacles to implementing climate-resilient solutions.

James, R., et al. (2004). "Histological processing of hydrogel scaffolds for tissue-engineering applications." Journal of Histotechnology **27**(2): 133-139.

Tissue-engineered scaffolds (e.g., select absorbable scaffolds or hydrogels) are very fragile in nature and are filled with severe histological artifacts when processed using routine histological techniques (e.g., paraffin processing). The presence of artifacts compromises adequate microscopic evaluation and the characterization of the material and device performance. This article discusses approaches used to histologically evaluate hydrogel scaffolds. In addition to routine techniques, the use of plastic resins such as Caroplastic and Technovit 7100 are discussed and illustrated. A modified Technovit 7100 embedding procedure was the most effective in preserving and retaining the hydrogel scaffold throughout the histological process. The dehydration and embedding protocol can be easily modified to accommodate scaffolds of different sizes as well as different physical and chemical properties. It is also possible to complete polymerization of the Technovit 7100 plastic resin at 4degreeC, which has the added benefit of preserving lipid and enzyme activity.

Jamieson, A. J., et al. (2019). "Microplastics and synthetic particles ingested by deep-sea amphipods in six of the deepest marine ecosystems on Earth." Royal Society Open Science **6**(2): 180667.

While there is now an established recognition of microplastic pollution in the oceans, and the detrimental effects this may have on marine animals, the ocean depth at which such contamination is ingested by organisms has still not been established. Here, we detect the presence of ingested microplastics in the hindguts of Lysianassoidea amphipod populations, in six deep ocean trenches from around the Pacific Rim (Japan, Izu-Bonin, Mariana, Kermadec, New Hebrides and the Peru-Chile trenches), at depths ranging from 7000 m to 10 890 m. This illustrates that microplastic contaminants occur in the very deepest reaches of the oceans. Over 72% of individuals examined (65 of 90) contained at least one microparticle. The number of microparticles ingested per individual across all trenches ranged from 1 to 8. The mean and standard error of microparticles varied per trench, from 0.9 +/- 0.4 (New Hebrides Trench) to 3.3 +/- 0.7 (Mariana Trench). A subsample of microfibres and fragments analysed using FTIR were found to be a collection of plastic and synthetic materials (Nylon, polyethylene, polyamide, polyvinyl alcohol, polyvinylchloride, often with inorganic filler material), semi-synthetic (rayon and lyocell) and natural fibre (ramie). Notwithstanding, this study reports the deepest record of microplastic ingestion, indicating that anthropogenic debris is bioavailable to organisms at some of the deepest locations in the Earth's oceans.

Jamiolkowski, R. M., et al. (2019). "Nanoaperture fabrication via colloidal lithography for single molecule fluorescence analysis." PLoS ONE **14**(10).

In single molecule fluorescence studies, background emission from labeled substrates often restricts their concentrations to non-physiological nanomolar values. One approach to address this challenge is the use of zero-mode waveguides (ZMWs), nanoscale holes in a thin metal film that physically and optically confine the observation volume allowing much higher concentrations of fluorescent substrates. Standard fabrication of ZMWs utilizes slow and costly E-beam nano-lithography. Herein, ZMWs are made using a self-assembled mask of polystyrene microspheres, enabling fabrication of thousands of ZMWs in parallel without sophisticated equipment. Polystyrene 1 μm dia. microbeads self-assemble on a glass slide into a hexagonal array, forming a mask for the deposition of metallic posts in the inter-bead interstices. The width of those interstices (and subsequent posts) is adjusted within 100–300 nm by partially fusing the beads at the polystyrene glass transition temperature. The beads are dissolved in toluene, aluminum or gold cladding is deposited around the posts, and those are dissolved, leaving behind an array ZMWs. Parameter optimization and the performance of the ZMWs are presented. By using colloidal self-assembly, typical laboratories can make use of sub-wavelength ZMW technology avoiding the availability and expense of sophisticated clean-room environments and equipment.

Jandric, A., et al. (2019). "Investigation of the heterogeneity of bromine in plastic components as an indicator for brominated flame retardants in waste electrical and electronic equipment with regard to recyclability." Journal of Hazardous Materials **(no pagination)**(121899).

Waste electrical and electronic equipment (WEEE) can contain brominated flame retardants (BFRs) that pose a threat to human health and the environment. In addition, Br-containing plastics reduce the recycling potential of WEEE. In order to gain a better insight into the distribution of Br in plastics from WEEE, the total concentration of Br was measured on the level of device types and plastic components using handheld X-ray fluorescence (hXRF). In 35 % of the sample size (882 components from 369 different devices, which originate from 6 device types) Br was detected, 5 % exceeded the RoHS limit. Only few and older devices contained high Br concentrations, while the majority were below the RoHS limit and could be recycled. In addition, 18 different plastic types were identified by infrared spectroscopy, with acrylonitrile butadiene styrene being the most abundant (44 % of all samples). Manual dismantling of devices into individual plastic components enabled us to examine Br hotspots and the variety of plastic types in WEEE. Based on this analytical procedure, WEEE recyclers could exclude certain equipment or plastic components (e.g. power supplies or PC housings) directly on-site prior to WEEE recycling and shredding in order to produce high-quality recycled products and avoid cross-contamination. Jang, M., et al. (2018). "Formation of microplastics by polychaetes (Marphysa sanguinea) inhabiting expanded polystyrene marine debris." Marine Pollution Bulletin **131**: 365-369.

Fragmentation of large plastic debris into smaller particles results in increasing microplastic concentrations in the marine environment. In plastic debris fragmentation processes, the influence of biological factors remains largely unknown. This study investigated the fragmentation of expanded polystyrene (EPS) debris by polychaetes (Marphysa sanguinea) living on the debris. A large number of EPS particles (131+or-131 particles/individual, 0.2-3.8 mm in length) were found in the digestive tracts of burrowing polychaetes living on EPS debris. To confirm the formation of microplastics by polychaetes and identify the quantity and morphology of produced microplastics, polychaetes were exposed to EPS blocks in filtered seawater under laboratory conditions. Polychaetes burrowed into the blocks and created numerous EPS microplastic particles, indicating that a single polychaete can produce hundreds of thousands of microplastic particles per year. These results reveal the potential role of marine organisms as microplastic producers in the marine environment.

Jang, M., et al. (2019). "A close relationship between microplastic contamination and coastal area use pattern." Water Research **171**: 115400.

Human activity is thought to affect the abundance and contamination characteristics of microplastics (MPs) in the environment, which may in turn affect aquatic species. However, few studies have examined the impact of coastal area use pattern on characteristics of MPs in coastal regions. In this study, we investigated MP contamination of abiotic matrices (seawater and sediment) and biotic matrices (bivalves and polychaetes) in three coastal regions characterized by different types of human activity, covering urban, aquafarm, and rural areas. MP abundance was higher in sediment from the urban site than in that from the rural site, but similar to that from the aquafarm site. In the abiotic matrices, different MP polymer compositions were observed among the three sites. Diverse polymers were found in marine matrices from the urban site, implying diverse MP sources in highly populated and industrialized areas. Polystyrene was more abundant in the aquafarm site, reflecting the wide use of expanded polystyrene aquaculture buoys. Polypropylene was more abundant at the rural site, probably due to the use of polypropylene ropes and nets in fishing activity. MP accumulation profiles in marine invertebrates showed trends similar to those exhibited by abiotic matrices, reflecting coastal area use patterns. These results indicate that marine MPs are generated from both land- and marine-based sources, and that the abiotic and biotic marine matrices reflect the MP characteristics.

Jang, M., et al. (2017). "Widespread detection of a brominated flame retardant, hexabromocyclododecane, in expanded polystyrene marine debris and microplastics from South Korea and the Asia-Pacific coastal region." Environmental Pollution **231**(Pt 1): 785-794.

The role of marine plastic debris and microplastics as a carrier of hazardous chemicals in the marine environment is an emerging issue. This study investigated expanded polystyrene (EPS, commonly known as styrofoam) debris, which is a common marine debris item worldwide, and its additive chemical, hexabromocyclododecane (HBCD). To obtain a better understanding of chemical dispersion via EPS pollution in the marine environment, intensive monitoring of HBCD levels in EPS debris and microplastics was conducted in South Korea, where EPS is the predominant marine debris originate mainly from fishing and aquaculture buoys. At the same

time, EPS debris were collected from 12 other countries in the Asia-Pacific region, and HBCD concentrations were measured. HBCD was detected extensively in EPS buoy debris and EPS microplastics stranded along the Korean coasts, which might be related to the detection of a quantity of HBCD in non-flame-retardant EPS bead (raw material). The wide detection of the flame retardant in sea-floating buoys, and the recycling of high-HBCD-containing EPS waste inside large buoys highlight the need for proper guidelines for the production and use of EPS raw materials, and the recycling of EPS waste. HBCD was also abundantly detected in EPS debris collected from the Asia-Pacific coastal region, indicating that HBCD contamination via EPS debris is a common environmental issue worldwide. Suspected tsunami debris from Alaskan beaches indicated that EPS debris has the potential for long-range transport in the ocean, accompanying the movement of hazardous chemicals. The results of this study indicate that EPS debris can be a source of HBCD in marine environments and marine food web.

Jang, S., et al. (2019). "Carbon-Based, Ultraelastic, Hierarchically Coated Fiber Strain Sensors with Crack-Controllable Beads." Acs Applied Materials & Interfaces **11**(16): 15079-15087.

Fiber-based electronics or textronics are spotlighted as a promising strategy to develop stretchable and wearable devices for conformable machine-human interface and ubiquitous healthcare systems. We have prepared a highly sensitive fiber-type strain sensor (maximum gauge factor (GF) = 863) with a broad range of strain (epsilon < 400%) by introducing a single active layer onto the fiber. In contrast to other metal-based fiber-type electronics, our hierarchical fiber sensors are based on coating carbon-based nanomaterials with responsive microbeads onto elastic fibers. Utilizing the formation of uniform cracks around the microbeads, the device performance was maximized by adjusting the number of microbeads in the carbon-coating layer. We overcoated the carbon-based coating layer of the elastic fiber with a protective polymeric layer and verified no effects on the GF and the range of strain. Our fiber sensors were repeatedly tested more than 5000 times, exhibiting excellent cyclic responses to on/off switching behaviors. For practical applications, the hierarchical fiber sensors were sewed into electrical fabric bands, which are integrable to a wireless transmitter to monitor waveforms of pulsations, respirations, and various postures of level of bending a spinal cord.

Janossy, G., et al. (2003). "New trends in affordable CD4+ T-cell enumeration by flow cytometry in HIV/AIDS." Clinical and Applied Immunology Reviews **4**(2): 91-107.

Inexpensive antiretroviral therapy (ART) might soon be available to treat human immunodeficiency virus (HIV) infections in resource-restricted areas of the globe. The number of CD4+ T-cells in the blood is the single most important laboratory parameter to select patients for therapy at the right time and to monitor the effect of ART. The question is asked whether flow cytometry is adaptable to change from an expensive and complicated scientific analytical instrumentation to become a practical diagnostic tool that can be widely operated. Recent studies indicate that a branch of clinical/practical flow cytometry is gaining a new identity by a confident simplification and improvement of clinical protocols. These new observations can be marshaled into three new areas of development. First, the changes in the choices of reagents and staining protocols have been initiated by the preferred use of primary immunological gating during the flow-cytometric analysis, exploiting the exquisite discriminating power of antibodies. The recent National Institutes of Health (NIH) and Centers for Disease Control and Prevention (CDC) guidelines introduced CD45-assisted protocols that are also at the heart of the PanLeucogating protocol that revitalized the testing of absolute CD4 counts on double-platform. With CD45 staining the leucocyte populations can be reliably studied in aging samples. It is now also documented that minimal technology, that is primary gating with CD4 (or CD8) antibodies, provides excellent CD4 (or CD8) T-cell counts. Consequently the optimal affordable protocol uses CD45 and CD4 antibodies in combination. The second area of development is the absolute counting facility on flow cytometers. Most frequently, microbeads are added to blood to define the sample volume in instruments that are not equipped with a volumetric microsyringe. The beads are, however, expensive, and the utilization of the stable flow rate of the excellent instruments might soon provide an answer to replace dear microbeads. With stable flow, the time span of analysis tells the sample volume and the absolute counts can be calculated. Finally, stabilized blood cell standards and blood stabilizing fluid, referred to as Transfix, have recently been introduced for quality assurance. These products are important to prove the precision and accuracy of the new affordable protocols and also to check, and guide if necessary, the performance of the laboratories even in remote areas. These recent developments provide evidence about the renaissance of affordable flow cytometry, a precise, costeffective and quantitative technology that is capable of providing CD4+ T-lymphocyte counts in as high volume as >400 patient assessment per day at the fraction of the cost of the current Western prices. These recent achievements need to be taken into consideration when alternative, nonflow CD4-counting methods are assessed. © 2003 Elsevier Inc. All Rights Reserved.

Janssen, C. R., et al. (1998). "The use of biomarkers in Daphnia magna toxicity testing -- III. Rapid toxicity testing of pure chemicals and sediment pore waters using ingestion and digestive enzyme activity." Chemosphere **37**(13): 2677.

In this study, 4 rapid (90 min) toxicity tests were developed using ingestion and digestive enzyme activity of Daphnia magna juveniles. Ingestion activity was assessed using fluorescent labelled latex micro-beads and digestive enzyme activity (trypsin, beta-galactosidase andesterase) was measured in homogenates using chromogenic (N-benzoyl-L-arginine-4-nitroanilide) and fluorogenic (4-methylumbelliferyl-B-D-galactoside and fluorescein diacetate) substrates. All assays and toxicity endpoints were evaluated for their potential use as routine toxicity testing tools for pure chemicals and sediment pore waters. The observed high correlation coefficients (r2>0.9) between the short-term toxicity values and the acute toxicity endpoint (24h EC50) for pure chemicals suggests that these biomarker-based assays are good predictors of acute toxicity levels to Daphnia magna.In the sediment pore water toxicity tests, ingestion activity was generally more sensitive than the conventional endpoint, while the enzymatic endpoints were less sensitive than the 24h immobility criterion. The use and limitations of the developed toxicity tests are discussed in the light of their application in ecotoxicity monitoring programmes. [ABSTRACT FROM AUTHOR]

Janssen, W. E. and A. M. Rios (1989). "Non-specific cell binding characteristics of para-magnetic polystyrene microspheres used for antibody-mediated cell selection." Journal of Immunological Methods **121**(2): 289-294.

The binding of cells to paramagnetic polystyrene microbeads in the absence of coupling antibodies was measured. Cells from normal bone marrow, from an acute lymphoblastic leukemia (ALL) cell line or from a neuroblastoma cell line, were labeled with the fluorochrome Hoechst 33342 and incubated with microbeads by rotation at 4 degrees C. Following this

incubation, the microbeads with all attached cells were collected using an externally applied magnetic field and visualized by microscopic examination under ultraviolet illumination. The incubation variables included the protein content of the medium, and the period of rotation. Normal bone marrow was found to adhere sparingly to the microbeads; less than 1.0% of the total nucleated cell population was recovered with the beads, whereas greater than 5% of the ALL cells and greater than 30% of the neuroblastoma cells were found to bind non-specifically to the microspheres. Neither changes in the protein concentration of the medium or in the incubation period significantly altered the non-specific binding of the cell types examined. It is thus apparent that the use of these microspheres for positive selection of cells, such as the collection of hematopoietic stem cells for transplantation, would be compromised by a sizeable non-specific interaction. Modification of the surface of the microspheres to substantially reduce this interaction will be necessary before efforts at positive selection using the magnetic microspheres can be fruitful.

Jasinska, U. T., et al. (2018). "Immobilization of Bifidobacterium infantis cells in selected hydrogels as a method of increasing their survival in fermented milkless beverages." Journal of Food Quality **9267038**(42).

The aim of the study was to examine whether immobilization of Bifidobacterium infantis inside hydrogels could prolong their survival in fermented milkless beverages. The starter culture Streptococcus thermophilus was used to obtain fermented nonmilk beverages: oat, oat-banana, and oat-peach. The biota of beverages were supplemented with Bifidobacterium infantis cells, free and immobilized, in three types of spherical hydrogel particles: microcapsules with a liquid and gelled core, microbeads of 0.5 mm diameter, and beads of 2.5 mm diameter. As a carrier material, low-methoxylated pectin and alginate were used. Microbeads and microcapsules were obtained using extrusion techniques: vibrating and electrostatic method, and beads were obtained using manual method with a syringe. A significantly lower decrease in the count of cells immobilized in hydrogels compared to free cells was observed during storage of fermented beverages at 4 degrees C. Microcapsules were more effective compared to microbeads in terms of bacterial cells protection. The observed effect was better for higher biopolymer concentration. The highest survival of the strain was noted in cells immobilized in low-methoxylated pectin beads of 2.5 mm diameter. Supplementing the biota of fermented beverages with microencapsulated bacteria did not negatively affect the overall sensory quality of beverages during the entire storage period.

Jasmine, F., et al. (2018). "A novel pooled-sample multiplex luminex assay for high-throughput measurement of relative telomere length." American Journal of Human Biology **30**(4): e23118.

OBJECTIVES: Relative telomere length (RTL) is a potential biomarker of aging and risk for chronic disease. Previously, we developed a probe-based RTL assay on Luminex platform, where probes for Telomere (T) and reference gene (R) for a given DNA sample were tested in a single well. Here, we describe a method of pooling multiple samples in one well to increase the throughput and cost-effectiveness.

METHODS: We used four different microbeads for the same T-probe and four different microbeads for the same R-probe. Each pair of probe sets were hybridized to DNA in separate plates and then pooled in a single plate for all the subsequent steps. We used DNA samples from 60 independent individuals and repeated in multiple batches to test the precision.

RESULTS: The precision was good to excellent with Intraclass correlation coefficient (ICC) of 0.908 (95% CI 0.856-0.942). More than 67% of the variation in the RTL could be explained by sample-to-sample variation; less than 0.1% variation was due to batch-to-batch variation and

0.3% variation was explained by bead-to-bead variation. We increased the throughput of RTL Luminex assay from 60 to 240 samples per run. The new assay was validated against the original Luminex assay without pooling (r = 0.79, P = 1.44 x 10⁻¹⁵). In an independent set of samples (n = 550), the new assay showed a negative correlation of RTL with age (r = -0.41), a result providing external validation for the method.

CONCLUSION: We describe a novel high throughput pooled-sample multiplex Luminex assay for RTL with good to excellent precision suitable for large-scale studies.

Jativa, F., et al. (2015). "Confined self-assembly of cellulose nanocrystals in a shrinking droplet." Soft Matter **11**(26): 5374-5380.

We have studied how cellulose nanocrystals (CNC) self-assemble into liquid crystalline phases in shrinking, isolated droplets. By adjusting the water dissolution rate of an aqueous CNC droplet immersed in a binary toluene-ethanol mixture we can control the final morphology of the consolidated microbead. At low ethanol concentration in the surrounding fluid dense microbeads of spherical morphology are produced while collapsed core-shell particles are obtained at high ethanol concentration. Polarized light microscopy was used to follow the spatial evolution and coalescence of birefringent spheroids during droplet shrinkage. Electron microscopy reveals the resultant nematic microstructure. This method of confined CNC assembly provides thus the possibility to prepare ordered microbeads, which can be useful as templates or for their optical properties.

Jawale, J. K. and A. D. Shinde (2015). "Formulation and evaluation of mucoadhesive drug delivery system of Valsartan." Der Pharmacia Lettre **7**(6): 10-30.

The purpose of the research work was to develop mucoadhesive drug delivery system of antihypertensive drug Valsartan by ionotropic gelation technique. In order to prolong the gastric residence time and increase the overall bioavailability of the drug from dosage form. The Microbeads were prepared by varying the concentration of sodium alginate and Sodiumcarboxymethylcellulose using calcium chloride as cross linking agent. The drugpolymer compatibility was studied by FTIR studies. The prepared Microbeads were evaluated for swelling ratio, particle size, and drug entrapment efficacy, scanning electron microscopy, differential scanning calorimetry, mucoadhesion study and in vitro release study. A 2-factor, 2-level full factorial design (2²) was employed for optimization of Valsartan beads with Sodium Alginate amount (%, X1) and polymers (SCMC%, X2) as the prime selected independent variables, which were varied at 2 different levels (low and high). The effect of formulation variables on the response variables were statistically evaluated by using a commercially available software package Design-Expert version 8.0.1. The mean particle size increases with increasing the polymer concentration. The drug entrapment efficacy for all formulation was found to be 65.38%-77.54%. The mucoadhesion test result reveled that as the concentration of mucoadhesive polymer decreased, mucoadhesion of beads also decreased. SEM results revealed that all beads prepared were spherical in shape that indicating uniform distribution of drug in polymer network. In vitro release studies were carried out in phosphate buffer pH 6.8. The optimized formulation shows the controlled drug release.

Jayapal, J., et al. (2014). "Studies on the plant diversity of Muniandavar sacred groves of Thiruvaiyaru, Thanjavur, Tamil nadu, India." Hygeia **6**(1): 48-62.

Plan: Muniandavar Sacred Groves from Vaduvakudi at Thiruvaiyaru Taluk, Thanjavur district of Tamil Nadu was selected for floristic exploration to know the plant diversity of the vegetation, the availability of rare and endangered floras, the ecological significance, regeneration status and the anthropogenic pressures, to document the religious beliefs and spirituality and the participation of locals on conservation. Outcome(s): In the present study, the flora of Muniandavar Sacred Groves comprises about 180 plant species belonging to 158 genera and 75 plant families, Key stone species available in the Sacred groves includes Anacardium occidentale, Borassus flabellifer, Ficus benghalensis that harbors a number of birds and other survival of many other species. Muniandavar sacred grove is in good vegetation status and the conservationists should take necessary action to protect this grove from plastic pollution. An environmental awareness programme is planned to conduct for the local people in order to safeguard this sacred grove from pollution. © 2014.

Jayasiri, H., et al. (2013). "Plastic litter accumulation on high-water strandline of urban beaches in Mumbai, India." Environmental Monitoring & Assessment **185**(9): 7709-7719.

Today, almost every beach on every coastline is threatened by human activities. The inadequate recycling and poor management of waste in developing countries has resulted in considerable quantities of plastic contaminating beaches. Though India has long coastline of 5,420 km along the mainland with 43 % of sandy beaches, data on litter accumulation, particularly the plastics, which are one of the most common and persistent pollutants in marine environment, are scanty. The abundance and distribution of plastic litter was quantitatively assessed in four sandy beaches in Mumbai, India, bimonthly from May 2011 to March 2012. Triplicates of 2 × 2 m (4 m) quadrats were sampled in each beach with a total of 72 quadrats. Overall, average abundance of 11.6 items m (0.25-282.5 items m) and 3.24 g m (0.27-15.53 g m) plastic litter was recorded in Mumbai beaches. Plastic litter accumulation significantly varied temporally and spatially at p = 0.05. Significantly higher plastic litter accumulation was recorded in Juhu beach. Furthermore, the highest abundance by weight was recorded in November and May numerically. More than 80 % of plastic particles were within the size range of 5-100 mm both by number and weight. Moreover, coloured plastics were predominant with 67 % by number of items and 51 % by weight. Probably, the intense use of beaches for recreation, tourism, and religious activities has increased the potential for plastic contamination in urban beaches in Mumbai. [ABSTRACT FROM AUTHOR]

Jayasiri, H. B., et al. (2013). "Quantitative analysis of plastic debris on recreational beaches in Mumbai, India." Marine Pollution Bulletin **77**(1-2): 107-112.

Plastic litter was quantified on four sandy beaches in Mumbai. The mean abundance of 7.49 g and 68.83 items per square metre was recorded. The abundance of plastics significantly varied among the beaches showing an increasing trend in the southern part. The abundance of plastics by weight in Dadar was significantly higher than that in Aksa. The size fractionation of plastics proved that small particles (1-20 mm) are predominant with 41.85% microplastics (1-5 mm) which emphasizes the high risk to marine organisms due to possible ingestion. The highest quantity of microplastics was seen in Juhu beach (55.33%) followed by Versova, Aksa and Dadar. The major contributing factors for the abundance are beach usage for different activities such as recreational, religious and fishing which suggest that the land-based sources provide major inputs to plastic pollution in these beaches.

Jayshree, P., et al. (2018). "Carcinogenic effects of plastic particulates in the air, water and food articles: a brief review article." Environment Conservation Journal **19**(1/2): 187-189.

In today's fast paced world, due to time crunch people are using packaged readymade food and water on a scale never seen before. Most of the packed food material, water and other beverages are served or sealed in plastic containers, plastic dissolves in miniscule quantities over a long period of time, which can lead to carcinogenic effects like respiratory, gastric tumours etc. Various short term and long-term research works are being done on this alarming condition. This article tries to throw some light on this Global health phenomena. The American Cancer Society estimates that 6% of cancers are related to environmental causes (https://www.polymersolutions.com).

Jazia, D. B., et al. (2013). "Absorption of water/ethanol microdroplets into model porous networks." Colloids and Surfaces A: Physicochemical and Engineering Aspects **436**: 363-370.

In this paper, the imbibition kinetics of model nanoporous substrates is analyzed. The model nanoporous networks were formed by polystyrene microbeads assemblies. Spontaneous imbibition of these structures with sessile droplets was achieved using water/ethanol mixtures of higher wettability than pure water. The lowest concentration of ethanol leading to the spontaneous imbibition was 30%, and the diameter of the microbeads that ranges from ~420nm to ~2230nm. For ethanol concentrations slightly above this threshold value of 30%, the time dependence of the penetration depth was found to follow the expected t^{0.5} time dependence. In this low ethanol concentration range, the imbibition rate was shown to decrease as the diameter of the microbeads increases. This result was attributed to the resistive filling of the throats formed around the contact between two beads that increases with the diameter of the microbeads. At constant bead diameter, an acceleration of the fluid progression was observed when increasing the ethanol concentration, i.e. the capillary force. At high ethanol concentrations the penetration no longer followed the t^{0.5} dependence, but linear time dependence over the whole life of the droplet. This acceleration of the imbibition rate was attributed to a prewetting of the internal porous structure by the most volatile ethanol component of the mixture that condenses in the throat formed around the contact between two beads. © 2013 Elsevier B.V.

Jeanes, C. (1996). "TURNING ENVIRONMENTAL CONCERN INTO REAL PROFIT." Recycling Textile & Plastic Waste: 29-31.

The article discusses the efforts of business institutions toward environment protection via waste management. It is stated that the growth of people who have woken up to the need for careful management of all assets and major changes of attitude are being brought about by government legislation. The legislation obliges all producers of waste to consider recycling instead of disposal in a landfill site or discharge into air or water. It highlights the prime opportunity for reducing waste which was identified in Wigan, England.

Jemec, A., et al. (2016). "Uptake and effects of microplastic textile fibers on freshwater crustacean Daphnia magna." Environmental Pollution **219**: 201-209.

Microplastic fibers (MP) from textile weathering and washing are increasingly being recognized as environmental pollutants. The majority of studies on the bioavailability and effects of microplastic focused on small polystyrene spherical plastic particles, while less data are available for fibers and for other materials besides polystyrene. We investigated the ingestion and effects of ground polyethylene terephthalate (PET) textile microfibers (length range: 62-1400 micro m,

width 31-528 micro m, thickness 1-21.5 micro m) on the freshwater zooplankton crustacean Daphnia magna after a 48 h exposure and subsequent 24 h of recovery in MP free medium and algae. The majority of ingested fibers by D. magna were around 300 micro m, but also some very large twisted MP fibers around 1400 micro m were found inside the gut. Exposure to these fibers results in increased mortality of daphnids after 48 h only in the case where daphnids were not pre-fed with algae prior to experiment, but no effect was found when daphnids were fed before the experiments. Regardless of the feeding regime, daphnids were not able to recover from MP exposure after additional 24 h incubation period in a MP free medium with algae. The uptake and effects of PET textile MP on D. magna are presented here for the first time.

Jemec Kokalj, A., et al. (2019). "An exploratory ecotoxicity study of primary microplastics versus aged in natural waters and wastewaters." Environmental Pollution **254**: N.PAG-N.PAG.

Current understanding of how environmental aging of microplastics contributes to their ecotoxicity is low. We investigated whether incubation of microplastics in waters with different organic load and toxic potential alters the toxicity of microplastics to crustacean Daphnia magna , fish embryos Danio rerio and plant Lemna minor. Polyethylene primary microplastics; specifically microbeads from facial scrub; were subjected to 3-weeks incubation in low affected spring water, river water, effluent from the municipal wastewater treatment plant (WWTP) and municipal landfill leachate. Primary microplastics had no acute effect on D. magna mobility and D. rerio embryos development. While high organic load wastewaters; WWTP effluent and landfill leachate; showed evident toxicity for D. magna and D. rerio embryos, microplastics aged in these wastewaters had no effect. This suggests that adsorption of pollutants from wastewaters to microplastic particles was not high enough to induce acute toxicity to D. magna and D. rerio. On the contrary, primary microplastics affected the root growth of L. minor. Interestingly, aging of microplastics in low organic-load waters mitigated the toxicity of microplastics for L. minor , while microplastics aged in high-organic load waters had the same adverse effect as primary microplastics. Partly, these effects can be explained by different extent of coating on microplastics in different water samples. This study suggests that aging of microplastics in wastewaters and natural waters did not significantly enhance the toxicity to selected test species, but further studies on plants may be of interest. Image 1 • Coating of aged microplastics in natural waters and wastewaters differs from primary microplastics. • Aged microplastics have different sinking properties. • Aging of microplastics does not increase the toxicity to daphnids, duckweed and zebrafish. • Primary microplastics affect only duckweed root length. • Aging in some waters may mitigate toxic effects of microplastics for roots. Microplastics aged in wastewaters and natural waters are not more toxic as primary microplastics. [ABSTRACT FROM AUTHOR]

Jendelova, P., et al. (2005). "Magnetic resonance tracking of human CD34+ progenitor cells separated by means of immunomagnetic selection and transplanted into injured rat brain." Cell Transplantation **14**(4): 173-182.

Magnetic resonance imaging (MRI) provides a noninvasive method for studying the fate of transplanted cells in vivo. We studied whether superparamagnetic nanoparticles (CD34

microbeads), used clinically for specific magnetic sorting, can be used as a magnetic cell label for in vivo cell visualization. Human cells from peripheral blood were selected by CliniMACS CD34 Selection Technology (Miltenyi). Purified CD34+ cells were implanted into rats with a cortical photochemical lesion, contralaterally to the lesion. Twenty-four hours after grafting, the implanted cells were detected in the contralateral hemisphere as a hypointense spot on T2 weighted images; the hypointensity of the implant decreased during the first week. At the lesion site we observed a hypointensive signal 10 days after grafting that persisted for the next 3 weeks, until the end of the experiment. Prussian blue and anti-human nuclei staining confirmed the presence of magnetically labeled human cells in the corpus callosum and in the lesion 4 weeks after grafting. CD34+ cells were also found in the subventricular zone (SVZ). Human DNA (a human-specific 850 base pair fragment of alpha-satellite DNA from human chromosome 17) was detected in brain tissue sections from the lesion using PCR, confirming the presence of human cells. Our results show that CD34 microbeads superparamagnetic nanoparticles can be used as a magnetic cell label for in vivo cell visualization. The fact that microbeads coated with different commercially available antibodies can bind to specific cell types opens extensive possibilities for cell tracking in vivo.

Jensen, L. H., et al. (2019). "Sources, distribution and fate of microfibres on the Great Barrier Reef, Australia." Scientific Reports **9**(1): 9021.

Marine microdebris, in particular microplastics (plastics <5 mm), has become an issue of international concern due to its prevalence, persistence and potential adverse impacts on marine ecosystems. Informing source reduction based on ecological effects requires an understanding of the origin, distribution and characteristics of microdebris and the interactions with marine organisms. Here we show widespread contamination of the central Great Barrier Reef environment with microdebris, with microfibres comprising 86% of all items detected. Microdebris intake by coral reef fish was non-random, with chemical composition, shape and colour differing significantly from that detected in surface waters. Furthermore, the origin of microdebris contamination in surface waters is non-random with riverine discharge a likely source for microdebris detected at inshore, but not at offshore reef locations. Our findings demonstrate the complexities associated with determining marine microdebris exposure and fate, and assist in improving future ecological assessments and prioritizing source reduction.

Jeon, C., et al. (2015). "Application of mage A1-6 and HTERT RT-PCR for detecting circulating tumor cells." Clinical Chemistry and Laboratory Medicine **1)**: S192.

BACKGROUND-AIM To detect circulating tumor cells (CTCs), we had designed melanoma associated gene (MAGE) A1-6 and human telomerase reverse transcriptase (hTERT) RT-PCR. The PCR methods were utilized for detecting CTCs. METHODS We had used 37 bloods of cancer patients and 47 bloods from the patients of benign diseases. The patients had been evaluated and diagnosed at the Daegu Catholic University Medical Center. Most of cancer patients were following up after surgical resection, chemotherapy or supportive treatments. After removal of red blood cells, cancer cells were enriched by magnetic separation with anti-CD45 microbeads (Miltenyi Biotec, Auburn, CA). The CD45 negative cells were extracted with RNeasy Mini Kit (Qiagen, Duesseldorf, Germany). To amplify the MAGE A1-6 and the hTERT gene, gene specific RT-nested PCR and oligo-dT RT PCR were used using LightCycler FastStart DNA Master SYBR Green I (Roche, Mannheim, Germany). As a control gene, protein tyrosine phosphatase receptor type C gene was amplified. RESULTS In the blood of benign diseases, MAGE A1-6, hTERT and the both gene RT PCR showed the specificities of 89.4%, 84.8% and 73.9%. In the blood of cancer patients, MAGE A1-6, hTERT and the both gene RT PCR showed the sensitivities of 48.6%, 51.4%

and 64.9%. In the patient of cholangio (N=4), colorectal (N=9), gastric (N=10) and hepatic (N=8) cancer, the positive rates of the both gene were 100%, 33.3%, 60% and 62.5% respectively. Between the cases of recurred or metastatic cases and those of negative, the positive rates of MAGE A1-6, hTERT and the both gene were 52.9% versus 31.3%, 52.9% versus 37.5%, and 76.5% versus 43.8% respectively. CONCLUSION MAGE A1-6 and hTERT gene RT PCR showed good specificities for CTCs detection. The both RT PCR showed high positive rates in the blood of cholangio and hepatic cancer patients. MAGE A1-6 and hTERT gene RT PCR results correlated with their clinical status of cancer patients.

Jeon, C., et al. (2014). "Detection of blood tumor cells by mage A1-6 and hTERT gene single tube nested PCR." Clinical Chemistry and Laboratory Medicine **1)**: S409.

BACKGROUND: Many researchers are studying to detect circulating tumor cells (CTC), but until now no definite method was developed. We developed single tube nested (STN) PCR method which used a same PCR tube for the first and the second round PCR to avoid target contamination. METHOD(S): We spiked SNU 1 gastric cancer cell lines to 2 mL of blood having 3,000 cells/mL, 300 cells/mL, 30 cells/ mL and 3 cells/mL. The blood were obtained from remnant bloods of non-malignant patients visiting Daegu Catholic University Medical Center (DCUMC). To remove red blood cells, the blood treated with ammonium chloride buffer, then SNU1 cells were enriched by magnetic separation with anti-CD45 microbeads (Miltenyi Biotec, Auburn, CA). The SNU1 cells and CD45 negative mononuclear cells were extracted with RNeasy Mini Kit (Qiagen, Duesseldorf, Germany). Melanoma associated gene (MAGE) A1-6 and human telomerase reverse transcriptase (hTERT) gene was amplified with STN PCR method using LightCycler FastStart DNA Master SYBR Green I (Roche, Mannheim, Germany). Ten folds high concentration of primer sets for the second round were added after the first round PCR for STN PCR. As negative controls, thirty remnant bloods of non-malignant patients diagnosed in the DCUMC were used. RESULT(S): MAGE A1-6 and hTERT gene STN PCR detected 3 SNU1 cells per milliliter. In the 30 negative controls, MAGE A1-6 gene STN PCR showed one positive results (96.7% of specificity), while hTERT STN PCR showed 5 positive results (83.3% of specificity). CONCLUSION(S): MAGE A1-6 and hTERT gene STN PCR showed sensitive and specific results for blood cancer cell detection. These method will be effectively utilized as a CTC detection tool. Especially, MAGE A1-6 STN PCR would be a very sensitive and specific method for MAGE expressing tumors.

Jeong, C.-B., et al. (2018). "Nanoplastic Ingestion Enhances Toxicity of Persistent Organic Pollutants (POPs) in the Monogonont Rotifer Brachionus koreanus via Multixenobiotic Resistance (MXR) Disruption." Environmental Science & Technology **52**(19): 11411.

Among the various materials found inside microplastic pollution, nanosized microplastics are of particular concern due to difficulties in quantification and detection; moreover, they are predicted to be abundant in aquatic environments with stronger toxicity than microsized microplastics. Here, we demonstrated a stronger accumulation of nanosized microbeads in the marine rotifer Brachionus koreanus compared to microsized ones, which was associated with oxidative stress-induced damages on lipid membranes. In addition, multixenobiotic resistance conferred by P-glycoproteins and multidrug resistance proteins, as a first line of membrane defense, was inhibited by nanoplastic pre-exposure, leading to enhanced toxicity of 2,2′,4,4′-tetrabromodiphenyl ether and triclosan in B. koreanus. Our study provides a molecular mechanistic insight into the toxicity of nanosized microplastics toward aquatic invertebrates and further implies the significance of synergetic effects of microplastics with other environmental persistent organic pollutants.

Jeong, J. and J. Choi (2019). "Adverse outcome pathways potentially related to hazard identification of microplastics based on toxicity mechanisms." Chemosphere **231**: 249-255.

Increasing concern over microplastics has recently brought increased attention to studies on microplastic toxicity. Here, we conduct a systematic review on toxicity of microplastics that focuses on identifying data gaps in the mechanisms of microplastic toxicity. We observe that microplastic toxicology research thus far has focused on ecotoxicity using apical endpoints and only a few studies deal with toxicity mechanisms. Based on this review, we propose putative Adverse Outcome Pathways (AOPs) applicable to microplastic management to understand microplastic toxicity. We matched toxicity mechanisms and apical endpoints to a key event (KE) and adverse outcome (AO) information from the AOP Wiki. Overall, our results suggest that the molecular initiating event (MIE) was reactive oxygen species (ROS) formation and the AO was increased mortality, decreased growth and feeding, and reproduction failure. However, there are a limited number of studies on toxicity mechanisms of microplastics and, therefore, evidence concerning the relationship between KEs is not sufficient. Clearly, more studies on toxicity mechanisms are required to fill these gaps in data. This study also suggests that the AOP framework is a suitable tool to integrate existing data from various literature sources and can identify data gaps in microplastic toxicity mechanisms. Image 1 • Microplastic toxicity mechanisms in terms of ecotoxicity and human health toxicity were reviewed. • Microplastic toxicology research has focused on ecotoxicity using apical endpoints. • Toxicity mechanisms matched with KE from the AOP Wiki and putative AOPs were proposed. • MIE is ROS formation and AOs are increasing mortality, reduction of growth, and reproduction failure. [ABSTRACT FROM AUTHOR]

Jerschow, E., et al. (2015). "H-PGD synthase (H-PGDS) gene expression increases in eosinophils of aspirin exacerbated respiratory disease (AERD) patients after oral graded aspirin challenge." Journal of Allergy and Clinical Immunology **1)**: AB160.

RATIONALE: 10% of adult asthmatics suffer from AERD, characterized by adult onset of moderate to severe asthma and nasal polyps, peripheral and tissue eosinophilia, and a hypersensitivity reaction (bronchospasm, rhinorrhea, and/or conjunctivitis) in response to cyclooxygenase-1 (COX- 1) inhibition. They also have increased PGD2metabolites in blood and urine that has been reported to come from mast cells. We hypothesized that eosinophils of AERD patients have a higher expression of the HPGDS gene after aspirin-induced hypersensitivity reaction. METHOD(S): We collected eosinophils from AERD patients (n=8) and aspirin-tolerant asthmatics (n=10) at baseline, and after oral graded aspirin challenge. Eosinophils were isolated to >97% purity by depletion of noneosinophils using magnetic labeling and conjugation to MicroBeads. RNA was extracted from eosinophils and RNA expression was measured in comparison to internal housekeeper transcripts using RNA-specific RTqPCR by RNA-specific RT-qPCR. RESULT(S): After an aspirin-induced hypersensitivity reaction, eosinophil H-PGDS gene expression significantly increased from baseline in AERD patients ($p<0.01$) in contrast to aspirin-tolerant asthmatics, where there was no change. Urine levels of PGD2 metabolite (tetranor PGDM) after aspirin challenge significantly increased in AERD patients

(p=0.02) and accompanied the increases in H-PGDS gene expression. Tetranor PGDM decreased in aspirin-tolerant asthmatics (p<0.01). CONCLUSION(S): Peripheral blood eosinophils differentially express the H-PGDS gene in response to aspirin challenges in AERD patients as compared to aspirin-tolerant asthmatics. In addition to the previously demonstrated PGD2 production by mast cells, our results suggest that eosinophils may contribute to the elevated PGD2 levels in this disorder.

Jesacher, A., et al. (2006). "Holographic optical tweezers for object manipulations at an air-liquid surface." Optics Express **14**(13): 6342-6352.

We investigate holographic optical tweezers manipulating micro-beads at a suspended air-liquid interface. Axial confinement of the particles in the two-dimensional interface is maintained by the interplay between surface tension and gravity. Therefore, optical trapping of the micro-beads is possible even with a long distance air objective. Efficient micro-circulation of the liquid can be induced by fast rotating beads, driven by the orbital angular momentum transfer of incident Laguerre-Gaussian (doughnut) laser modes. Our setup allows various ways of creating a tailored dynamic flow of particles and liquid within the surface. We demonstrate examples of surface manipulations like efficient vortex pumps and mixers, interactive particle flow steering by arrays of vortex pumps, the feasibility of achieving a "clocked" traffic of micro beads, and size-selective guiding of beads along optical "conveyor belts".

Jha, A. K. and A. Bhattacharya (2009). "Preparation and evaluation of sweet potato starch-blended sodium alginate microbeads." Asian Journal of Pharmaceutics **3**(4): 299-303.

The design of effective drug delivery systems has recently become an integral part of the development of new medicines. Hence, research continuously keeps searching for ways to deliver drugs over an extended period of time with a well- controlled release profile. The ionotropic gelation method was used to prepare sweet potato starch-blended controlled release alginate microbeads of ibuprofen. Sweet potato is an important crop in many developing countries. Although sweet potato originated from Central America, its ability to adapt to a wide variety of climatic conditions allows it to grow both in tropical and in moderate temperature regions of Africa, Asia and the Americas. The influence of various formulation factors such as in vitro drug release, entrapment efficiency, swelling study and micrometric properties was investigated. Other variables included sweet potato starch concentration, percentage drug loading, curing time, cross-linking agent and stirring speed during the microencapsulation process. The entrapment efficiencies were found in the range of 71.85 2.04 - 94.53 1.02%. The particle sizes were found in the range of 0.82 0.006 - 1.08 0.009 mm. This suggested that the ionotropic gelation method was successful in producing sweet potato starch-blended alginate microbeads.

Ji, C., et al. (2019). "Establishment of fluorescent microbead-based immunoassay for the detection of IgG antibodies against H1 and H3 subtypes swine influenza virus." Chinese Veterinary Science / Zhongguo Shouyi Kexue **49**(2): 159-168.

Effective prevention and control of swine influenza requires the help of accurate and rapid detection methods. In order to establish a highly efficient and rapid multiple detection method, this study applied H1 and H3 subtypes swine influenza virus (SIV) hemagglutinin (HA) protein antigen coupled with different encoded fluorescent microspheres, and used the indirect method for detecting the IgG antibodies against H1 and H3 subtypes SIV. The immunological microspheres of IgG antibodies against swine influenza virus were detected and compared with the methods of blood coagulation inhibition test (HI), virus neutralization test (VN) and enzyme linked immunosorbent assay (ELISA). The results showed that the detection sensitivity of the antibodies was 100-1 000 times higher than that of the ELISA method. There was no cross-reactivity with the positive serum with porcine reproductive and respiratory syndrome virus, type II porcine circovirus, swine fever virus, pseudorabies virus and Japanese encephalitis virus and there was no cross-reaction between the H1 and H3 subtype SIV sera. Repeatability experiments showed that the intra and inter batch precision test indexes were 10.2% and 12.8% respectively. Compared with HI, VN and ELISA, the total coincidence rates were 97.82%, 98.27% and 97.83% respectively. In conclusion, the detection method established in this study has dual detection characteristics, good specificity, high sensitivity and strong repeatability, which can be used for the differential diagnosis of the antibodies of H1 and H3 subtype SIV.

Ji, S., et al. (2019). "Human Umbilical Cord Mesenchymal Stem Cells Attenuate Ocular Hypertension-Induced Retinal Neuroinflammation via Toll-Like Receptor 4 Pathway." Stem Cells International **2019**.

Glaucoma is characterized by progressive, irreversible damage to the retinal ganglion cells (RGCs) and their axons. Our previous study has shown that the intravitreal transplantation of human umbilical cord mesenchymal stem cells (hUC-MSCs) reveals a neuroprotective role in microsphere injection-induced ocular hypertension (OHT) rat models. The protection is related to the modulation of glial cells, but the mechanisms are still unknown. The purpose of the present study is to clarify the potential neuroinflammatory mechanisms involved in the neuroprotective role of hUC-MSCs. OHT models were established with SD rats through intracameral injection of polystyrene microbeads. The animals were randomly divided into three groups: The normal group, the OHT+phosphate-buffered saline (PBS) group, and the OHT+hUC-MSC group. Retinal morphology was evaluated by measuring the inner retinal thickness via optical coherence tomography (OCT). Retinal cell apoptosis was examined by TUNEL staining and Bax expression 14 days following hUC-MSC transplantation. The expression levels of glial fibrillary acidic protein (GFAP), ionized calcium binding adapter molecule 1 (iba-1), and toll-like receptor 4 (TLR4) were assessed via immunohistochemistry, real-time quantitative PCR, and Western blot. RNA and proteins were extracted 14 days following transplantation, and the expression levels of the TLR4 signaling pathways and proinflammatory cytokines-myeloid differentiation factor 88 (MyD88), IL-1β, IL-6, and TNF-α-were determined. OCT showed that the intravitreal transplantation of hUC-MSCs significantly increased the inner thickness of the retina. A TUNEL assay and the expression of Bax suggested that the apoptosis of retinal cells was decreased by hUC-MSCs 14 days following transplantation. Intravitreal hUC-MSC transplantation resulted in a decreased expression of GFAP, iba-1, TLR4, MyD88, IL-1β, IL-6, and TNF-α 14 days following transplantation. In addition, via in vitro experiments, we found that the increased expression of the TLR4 signaling pathway induced by lipopolysaccharide (LPS) was markedly decreased after hUC-MSCs were cocultured with rMC-1 and BV2 cells. These findings indicate that hUC-MSC transplantation attenuates OHT-induced retinal neuroinflammation via the TLR4 pathway. © 2019 Shangli Ji et al.

Ji, X., et al. (2017). "A novel method for plastic particle sizing in suspension based on acoustic impedance spectrum." Ultrasonics **77**: 224-230.

The objective of this paper is to explore the relationship between the characteristics of plastic particles in suspension and acoustic impedance spectrum and to present a novel non-invasive methodology for both spherical and non-spherical particle sizing. By modifying the ultrasonic attenuation spectral model, theories relating acoustic impedance spectrum to particle characteristics have been established to implement quite a few numerical simulations for the first time, revealing that the acoustic impedance of plastic particles is sensitive to changes in particle concentration and size. Afterwards, experiments were carried out on polystyrene suspensions made by particles with different sizes. On the basis of the theoretical analysis, different transducers were employed over a frequency varied from 10MHz to 100MHz for different particle sizes respectively. Not only were spherical particles chosen for the experiment, but also non-spherical particles with three different size distributions considering the fact that practical particles have irregular shapes. All the samples were verified by optical microscope technique and their comparisons with the experimental results show that the plastic particles with different sizes are distinguishable by using acoustic impedance spectrum.

Jia, M. J., et al. (2019). "Cherenkov-excited luminescence scanned imaging using scanned beam differencing and iterative deconvolution in dynamic plan radiation delivery in a human breast phantom geometry." Medical Physics **46**(7): 3067-3077.

Purpose: The purpose of this study was to demonstrate high resolution optical luminescence sensing, referred to as Cherenkov excited luminescence scanning imaging (CELSI), could be achieved during a standard dynamic treatment plan for a whole breast radiotherapy geometry. Method(s): The treatment plan beams induce Cherenkov light within tissue, and this excitation projects through the beam trajectory across the medium, inducing luminescence where there can be molecular reporter. Broad beams generally produce higher signal but low spatial resolution, yet for dynamic plans the scanning of the multileaf collimator allows for a beam-narrowing strategy by recursively temporal differencing each of the Cherenkov images and associated luminescence images. Then reconstruction from each of these size-reduced beamlets defined by the differenced Cherenkov images provides a well-conditioned matrix inversion, where the spatial frequencies are limited by the higher signal-to-noise ratio beamlets. A built-in stepwise convergence relies on stepwise beam size reduction, which is associated with a widening of the bandwidth of Cherenkov spatial frequency and resultant increase in spatial resolution. For the phantom experiments, europium nanoparticles were used as luminescent probes and embedded at depths ranging from 3 to 8 mm. An intensity modulated radiotherapy (IMRT) plan was used to test this. Result(s): The Cherenkov images spatially guided where the luminescence was measured from, providing high lateral resolution, and iterative reconstruction convergence showed that optimization of the initial and stopping beamlet widths could be achieved with 15 and 4.5 mm, respectively, using a luminescence imaging frame rate of 5/s. With the IMRT breast plan, the original lateral resolution was improved 2X, that is, 0.08-0.24 mm for target depths of 3-8 mm. In comparison, a dynamic wedge (DW) plan showed an inferior image fidelity, with relative contrast recovery decreasing from 0.86 to 0.79. The methodology was applied to a three-dimensional dataset to reconstruct Cherenkov excited luminescence intensity distributions showing volumetric recovery of a 0.5 mm diameter object composed of 0.5 muM luminescent microbeads. Conclusion(s): High resolution CELSI was achieved with a clinical breast external beam radiotherapy (EBRT) plan. It is anticipated that this method can allow visualization and localization for luminescence/fluorescence tagged vasculature, lymph nodes, or superficial tagged regions with most dynamic treatment plans. Jia, Q. L., et al. (2019). "[Removal of Microplastics by Different Treatment Processes in Shanghai Large Municipal Wastewater Treatment Plants]." Huanjing Kexue/Environmental Science **40**(9): 4105-4112.

Wastewater treatment plants are important sources of microplastics (MPs) in aquatic environments. The present study was conducted to investigate the number concentration, removal rate, and fate of MPs in two large municipal treatment plants in Shanghai. The MPs

number concentration in the influent water of WWTP1 and WWTP2 were (226.27+/-83.00) piece.L⁻¹ and (171.89+/-62.98) piece.L⁻¹, respectively. WWTP1 had a MPs removal efficiency of 63.25%, which is slightly higher than that of WWTP2, at 59.84%. The removal efficiency during the primary treatment process of the two sewage treatment plants on MPs accounted for 70%-80% of the whole treatment process. The primary treatment process and secondary treatment process transferred (48.10%+/-1.62%) and (12.97%+/-0.05%) of MPs in the sewage to the sludge, respectively. As a whole, (38.82%+/-1.55%) of MPs in the sewage treatment plants were finally discharged into natural waters, and the remaining (61.18%+/-1.55%) entered the sludge. This study shows that the removal rate of MPs in Shanghai's municipal treatment plants is low and that after treatment, large amounts still enter the natural waters with the final effluent, which causes significant ecological risks. This study provides basic data of MPs removal and trends of large urban sewage treatment plants in a plain river network area, which can provide reference for further design of MPs removal processes.

Jia, X., et al. (2018). "The aberrant expression of microRNAs in B lymphocytes of patients with immune thrombocytopenia." Research and Practice in Thrombosis and Haemostasis **2 (Supplement 1)**: 51.

Background: Immune thrombocytopenia (ITP) is an acquired autoimmune disease characterized by a transient or persistent decrease in platelet count. The pathogenesis of ITP has proven complicated, involving CTL-mediated platelet lysis, disturbed T helper cell response balance, dysregulated secretion of cytokines, etc. Among all of these pathological factors, autoreactive B cells that produce platelet antigen specific autoantibodies still take center stage. Altered expression of microRNAs (miRNAs) have been reported in patients with ITP. However, the levels of miRNAs in B cells and their effects on ITP remain unclear. Aim(s): To investigate the expression profiles of five disease-related miRNAs (miR-144-3p, -142-3p, -3162-3p, -320c and let-7b-5p) in CD19⁺ B cells of ITP patients and healthy controls. Target prediction and pathway enrichment analysis were performed. Method(s): The peripheral blood samples of 21 ITP patients and 21 healthy controls were obtained. The CD19⁺ B cells were isolated from PBMCs using immunomagnetic microbeads. The miRNA levels were detected by quantitative real-time PCR and calculated using the comparative cycle threshold method. Result(s): The expression of five miRNAs in CD19⁺ B cells of ITP patients and healthy controls were evaluated. The levels of miR-3162-3p and let-7b-5p were significantly increased in ITP patients compared to healthy controls (P=0.0341 and P<0.0001, respectively) (Figure 1). No significant difference for miR-144-3p, -142-3p and -320c was found. The association between miRNAs and peripheral platelet count in ITP patients was also analyzed and no significance was found. Bioinformatics analysis indicated that the highest scoring functional pathways associated with ITP were cell cycle and thyroid hormone signaling pathway. Conclusion(s): The aberrant expression of miR-3162-3p and let-7b-5p were verified in CD19⁺ B cells of ITP patients, which may contribute to ITP pathogenesis by targeting cell cycle and thyroid hormone signaling pathway (Figure Presented).

Jia, Y. W., et al. (2019). "Occurrence and mass loads of biocides in plastic debris from the Pearl River system, South China." Chemosphere **246**: 125771.

Chemical pollution in the plastic debris is an increasing global concern as most pollutants might transfer from the environment to living organisms via plastic debris. In this study, biocides in the plastic debris floating on the surface water of the Pearl River system were investigated. The abundances of large plastic debris and microplastics in the surface water were 0.07 +/- 0.13 and 0.94 +/- 1.87 items/m³, respectively. Totally, 15 and 16 out of 19 biocides were detected in the large plastic debris and microplastics, with the concentration of each biocide in the ranges of 22.6-2460 ng/g and 16.9-2890 ng/g, respectively. Meanwhile, the concentration ranges of the detected biocides were 0.01-215 ng/L in surface water. Triclosan, triclocarban, methylparaben, and N,N-diethyl-3-methylbenzamide (DEET) were the frequently detected compounds in the plastic samples and surface water. The partition coefficients (K_d) of biocides between the plastic debris and surface water showed a weak positive correlation with K_{ow} values. Biocides were also detected on the natural floats (tree leaves and branches) at concentrations of 13.7-786 ng/g. The annual mass load of biocides in plastic debris at each site was up to 265 g/y, thereby suggesting that plastic debris might be an important carrier for the emerging contaminants, such as biocides.

Jiang, C., et al. (2019). "Microplastic pollution in the rivers of the Tibet Plateau." Environmental Pollution **249**: 91-98.

The presence of microplastics was detected in the rivers of the Tibet Plateau. The Tibet Plateau, the so-called Third Pole of the world, is home to the headstreams of many great rivers. The levels of microplastic pollution in those rivers, however, are unknown. In this study, surface water and sediment samples were collected from six sampling sites along five different rivers. The surface water and sediment samples were collected with a large flow sampler and a stainless steel shovel, respectively. The abundance of microplastics ranged from 483 to 967 items/m³ in the surface water and from 50 to 195 items/kg in the sediment. A large amount of small, fibrous, transparent microplastics were found in this study. Five types of microplastics with different chemical compositions were identified using micro-Raman spectroscopy: polyethylene terephthalate (PET), polyethylene (PE), polypropylene (PP), polystyrene (PS), and polyamide (PA). These results demonstrate that rivers in the Tibet Plateau have been contaminated by microplastics, not only in developed areas with intense human activity but also in remote areas, where microplastic pollution requires further attention. Jiang, H., et al. (2012). "Effects of cobalt nanoparticles on human T cells in vitro." Biological Trace Element Research **146**(1): 23-29.

Limited information is available on the potential risk of degradation products of metal-on-metal bearings in joint arthroplasty. The aim of this study was to investigate the cytotoxicity and genotoxicity of orthopedic-related cobalt nanoparticles on human T cells in vitro. T cells were collected using magnetic CD3 microbeads and exposed to different concentrations of cobalt nanoparticles and cobalt chloride. Cytotoxicity was evaluated by methyl thiazolyl tetrazolium and lactate dehydrogenase release assay. Cobalt nanoparticles dissolution in culture medium was determined by inductively coupled plasma-mass spectrometry. To study the probable mechanism of cobalt nanoparticles effects on T cells, superoxide dismutase, catalase, and glutathione peroxidase level was measured. Cobalt nanoparticles and cobalt ions could inhibit cell viability and enhance lactate dehydrogenase release in a concentration- and time-dependent manner ($P < 0.05$). The levels of cobalt ion released from cobalt nanoparticles in the culture medium were less than 40% and increased with cobalt nanoparticles concentration. Cobalt nanoparticles could induce primary DNA damage in a concentration-dependent manner, and the DNA damage caused by cobalt nanoparticles was heavier than that caused by cobalt ions. Cobalt nanoparticles exposure could significantly decrease superoxide dismutase, catalase, and glutathione peroxidase activities at subtoxic concentrations (6 muM, <CC(50)). These findings suggested that cobalt nanoparticles could generate potential risks to the T cells of patients suffer from metal-on-metal total hip arthroplasty, and the inhibition of antioxidant capacity may play important role in cobalt

nanoparticles effects on T cells.

Jiang, M., et al. (2009). "Anti-inflammatory cytokines suppress the TLR3-induced antiviral activity of non-parenchymal liver cells." Journal of Hepatology **1)**: S324.

Background and Aims: The liver is constantly exposed to a variety of foreign pathogens including HBV and HCV that can lead to chronic hepatitis. Here, Kupffer cells (KC) and liver sinusoidal endothelial cells (LSEC), as the most abundant non-parenchymal liver cells (NPC), have unique and important functions in innate and adaptive immune responses against these viruses. HCV in particular has been shown to induce IFNs and other cytokines by activating the Toll-like receptor (TLR) 3 pathway. However, only little is known about the regulation of this pathway by anti-inflammatory cytokines in NPC. Method(s): We have isolated murine KC by counterflow elutriation as well as murine LSEC by anti-LSEC microbeads (>99% purity as controlled by FACS). Cells were cultivated in the presence or absence of anti- inflammatory cytokines (IL-10, TGF-beta) and stimulated by TLR3 ligands (poly I:C). Then, supernatants were collected to perform antiviral assays (EMCV) on L929 cells. Neutralizing antibodies against IFN-alpha and IFN-beta were used to block the antiviral effects. To assess the effects on the transcriptional level total RNA was isolated and analyzed by quantitative rt-PCR. Result(s): TLR3 stimulation had no direct antiviral effect on L929 cells. When supernatants from TLR3-stimulated KC and LSEC were used, however, a potent, dose-dependent antiviral activity could be observed as early as 4 hours after stimulation. Poly I:C induced a number of ISGs in murine KC and LSEC. Pretreatment of KC and LSEC with IL-10 or TGF-beta strongly suppressed the antiviral activity of TLR3-stimulated NPC which correlated with suppressed ISG induction by poly I:C on the transcriptional level. The suppressive effects of IL-10 and TGF-beta were dose-dependent and can, at least in part, be explained by a down-regulation of TLR3 expression by these cytokines. Conclusion(s): Our data indicate for the first time that the TLR3-induced antiviral activity of NPC can be suppressed by anti-inflammatory cytokines. This is of particular relevance for the regulation of the local innate immune response against viral infections of the liver.

Jiang, N., et al. (2018). "Microfluidic Contact Lenses." SMALL **14**(15): e1704363.

Contact lens is a ubiquitous technology used for vision correction and cosmetics. Sensing in contact lenses has emerged as a potential platform for minimally invasive point-of-care diagnostics. Here, a microlithography method is developed to fabricate microconcavities and microchannels in a hydrogel-based contact lens via a combination of laser patterning and embedded templating. Optical microlithography parameters influencing the formation of microconcavities including ablation power (4.3 W) and beam speed (50 mm s⁻¹) are optimized to control the microconcavity depth (100 micro m) and diameter (1.5 mm). The fiber templating method allows the production of microchannels having a diameter range of 100-150 micro m. Leak-proof microchannel and microconcavity connections in contact lenses are validated through flow testing of artificial tear containing fluorescent microbeads (O = 1-2 micro m). The microconcavities of contact lenses are functionalized with multiplexed fluorophores (2 micro L) to demonstrate optical excitation and emission capability within the visible spectrum. The fabricated microfluidic contact lenses may have applications in ophthalmic monitoring of metabolic disorders at point-of-care settings and controlled drug release for therapeutics.

Jiang, R., et al. (2018). "Quantifying nanoplastic-bound chemicals accumulated in <i>Daphnia magna</i> with a passive dosing method." Environmental Science: Nano **5**(3): 776-781.

Because of their large surface area and high hydrophobicity, nanoplastics (NPs) possess a large

sorption capacity for and strong affinity to hydrophobic organic chemicals, which may substantially alter the environmental behavior, especially the bioaccumulation of hydrophobic organic compounds. The present study aims to examine the effects of nano-size polystyrene (PS) on the bioaccumulation of polychlorinated biphenyls (PCBs) in Daphnia magna. A novel passive dosing method was developed to quantify the accumulation of NPs in D. magna in different exposure suspensions with various NP concentrations during 2 h and 24 h exposure. Addition of NPs enhanced the amount of PCBs accumulated in D. magna by 1.4–2.6 times compared to no presence of NPs during 24 h exposure. The relative amounts of NP-bound PCBs accumulated in D. magna were 18% to 81% for different PCB congeners at various NP concentrations. The significance of different uptake pathways in the accumulation of PCBs in D. magna with the presence of NPs was found to relate to the chemical properties of PCBs, the ingestion rate of plastics and the exposure conditions. These results have justified additional research efforts toward investigating the fate and toxic effects of NP-bound contaminants ingested by organisms.

Jiang, W., et al. (2013). "DNA-polyfluorophore Chemosensors for Environmental Remediation: Vapor-phase Identification of Petroleum Products in Contaminated Soil." Chemical Science **4**(8): 3184-3190.

Contamination of soil and groundwater by petroleum-based products is an extremely widespread and important environmental problem. Here we have tested a simple optical approach for detecting and identifying such industrial contaminants in soil samples, using a set of fluorescent DNA-based chemosensors in pattern-based sensing. We used a set of diverse industrial volatile chemicals to screen and identify a set of five short oligomeric DNA fluorophores on PEG-polystyrene microbeads that could differentiate the entire set after exposure to their vapors in air. We then tested this set of five fluorescent chemosensor compounds for their ability to respond with fluorescence changes when exposed to headgas over soil samples contaminated with one of ten different samples of crude oil, petroleum distillates, fuels, lubricants and additives. Statistical analysis of the quantitative fluorescence change data (as DELTA(R,G,B) emission intensities) revealed that these five chemosensors on beads could differentiate all ten product mixtures at 1000 ppm in soil within 30 minutes. Tests of sensitivity with three of the contaminant mixtures showed that they could be detected and differentiated in amounts at least as low as one part per million in soil. The results establish that DNA-polyfluorophores may have practical utility in monitoring the extent and identity of environmental spills and leaks, while they occur and during their remediation.

Jiang, X., et al. (2019). "Toxicological effects of polystyrene microplastics on earthworm (Eisenia fetida)." Environmental Pollution **259**: 113896.

Microplastics are plastic fragments of particle sizes less than 5 mm, which are widely distributed in marine and terrestrial environments. In this study, earthworms Eisenia fetida were exposed to 100 and 1000 mug of 100 nm and 1300 nm fluorescent polystyrene microplastics (PS-MPs) per kg of artificial soil for 14 days. Uptake or accumulation of PS-MPs in earthworm intestines, histopathological changes, oxidative stress, and DNA damage were assessed to determine the toxicological effects of PS-MPs on E. fetida. The results showed that the average accumulated concentrations in the earthworm intestines were higher for 1300 nm PS-MPs (0.084 +/- 0.005 and 0.094 +/- 0.003 mug/mg for 100 and 1000 mug/kg, respectively) than for 100 nm PS-MPs (0.015 +/- 0.001 and 0.033 +/- 0.002 mug/mg for 100 and 1000 mug/kg, respectively). In addition, histopathological analysis indicated that the intestinal cells were damaged after exposure to PS-MPs. Furthermore, PS-MPs significantly changed glutathione (GSH) level and

superoxide dismutase (SOD) activity. The GSH levels were 86.991 +/- 7.723, 165.436 +/- 4.256-167.767 +/- 18.642, and 93.590 +/- 4.279-173.980 +/- 15.523 mumol/L in the control, 100 nm, and 1300 nm PS-MPs treatment groups. In addition, the SOD activities were 10.566 +/- 0.621, 9.039 +/- 0.787-9.408 +/- 0.493, and 7.959 +/- 0.422-9.195 +/- 0.327 U/mg protein for the control, 100 nm, and 1300 nm PS-MPs treatment groups, respectively, indicating that oxidative stress was induced after PS-MPs exposure. Furthermore, the comet assay suggested that exposure to PS-MPs induced DNA damage in earthworms. Overall, 1300 nm PS-MPs showed more toxic effect than 100 nm PS-MPs on earthworms. These findings provide new insights regarding the toxicological effects of low concentrations of microplastics on earthworms, and on the ecological risks of microplastics to soil animals.

Jiang, X., et al. (2019). "Ecotoxicity and genotoxicity of polystyrene microplastics on higher plant Vicia faba." Environmental Pollution **250**: 831-838.

Nano- and microplastics have been widely spread in environmental matrices, especially in marine and terrestrial systems. In this study, higher plant Vicia faba root tips were exposed to 5mum and 100nm with 10, 50 and 100mg/L polystyrene fluorescent microplastics (PS-MPs) for 48h. Root length, weight, oxidative stress and genotoxicity of V. faba were assessed to investigate toxic effects of PS-MPs. The results showed that the biomass and catalase (CAT) enzymes activity of V. faba roots decreased under 5mum PS-MPs whereas superoxide dismutase (SOD) and peroxidase (POD) enzymes activity significantly increased. Under the 100nm PS-MPs exposure a significant decrease of growth was observed only at the highest concentration (100mg/L). However, micronucleus (MN) test and antioxidative enzymes activities showed that 100nm PS-MPs induce higher genotoxic and oxidative damage to V. faba than 5mum PS-MPs. Furthermore, the laser confocal scanning microscopy (LCSM) demonstrated that 100nm PS-MPs can accumulate in V. faba root and most probably block cell connections or cell wall pores for transport of nutrients. These findings provide a new insight into the toxic effects of microplastics on V. faba, and further apply to the ecological risk assessment of microplastics on higher plants.

Jiang, X., et al. (2019). "Quantifying the bioaccumulation of nanoplastics and PAHs in the clamworm Perinereis aibuhitensis." Science of the Total Environment **655**: 591-597.

The impact of nanometer-scale plastics (<1000 nm nanoplastics, NPs) on the bioaccumulation of hydrophobic organic pollutants, and especially polycyclic aromatic hydrocarbons (PAHs), in marine organisms has become of urgent concern. However, simultaneous determinations of the bioaccumulation of NPs and PAHs have been hindered by the lack of an efficient digestion method that removes background interference from the tissue without altering the surface properties of the plastic and destroying the PAHs. To solve this problem, an enzymatic digestion-based protocol using proteinase K and subsequent quantification methods were developed on a typical marine benthic invertebrate - the clamworm Perinereis aibuhitensis. Enzymatic digestion removed 91% of the biological tissues, comparable to the amount removed using 65% HNO<inf>3</inf> (93% removed) and better than that removed using 30% H<inf>2</inf>O<inf>2</inf> or 10% KOH digestion (76% and 66%, respectively). After enzymatic digestion, roughly 92% of the NPs and 88% of the amount of pyrene were recovered, without significant modification of the NPs or pyrene degradation. By contrast, the NP and pyrene recovery achieved with HNO<inf>3</inf> digestion was only 1.4% and 0.1%, respectively. The newly developed protocol was successfully applied to a 96-h bioaccumulation study. The use of radioactively labeled ¹⁴C-pyrene and fluorescently labeled NPs allowed the simultaneous quantification of NPs and PAHs in the clamworm and revealed a bioconcentration factor (BCF) of 1.96 +/- 0.93 and 402.7 +/- 47.0, respectively. The quantification of NPs and pyrene indicated that NP-adsorbed pyrene accounted for <1% of the total pyrene accumulation in the clamworm body when the concentration of NPs in seawater was as low as 0.4 mg/L. Our enzymatic digestion and dual-labeling technique thus provides the first reported BCF value of NPs in a marine benthic organism and new insights into the vector effects of these particles on the bioaccumulation of organic contaminants in a marine ecosystem. Jiang, X. F., et al. (2005). "[VEGF-induced tubulogenesis of endothelial cells from human brain malignant glioma in the three dimentional model]." Chung-Hua Ping Li Hsueh Tsa Chih - Chinese Journal of Pathology **34**(9): 579-582.

OBJECTIVE: To compare the tubulogenesis capability of malignant glioma-derived microvessel endothelial cells (GDMEC) from human brain with that of ECV304 cells in a three dimentional model and to explore the significance of GDMEC in the study on angiogenesis.

METHODS: The GDMEC were isolated from malignant gliomas of human brain and purified by selective binding to the monoclonal antibody against CD105 bound to the magnetic MACS MicroBeads. GDMEC and endothelial-like cell line ECV304 were compared with their capabilities of formatting tubule-like structure (TLS) in the three dimentional collagen matrix, with or without inducement by various concentration of vascular endothelial growth factor (VEGF).

RESULTS: The obtained GDMEC had a high purification (98%) and could be successfully cultured in vitro. GDMECs formed more TLS than ECV304 cells of the same number and at the same time points. VEGF could induce rapid formation of TLS in a dose-dependent manner, however, ECV304 cells were less response to VEGF stimulation.

CONCLUSIONS: GDMEC could maintain their endothelial characteristics and potential capability of angiogenesis. They were more response to VEGF than ECV304, therefore, more suitable for in vitro studies on tumor angiogenesis.

Jiang, Y., et al. (2019). "Heterogeneous Strain Distribution of Elastomer Substrates To Enhance the Sensitivity of Stretchable Strain Sensors." Accounts of Chemical Research **52**(1): 82-90.

Stretchable strain sensors, which convert mechanical stimuli into electrical signals, largely fuel the growth of wearable bioelectronics due to the ubiquitous, health-related strain in biological systems. In contrast to rigid conventional strain sensors, stretchable strain sensors present advantages of conformality and stretchability, solving the mechanical mismatch between electronics and the human body. However, the great challenge of stretchable strain sensors lies in achieving high sensitivity, which is required for both signal fidelity and cost considerations. Recent advances to solve this sensitivity challenge have focused on material optimization, in search of the optimum combination of conductive active materials and elastomer substrates among a myriad of artificial or natural materials. However, high sensitivity with a gauge factor larger than 50 remains a grand challenge, especially within large-strain regions. Here we present heterogeneous strain distribution of elastomer substrates as a powerful strategy to significantly enhance the sensitivity of stretchable strain sensors. The theoretical foundation of this strategy is mathematically proven on the basis of Ohm's law in electrics and mechanics of materials. First, the extent of the sensitivity enhancement is proved to be determined by the local strain in resistance-testing segments of heterogeneous strain sensors. Next, the local strain is proved to be quantitatively decided by material properties such as section area and Young's modulus. Thus, the necessary and sufficient condition to achieve high sensitivity in heterogeneous strain sensors is that the Young's modulus reciprocal or section area reciprocal in the resistance-testing segment is larger than the mean value. This provides a theoretical design guideline to achieve high sensitivity via heterogeneous strain distribution. On the basis of this guideline, we systematically summarize concrete instances of heterogeneity-induced sensitivity improvement in stretchable strain sensors, in sequence of increasing dimensionality. A typical example of a one-dimensional heterogeneous strain sensor is a structured fiber with microbeads, where the varied section area along the fiber axis results in heterogeneous strain and sensitivity improvement. Two-dimensional heterogeneous sensors in the form of thin films contain thickness gradient sensors and auxetic mechanical metamaterial sensors. The former exhibit heterogeneous section area via the self-pinning method, while the latter show heterogeneity in both the strain direction and amplitude, leading to a 24-fold improvement in sensitivity. Three-dimensional strain sensors include rationally structured sensors for out-of-plane force detection and asymmetric active materials in electronic whiskers. The resultant enhanced sensitivity in these heterogeneous strain sensors is beneficial for applications such as continuous health monitoring, biomedical diagnostics, and replacement prosthetics, taking advantage of augmented detection accuracy and declined device cost. Finally, we discuss possible future work in exploiting heterogeneous strain distributions, involving extended methodology to achieve heterogeneity, employing suppressed strain for stretchable electrodes, cyclic durability for long-term applications, and multifunctional system-level integration. We believe that this strategy of using heterogeneous strain distribution to enhance sensitivity can strongly promote the development of stretchable strain sensors for both practical and theoretical requirements.

Jimenez, C., et al. (2010). "A single dose of vitamin A improves haemoglobin concentration, retinol status and phagocytic function of neutrophils in preschool children." British Journal of Nutrition **103**(6): 798-802.

Since there is a reported interrelationship between vitamin A and Fe metabolism, and with immunological response, the objective was to evaluate the effect of a single dose of vitamin A administered to preschool children, on Fe and vitamin A nutritional status, anaemia and phagocytic function of neutrophils, 30 d after supplementation. A total of eighty children (sixty-eight supplemented and twelve controls) were supplemented orally with 200,000 IU (60 mg) vitamin A, and evaluated for nutritional, haematological and immunological responses at the beginning of the study and 30 d after supplementation. Parameters studied included Hb, serum ferritin, retinol and Fe concentrations, transferrin saturation, IL-4, interferon-gamma and phagocityc capacity of neutrophils using non-fluorescent latex microbeads. After supplementation there was a significant increase in Hb concentration ($P = 0.03$), mean corpuscular Hb concentration ($P = 0.001$) and serum retinol ($P = 0.0078$). Prevalences of anaemia and vitamin A deficiency decreased significantly from 17.6 % to 13.2 % and from 25 % to 13.2 %, respectively. Regarding phagocytic function, there was a significant increase in the number of microbeads engulfed by neutrophils ($P < 0.05$) and no significant changes in cytokine concentrations at 1 month after treatment. A single dose of 200,000 IU (60 mg) vitamin A administered orally to a group of preschool children with a high prevalence of vitamin A deficiency enhanced serum retinol and Hb concentrations, decreased the prevalence of anaemia and vitamin A deficiency and improved the constitutive phagocytic capacity of neutrophils. Vitamin A supplementation could help to decrease vitamin A deficiency, anaemia prevalence and to improve the innate immunity response in preschool children. The effects were obtained without Fe supplementation.

Jimenez, S., et al. (2011). "Analysis of Environmental Management for the Treatment of Plastic Waste in Mexico: Government Strategies." Journal of Environmental Science and Engineering **5**(8): 1031-1042.

In Mexico, garbage represents a high pollution index according to national and international

organizations; eighty percent of waste products stay in sanitary landfills, out of doors, where no tailings management exists. Plastic products represent 16% of this pollution (one and one-half kilos daily per person in a country with a population of 107 million people). These sanitary landfills are methane deposits, and consequently emit gases and toxins that cause serious health problems. The object of this is to analyze governmental programs, strategies, policies and procedures which regulate both industrial sectors and society. Society and government share a responsibility since they must implement norms which include the separation, reduction, recycling and reuse of garbage. Results demonstrate that government strategies used to treat tailings are complex and are directed more towards sanctions than to motivation. Furthermore these strategies discourage a cultural transformation toward industrial sustainability. Instead of reducing the garbage accumulation problem, they increase the difficulty.

Jin, L., et al. (2014). "Polybrominated diphenyl ethersin in plants from a plastic waste recycling area in China." Environmental Chemistry - Huanjing Huaxue **33**(6): 901-907.

Levels and profiles of polybrominated diphenyl ethers (PRDEs) were investigated in 13 plants from a typical plastic waste recycling site in north China, in order to understand the plant accumulation in the heavily polluted soils. The investigated results showed that the concentrations of 21 congeners of PRDEs ranged from 11.3 to 122 ng times g super(-1) dry weight (dw), with a mean value of 51.2 ng times g super(-1) dw. Compared with some previous studies, the results showed that PRDE levels in plants in this study were similar to those in some e-waste recycling areas, but much higher than those in other general areas. There was obvious difference among the plants. The highest concentration of PRDEs was detected in Pharbitis nil (Linn.) Choisy. RDE 209 was the dominant congener (mean 96.9%) in all samples, which ranged from 10.8 to 116 ng times g super(-1). Among the other congeners, RDE 47 and RDE 208 were relatively higher but accounted for less than 1% of the total concentrations of 21 congeners. The PRDE congener profiles in these plant samples from our studied area exhibited more distinguishable sources from deca-RDE products than those in e-waste recycling areas and other areas.

Jin, S. Q., et al. (2009). "Multiplexed bead-based mesofluidic system for detection of food-borne pathogenic bacteria." Applied & Environmental Microbiology **75**(21): 6647-6654.

In the present study, a simple and rapid multiplexed bead-based mesofluidic system (BMS) was developed for simultaneous detection of food-borne pathogenic bacteria, including Staphylococcus aureus, Vibrio parahaemolyticus, Listeria monocytogenes, Salmonella, Enterobacter sakazakii, Shigella, Escherichia coli O157:H7, and Campylobacter jejuni. This system is based on utilization of isothiocyanate-modified microbeads that are 250 mum in diameter, which were immobilized with specific amino-modified oligonucleotide probes and placed in polydimethylsiloxane microchannels. PCR products from the pathogens studied were pumped into microchannels to hybridize with the oligonucleotide-modified beads, and hybridization signals were detected using a conventional microarray scanner. The short sequences of nucleic acids (21 bases) and PCR products characteristic of bacterial pathogens could be detected at concentrations of 1 pM and 10 nM, respectively. The detection procedure could be performed in less than 30 min with high sensitivity and specificity. The assay was simple and fast, and the limits of quantification were in the range from 500 to 6,000 CFU/ml for the bacterial species studied. The feasibility of identification of food-borne bacteria was investigated with samples contaminated with bacteria, including milk, egg, and meat samples. The results demonstrated that the BMS method can be used for effective detection of multiple pathogens in different foodstuffs.

Jin, Y., et al. (2019). "Impacts of polystyrene microplastic on the gut barrier, microbiota and metabolism of mice." Science of the Total Environment **649**: 308-317.

Microplastics (MPs), which are new environmental pollutants with a diameter of <5 mm, have received wide attention in recent years. However, there are still very limited data regarding the risks of MPs to animals, especially higher mammals. In this study, we exposed male mice to 5 micro m pristine and fluorescent polystyrene MP for six weeks. The results showed that the polystyrene MP was observed in the guts of mice and could reduce the intestinal mucus secretion and cause damage the intestinal barrier function. In addition, high-throughput sequencing of the V3-V4 region of the 16S rRNA gene was used to explore the change of the gut microbiota composition in the cecal content. At the phylum level, the content of Actinobacteria decreased significantly in the polystyrene MP-treated group. The PD whole-tree indexes of the alpha diversity and principal component analysis (PCA) of the beta diversity indicated that the diversity of gut microbiota was altered after polystyrene MP exposure. At the genus level, a total of 15 types of bacteria changed significantly after exposure to polystyrene MP. Furthermore, the predicted KEGG (Kyoto Encyclopedia of Genes and Genomes) metabolic pathway differences indicated that the main metabolic pathways of the functional genes in the microbial community were significantly influenced by the polystyrene MP. In addition, indexes of amino acid metabolism and bile acid metabolism in the serum were analyzed after polystyrene MP exposure. These results indicated that polystyrene MP caused metabolic disorders. In conclusion, the polystyrene MP induced gut microbiota dysbiosis, intestinal barrier dysfunction and metabolic disorders in mice. This study provided more data on the toxicity of MPs in a terrestrial organism to aid in the assessment of the health risks of polystyrene MP to animals.

Jin, Y., et al. (2018). "Polystyrene microplastics induce microbiota dysbiosis and inflammation in the gut of adult zebrafish." Environmental Pollution **235**: 322-329.

Microplastic (MP) are environmental pollutants and have the potential to cause varying degrees of aquatic toxicity. In this study, the effects on gut microbiota of adult male zebrafish exposed for 14 days to 100 and 1000 micro g/L of two sizes of polystyrene MP were evaluated. Both 0.5 and 50 micro m-diameter spherical polystyrene MP increased the volume of mucus in the gut at a concentration of 1000 micro g/L (about 1.456x10¹⁰ particles/L for 0.5 micro m and 1.456x10⁴ particles/L for 50 micro m). At the phylum level, the abundance of Bacteroidetes and Proteobacteria decreased significantly and the abundance of Firmicutes increased significantly in the gut after 14-day exposure to 1000 micro g/L of both sizes of polystyrene MP. In addition, high throughput sequencing of the 16S rRNA gene V3-V4 region revealed a significant change in the richness and diversity of microbiota in the gut of polystyrene MP-exposed zebrafish. A more in depth analysis, at the genus level, revealed that a total of 29 gut microbes identified by operational taxonomic unit (OTU) analysis were significantly changed in both 0.5 and 50 micro m-diameter polystyrene MP-treated groups. Moreover, it was observed that 0.5 micro m polystyrene MP not only increased mRNA levels of IL1 alpha , IL1 beta and IFN but also their protein levels in the gut, indicating that inflammation occurred after polystyrene MP exposure. Our findings suggest that polystyrene MP could induce microbiota dysbiosis and inflammation in the gut of adult zebrafish.

Jinhui, S., et al. (2019). "Effects of microplastics and attached heavy metals on growth, immunity, and heavy metal accumulation in the yellow seahorse, Hippocampus kuda Bleeker." Marine Pollution Bulletin **149**: 110510.

Microplastics represent a new kind of environmental pollutant that has recently attracted extensive attention and become a research hotspot. Microplastics are similar in size to the food items of many marine organisms and are thus, often consumed by them, with potentially harmful and toxic effects. We examined the effects of microplastics on the growth of the yellow seahorse Hippocampus kuda. Seahorses were split into three groups fed Mysis+microplastics+heavy metals (group A), Mysis+microplastics (group B), and Mysis alone (group C). We analyzed and compared the accumulations of microplastics and heavy metals among the groups and monitored seahorse growth following the different treatments. Body length, body weight, condition factor, specific growth rate, and survival rate were all lower in group A compared with the other groups, but there was no significant difference in any of the parameters between groups B and C. The accumulation of microplastics was similar in groups A and B, and the accumulation of heavy metals was similar in groups B and C. These results suggest that the effect of microplastics on seahorse growth is caused by the accumulation of heavy metals, rather than by the microplastics themselves.

Jitraruch, S., et al. (2017). "Cryopreservation of Hepatocyte Microbeads for Clinical Transplantation." Cell Transplantation **26**(8): 1341-1354.

Intraperitoneal transplantation of hepatocyte microbeads is an attractive option for the management of acute liver failure. Encapsulation of hepatocytes in alginate microbeads supports their function and prevents immune attack of the cells. Establishment of banked cryopreserved hepatocyte microbeads is important for emergency use. The aim of this study was to develop an optimized protocol for cryopreservation of hepatocyte microbeads for clinical transplantation using modified freezing solutions. Four freezing solutions with potential for clinical application were investigated. Human and rat hepatocytes cryopreserved with University of Wisconsin (UW)/10% dimethyl sulfoxide (DMSO)/5% (300 mM) glucose and CryoStor CS10 showed better postthawing cell viability, attachment, and hepatocyte functions than with histidine-tryptophan-ketoglutarate/10% DMSO/5% glucose and Bambanker. The 2 freezing solutions that gave better results were studied with human and rat hepatocytes microbeads. Similar effects on cryopreserved microbead morphology (external and ultrastructural), viability, and hepatocyte-functions post thawing were observed over 7 d in culture. UW/DMSO/glucose, as a basal freezing medium, was used to investigate the additional effects of cytoprotectants: a pan-caspase inhibitor (benzyloxycarbonyl-Val-Ala-dl-Asp-fluoromethylketone [ZVAD]), an antioxidant (desferoxamine [DFO]), and a buffering and mechanical protectant (human serum albumin [HSA]) on RMBs. ZVAD (60 micro M) had a beneficial effect on cell viability that was greater than with DFO (1 mM), HSA (2%), and basal freezing medium alone. Improvements in the ultrastructure of encapsulated hepatocytes and a lower degree of cell apoptosis were observed with all 3 cytoprotectants, with ZVAD tending to provide the greatest effect. Cytochrome P450 activity was significantly higher in the 3 cytoprotectant groups than with fresh microbeads. In conclusion, developing an optimized cryopreservation protocol by adding cytoprotectants such as ZVAD could improve the outcome of cryopreserved hepatocyte microbeads for future clinical use.

Jitraruch, S., et al. (2014). "Alginate microencapsulated hepatocytes optimised for transplantation in acute liver failure." PLoS ONE [Electronic Resource] **9**(12): e113609.

BACKGROUND AND AIM: Intraperitoneal transplantation of alginate-microencapsulated human hepatocytes is an attractive option for the management of acute liver failure (ALF) providing short-term support to allow native liver regeneration. The main aim of this study was to establish an optimised protocol for production of alginate-encapsulated human hepatocytes and evaluate their suitability for clinical use.

METHODS: Human hepatocyte microbeads (HMBs) were prepared using sterile GMP grade materials. We determined physical stability, cell viability, and hepatocyte metabolic function of HMBs using different polymerisation times and cell densities. The immune activation of peripheral blood mononuclear cells (PBMCs) after co-culture with HMBs was studied. Rats with ALF induced by galactosamine were transplanted intraperitoneally with rat hepatocyte microbeads (RMBs) produced using a similar optimised protocol. Survival rate and biochemical profiles were determined. Retrieved microbeads were evaluated for morphology and functionality.

RESULTS: The optimised HMBs were of uniform size (583.5+/-3.3 micro m) and mechanically stable using 15 min polymerisation time compared to 10 min and 20 min (p<0.001). 3D confocal microscopy images demonstrated that hepatocytes with similar cell viability were evenly distributed within HMBs. Cell density of 3.5x10(6) cells/ml provided the highest viability. HMBs incubated in human ascitic fluid showed better cell viability and function than controls. There was no significant activation of PBMCs co-cultured with empty or hepatocyte microbeads, compared to PBMCs alone. Intraperitoneal transplantation of RMBs was safe and significantly improved the severity of liver damage compared to control groups (empty microbeads and medium alone; p<0.01). Retrieved RMBs were intact and free of immune cell adherence and contained viable hepatocytes with preserved function.

CONCLUSION: An optimised protocol to produce GMP grade alginate-encapsulated human hepatocytes has been established. Transplantation of microbeads provided effective metabolic function in ALF. These high quality HMBs should be suitable for use in clinical transplantation.

Jitraruch, S., et al. (2012). "Human hepatocyte alginate microbeads: Preparation under GMP conditions and assessment of cell viability, metabolic function and physical integrity." Hepatology **1)**: 728A-729A.

Encapsulated human hepatocyte (microbeads) transplantation is an attractive option in the management of acute liver failure in children. Microbeads can be safely and easily transplanted intraperitoneally and avoids the need of immunosuppression. Cell function could be demonstrated for 4-6 weeks giving either the native liver time to recover or act as bridge to whole liver replacement. However, there are limited data on synthetic and detoxification functions of hepatocytes and physical integrity of microbeads prepared under GMP conditions. AIM: To evaluate hepatocyte-specific functions and activities, and assess physical integrity of human hepatocyte alginate microbeads. Also to investigate cell number and viability in relation to cell distribution in microbeads. METHOD(S): Microbeads were produced using an encapsulator (250mu nozzle) and GMP grade materials. Human hepatocytes were encapsulated (1.5% sodium alginate solution; polymerised in 1.2% calcium chloride for 10min; 2.5x106cells/ml alginate). Immediately after encapsulation (control group), human hepatocyte microbeads (HMBs) were assessed for cell overall metabolic activity (MTT assay), viability [fluorescein diacetate/propidium iodide (FDA/PI) staining], and morphology. Physical stability of HMBs was determined using an osmotic pressure test by incubation for 3h in transplant medium (CMRL; isotonic) or water (hypotonic). Microbead size (n=100/sample), MTT assay and viability (FDA/PI) were evaluated. Hepatocyte-specific functions (albumin and urea synthesis) in HMBs were assessed after maintenance in CMRL for 24h. Average cell number and viability per microbead was determined using FDA/PI and 3D confocal microscopy. RESULT(S): GMP grade HMBs obtained were of uniform size and shape (mean diameter: 584.0+/-SEM 0.9mum). HMBs maintained their size and functional activity when incubated for 3h in CMRL. HMBs had similar hepatocyte overall activity and viability after 24h incubation in CMRL compared to control. Synthesis of albumin was 64.0+/-18.8ng, and urea was 4.25+/-1.85mug per ml/1x106cells/day. There was a statistically significant increase in microbead diameter after incubation in water

(671.0+/-1.4mum) vs control (p<0.001) without leading to disintegration. 3D reconstruction of confocal microscope images demonstrated that average cell number per microbead was 238+/-23, with no significant difference in cell viability within the microbead (inner half 61.2+/-5.4% vs outer half 61.4+/-3.7%). CONCLUSION(S): GMP grade human hepatocyte microbeads were produced, which had good cell viability, function, and physical integrity. These conditions may be used for preparation of hepatocyte microbeads for clinical transplantation.

João Pinto da, C., et al. (2019). "Microplastics in soils: assessment, analytics and risks." Environmental chemistry (Online) **16**(1): 18-30.

Abstract. There has been an increasing interest by both the general public and the scientific community in microplastic-related pollution. Owing to their physical and chemical characteristics, these highly ubiquitous contaminants may be ingested by numerous organisms at the base of food-webs. Furthermore, owing to their tendency to adsorb other chemical substances, such as persistent organic pollutants (POPs), these plastic particles can lead to bioaccumulation and bioamplification phenomena, which significantly increases their potential environmental effects. However, most of the current research available is focussed on the prevalence and effects of these materials in water, and, more precisely, in oceans. Although this is understandable, owing to the alarming accumulation of plastics in this environmental compartment, little attention has been paid to the sources, fate and effects of microplastics (MPs) in terrestrial settings. This is further complicated by the current lack of universally accepted methods for the assessment and identification of MPs, not only in liquid, but also in solid matrices. We overview the most current data regarding the presence and prevalence of MPs in soils and evaluate their recognised impacts and potential consequences. We also appraise the current sampling, isolation and identification methodologies and suggest methods that may contribute to the development of standard operating procedures (SOPs) for the sampling and characterisation of these pervasive pollutants in complex matrices, such as soils.

Johansen, M. P., et al. (2019). "Biofilm-enhanced adsorption of strong and weak cations onto different microplastic sample types: Use of spectroscopy, microscopy and radiotracer methods." Water Research **158**: 392-400.

The adsorption of metals and other elements onto environmental plastics has been previously quantified and is known to be enhanced by surface-weathering and development of biofilms. However, further biofilm-adsorption characterisation is needed with respect to the fate of radionuclides. This study uses spectroscopy, microscopy and radiotracer methods to investigate the adsorption capacity of relatively strong and weak cations onto different microplastic sample types that were conditioned in freshwater, estuarine and marine conditions although marine data were limited. Fourier-transform infrared spectroscopy confirmed that surface oxidation chemistry changes induced by gamma irradiation were similar to those resulting from environmental exposures. Microscopy elemental mapping revealed patchy biofilm development, which contained Si, Al, and O, consistent with microbial-facilitated capture of clays. The plastics+biofilm of all sample types had measurable adsorption for Cs and Sr radiotracers, suggesting environmental plastics act broadly as a sink for the key pervasive environmental radionuclides of ¹³⁷Cs and ⁹⁰Sr associated with releases from nuclear activities. Adsorption onto high-density polyethylene plastic types was greater than that on polypropylene. However, in most cases, the adsorption rates of all types of plastic+biofilm were much lower than those of reference sediments and roughly consistent with their relative exchangeable surface areas.

Johansen, M. P., et al. (2018). "Initial data on adsorption of Cs and Sr to the surfaces of microplastics with biofilm." Journal of Environmental Radioactivity **190-191**: 130-133.

The adsorption of radiocesium and radiostrontium onto a range of natural materials has been well quantified, but not for the new media of environmental plastics, which may have enhanced adsorption due to surface-weathering and development of biofilms. Microplastic samples were deployed in freshwater, estuarine and marine conditions, then characterised using infrared spectroscopy to document changes to the plastic surface (vs interior). Synchrotron elemental mapping data revealed surfaces that were well-covered by accumulation of reactive water solutes and sulphur, but, in contrast, had highly discrete coverage of elements such as Fe and Ti, indicating adhered mineral/clay-associated agglomerates that may increase overall adsorption capacity. Plastics that had been deployed for nearly five months adsorbed radionuclides in both freshwater and estuarine conditions with the highest K<inf>d</inf> for cesium (Cs) in freshwater (80 ml g⁻¹) and lowest for strontium (Sr) in estuarine conditions (5 ml g⁻¹). The degree of Cs and Sr adsorption onto plastics appears to be approximately 2-3 orders of magnitude lower than for sediment reference values. While lower than for sediments, adsorption occurred on all samples and may indicate a significant radionuclide reservoir, given that plastics are relatively buoyant and mobile in water regimes, and are increasing in global aquatic systems. Johansson, J.-E. (2009). "VARIED APPROACHES TO PLASTICS PROBLEM." Materials Recycling Week **193**(2): 12-13.

The article provides information about several issues related to the plastic industry in Great Britain. According to a report, nine of the 29 countries studied already recover more than 80 percent of their plastics waste through a combination of recycling and energy recovery. The European collection rate for mechanical recycling of post-consumer plastics waste has shown an increment of 20.1 percent in 2007 from 11 percent in 2006. This increase is a result of higher polymer prices and improved collection and sorting technology. Several graphs are also presented providing information about the decoupling of plastic waste and landfill, and growth of recycling and energy recovery.

Johansson, M. W., et al. (2013). "Alphambeta2 integrin-mediated adhesion and motility of interleukin-5-stimulated eosinophils on periostin." American Journal of Respiratory and Critical Care Medicine. Conference: American Thoracic Society International Conference, ATS **187**(MeetingAbstracts).

RATIONALE: Periostin is an extracellular matrix protein that is up-regulated by T helper cell type 2 (Th2) cytokines in the asthmatic airway, considered a marker of "Th2-high" asthma, and implicated in mouse and human studies as promoting or being associated with airway eosinophilic inflammation. We asked whether periostin modulates eosinophil adhesion and motility in vitro. METHOD(S): Adhesion of purified human blood eosinophils to adsorbed periostin in the absence or presence of different concentrations of a cytokine was studied in polystyrene multi-well plates using eosinophil peroxidase as a readout. Adhesive structures were imaged by fluorescent microscopy. Random motility of adherent eosinophils was assayed using a microbead monolayer assay. RESULT(S): Periostin supported adhesion of eosinophils stimulated by interleukin-5 (IL-5), IL-3, or granulocyte macrophage-colony stimulating factor (GM-CSF), but did not support adhesion of eosinophils treated with IL-4 or IL-13. The degree of adhesion depended on the concentrations of periostin during coating and activating cytokine during the adhesion assay. Both full-length periostin and alternatively spliced periostin, lacking C-terminal exons 17, 18, 19, and 21, supported adhesion. Adhesion was inhibited by monoclonal antibody to alphaM or beta2 integrin subunits, but not by antibodies to other eosinophil

integrin subunits. In the presence of IL-5, eosinophils adherent on periostin formed punctate structures positive for filamentous actin, gelsolin, and phosphotyrosine. These structures fit the criteria for podosomes, highly dynamic adhesive contacts that are distinct from classical focal adhesions and have been suggested to be required for or facilitate migration of many cell types. Periostin supported alphaMbeta2-dependent random motility of IL-5-stimulated eosinophils with optimal movement at an intermediate coating concentration. CONCLUSION(S): The results establish alphaMbeta2 integrin (CD11b/CD18, Mac-1) as an adhesive and pro-migratory periostin receptor on cytokine-stimulated eosinophils and suggest that periostin may function as a haptotactic stimulus able to guide eosinophils to areas of high periostin density in the asthmatic airway. The periostin-alphaMbeta2 interaction may be a possible therapeutic target in asthma.

Johnsen, H. E., et al. (1999). "Selective loss of progenitor subsets following clinical CD34+ cell enrichment by magnetic field, magnetic beads or chromatography separation." Bone Marrow Transplantation **24**(12): 1329-1336.

In this preclinical evaluation we have compared the efficacy of three clinical CD34+enrichment procedures with respect to purity, yield and recovery, as well as risk of selective loss of CD34+ lineage-specific subsets. The three devices work by different principles and have several different manipulation steps: The magnetic field separator uses paramagnetic iron-dextran particles; the magnetic microbead selection is based on the advantage of a large surface area for immobilisation of the monoclonal antibody within a very small volume; the original immunoabsorption technique is based on the use of biotinylated antibody applied to a column of avidin-coated sephadex beads. The results of this evaluation gave a median purity 96% (88-98%), 86% (62-97%), and 49% (18-85%), and median yield of 65% (54-100%), 40% (21-74%), and 30% (8-55%), respectively. Subset analysis recognised a selective loss of CD34+/61+ after enrichment, most likely due to class I-II antibodies used for the enrichment step or, alternatively, nonspecific binding of megakaryocytic progenitors. Tumour cell spiking experiments on a clinical scale documented an expected 2-4 log reduction resulting in a number of potentially malignant cells in the CD34 enriched product. Our data support four major conclusions: First, that magnetic field separation is superior to magnetic beads and chromatography selection, mainly due to the risk of cell loss and insufficient recovery with the two latter methods. Second, that late differentiated progenitors with CD34 class III epitopes present are lost during the enrichment procedures. The third major conclusion is that chromatography selection results in a selective loss of CD34bright cells, which are most likely uncommitted early progenitors. This was an unexpected finding which may be a consequence of an imbalance between the strong forces between biotin-avidin and insufficient physical manipulation for CD34+ cell release. Finally, the data document that CD34 selection alone is an inappropriate way to eliminate tumour cells due to the uncontrolled variables and the inconsistent outcome. The only products which can be expected to be purged free of tumour cells are the ones with very minimal (<10-5) contamination in the starting products, ie products documented tumour free with the most sensitive techniques for quantitation. If this is not the case, the optimal purging strategy may be a two-step procedure including CD34 selection and subsequent depletion of the tumour cells in question.

Johnson, G. (2015). "MICROPLASTIC pollution." Alive: Canada's Natural Health & Wellness Magazine(395): 103-106.

Johnston, B., et al. (2018). "The Microbial Production of Polyhydroxyalkanoates from Waste Polystyrene

Fragments Attained Using Oxidative Degradation." Polymers **10**(9): 29.

Excessive levels of plastic waste in our oceans and landfills indicate that there is an abundance of potential carbon sources with huge economic value being neglected. These waste plastics, through biological fermentation, could offer alternatives to traditional petrol-based plastics. Polyhydroxyalkanoates (PHAs) are a group of plastics produced by some strains of bacteria that could be part of a new generation of polyester materials that are biodegradable, biocompatible, and, most importantly, non-toxic if discarded. This study introduces the use of prodegraded high impact and general polystyrene (PS0). Polystyrene is commonly used in disposable cutlery, CD cases, trays, and packaging. Despite these applications, some forms of polystyrene PS remain financially and environmentally expensive to send to landfills. The prodegraded PS0 waste plastics used were broken down at varied high temperatures while exposed to ozone. These variables produced PS flakes (PS1-3) and a powder (PS4) with individual acid numbers. Consequently, after fermentation, different PHAs and amounts of biomass were produced. The bacterial strain, Cupriavidus necator H16, was selected for this study due to its well-documented genetic profile, stability, robustness, and ability to produce PHAs at relatively low temperatures. The accumulation of PHAs varied from 39% for prodegraded PS0 in nitrogen rich media to 48% (w/w) of dry biomass with the treated PS. The polymers extracted from biomass were analyzed using nuclear magnetic resonance (NMR) and electrospray ionization tandem mass spectrometry (ESI-MS/MS) to assess their molecular structure and properties. In conclusion, the PS0-3 specimens were shown to be the most promising carbon sources for PHA biosynthesis; with 3-hydroxybutyrate and up to 12 mol % of 3-hydroxyvalerate and 3-hydroxyhexanoate co-monomeric units generated.

Johnston, L., et al. (2015). "Comparing methods for ex vivo characterization of human monocyte phenotypes and in vitro responses." Immunobiology **220**(12): 1305-1310.

Monocytes are key innate effector cells and their phenotype and function may be a useful biomarker of disease state or therapeutic response. However, for such an assay to be clinically feasible it needs to be simple and reproducible, which this study aimed to address. Peripheral blood mononuclear cells (PBMC)(2) isolated from whole blood using Histopaque-1077 or cell preparation tubes (CPT) showed no difference in the ex vivo monocyte activation marker expression or in vitro responses; however, a delayed isolation using CPT significantly altered ex vivo and in vitro phenotypes and responses. Furthermore, purification of monocytes using CD14(+) microbeads resulted in a loss of CD14(low)CD16(+) monocytes compared to PBMC samples. Thus, the use of CPT reduced complexity and time compared to Histopaque, and PBMC isolation allowed the analysis of all 3 major monocyte subsets. Finally, because the delayed isolation of PBMC from CPT significantly altered monocytes, time delays should be standardized.

Jonas Germain, L. and R. C. Burns (2018). "Drinking water in West Virginia (USA): tap water or bottled water – what is the right choice for college students?" Journal of Water and Health **16**(5): 827-838.

West Virginia has had a history of water quality issues. In parallel, the world is facing a plastic pollution crisis. In order to better understand behavioral responses to perceived water quality, a survey was conducted at a major research university to ask participants about water quality perceptions and drinking water behaviors. A total of 4,188 students completed the survey during the Spring 2017 semester. Logistic regression analyses were used to predict behaviors. Results indicated that a third of the student population primarily used bottled water for drinking purposes at home, while 39% used a filter at home and 26% drank water directly from the tap. On campus, bottled water use was reported by 36% of the students, water fountain use represented 31%, and 29% of the students brought their own water with reusable cups/bottles.

Health risk perceptions, organoleptic perceptions (i.e., taste, odor, color), and environmental concern were predictors of the different behaviors. Students originally from West Virginia had a higher propensity of using bottled water. We argue that bottled water consumption should be reduced in areas where water quality is not an issue. In this sense, there is a need for education among the student population in West Virginia.

Jones, E. A., et al. (2006). "Optimization of a flow cytometry-based protocol for detection and phenotypic characterization of multipotent mesenchymal stromal cells from human bone marrow." Cytometry Part B, Clinical Cytometry **70**(6): 391-399.

BACKGROUND: To study the biology of rare bone marrow (BM) multipotent mesenchymal stromal cells (MSCs), recognized protocols are needed. Colony-forming unit-fibroblast (CFU-F) assays have historically been used for the enumeration of MSCs. However, the need to isolate and further analyze MSCs requires new strategies based on cell surface markers. The purpose of this work was to verify the phenotype of BM MSCs in vivo and to develop flow cytometry-based methods for their evaluation.

METHODS: Pre-enrichment with D7-FIB-conjugated microbeads, cell sorting for CD45low D7-FIB+ LNGFR+ cells, and CFU-F assay were used to confirm the phenotype of BM MSCs in vivo. Further phenotypic characterization of MSCs was performed using three-color flow cytometry following pre-enrichment or by direct four-color flow cytometry. The sensitivity of direct flow cytometry/rare event analysis for the accurate enumeration of MSCs was validated using 85 samples from patients with neoplastic BM diseases.

RESULTS: In normal BM, a significant correlation was found between the frequencies of CFU-Fs and CD45low D7-FIB+ LNGFR+ cells ($n = 19$, $R = 0.719$, $P = 0.001$). Following cell sorting, 15% of these cells were clonogenic. The same cells were enriched using LNGFR-based positive selection, CD45/Glycophorin A-based depletion, or plastic adherence. CD45low D7-FIB+ LNGFR+ cells expressed classic makers of cultured MSCs CD73/SH3 and CD105/SH2 and markers of stromal reticular cells CD106/VCAM and alkaline phosphatase. Novel markers were identified including leukemia inhibitory factor receptor and gp130. CD45low D7-FIB+ LNGFR+ cells were increased fourfold in the floating fat fraction of normal BM aspirates. Their frequency was decreased in chronic lymphocytic leukemia (threefold, $n = 13$, $P = 0.049$) and chronic myelogenous leukemia (ninefold, $n = 11$, $P = 0.001$) compared with that in age-matched controls ($n = 26$ and $n = 31$, respectively).

CONCLUSIONS: This study demonstrates the usefulness of flow cytometry-based methods for the detection, enumeration and further phenotypic analysis of BM MSCs. These findings have broad applications for the future evaluation of BM MSCs in health and disease.

Jones, E. A., et al. (2002). "Isolation and characterization of bone marrow multipotential mesenchymal progenitor cells." Arthritis & Rheumatism **46**(12): 3349-3360.

OBJECTIVE: There is an increased interest in rheumatology in mesenchymal progenitor/stem cells (MPCs) and their roles in rheumatic diseases, but little is known about the phenotype of these cells in vivo. The aim of this study was to isolate and characterize human bone marrow (BM) MPCs.

METHODS: Fluorescence microscopy was used to identify putative MPCs among adherent BM cells. To purify them, a positive selection with antifibroblast microbeads was used, combined with fluorescence-activated cell sorting (FACS) for microbead+,CD45(low) cells. A more detailed phenotype of these cells was determined using 4-color flow cytometry, and standard chondrogenic, osteogenic, and adipogenic assays were used to investigate their differentiation potentials.

RESULTS: Putative MPCs microscopically identified as large, fibroblast-like, D7-FIB+ cells were purified using positive selection with D7-FIB-conjugated (antifibroblast) microbeads followed by FACS for specifically bound microbead+,CD45(low) cells. These cells represented 0.01% of mononuclear cells in the BM. They were uniformly positive for CD105, LNGFR, HLA-DR, CD10, CD13, CD90, STRO-1, and bone morphogenetic protein receptor type IA (BMPRIA) and were negative for CD14, CD34, CD117, and CD133. Only cells with this phenotype could proliferate and produce adherent cell monolayers capable of chondrogenic, osteogenic, and adipogenic differentiation. D7-FIB- cells in the BM lacked any MPC activity. Uncultured skin fibroblasts had a phenotype similar to that of BM MPCs, but were negative for LNGFR, STRO-1, HLA-DR, and BMPRIA.

CONCLUSION: This study shows the distinct phenotype, morphology, and method of isolation of BM MPCs. The findings may have implications for defining the physiologic roles of MPCs in arthritis, bone diseases, and joint regeneration.

Jones, J. E., et al. (2013). "Skin grafting for venous leg ulcers." Cochrane Database of Systematic Reviews(1): CD001737.

BACKGROUND: Venous leg ulceration is a recurrent, chronic, disabling condition. It affects up to one in 100 people at some time in their lives. Standard treatments are simple dressings and compression bandages or stockings. Sometimes, despite treatment, ulcers remain open for months or years. Sometimes skin grafts are used to stimulate healing. These may be taken, or grown into a dressing, from the patient's own uninjured skin (autografts), or applied as a sheet of bioengineered skin grown from donor cells (allograft). Preserved skin from other animals, such as pigs, has also been used (xenografts).

OBJECTIVES: To assess the effect of skin grafts for treating venous leg ulcers.

SEARCH METHODS: For this update we modified the search strategies and conducted searches of The Cochrane Wounds Group Specialised Register (searched 27 July 2012); The Cochrane Central Register of Controlled Trials (CENTRAL) (The Cochrane Library 2012, Issue 7); Ovid MEDLINE (2008 to July Week 3 2012); Ovid MEDLINE (In-Process & Other Non-Indexed Citations, July 26, 2012); Ovid EMBASE (2008 to 2012 Week 29); and EBSCO CINAHL (2008 to 26 July 2012). We did not apply date or language restrictions.

SELECTION CRITERIA: Randomised controlled trials (RCTs) of skin grafts in the treatment of venous leg ulcers.

DATA COLLECTION AND ANALYSIS: Two review authors independently undertook data extraction and assessment of study quality.

MAIN RESULTS: For this update of the review, we identified one new trial, bringing the total to 17 trials (1034 participants) - all of which were generally at moderate or high risk of bias. In 12 trials participants also received compression bandaging.Eleven trials compared a graft with standard care in which no graft was used. Two of these trials (102 participants) compared a dressing with an autograft; three trials (80 participants) compared frozen allografts with dressings, and two trials (45 participants) compared fresh allografts with dressings. Two trials (345 participants) compared tissue-engineered skin (bilayer artificial skin) with a dressing. In two trials (97 participants) a single-layer dermal replacement was compared with standard care.Six trials compared alternative skin grafting techniques. The first trial (92 participants) compared autografts with frozen allograft, a second (51 participants) compared a pinch graft (autograft) with porcine dermis (xenograft), the third (110 participants) compared growth-arrested human keratinocytes and fibroblasts with placebo, the fourth (10 participants) compared an autograft delivered on porcine pads with an autograft delivered on porcine gelatin microbeads, the fifth trial (92 participants) compared a meshed graft with a cultured keratinocyte autograft, and the sixth trial (50 participants) compared a frozen keratinocyte allograft with a lyophilised

(freeze-dried) keratinocyte allografts.Significantly more ulcers healed when treated with bilayer artificial skin than with dressings. There was insufficient evidence from the other trials to determine whether other types of skin grafting increased the healing of venous ulcers.
AUTHORS' CONCLUSIONS: Bilayer artificial skin, used in conjunction with compression bandaging, increases venous ulcer healing compared with a simple dressing plus compression. Further research is needed to assess whether other forms of skin grafts increase ulcer healing.

Jones, K. L., et al. (2020). "Microplastic accumulation in a Zostera marina L. bed at Deerness Sound, Orkney, Scotland." Marine Pollution Bulletin **152**: 110883.

Seagrasses have global distribution and are highly productive and economically valuable habitats. They are sensitive and vulnerable to a range of human-induced pressures, including ongoing exposure to marine litter, such as microplastic particles (<5mm). In this study, a Zostera marina bed in Deerness Sound, Orkney was selected to determine whether microplastics accumulate in seagrass beds and adhere to seagrass blades. Sediment, seagrass blade, biota and seawater samples were collected. 280 microplastic particles (0.04 to 3.95mm (mean=0.95mm+/-0.05 SE)) were observed in 94% of samples collected (n=111). These were visually categorised into type (fibre, flake, fragment) and colour, and 50 were successfully identified as plastic using ATR-FTIR. Fibres contributed >50% of the total microplastics observed across all samples. This is the first known study on Z. marina to describe microplastic loading within a seagrass bed and to identify microplastic adherence to seagrass blades.

Jones, P. H., et al. (1974). "Biodegradability of photodegraded polymers. I. Development of experimental procedures." Environmental Science and Technology **8**(10): 919-923.

Methods have been developed to study the biological oxidation of plastic fragments in natural soils and sewage sludge using a modification of the conventional Warburg apparatus. Rates of biodegradation are estimated from the consumption of oxygen under carefully controlled conditions. Whereas high molecular weight plastic particles are shown to be resistant to biodegradation, degraded branched polyethylene and polypropylene show significant rates of oxidation in both environments. Degraded polystyrene appears to be more resistant to microbial attack.

Jones, P. H., et al. (1974). "Biodegradability of Photodegraded Polymers: 1. Development of Experimental Procedures." Environmental Science & Technology **8**(10): 919.

Methods are developed for studying the biological oxidation of plastic fragments in natural soils and sewage sludge using a modification of the conventional warburg apparatus. Biodegradation rates are estimated from oxygen consumption under carefully controlled conditions. High-molecular-weight plastic particles are shown to be resistant to biodegradation, degraded branched polyethylene and polypropylene show significant oxidation rates, and degraded polystyrene seems to be more resistant to microbial attack.

Joo, S. H. (2007). Synthesis and screening of support-bound combinatorial cyclic peptide and free carbon-terminal peptide libraries.

One-bead one-compound (OBOC) peptide libraries have been useful tools in the biomedical sciences. However, OBOC peptide libraries usually display the N-termini of peptides on the surface as conventional solid phase peptide synthesis proceeds in the C to N direction. While large combinatorial libraries of cyclic peptides can be synthesized by the split-and-pool synthesis method, the sequence determination has been a challenge. Also, peptide libraries with free C-termini face the same problem as well as the difficulty of synthesis in the N to C direction. We report here the development of cyclic peptide libraries and C-terminal peptide libraries for high-throughput screening and sequencing. TentaGel microbeads (90 mu m) were spatially segregated into outer and inner layers; cyclic peptides were displayed on the bead surface, whereas the inner core of each bead contained the corresponding linear encoding peptide. After screening of the cyclic peptide library, the identity of hit peptides was determined by sequencing the linear encoding peptides using a partial Edman degradation/mass spectrometry method. Using the same spatial segregation approach peptides were synthesized in the conventional C to N direction, with their C-termini attached to the support through an ester linkage on the bead surface but through an amide bond in the inner layer. The surface peptides were cyclized between N-terminal amine and a carboxyl group installed at a C-terminal linker sequence, while the internal peptides stayed in the linear form. Base hydrolysis of the ester linkage in the cyclic peptides exposed a free alpha -carboxyl group at the C-termini of the peptides attached to the resin via the N-termini. An inverted peptide library containing five random residues was synthesized and screened for binding to PDZ domains. The identity of the binding peptides was determined from the encoding peptides. Consensus recognition motifs were identified for the PDZ domains and representative peptides were individually synthesized and confirmed for binding to their cognate PDZ domains. These methods expanded the utility of OBOC peptide libraries by displaying peptides in different ways.

Jordan, D. R. (2003). "Soft-tissue fillers for wrinkles, folds and volume augmentation." Canadian Journal of Ophthalmology **38**(4): 285-288.

Hyaluronic acid gels, with or without dextran beads, and collagen with suspended PMMA microbeads are exciting new soft-tissue fillers that are becoming increasing popular for facial rejuvenation. Each material provides wrinkle reduction, contour improvement and volume augmentation when placed into lines and furrows or when used for lip augmentation. The duration of action varies from 6 months to permanent, depending on the product. [References: 17]

Joshi, C., et al. (2019). "A perspective on a locally managed decentralized circular economy for waste plastic in developing countries." Environmental Progress & Sustainable Energy **38**(1): 3-11.

Unsound post-consumer disposal is the primary pathway of plastic into the ecosystem. One way of addressing this problem is through the establishment of a circular economy for plastic. Much of the unsound disposal comes from economically disadvantaged regions where waste disposal and recycling infrastructure is limited. In economically disadvantaged regions however, the establishment of a circular economy for plastic must be locally managed and decentralized, meaning that the disposal, collection, remanufacture, and use must all occur within the same community. We suggest that waste plastic abatement strategies must be targeted to reduce, reuse, and recycle plastic waste onsite at the local level, initiating a circular economy appropriate for infrastructure limited regions. Technologies for recycling plastic must be low cost, economically viable, socially acceptable, and not adversely impact the environment, and also produce a product that has a ready local market. This is critical because unless proposed solutions are also economically viable and socially appropriate, they are unlikely to be successful, especially in underdeveloped regions. Using big data analysis, a metric for identifying countries that will have the most potential to benefit from a locally managed decentralized circular economy for plastic has been developed. The information obtained from this metric will help researchers and policy makers promote a locally managed decentralized circular economy of plastic for managing the accumulation of waste on land and its eventual migration into waterways. Additionally, we present a case study of a proposed locally managed decentralized

waste plastic abatement strategy in the municipal solid waste infrastructure limited country of Uganda. © 2018 American Institute of Chemical Engineers Environ Prog, 38: 3–11, 2019 [ABSTRACT FROM AUTHOR]

Jouet, E., et al. (2017). "Let us resuscitate our waste." Annals of Intensive Care **7 (1 Supplement 1)**: 181-182.

Introduction The healthcare activity is recognized as a major polluting activity. In France, it generates 800,000 tons of waste cremated each year, and represents 12% of the tertiary energy consumptions. In the United States, it generates 7000 tons of waste per day and 7% of total CO<inf>2</inf> emissions in 2007 were attributed to him. Ultimately, such waste production is associated with adverse environmental and health effects. Nevertheless, near half of the hospital waste would be recyclable, particularly in our intensive care units (ICU) [1]. Furthermore, sustainable development solutions generate profts. The aim of this study is to make an overview of waste produced in a ICU and offer solutions to conserve natural resources and reduce the carbon footprint bound to the healthcare activity. Materials and methods Experimental study, single-center, concerning a period of 6 months in an ICU-high surveillance unit compound of 16 beds. We have identifed all waste generated. Our packaging were given to the recycling company in connection with the hospital. Then we have studied the impact of the implementation of sustainable development solutions. Results Firstly, we have studied the non-recycled waste and the quantity produced over a period of 1 month. Approximately 8 kg of waste is produced per patient per day with 45% of infectious waste and 55% of general waste. These results were linked with a bad distribution of garbage bags in the rooms (130 L of infectious waste versus 50 L of general waste). Secondly, we have improved our way to sort and consume and we have created recycling dies without compromising patient safety. All these measures have not increased workload. Changing bags in the rooms (20 L of infectious waste and 2 bags of 50 L of general waste) allowed to reach the normal goals of 2 sectors with a net beneft estimated at 4500 euros per year. The medical broken glass containing drugs was thrown into plastic containers of 5 L for infectious waste to prevent the risk of cuts. By creating a specifc die intended to the general waste, we could quantify the production of this glass to 10 kg per week and to spare the use and the incineration of 350 containers of 5 L per year (global economy of 1000 euros). Plastic packaging represented an important proportion of the cremated waste. We have created 3 sectors of recycling including the polypropylene (80-200 kg per month), the polyethylene colorless and colored polyethylene. This plastic is sold to be recycled without additional cost for the hospital. The linerboards was cremated. We have created a recycling die (50 kg per month). This sector was subsequently extended to the entire hospital structure, particularly the pharmacy that produces 12 containers of 400 L per month. They are now sold without additional cost. Many unnecessary plastic waste is generated daily. We have removed using mild soap plastic bottles of 30 ml by using the same mild soap in pump of 500 ml (economy of 1000 euros). The use of 100 L plastic bags for the transitional deposit of linen has been deleted (economy of 450 euros). Concerning the paper: 100% of the impressions were made in simplex. Printers were parametrized on both sides by default allowing the economy of 60 reams per year (30,000 sheets), several thousand liters of water and the reduction of CO 2 emissions. Discussion Recycling is only one component of the sustainable development in health. Other avenues that could be considered to improve ICU sustainability would include examining water use (for linen), electricity use (reducing non-essential use at night). Beyond these actions, we need to encourage our suppliers to turn to sustainable and recyclable packages to reduce the use of polluting and depletable fossil fuels such as oil. But also to develop with them circular economies where waste is returned to them to be reused. Conclusion We must ask the question also resuscitate our tons of waste. Our ICU produce large quantities of waste (over 2 tons per year per bed). However, a signifcant proportion, especially plastic, is recyc able with a signifcant environmental and fnancial beneft. Waste management also requires an optimal and rational use of supplies because "the best waste is that which is not producedTM and that excess is not a guarantee of quality. As already said St Exupery in 1939: "We do not inherit the Earth from our parents, we borrow it from our children.TM So do not expect tomorrow to reduce major adverse ecological impact paradoxically generated by a great profession whose ultimate goal is to cure people.

Jovanović, B. (2017). "Ingestion of microplastics by fish and its potential consequences from a physical perspective." Integrated Environmental Assessment & Management **13**(3): 510-515.

ABSTRACT The European Marine Strategy Framework Directive and the United States Microbead Free Waters Act are credited for being ambitious in their goals for protecting the marine environment from microplastics pollution. As a result, the microplastic pollution of marine environments and the incidence of microplastic ingestion by fish is rapidly receiving an increase in overdue attention. This commentary summarizes recent discoveries regarding the potential negative effects of micro- and nanoplastic ingestion by fish. Analysis shows that the occurrence of microplastics in the gastrointestinal tract of fish is ephemeral, with low accumulation potential in the gastrointestinal tract, although translocation to the liver may occur. Nevertheless, the total load of micro- and nanoplastics that will pass through the gastrointestinal tract of a fish in its lifetime is likely high and will keep increasing in the future. This may pose a risk because there is evidence that micro- and nanoplastic ingestion can interfere with fish health. Observed effects of microplastics ingestion include (but are not necessarily limited to) intestinal blockage, physical damage, histopathological alterations in the intestines, change in behavior, change in lipid metabolism, and transfer to the liver. Integr Environ Assess Manag 2017;13:510-515. © 2017 SETAC [ABSTRACT FROM AUTHOR]

Jovanovic, B., et al. (2018). "Virgin microplastics are not causing imminent harm to fish after dietary exposure." Marine Pollution Bulletin **130**: 123-131.

Among aquatic organisms, fish are particularly susceptible to ingesting microplastic particles due to their attractive coloration, buoyancy, and resemblance to food. However, in previous experimental setups, fish were usually exposed to unrealistically high concentrations of microplastics, or the microplastics were deliberately contaminated with persistent organic chemicals; also, in many experiments, the fish were exposed only during the larval stages. The present study investigated the effects of virgin microplastics in gilt-head seabream (Sparus aurata) after 45 days' exposure at 0.1 g kg⁻¹ bodyweight day⁻¹ to 6

common types of microplastics. The overall growth, biochemical analyses of the blood, histopathology, and the potential of the microplastics to accumulate in gastrointestinal organs or translocate to the liver and muscles were monitored and recorded. The results revealed that ingestion of virgin microplastics does not cause imminent harm to the adult gilt-head seabream during 45 days of exposure and an additional 30 days of depuration. The retention of virgin microplastics in the gastrointestinal tract was fairly low, indicating effective elimination of microplastics from the body of the fish and no significant accumulation after successive meals. Therefore, both the short- and the long-term retention potential of microplastics in the gastrointestinal tract of fish is close to zero. However, some large particles remained trapped in the liver, and 5.3% of all the livers analyzed contained at least one microplastic particle. In conclusion, the dietary exposure of S. aurata to 6 common types of virgin microplastics did not induce stress, alter the growth rate, cause pathology, or cause the microplastics to accumulate in the gastrointestinal tract of the fish.

Jovanovic, Z., et al. (2012). "In vitro investigation of cytotoxicity and antimicrobial activity of silver/alginate nanocomposite microbeads." Journal of Tissue Engineering and Regenerative Medicine **1)**: 218.

Biomaterials are often used as carriers or matrixes in different medical applications, which usually demand the use of multifunctional materials meeting the requirements of their purpose without being harmful to the surrounding tissue. Here, silver/alginate nanocomposite microbeads were obtained using electrochemical synthesis of silver nanoparticles in alginate solution at constant current density of 50 mA/cm-2, followed by electrostatic extrusion of synthesized Ag/alginate colloid solution. In vitro determination of Ag/alginate microbeads cytotoxicity against immunocompetent peripheral blood mononuclear cells (PBMC) was performed by MTT test. In order to investigate the antimicrobial activity against E. coli and S. aureus using the test in suspension, Ag/ alginate microbeads were synthesized so to have Ag concentration equal to that without cytotoxic effects against PBMC. The presence of Ag/alginate microbeads having 1 mM AgNO3 in the initial solution for synthesis and less decreased the PBMC survival up to 59.04 +/- 35.45%. Higher concentrations of nanosilver in Ag/alginate microbeads induced pronounced decrease in PBMC survival. Ag/alginate microbeads obtained from initial Ag/alginate colloid solution with 1 mM AgNO3 significantly decreased the bacterial colonies count of E. coli and S. aureus comparing to the control sample for 2 and 3 orders of magnitude, respectively. This work has shown potentials for biomedical applications of Ag/alginate nanocomposite microbeads.

Jowett, E. C. and M. L. McMaster (1995). "On-site wastewater treatment using unsaturated absorbent biofilters." Journal of Environmental Quality **24**(1): 86-95.

A new type of single-pass aerobic biofilter is being developed as an alternative to the conventional septic tile bed and for treatment of wastewater in general. The Waterloo Biofilter uses absorbent filter media that combine long retention times, separate flowpaths for wastewater and air, and large surface areas, thereby enabling loading rates 10 times greater than that for solid particle filter media. Although absorbent sphagnum peat and coarse sand plug readily at loading rates of 50 to 80 cm d⁻¹, absorbent plastic particles provide consistent treatment with no plugging problems. The latest field trial removes 97.8% BOD<inf>7</inf>, 96.1% TSS, and 99.5% fecal coliform bacteria with 12 to 16degreeC wastewater loaded at 49 cm d⁻¹. Surge flows up to 204 cm d⁻¹ over several days are handled with little effect on effluent quality. In laboratory column experiments, removal of fecal coliforms averages >99.99% at 80 cm d⁻¹ loading, and >99.999% at

10 cm d⁻¹ after a 10- to 14-d acclimatization period. Ammonium is thoroughly oxidized to NO<inf>3</inf>/⁻ with typically <2.5 mg L⁻¹ NH<inf>4</inf>/⁺-N in the effluent. Overall treatment improves with forced air flow compared with natural convection. Cold influent and plugging by freezing are the main causes of poor treatment. A typical household would likely require a biofilter with 3.3-m² surface area in cold climates when flow is balanced, possibly less in warmer areas. This biofilter should also find general application in renovating polluted water, including water for domestic consumption in developing regions of the world.

Ju, H., et al. (2019). "Effects of polyethylene microplastics on the gut microbial community, reproduction and avoidance behaviors of the soil springtail, Folsomia candida." Environmental Pollution **247**: 890-897.
Microplastics (MPs) are an emerging contaminant and are confirmed to be ubiquitous in the environment. Adverse effects of MPs on aquatic organisms have been widely studied, whereas little research has focused on soil invertebrates. We exposed the soil springtail Folsomia candida to artificial soils contaminated with polyethylene MPs (<500 micro m) for 28 d to explore the effects of MPs on avoidance, reproduction, and gut microbiota. Springtails exhibited avoidance behaviors at 0.5% and 1% MPs (w/w in dry soil), and the avoidance rate was 59% and 69%, respectively. Reproduction was inhibited when the concentration of MPs reached 0.1% and was reduced by 70.2% at the highest concentration of 1% MPs compared to control. The half-maximal effective concentration (EC₅₀) value based on reproduction for F. candida was 0.29% MPs. At concentrations of 0.5% dry weight in the soil, MPs significantly altered the microbial community and decreased bacterial diversity in the springtail gut. Specifically, the relative abundance of Wolbachia significantly decreased while the relative abundance of Bradyrhizobiaceae, Ensifer and Stenotrophomonas significantly increased. Our results demonstrated that MPs exerted a significant toxic effect on springtails and can change their gut microbial community. This can provide useful information for risk assessment of MPs in terrestrial ecosystems.

Judy, J. D., et al. (2019). "Microplastics in municipal mixed-waste organic outputs induce minimal short to long-term toxicity in key terrestrial biota." Environmental Pollution **252**(Part A): 522-531.
Sustainable alternatives to landfill disposal for municipal mixed wastes represents a major challenge to governments and waste management industries. In the state of New South Wales (NSW) Australia, mechanical biological treatment (MBT) is being used to reduce the volume and pathogen content of organic matter isolated from municipal waste. The product of this treatment, a compost-like output (CLO) referred to as mixed waste organic output (MWOO), is being recycled and applied as a soil amendment. However, the presence of contaminants in MWOO including trace organics, trace metals and physical contaminants such as microplastic fragments has raised concerns about potential negative effects on soil health and agriculture following land application. Here, we used multiple lines of evidence to examine the effects of land application of MWOO containing microplastics in three soils to a variety of terrestrial biota. Treatments included unamended soil, MWOO-amended soil and MWOO-amended soil into which additional high-density polyethylene (HDPE), polyethylene terephthalate (PET), or polyvinyl chloride (PVC) microplastics were added. Tests were conducted in soil media that had been incubated for 0, 3 or 9 months. Addition of microplastics had no significant negative effect on wheat seedling emergence, wheat biomass production, earthworm growth, mortality or avoidance behaviour and nematode mortality or reproduction compared to controls. There was also little evidence the microplastics affected microbial community diversity, although measurements of microbial community structure were highly variable with no clear trends.

Julienne, F., et al. (2019). "From macroplastics to microplastics: Role of water in the fragmentation of polyethylene." Chemosphere **236**: 124409.

In this work, the artificial photodegradation of polyethylene films was studied in laboratory to compare the fragmentation pathways of this polymer at air and in water. Oxidation, surface mechanical properties, crystallinity and crack propagation were monitored to investigate their influence on fragmentation. Without any external stress, fragmentation only occurred in water despite a higher level of oxidation for films weathered at air. The cracking of the films did not appear correlated with the oxidation level and the presence of water appeared as a promoter of cracking propagation. The results also showed that the mechanical properties at the surface play a major role in the fragmentation pathway whereas the fabrication process may influence the propagation direction of the cracks. Consequently, the distribution in size of plastic fragments in the aquatic environment may be linked to the nature of the polymer but also to its manufacturing process. In this study, after 25 weeks of weathering in water, 90% of the fragments were >1mm with very similar shapes showing that micrometric fragments were not yet abundant. These results suggest that long times of weathering in water and many steps of fragmentation appear necessary from macroplastics to reach sizes <1mm in the aquatic environment. These results constitute a first attempt to understand the pathways leading from macroplastics to microplastics in water. They have to be confirmed for other polymers and the long-term behavior of the fragments needs to be studied to predict their decrease in size among time.

Jun, B. H., et al. (2012). "Fluorescence-based multiplex protein detection using optically encoded microbeads." Molecules **17**(3): 2474-2490.

Potential utilization of proteins for early detection and diagnosis of various diseases has drawn considerable interest in the development of protein-based multiplex detection techniques. Among the various techniques for high-throughput protein screening, optically-encoded beads combined with fluorescence-based target monitoring have great advantages over the planar array-based multiplexing assays. This review discusses recent developments of analytical methods of screening protein molecules on microbead-based platforms. These include various strategies such as barcoded microbeads, molecular beacon-based techniques, and surface-enhanced Raman scattering-based techniques. Their applications for label-free protein detection are also addressed. Especially, the optically-encoded beads such as multilayer fluorescence beads and SERS-encoded beads are successful for generating a large number of coding.

Jung, I., et al. (2014). "A dip-stick type biosensor using bioluminescent bacteria encapsulated in color-coded alginate microbeads for detection of water toxicity." Analyst **139**(18): 4696-4701.

The use of genetically engineered bioluminescent bacteria, in which bioluminescence is induced by different modes of toxic action, represents an alternative to acute toxicity tests using living aquatic organisms (plants, vertebrates, or invertebrates) in an aqueous environment. A number of these bacterial strains have been developed, but there have been no attempts to develop a hand-held type of biosensor for monitoring or identification of toxicity. We report a facile dip-stick type biosensor using genetically engineered bioluminescent bacteria as a new platform for classification and identification of toxicity in water environments. This dip-stick type biosensor is composed of eight different optically color-coded functional alginate beads that each encapsulates a different bioluminescent bacterial strain and its corresponding fluorescent microbead. These color-coded microbeads exhibit easy identification of encapsulated microbeads, since each microbead has a different color code depending on the bioluminescent bacterial strain contained and improved cell-stability compared to liquid culture. This dip-stick type biosensor can discriminate different modes of toxic actions (i.e. DNA damage, oxidative damage, cell-membrane damage, or protein damage) of sample water tested by simply dipping the stick into the water samples. It was found that each color-coded microbead emitted distinct bioluminescence, and each dip-stick type biosensor showed different bioluminescence patterns within 2 hours, depending on the toxic chemicals contained in LB medium, tap water, or river water samples. This dip-stick type biosensor can, therefore, be widely and practically used in checking toxicity of water in the environment primarily in situ, possibly indicating the status of biodiversity.

Jung, J., et al. (2019). "Valorization of sewage sludge via non-catalytic transesterification." Environment International **131**(105035).

To seek a way to valorize sewage sludge (SS), it was chosen as a raw material for biodiesel production. As such, non-catalytic transesterification of dried SS was carried out, to enhance its value. Note that picking a waste material such as SS as an inexpensive lipid feedstock for biodiesel production, without lipid extraction, greatly increases the economic viability of biodiesel. Also, to enhance biodiesel sustainability, ethanol (EtOH) was employed as the acyl acceptor, in this study, and this was experimentally justified by results showing that employing EtOH as an acyl acceptor provided an effective means for compensating for the lower heating value arising from the large amount of palmitic (C₁₆) acid in SS. This study experimentally proved that the fatty acid ethyl ester (FAEE) yield at 380 degrees C reached up to 13.33 wt% of dried SS. Given that the lipid content of dried SS is 14.01+or-0.64 wt%, the FAEE yield of 13.33 wt% implied that 95.14 wt% of lipid in dried SS had been converted into FAEEs. The introduced SS valorization in this study offered an excellent opportunity to address diverse environmental hazards arising from SS and associated emerging contaminants. Given that the optimal temperature for the non-catalytic conversion for biodiesel production from SS was found to be 380 degrees C, emerging contaminants, such as microplastics and antimicrobials, were simultaneously degraded, due to their inferior thermal stabilities. Lastly, considering that the introduced biodiesel conversion process is thermally induced, the SS reside after the biodiesel conversion process can be further used in thermo-chemical processes as raw materials for gasification and pyrolysis (future work).

Jungnickel, H., et al. (2016). "Time-of-flight secondary ion mass spectrometry (ToF-SIMS)-based analysis and imaging of polyethylene microplastics formation during sea surf simulation." Science of the Total Environment **563-564**: 261-266.

Plastic particles smaller than 5mm, so called microplastics have the capability to accumulate in rivers, lakes and the marine environment and therefore have begun to be considered in eco-toxicology and human health risk assessment. Environmental microplastic contaminants may originate from consumer products like body wash, tooth pastes and cosmetic products, but also from degradation of plastic waste; they represent a potential but unpredictable threat to aquatic organisms and possibly also to humans. We investigated exemplarily for polyethylene (PE), the most abundant constituent of microplastic particles in the environment, whether such fragments could be produced from larger pellets (2mmx6mm). So far only few analytical methods exist to identify microplastic particles smaller than 10mum, especially no imaging mass spectrometry technique. We used at first time-of-flight secondary ion mass spectrometry (ToF-SIMS) for analysis and imaging of small PE-microplastic particles directly in the model system Ottawa sand during exposure to sea surf simulation. As a prerequisite, a method for identification of PE was established by identification of characteristic ions for PE out of an analysis of grinded polymer samples. The method was applied onto Ottawa sand in order to investigate the influence of simulated environmental conditions on particle transformation. A severe degradation of the primary PE pellet surface, associated with the transformation of larger particles into smaller ones already after 14days of sea surf simulation, was observed. Within the subsequent period of 14days to 1month of exposure the number of detected smallest-sized particles increased significantly (50%) while the second smallest fraction increased even further to 350%.

Jun-Kit, W., et al. (2018). "Distribution of Microplastics and Nanoplastics in Aquatic Ecosystems and Their Impacts on Aquatic Organisms, with Emphasis on Microalgae." Reviews of Environmental Contamination & Toxicology **246**: 133-158.

Jurischka, C., et al. (2019). "Tyramide signal amplification as universal detection method on protein coated microbeads." Journal of Cellular Biotechnology **4**(1-2): 15-22.

Quantitative analysis of a target molecule in a microbead-based fluorescent assay requires a specific labeling procedure. For nucleic acid analysis the hybridization with florescent labeled oligonucleotides is the most common method. However, disadvantages are the necessity for direct labeling of probes and the sensitivity to detect low amounts of target molecules. In this study we established an alternative detection method for biomolecules on microbeads, the tyramide signal amplification (TSA). Hereby, biomolecules are detected by enzymatically activated and fluorophore-conjugated tyramides that bind to specific protein residues. This method has proven to be a versatile and robust enzyme amplification technique for sensitive immunohistochemical detection. Now, we present the feasibility of the TSA procedure to detect hybridized biotinylated oligonucleotide probes bound to protein coated microbead surfaces TSA was performed using fluorescent, sizeencoded and streptavidin coated microbeads that were loaded with dual-biotinylated DNA capture probes, prepared from polymerase chain reaction. Beside streptavidin alone for surface coating of those microbeads, we applied different quantities of streptavidin in combination with bovine serum albumin, immunoglobulin G or Protein G/A, to check for positive effects on the resulting signal intensities through specific binding of tyramide molecules. For this method, streptavidin turned out as appropriate protein for the surface binding, without the need for further molecules. In comparison to a standard detection with common streptavidin-fluorophore-conjugates TSA showed its advantage in the detection of low probe amounts down to a concentration of 3.310-4 ng/L. Kaartinen, T., et al. (2017). "Low interleukin-2 concentration favors generation of early memory T cells over effector phenotypes during chimeric antigen receptor T-cell expansion." Cytotherapy **19**(6): 689-702.

BACKGROUND: Adoptive T-cell therapy offers new options for cancer treatment. Clinical results suggest that T-cell persistence, depending on T-cell memory, improves efficacy. The use of interleukin (IL)-2 for in vitro T-cell expansion is not straightforward because it drives effector T-cell differentiation but does not promote the formation of T-cell memory. We have developed a cost-effective expansion protocol for chimeric antigen receptor (CAR) T cells with an early memory phenotype.

METHODS: Lymphocytes were transduced with third-generation lentiviral vectors and expanded using CD3/CD28 microbeads. The effects of altering the IL-2 supplementation (0-300 IU/mL) and length of expansion (10-20 days) on the phenotype of the T-cell products were analyzed.

RESULTS: High IL-2 levels led to a decrease in overall generation of early memory T cells by both decreasing central memory T cells and augmenting effectors. T memory stem cells (T_{SCM}, CD95⁺CD45RO⁻CD45RA⁺CD27⁺) were present variably during T-cell expansion. However, their presence was not IL-2 dependent but was linked to expansion kinetics. CD19-CAR T cells generated in these conditions displayed in vitro antileukemic activity. In summary, production of CAR T cells without any cytokine supplementation yielded the highest proportion of early memory T cells, provided a 10-fold cell expansion and the cells were functionally potent.

DISCUSSION: The number of early memory T cells in a T-cell preparation can be increased by simply reducing the amount of IL-2 and limiting the length of T-cell expansion, providing cells with potentially higher in vivo performance. These findings are significant for robust and cost-effective T-cell manufacturing.

Kacemi, A., et al. (1996). "Culture of endothelial cells from human placental microvessels." Cell & Tissue Research **283**(2): 183-190.

Endothelial cells are known to participate in angiogenesis, adaptation of vascular tonus and maintenance of blood fluidity in the microcirculation. To investigate these functions in the placenta, we devised a method of isolation and culture of endothelial cells from villous microvessels. In primary culture, these intraplacental endothelial cells exhibited many features observed in microvascular endothelium from other organs: spindle-shape, rosette associations, circular arrangements and confluence. In contrast to the confluent endothelial cells derived from the umbilical vein, cells from microvessels did not form a cobblestone network. After trypsin digestion of microvessels, magnetic microbeads coated with S-Endol immunoglobulin, antithrombomodulin and Ulex europaeus-I lectins were tested for sorting endothelial cells. Only the microbeads coated with antithrombomodulin allowed a suitable magnetic cell separation after trypsinization. By contrast, the microbeads coated with each of these antibodies or with lectins attached to confluent cells from the second passage. The microbeads detached from the cells at different rates. Their examination by scanning microscopy indicates that a portion of these microbeads was phagocytosed. Microvascular endothelial cells from the second passage were intensively stained by the anti-von Willebrand reaction and only weakly by the anti-smooth muscle alpha-actin reaction. They incorporated acetylated-low density lipoproteins coupled to a fluorescent probe. The positive reactions against the anti-von Willebrand factor and the uptake of the fluorescent acetylated-low density lipoproteins were modified after eight passages.

Kadiombo, T. A., et al. (2016). "Glomerular chemokine expression in murine lupus nephritis." International Journal of Rheumatic Diseases **19 (Supplement 2)**: 18.

Background/Purpose: Although chemokines are thought to play a crucial role in recruiting inflammatory cells to local diseased sites, little is known about profiles of glomerular chemokine expression in lupus nephritis. The objective of the current study is to explore the profiles of chemokine gene expression in isolated glomeruli from lupus-prone mice and to examine their relationship with infiltrating inflammatory cells and glomerular damages. Method(s): Glomerular expressions of CCL-2, CCL-5, and CXCL-10, which are potent chemotractants for T cells and monocytes, were examined with real-time polymerase chain reaction after purifying glomeruli using the magnetic microbead method from lupus-prone MRL/lpr mice and control MRL/+ mice. Infiltrating T-cells and monocytes in glomeruli were detected by immunohistochemistry using anti-CD3 and F4/80 antibodies, respectively. Histologic glomerular damages were scored semi-quantitatively. Result(s): The number of infiltrating T cells and monocytes and chemokine expressions in glomeruli of MLR/lpr mice significantly increased with age. Among the parameters examined, glomerular damage score was significantly correlated with number of monocytes, T-cells, and the expression level of glomerular CCL-2 ($r = 0.745$, $P = 0.002$; $r = 0.730$, $P < 0.001$; $r = 0.513$, $P = 0.012$, respectively). There was no correlation between damage score and CCL- 5 or CXCL-10. Of note, number of infiltrating monocytes was highly correlated with glomerular CCL-2 ($r = 0.865$, $P < 0.001$). Conclusion(s): Our data suggest that glomerular infiltrating T cells, monocytes and CCL-2 might have a potential role in glomerular damage of lupus-prone mice. (Figure Presented).

Kadish, A. H. (1947). "Coagulation of the blood in lusteroid tubes: A study of normal persons and patients with arterial or venous thrombosis." American Heart Journal **34**(2): 212-224.

The clotting time of whole blood in lusteroid (a synthetic plastic resin) tubes was studied in an effort to find a means of estimating an acceleration of the clotting process. The technique employed was essentially the standard Lee-White procedure; paraffined syringes and needles were used. The end-point was inversion of the tube without displacing the clot, tested at 30-second intervals. According to this test the time for 50 normal persons 18 to 40 years of age averaged 19 minutes with a range of 14 to 28 minutes. Different batches of lusteroid tubes give significantly different times and this may account for the lack of agreement on 'normal' clotting time in 'lusteroid' tubes. It also appears that tube diameter is a very important factor when the end-point is determined by inverting the tube. The coagulation time of the blood of 18 patients with arteriosclerosis obliterans was shorter than normal in nine cases; three of ten patients with thrombo-angiitis obliterans and eight of eleven patients with thrombophlebitis showed shorter times. The frequency of shortened times was greater with lusteroid tubes than with glass tubes. The data are too few for the statistical analysis called for in view of overlap of control and diseased ranges.

Kadleck, C. (2010). "U.S. PET recycling rate rises by 1% for 2009." Waste & Recycling News **16**(14): 12-12.

The article reports that the recycling rate of polyethylene terephthalate containers increased in 2009. According to the National Association for PET Container Resources and the Association of Postconsumer Plastic Recyclers, the recycling rate has increased for the sixth time in the U.S., consecutively. It mentions that recycled PET was used in several applications including strapping, food containers, and carpets.

Kain, E. C., et al. (2016). "Plastic ingestion by Newell's (Puffinus newelli) and wedge-tailed shearwaters (Ardenna pacifica) in Hawaii." Environmental science and pollution research international **23**(23): 23951-23958.

The ingestion of plastic by seabirds has been used as an indicator of pollution in the marine environment. On Kaua'i, HI, USA, 50.0 % of Newell's (Puffinus newelli) and 76.9 % of wedge-tailed shearwater (Ardenna pacifica) fledglings necropsied during 2007-2014 contained plastic items in their digestive tract, while 42.1 % of adult wedge-tailed shearwaters had ingested plastic. For both species, the frequency of plastic ingestion has increased since the 1980s with some evidence that the mass and the number of items ingested per bird have also increased. The color of plastic ingested by the shearwaters was assessed relative to beach-washed plastics by using Jaccard's index (where $J = 1$ complete similarity). The color ($J = 0.65$-0.68) of items ingested by both species, and the type ingested by wedge-tailed shearwaters ($J = 0.85$-0.87), overlapped with plastic available in the local environment indicating moderate selection for plastic color and type. This study has shown that the Hawaiian populations of shearwaters, like many seabird species, provide useful but worrying insights into plastic pollution and the health of our oceans.

Kairesalo, T. and S. Penttila (1990). "Effect of Light and Water Flow on the Spatial Distribution of Littoral Bosmina longispina Leydig (Cladocera)." Internationale Vereinigung fuer Theoretische und Angewandte Limnologie. Verhandlungen IVTLAP, Vol. 24, No. 1, p 682-687, September 1990. 5 fig, 17 ref.

The zooplankton community within the littoral macrophyte zone of lakes is often extremely patchy and subject to dramatic fluctuations in both abundance and species composition. Predation, food limitations and exploitative competition have been considered the key factors in influencing the spatial distribution of cladoceran zooplankton, but the importance of physical factors has seldom been evaluated. The response of Bosmina longispina to different flow velocities and light was investigated in the laboratory at room temperature (22 C) in flow-through tubes. Flow rates in the water were measured as the speed of small, light, submerged plastic particles. Field studies were carried out in the littoral zone of Lake Paajarvi. Diel fluctuations in the distribution and patchiness of Bosmina populations within the macrophytic vegetation was studied by taking water samples from 6 sampling points with a 100 ml plastic syringe connected to a 1 m wooden pole. In the aquarium , Bosmina moved towards a light spot of 10 to 20 microE/sq m/sec , but no distinct and stable swarm developed until the light intensity was 90 to 100 microE/sq m/sec. The Bosmina could resist flows up to 2 cm/sec, but when the flow exceeded 2.5 cm/sec all the animals were carried away by the throughflow water. Field experiments supported the hypothesis that light controls the swarming behavior of Bosmina in littoral water. Bright light enhances algal production and hence also increases food availability for cladocerans. Orientation towards light, together with enhanced grazing, can be understood as a behavioral adaptation for food seeking. The results suggest that diel and seasonal changes in the intensity and direction of light and ambient water flows may largely control the distribution of littoral Bosmina, and therefore, those environmental variables should be taken into consideration when designing a sampling program for littoral cladocerans, and when interpreting the results. (Brunone-PTT)

Kajiwara, H., et al. (2016). "Immobilized sialyltransferase fused to a fungal biotin-binding protein: Production, properties, and applications." Journal of Bioscience & Bioengineering **121**(4): 390-393.

A beta-galactoside alpha2,6-sialyltransferase (ST) from the marine bacterium Photobacterium sp. JT-ISH-224 with a broad acceptor substrate specificity was fused to a fungal biotin-binding protein tamavidin 2 (TM2) to produce immobilized enzyme. Specifically, a gene for the fusion protein, in which ST from Photobacterium sp. JT-ISH-224 and TM2 were connected via a peptide linker (ST-L-TM2) was constructed and expressed in Escherichia coli. The ST-L-TM2 was produced in the soluble form with a yield of approximately 15,000 unit/300 ml of the E. coli culture. The ST-L-TM2 was partially purified and part of it was immobilized onto biotin-bearing magnetic microbeads. The immobilized ST-L-TM2 onto microbeads could be used at least seven consecutive reaction cycles with no observed decrease in enzymatic activity. In addition, the optimum pH and temperature of the immobilized enzyme were changed compared to those of a free form of the ST. Considering these results, it was strongly expected that the immobilized ST-L-TM2 was a promising tool for the production of various kind of sialoligosaccharides.

Kakaei, K. and A. R. Bakhtiari (2018). "Investigating the impact of Hamedan landfill on groundwater and soil." Journal of Water and Soil Science **22**(1): e87-Pe96.

Landfill sites are one of the most important sources of contaminant entry to the environment. In this research, the concentrations of Cu, Pb, Ni, Cd, and organic compound BPA in Hamadan

landfill were evaluated to determine the status of its burial environment in 2014. Seven water samples (2 samples from spring and 5 samples from well), 2 leachate samples and 15 soil samples were collected from Hamadan landfill. Evaluation of the concentrations of Cu, Pb, Ni, Cd and the organic compound BPA was done by atomic absorption and gas chromatography with mass spectrometry. The concentrations of metals (Cu, Pb, Ni and Cd) in water samples (wells and springs) Pb < Cu < Cd < Ni, the leachate samples Cu < Pb < Ni < Cd and finally, the soil samples Cd < Cu < Pb < Ni, were obtained, respectively. Water samples (wells and springs), only in a 7W handheld water well sample (the nearest to the buried well) related to BPA 22.35 (micro g /l) composition, waste leachate samples for the concentrations of BPA, 103.3 (micro g /l), and soil samples for the combined concentration of BPA 5.52 (ng /g) were obtained. High concentrations of Ni, Pd and Cd and high concentrations of BPA in the samples of leachate composition, soil samples of landfill, and the 7W handheld water well samples were due to the high volume of electronic waste and plastic waste.

Kakutani, M., et al. (1999). "JTE-607, a novel inflammatory cytokine synthesis inhibitor without immunosuppression, protects from endotoxin shock in mice." Inflammation Research **48**(8): 461-468.

OBJECTIVE AND DESIGN: We investigated the effect of a novel N-benzoyl-L-phenylalanine derivative compound (JTE-607) on production of various cytokines and other immune responses in vitro and on endotoxin shock in vivo.

MATERIALS AND METHODS: Human, monkey, rabbit, mouse and rat peripheral blood mononuclear cells (PBMCs), and human fibroblasts, umbilical vein endothelial cells (HUVEC), mesangial cells and T cells were used in vitro. Endotoxin shock was induced by lipopolysaccharide (LPS) in Corynebacterium parvum (C. parvum) sensitized male C57BL/6 mice in vivo.

RESULTS: JTE-607 inhibited inflammatory cytokine production, including tumor necrosis factor (TNF)-alpha, interleukin (IL)-1beta, IL-6, IL-8 and IL-10, from LPS-stimulated human PBMCs, with IC50 values of 11, 5.9, 8.8, 7.3 and 9.1 nM, respectively. The inhibitory effects of JTE-607 were also seen in mRNA expression of those cytokines. The potency of JTE-607 on cytokine production from PBMCs of other species, and from other human cells were much lower than that on human PBMCs. JTE-607 did not affect either LPS-stimulated microbead phagocytosis or reactive oxygen species production at 1 microM in human PBMCs but slightly suppressed expression of major histocompatibility complex class II antigen at 1 microM, although it was 100-fold less active than it was as a cytokine inhibitor. JTE-607 (0.3-10 mg/kg, i.v.) showed dose dependent inhibition of mortality after LPS challenge in C. parvum sensitized mice in accordance with a decrease of plasma TNF-alpha.

CONCLUSIONS: These results suggest that JTE-607 is a multiple cytokine inhibitor specific for human PBMCs. This compound may be useful for the treatment of various cytokine mediated diseases such as septic shock without causing immunosuppression.

Kalanatarifard, A. and G. S. Yang (2012). "Identification of the Municipal Solid Waste Characteristics and Potential of Plastic Recovery at Bakri Landfill, Muar, Malaysia." Journal of Sustainable Development **5**(7): 11.

The objective of this study was to evaluate the composition and characteristics of the generated municipal solid waste (MSW) in order to obtain information about the quantity of recoverable plastic at Bukit Bakri landfill Muar, Malaysia. Solid waste sampling and laboratory analysis were carried out according to the random sampling method based on American Society of Testing and Materials (ASTM) standards to determine the waste compositions and proximate analysis (moisture content, volatile matter, ash content and fixed carbon). The total quantity of MSW generated at the site was 330 ton/day made up of 25 individual types of waste. The main

compositions of the generated waste were 39% food waste, 12% plastic waste and 16% paper which accounted for about 67% by weight. About 12% of disposed materials at Bakri landfill consisted of recoverable plastics of which 9% plastic film, 2% rigid plastic and 1% plastic foam. The average moisture content of the waste was between 50-58%. Although, there is significant volume of recoverable plastic at the disposal site (approximately 35 tons/day), this materials are still being land filled without any form of treatments. Based on the results obtained, this study has recommended the plastic recovery plan as a feasible MSW strategy to reduce the amount of disposed waste at Bakri landfill.

Kalcikova, G., et al. (2017). "Wastewater treatment plant effluents as source of cosmetic polyethylene microbeads to freshwater." Chemosphere **188**: 25-31.

Microplastics in the environment are either a product of the fractionation of larger plastic items or a consequence of the release of microbeads, which are ingredients of cosmetics, through wastewater treatment plant (WWTP) effluents. The aim of this study was to estimate the amount of microbeads that may be released by the latter pathways to surface waters using Ljubljana, Slovenia as a case study. For this purpose, microbeads contained in cosmetics were in a first step characterized for their physical properties and particle size distribution. Subsequently, daily emission of microbeads from consumers to the sewerage system, their fate in biological WWTPs and finally their release into surface waters were estimated for Ljubljana. Most of the particles found in cosmetic products were <100 mum. After application, microbeads are released into sewerage system at an average rate of 15.2 mg per person per day. Experiments using a lab-scale sequencing batch biological WWTP confirmed that on average 52% of microbeads are captured in activated sludge. Particle size analyses of the influent and effluent confirmed that smaller particles (up to 60-70 mum) are captured within activated sludge while bigger particles were detected in the effluent. Applying these data to the situation in Ljubljana indicates that about 112,500,000 particles may daily be released into the receiving river, resulting in a microbeads concentration of 21 particles/m³. Since polyethylene particles cannot be degraded and thus likely accumulate, the data raise concerns about potential effects in aquatic ecosystems in future.

Kalcikova, G., et al. (2017). "Impact of polyethylene microbeads on the floating freshwater plant duckweed Lemna minor." Environmental Pollution **230**: 1108-1115.

Microplastics (MP), small plastic particles below 5 mm, have become one of the central concerns of environmental risk assessment. Microplastics are continuously being released into the aquatic environment either directly through consumer products or indirectly through fragmentation of larger plastic materials. The aim of our study was to investigate the effect of polyethylene microbeads from cosmetic products on duckweed (Lemna minor), a freshwater floating plant. The effects of microbeads from two exfoliating products on the specific leaf growth rate, the chlorophyll a and b content in the leaves, root number, root length and root cell viability were assessed. At the same time, water leachates from microbeads were also prepared to exclude the contribution of cosmetic ingredients on the measured impacts. Specific leaf growth rate and content of photosynthetic pigments in duckweed leaves were not affected by polyethylene microbeads, but these microbeads significantly affected the root growth by mechanical blocking. Sharp particles also reduced the viability of root cells, while the impact of microbeads with a smooth surface was neglected. It was concluded that microbeads from cosmetic products can also have negative impacts on floating plants in freshwater ecosystems.

Kaleniecka, A. and P. K. Zarzycki (2019). "Degradation Studies of Selected Bisphenols in the Presence of

beta-Cyclodextrin and/or Duckweed Water Plant." Journal of AOAC International **23**: 23.

Background: This research reports a multivariate experiment enabling observation of the potential application of macrocyclic compound [beta-cyclodextrin (beta-CD)] and/or duckweed organisms as the active factors for elimination of selected bisphenols A, B, and S from water samples. Objective: Target bisphenols selection was based on observation that such components can be present in food or environmental samples (e.g., vegetable/fruit juices, milk, drinking water, or treated wastewater). Methods: Biological research was carried out using aquatic organisms containing chlorophyll, particularly duckweed (Lemna minor L), that may work as an active biomass for the elimination or extraction of bisphenols micropollutants from water. Using such a system, we studied the potential encapsulation effect and removal efficiency of nontoxic macrocyclic oligosaccharide (beta-cyclodextrin) acting as an encapsulation reagent to promote the removal of selected bisphenols from liquid phase both with and without the presence of duckweed biomass. Results: Experimental data have revealed that beta-CD or combined beta-CD/duckweed system has an effect on bisphenols elimination from water. The initial data set obtained from this preliminary experiment (and combined with supramolecular complex formation data calculated from chromatographic experiments, published previously) enables designing of further experiments focusing on the development of green chemistry technology. Conclusions: It is hoped that this may be used for the efficient removal of low-molecular-mass micropollutants using classical technological wastewater treatment processes modified by biomass and macrocyclic additives. This process needs to be optimized, but the results presented have revealed that such green chemistry technology, if successful, may be an interesting alternative for the selective removal of the micropollutants investigated from wastewater using classical adsorbents (e.g., carbons and carbon-related nanomaterials), particularly in terms of the worldwide problem with microplastic pollutants in the environment and food products.

Kaliyavaradhan, S. K., et al. (2019). "Waste resources recycling in controlled low-strength material (CLSM): A critical review on plastic properties." Journal of Environmental Management **241**: 383-396.

The exponential growth of waste generation is posing serious environmental issues and thus requires urgent management and recycling action to achieve green sustainable development. Controlled low-strength material (CLSM) is a highly flowable cementitious backfill material with self-consolidating properties. The CLSM efficiency during construction and final performance at the site depends on its plastic properties. Plastic properties are responsible for workability, pumpability, stability, and lateral pressure on adjacent soils. This paper presents a critical review to date on the use of waste materials and/or by-products and their impacts on the plastic properties of the CLSM. Extensive previous studies demonstrated that the basic properties and content of waste materials as well as the amount of water in the mix design, play a dominant role in determining the plastic properties of CLSM. The discussed plastic properties of CLSM include flowability, bleeding, segregation, and hardening time, which are found to be inter-related. Proper mix design adjustment to accommodate the use of waste materials is possible to produce sustainable CLSM with acceptable plastic properties. Additionally, the discussion and analysis presented in this paper could provide a basis for future research advances and the development of sustainable CLSM prepared with waste materials. Image 1 • A critical review to date on effects of waste materials on the plastic properties of CLSM is presented. • The discussed properties include flowability, bleeding, segregation and hardening time. • A large volume of waste materials can be utilized in the production of CLSM. • Utilization of waste materials in CLSM holds great potential for sustainable development. [ABSTRACT FROM AUTHOR]

Kaluevi, A., et al. (2012). Encapsulation of basil (Ocimum basilicum) essential oil. 6th Central European Congress on Food, CEFood 2012, May 23, 2012 - May 26, 2012, Novi Sad, Serbia, University of Novi Sad, Faculty of Technology.

Basil (Ocimum basilicum) is an aromatic plant widely used as a culinary herb, commonly added as fresh. There are many scientific studies that have confirmed health benefits of the basil oil. Bioactive compounds of the essential oils found in basil have antioxidant and antimicrobial properties. However, effectiveness of these compounds depends on preserving their stability, which can be increased by encapsulation. The aim of this study was to encapsulate the basil essential oil (EO) in alginate microbeads in order to protect and stabilize bioactive compounds in it. Calcium alginate microbeads entrapping the EO were produced by electrostatic extrusion technique. The obtained microbeads were characterized from the aspect of total phenol content, encapsulation efficiency and antioxidant capacity. Total polyphenol content (TPC) of microbeads was analyzed by the Folin-Ciocalteu reagent. Encapsulation efficiency was calculated as the ratio between the TPC in the citrate solution of dissolved microbeads and the TPC of the initial EO. The radical scavenging activity was determined as Trolox equivalent antioxidant capacity (TEAC) and by using stable free radical 1,1-diphenyl-2-picrylhydrazyl (DPPH). The rehydration properties of air dried calcium alginate gel microbeads were investigated in water and phosphate buffer solution. Also, samples were analyzed by optical microscopy (OM). Encapsulation efficiency was obtained to be approximately 60 %. The results of TEAC and DPPH tests indicate that antioxidant activity was preserved at a satisfactory level. The average diameters of fresh and dried microbeads were 860.844.9 and 416.037.2 m, respectively. The particles, with and without EO, rehydrated in buffer were highly swollen, from 5000 to 10000 %w/w. The results suggest that alginate microbeads encapsulating EO appeared to be suitable dosage forms. Thus, possible applications of these microbeads could be in the production of functional foods.

Kaluzova, M., et al. (2010). "Imaging, targeted therapy, and identification of candidate proteins of glioma stem cells. EGFRvIII antibody-conjugated magnetic nanoparticles inhibit formation and proliferation of GBM-derived neurospheres." Neuro-Oncology **4)**: iv125.

INTRODUCTION: Glioblastoma multiforme (GBM) is the most common and lethal malignant primary brain tumor in adults. EGFRvIII, a constitutively active truncated form of EGFR, is expressed in a subset of GBM with a particularly poor prognosis. Glioma stem cells (GSCs) have properties of self-renewal, pluripotency, and high tumorigenicity. Magnetic iron oxide nanoparticles (IONPs) have emerged as a potential multifunctional clinical tool that can provide cancer cell-targeted delivery of agents. In this study, we have examined differential activation of signaling pathways in purified CD133-positive GSCs in an effort to identify candidate proteins for the targeted imaging and therapy of GSC via magnetic nanoparticles. We have also studied the effect of IONPs conjugated with an EGFRvIII antibody on the formation and proliferation of GBM-derived neurospheres and apoptotic induction in neurospheres and GSCs. METHOD(S): Glioblastoma tumor specimens were used to isolate neurospheres in Neurobasal A-medium containing bFGF and EGF. Neurospheres of EGFRvIII-negative and EGFRvIII-positive GBM tumors were further enriched for CD133-positive cells using a CD133 MicroBeads kit or FACS analysis. Magnetic nanoparticles were conjugated with the EGFRvIII antibody using Ocean NanoTech kit and conjugation was verified by agarose gel. RESULTS AND CONCLUSION(S): We identified Nestin, wild-type (wt)-EGFR, EGFRvIII, PDGFRbeta, CAIX, and podoplanin as candidate proteins in CD133-positive GSCs. Hypoxia massively enhanced expression of the CD133 antigen in EGFRvIII-positive neurospheres. Antibodies against the candidate proteins, conjugated to magnetic nanoparticles, may form the basis of imaging and targeted therapy. IONPs conjugated to an antibody specific to the EGFRvIII deletion mutant inhibit proliferation and neuro-sphere formation and can promote apoptosis in CD133-positive GSC neuro-spheres, but also in CD133-negative neurospheres. In conclusion, a therapy in which GSCs are targeted with antibody-conjugated nanoparticles with high magnetic potential, followed by exposure to alternating magnetic fields to generate local hyperthermia, could have a strong therapeutic effect.

Kam, Y. W., et al. (2017). "Specific Biomarkers Associated With Neurological Complications and Congenital Central Nervous System Abnormalities From Zika Virus-Infected Patients in Brazil." Journal of Infectious Diseases **216**(2): 172-181.

Background: Zika virus (ZIKV) infections have been linked to different levels of clinical outcomes, ranging from mild rash and fever to severe neurological complications and congenital malformations.

Methods: We investigated the clinical and immunological response, focusing on the immune mediators profile in 95 acute ZIKV-infected adult patients from Campinas, Brazil. These patients included 6 pregnant women who later delivered during the course of this study. Clinical observations were recorded during hospitalization. Levels of 45 immune mediators were quantified using multiplex microbead-based immunoassays.

Results: Whereas 11.6% of patients had neurological complications, 88.4% displayed mild disease of rash and fever. Several immune mediators were specifically higher in ZIKV-infected patients, and levels of interleukin 10, interferon gamma-induced protein 10 (IP-10), and hepatocyte growth factor differentiated between patients with or without neurological complications. Interestingly, higher levels of interleukin 22, monocyte chemoattractant protein 1, TNF-alpha, and IP-10 were observed in ZIKV-infected pregnant women carrying fetuses with fetal growth-associated malformations. Notably, infants with congenital central nervous system deformities had significantly higher levels of interleukin 18 and IP-10 but lower levels of hepatocyte growth factor than those without such abnormalities born to ZIKV-infected mothers.

Conclusions: This study identified several key markers for the control of ZIKV pathogenesis. This will allow a better understanding of the molecular mechanisms of ZIKV infection in patients.

Kamaya, M., et al. (2011). "A Simple Bioassay Using Fluorescent Microbeads and Daphnia magna." Journal of Environmental Science and Engineering **5**(12): 1613-1616.

The amount of microbeads ingested by Daphnia magna decreases on exposure to toxic materials; this behavior was used to develop a toxicity test. To determine the toxicity of seven metals, D. magna were collected and homogenized, and the fluorescence intensity of the microbeads ingested by D. magna was measured. The amount of ingestion was determined from fluorescence intensity. The fluorescence intensity was half of that of the controls which was measured as the 30 min-FI50, and these data correlated well with those from an acute immobilization method (24 h-EC50). An advantage of the method using fluorescent beads is that an estimate of the 24 h-EC50 can be obtained.

Kamel, A., et al. (2010). "Cytokine production by graft cells in response to patient's antigens may predict the occurrence of acute graft versus host disease in allogeneic hematopoietic stem cell transplantation from a sibling." Haematologica **2)**: 443.

Background: Allogeneic hematopoietic stem cell (HSC) transplantation whether bone marrow (BM) or peripheral blood (PBSCT) is a widely used therapeutic modality. Graft vs. host disease (GVHD) continues to be the main concern of transplanters. There is substantial evidence to implicate that cytokines play a major role in GVHD induction and grade. GVHD was reported to be associated with increased production of IFNgamma and IL10. IL 10 cytokine level and gene polymorphism have been used as predictors of acute GVHD (aGVHD). IFNgamma was also reported to have a protective role if administered at the time of transplantation possibly via induction of T regulatory cells and immunological tolerance. Aims. The aim of this work was to develop an experimental setup to mimic the response of the immune cells of the graft to the host antigens expressed by cytokine production. The final aim was to correlate the cytokine pattern to the development of aGVHD and verify if this pattern could possibly predict the occurrence of aGVHD. Method(s): The study included 46 patients who received allogeneic PBSCT from an identical sibling. Under informed consent, a sample was obtained from the patient before conditioning, mononuclear cells separated and cryopreserved. On the day of transplant, the cryopreserved cells were thawed, mitomycin treated to serve as stimulators while the mononuclear cells of the graft served as the responders in a mixed lymphocyte culture setup. After 3 days culture, supernatant was collected and stored at -80 degree C till tested. IFNgamma and IL10 were measured by microbead array technology using luminex 200. Patients were followed up and development of aGVHD was recorded. Result(s): Of the 46 patients, 14 developed aGVHD. In the culture supernatant, cytokines were below the detection limit in 26/32 of cases that did not and in 3/14 of those who developed aGVHD. The level of cytokines in the other cases varied widely. Of the 11 cases that showed cytokine production, 4 produced IFNgamma only and one produced IL10 only. The other 6 cases produced both; IL10 was higher in one case; in the other 5 cases, IFNgamma was much higher. In the 6/32 cases without GVHD, IL10 only was detected in 3 cases; the other 3 cases showed much higher level of IL10 than IFNgamma. At a cutoff level of 15.9 pg/mL, IFNgamma was predictive of aGVHD with a sensitivity of 64.3%, specificity of 96.8% and a total accuracy of 80.4%. At a cutoff of 2.27pg/mL, IL10 showed a sensitivity of 50%, specificity of 80.6% and a total accuracy of 71.1%. At a cutoff of 1.13, IFNg/IL10 ratio showed a sensitivity of 85.7%, specificity of 83.3% and a total accuracy of 84.6%. Conclusion(s): In vitro cytokine production by graft immune cells in response to host antigens is extremely variable; it may serve as a surrogate system of the immune reaction following allogeneic stem cell transplantation. IFNgamma production apparently reflects potential development of aGVHD while IL10 production is apparently protective. When both are produced the IFNgamma/IL10 ratio is more informative than either alone.

Kamel, A. M., et al. (2012). "Interleukin 12 (IL12) and interferon gamma (IFN{gamma}) of donor origin not of patient origin may predict acute graft versus host disease after allogeneic hematopoietic stem cell transplantation (HSCT)." Blood. Conference: 54th Annual Meeting of the American Society of Hematology, ASH **120**(21).

One persistent problem following allogeneic HSCT is acute graft versus host disease (GVHD). A major role of cytokines in the pathogenesis of GVHD has been acknowledged with a lot of controversial reports. This study aimed at the possible prediction of the occurrence of acute GVHD through studying the pattern of interleukin 12 (IL12) and interferon {gamma} (IFN{gamma}) production. We used two approaches: (i) In vitro cytokine production by graft cells in response to recipient antigens, in a mixed lymphocyte culture setup. (ii) Measurement of cytokines levels in the patient's plasma prior to transplant and during the aplastic phase representing cytokines of patient's origin as well as at engraftment representing cytokines of donor's origin. The work was performed according to Helsinki declaration, the protocol was approved by the IRB of the NCI, Cairo University and an informed consent was obtained from all subjects. The study comprised 45 patients who received fully matched allogeneic peripheral blood stem cell transplantation from a sibling donor in the period from November 2006 until May 2010 at Nasser Institute. They included 26 males and 19 females with an age range of 6-41 with a median of 22 years. The study cohort included 18 AML, 15 CML, 4 ALL, 4 aplastic anemia, 3 MDS and one patient with Fanconi's anemia. IL12 and IFN{gamma} were measured by microbead array technology using Luminex 200 and Flourokine MAP kit provided by R & D Company. Patients were followed up for at least one year. Fourteen/45 patients developed acute GVHD, 4 grade I, six grade II and 4 grade III. Seven patients developed chronic GVHD; 3 of them on top of acute GVHD. Patients who developed chronic GVHD showed no statistically significant differences in any of the tested parameters and will not be mentioned any more. Positive correlation between IL12 and IFN{gamma} of donor's origin was encountered in both culture supernatant (r = 0.75, P <0.001) and patient's plasma at engraftment (r = 0.57, P <0.001). In culture supernatant, IL12 was undetectable in 7/14 cases with acute GVHD. The other 7 cases showed a level of 2.0 - 463.5 with a median of 14.6 pg/ml. It was not detected in any of the 31 cases without GVHD (P <0.001). IFN{gamma} was undetectable in 4/14 cases with acute GVHD. The other 10 cases showed a level of 6.2 - 19.000 with a median of 133.5pg/ml. It was undetectable in 28/31 cases without GVHD. The other 3/31 cases showed a level of 1.1- 80.01 with a median of 8.1 pg/ml. (P <0.001). In patient's plasma at engraftment, IL12 was undetectable in 7/14 cases with acute GVHD; the other 7 cases showed a level of 3.89 - 608.5 with a median of 51.8 pg/ml. It was undetectable in 26/31 cases without GVHD; the other 5 cases showed a level of 2.0 - 6.88 with a median of 2.93 pg/ml. (P = 0.008). IFN {gamma} was undetectable in 3/14 cases with acute GVHD; the other 11cases showed a level of 11 - 427 with a median of 77.9 pg/ml. It was undetectable in 24/31 cases without GVHD; the other 7 cases showed a level of 0.27- 26.67 with a median of 15.8 pg/ml (P <0.001). At a cut off value of 15.9 pg/ml in either culture supernatant or patient's plasma at engraftment, IFN {gamma} showed a sensitivity of 64.3%, a specificity of 96.8 % and a total accuracy of 80.4%. Nine/10 cases that had a level >=the cutoff in the culture supernatant developed acute GVHD as compared to 5/35 with levels below the cutoff (p=0.001). While 9/12 cases that had a level >=the cutoff in patient's plasma at engraftment developed acute GVHD as compared to 5/33 with levels below the cutoff (p=0.001). At a cutoff value of 0.89 pg/ml, the level of IL12 in culture supernatant showed a sensitivity of 50.0%, absolute specificity of 100.0% and a total accuracy of 83.3%. All 7 cases that had a level >=the cutoff developed acute GVHD as compared to 7/38 with levels below the cutoff (p=0.000). At a cutoff value of 1.0 pg/ml, the level of IL12 at engraftment showed a sensitivity of 50.0%, a specificity of 83.9% and a total accuracy of 72.3%. Seven/12 cases that had a level >=the cutoff deve oped acute GVHD as compared to 7/33 with levels below the cutoff (p=0.023). On the other hand no significant difference was encountered in the levels of either cytokine of patient's origin between cases who developed and those who did not develop acute GVHD. In conclusion, IFN {gamma} and IL12 of donor but not of patient's origin might predict the occurrence of acute GVHD. IL12 in culture supernatant is a potential absolute positive but not negative predictor. A validation cohort is needed to verify these assumptions.

Kaminuma, T., et al. (2000). "[Distribution and origin of plastic resin pellets as environmental pollutants at the East China Sea area]." Kokuritsu Iyakuhin Shokuhin Eisei Kenkyusho Hokoku(118): 90-99.

Plastic debris are important marine pollutants. Plastic debris consist of resin pellets and waste plastics. We are particularly interested in resin pellets. We made field survey of resin pellets at nearly 400 sites in 200 beaches in Japan and neighboring countries. The pellets were found at all most all Japan coasts we surveyed and at some beaches of Macao, Hong Kong, Xiamen, the north of Taipei, and Cheju Island in Korea. The number of pellets was more than 1000 pieces per m2 on the most abundant beach in Japan. Through further analysis using GC/ECD, endocrine disrupting chemicals, PCBs, DDTs, HCHs and Nonylphenol were detected in selected samples. Biota such as Bryozoa were observed on the surface of pellets washed up on the beaches in subtropical areas. Pellets has been suspected to affect wildlife and human health, but we have no report on affection to human.

Kamiya, K., et al. (2010). "Detection of Spontaneous Combustion of Plastic Waste by Odor." Fire Science and Technology **29**(1): 1-14.

Accumulated plastic waste is concerned to cause a spontaneous combustion. It is extremely difficult to notice the minor signs indicating the start of combustion inside the accumulated material. Spontaneous combustion of plastic waste was simulated using a temperature-controlled furnace, and the temperature of the sample and the intensity as well as quality of odorous gases emitted were measured during the process of self-ignition. Mixed plastic waste consisting of various plastics of food wrapping was subjected to heating furnace experiment as a single specimen. The odors generated from this specimen and each single individual plastic were measured. The ratio of the similarity indices aldehyde/ammonia was found to increase during the ignition process due to the accumulated heat in the central part of accumulated material. Specimens of individual plastic was burnt and thermally decomposed using TG-DTA under the normal atmospheric condition, the odor also showed a similar tendency with that obtained in the experiment for the mixed specimen.

Kanangat, S., et al. (2010). "Painful family "memories"?" Human Immunology **1)**: S61.

Aim: To investigate two cases of acute renal transplant rejection despite total absence of HLA antibodies in recipients' pretransplant sera and negative T/B cell cross match prior to transplantation. Method(s): Patients/Donors: Two female living donor renal transplant recipients, a 62 year old female who received kidney from her child, and a 58 year old female who received kidney from her husband, both rejected the allograft shortly after transplantation. Alloimmune response analysis: Flow cytometry based HLA antibody screening, Luminex-Microbead array based Labscreen PRA, Flow Cytometry based T and B cell Cross match, and CDC-AHG Cross match were used for pretransplant HLA antibody detection. Post transplant HLA antibodies were detected by single antigen microbead array (One Lambda). Result(s): Pretransplant sera were negative for both Class I and Class II antibodies and both Flow Cytometry and CDC-AHG cross matches using T and B cells prior to transplant were also negative in both patients. Post transplant serum from both patients had significant levels of multiple DSA as detected by Single antigen bead assay. Conclusion(s): Both patients could have been exposed to their donor's HLA prior to their transplants. The recipient mother would have had exposure to the child's paternally derived HLA during gestation. Similarly, the patient who received kidney from her husband would have had exposure to his HLA through pregnancies. Although such exposure to foreign antigens during gestation could result in tolerization, it could also result in alloimmunization. Both patients may have had memory cells to their donor's HLA. Some long-lived plasma cells may not respond to certain immunosuppressants resulting in vigorous response upon contact with recall antigen after transplant. Therefore, a pretransplant negative cross do not completely rule out the possibilities of an undesired anamnestic alloimmune response.

Kandabashi, T., et al. (2003). "Evidence for Protein Kinase C-Mediated Activation of Rho-Kinase in a Porcine Model of Coronary Artery Spasm." Arteriosclerosis, Thrombosis, and Vascular Biology **23**(12): 2209-2214.

Objective-We have recently demonstrated that protein kinase C (PKC) and Rho-kinase play important roles in coronary vasospasm in a porcine model. However, it remains to be examined whether there is an interaction between the two molecules to cause the spasm. Methods and Results-A segment of left porcine coronary artery was chronically treated with IL-beta-bound microbeads in vivo. Two weeks after the operation, phorbol ester caused coronary spasm in vivo and coronary hypercontractions in vitro at the IL-beta-treated segment; both were significantly inhibited by hydroxyfasudil, a specific Rho-kinase inhibitor. Guanosine 5'-[gamma-thio] triphosphate (GTPgammaS), which activates Rho with a resultant activation of Rho-kinase, enhanced Ca²⁺ sensitization of permeabilized vascular smooth muscle cells, which were resistant to the blockade of PKC by calphostin C. The GTPgammaS-induced Ca²⁺ sensitization was greater in the spastic segment than in the control segment. Western blot analysis revealed that only PKCdelta isoform was activated during the hypercontraction. Conclusions-These results demonstrate that PKC and Rho-kinase coexist on the same intracellular signaling pathway, with PKC located upstream on Rho-kinase, and that among the PKC isoforms, only PKCdelta may be involved. Thus, the strategy to inhibit Rho-kinase rather than PKC may be a more specific and useful treatment for coronary spasm.

Kandasamy, S. P., et al. (2013). "Municipal solid waste management at Chennai in southern India - An occupational health perspective." International Journal of Health Promotion and Education **51**(1): 50-61.

The reasonable concern of India is the health of municipal solid waste (MSW) workers (rag pickers in particular) who scavenge recyclables. A study was conducted among the conservancy staff and rag pickers to examine the occupational health of MSW workers in India. A cross-sectional survey was conducted to collect data on the demographic and socio-economic characteristics of the rag pickers, conservancy staff and residents through a questionnaire survey. The health evaluation was performed using a combination of a detailed medical history, clinical examinations, blood investigations, pulmonary function tests, X-rays and serology on all associated workers. Pulmonary function test results were significantly lower than predicted for both male and female study groups, viz. residents, rag pickers and conservancy workers. Most significant among the findings were the high prevalence of eosinophilia and hepatitis B. Prevalence of 8% hepatitis B carriers among conservancy workers points to the imminent need for prophylactic immunizations within this group of conservancy workers. A high prevalence of eosinophilia is not surprising given the multitude of allergen exposures. As compared to permissible biological exposure indices (BEI) in blood (ACGIH 2005), levels of metals were higher than BEIs, viz. mercury in 10% of workers, lead in 15% of workers, chromium in 12% of workers and cadmium in 3% of workers. As a means of organizing MSW management, the role of informal sector in recycling resources was recognized in the latest Plastic Waste (Management and Handling) Rules, 2011 in India. © 2013 Institute of Health Promotion and Education.

Kanderova, V., et al. (2013). "Novel flow cytometry-based method of affinity proteomics revealing expression, post-translational modification and proteolysis in primary childhood acute Leukemias." Blood. Conference: 55th Annual Meeting of the American Society of Hematology, ASH **122**(21).

Leukemia is a complex disease pathologically manifested at the DNA, mRNA and protein level. Understanding leukemia pathogenesis is prevalently focused on mutations at the DNA (or mRNA) level, however the functional consequences of these changes on cellular machineries are

not fully clarified. Since proteome analysis provides link between gene sequence and cellular physiology, proteomics can contribute to elucidate mechanism of disease and response to treatment. Moreover some alterations are manifested only at the protein level including subcellular localisation, post-translational modification (e.g. phosphorylation), protein cleavage or protein-protein interactions. Performing large-scale protein analysis of primary leukemia samples requires the development of more effective proteomic approaches as well as new analytical strategies. Here, we present novel microsphere-based antibody array format with automatical analysis tool that can follow changes in expression and post-translational modification of leukemia associated proteins with regards to intracellular localisation and protein cleavage in primary childhood acute leukemia (AL). Size Exclusion Chromatography-Microsphere-based Affinity Proteomics (SEC-MAP) is a set of 1728 populations of fluorescently-labeled microbeads, each carrying an antibody against respective human protein. Native cellular proteins (and their complexes) are isolated using detergents, labeled with biotin and subjected to size exclusion chromatography to obtain 24 molecular weight fractions. The fractions are incubated with SEC-MAP microbeads and the antibody-protein binding is detected using fluorescently-labeled streptavidin by flow cytometry. Flow cytometer resolves color-code of each microbead population and reads the amount of bound protein. The signals from 24 size fractions are combined and protein binding is detected as protein reactivity peaks similar to bands on western blot. The analysis is performed using automatic software created in R. It allows for automatic processing of fcs files as well as advanced follow-up analysis including quality control, normalisation, protein peaks recognition and clustering of results We have examined the expression of cytoplasmic (n=980) and membrane (n=769) proteins in 69 primary samples of AL obtained at diagnosis according to the Institutional Ethics Committee Giudelines. For the normalisation of protein expression we have used Loess normalisation commonly used in mRNA profiling studies. Due to ability of SEC-MAP to separate proteins according their molecular weight we have identified not only the expression of proteins but also the size that corresponds to its monomeric or multimeric presence and furthermore could serve as a control of proteolysis. We have revealed the sensitivity to proteolysis of 4 standard house-keeping proteins (Akt, Abl, beta-actin and beta2-microglobulin). Abl and Akt proved to be better controls of proteolysis. Detected with SEC-MAP or western blot, beta-actin and beta2-microglobulin, unlike Abl and Akt, have not been found in their cleaved forms in the proteolytically digested samples. Thus we have identified proteolysis in 12 samples which have been subsequently excluded from the analysis. So far we have identified 44 proteins (including CD markers distinguishing lineage specificity e.g. CD22, CD3, CD33) which have been differentially expressed in different subtypes of AL (B-cell precursor acute lymphoblastic leukemia, BCP-ALL, n=35), T-cell acute lymphoblastic leukemia (T-ALL, n=9) and acute myeloid leukemia (AML, n=13) (Multiple Testing Procedures - Bioconductor Package multtest, $p<0.05$). We have verified the expression using flow cytometry or western blot. From non-CD markers, we have found e.g. BLNK, DBN1, PAX5, PTK2 overexpressed in BCP-ALL, EIF5A, LAT, SH2D1A, SSEA4 overexpressed in T-ALL and CEBPA, CTBP2, GLUD1, LCP(pY145) and PTPN6 overexpressed in AML. In summary, SEC-MAP proved to be strong proteomic tool capable of identifying leukemia phenotype as well as providing novel insights into the protein expression and post-translational modification of primary childhood AL. Moreover it can bring complementary information about proteolysis not captured by planar arrays (western blot) which can significantly affect proteomic results.

Kandil, S., et al. (2004). "Controlled release of 2-methyl-4-chlorophenoxy acetic acid herbicide from waste gelatin-based blends and composites." Journal of Applied Polymer Science **94**(4): 1420-1427.

The volume of plastic waste is becoming a serious problem for waste management. Waste management is based on four hierarchical approaches: reduction, reuse, recycling, and energy recovery. We now report on recycling of gelatin scraps that are derived during the production of pharmaceutical capsules, by using the gelatin scraps in the production of controlled-release systems. This may help to minimize the side effects that often accompany the conventional application of pesticides. More important, the gelatins themselves, when degraded, might be useful to soil solarization and crop growth. Using and recycling these waste materials in the proposed application would save natural resources and consequently would be economically useful. The synthesis of gelatin films, and composites incorporating 2-methyl-4-chlorophenoxy acetic acid (MCPA) as herbicide, will be described. Morphology and mechanical properties of the films were investigated by scanning electron microscopy and tensile tests, respectively. The release of the MCPA herbicide from the prepared blends and composites was investigated. The prepared formulation proved to be useful for agricultural applications.

Kandil, S., et al. (2004). "Recycling of Pharmaceutical Waste Gelatin for Controlled Release Applications II: A Tri-fluralin Based System." Polymer-Plastics Technology & Engineering **43**(6): 1695-1709.

During the latter half of last century, the production and consumption of synthetic plastics and fibers has vastly grown. The plastics wastes have continuously increased over recent decades. Concerns over this have now resulted in mandatory recycling laws and demands for degradable polymers. Management of plastic wastes cannot be treated as an individual problem; it must be considered as an integral part of the global waste management system. The development of recycling processes leading to higher quality recycled products would help the recycling economy. In this study, recycling of pharmaceutical gelatin scraps will be conducted by incorporating them in biodegradable mulching films. The formulation and preparation of these films is described and the effect of different additives on the rate of release of the bioactive agent (trifluralin) is reported. The results showed that the produced films have controlled release properties and the presence of cross-linked agent decreased the release rate of trifluralin. [ABSTRACT FROM AUTHOR]

Kang, J. H., et al. (2013). "Clinical utility and analytical challenges in measurement of cerebrospinal fluid amyloid-beta(1-42) and tau proteins as Alzheimer disease biomarkers." Clinical Chemistry **59**(6): 903-916.

BACKGROUND: Over the past 2 decades, clinical studies have provided evidence that cerebrospinal fluid (CSF) amyloid beta(1-42) (Abeta(1-42)), total tau (t-tau), and tau phosphorylated at Thr181 (p-tau(181)) are reliable biochemical markers of Alzheimer disease (AD) neuropathology.

CONTENT: In this review, we summarize the clinical performance and describe the major challenges for the analytical performance of the most widely used immunoassay platforms [based on ELISA or microbead-based multianalyte profiling (xMAP) technology] for the measurement of CSF AD biomarkers (Abeta(1-42), t-tau, and p-tau(181)). With foundational immunoassay data providing the diagnostic and prognostic values of CSF AD biomarkers, the newly revised criteria for the diagnosis of AD include CSF AD biomarkers for use in research settings. In addition, it has been

suggested that the selection of AD patients at the predementia stage by use of CSF AD biomarkers can improve the statistical power of clinical trial design. Owing to the lack of a replenishable and commutable human CSF-based standardized reference material (SRM) and significant differences across different immunoassay platforms, the diagnostic-prognostic cutpoints of CSF AD biomarker concentrations are not universal at this time. These challenges can be effectively met in the future, however, through collaborative ongoing standardization efforts to minimize the sources of analytical variability and to develop reference methods and SRMs.

SUMMARY: Measurements of CSF Abeta(1-42), t-tau, and p-tau(181) with analytically qualified immunoassays reliably reflect the neuropathologic hallmarks of AD in patients at the early predementia stage of the disease and even in presymptomatic patients. Thus these CSF biomarker tests are useful for early diagnosis of AD, prediction of disease progression, and efficient design of drug intervention clinical trials.

Kang, J. H., et al. (2012). "A combined micromagnetic-microfluidic device for rapid capture and culture of rare circulating tumor cells." Lab on a Chip **12**(12): 2175-2181.

Here we describe a combined microfluidic-micromagnetic cell separation device that has been developed to isolate, detect and culture circulating tumor cells (CTCs) from whole blood, and demonstrate its utility using blood from mammary cancer-bearing mice. The device was fabricated from polydimethylsiloxane and contains a microfluidic architecture with a main channel and redundant 'double collection' channel lined by two rows of dead-end side chambers for tumor cell collection. The microdevice design was optimized using computational simulation to determine dimensions, magnetic forces and flow rates for cell isolation using epithelial cell adhesion molecule (EpCAM) antibody-coated magnetic microbeads (2.8 mum diameter). Using this device, isolation efficiencies increased in a linear manner and reached efficiencies close to 90% when only 2 to 80 breast cancer cells were spiked into a small volume (1.0 mL) of blood taken from wild type mice. The high sensitivity visualization capabilities of the device also allowed detection of a single cell within one of its dead-end side chambers. When blood was removed from FVB C3(1)-SV40 T-antigen mammary tumor-bearing transgenic mice at different stages of tumor progression, cells isolated in the device using anti-EpCAM-beads and magnetically collected within the dead-end side chambers, also stained positive for pan-cytokeratin-FITC and DAPI, negative for CD45-PerCP, and expressed SV40 large T antigen, thus confirming their identity as CTCs. Using this isolation approach, we detected a time-dependent rise in the number of CTCs in blood of female transgenic mice, with a dramatic increase in the numbers of metastatic tumor cells appearing in the blood after 20 weeks when tumors transition to invasive carcinoma and exhibit increased growth of metastases in this model. Importantly, in contrast to previously described CTC isolation methods, breast tumor cells collected from a small volume of blood removed from a breast tumor-bearing animal remain viable and they can be easily removed from these devices and expanded in culture for additional analytical studies or potential drug sensitivity testing.

Kang, J.-H., et al. (2013). "Clinical Utility and Analytical Challenges in Measurement of Cerebrospinal Fluid Amyloid-[Beta]^sub 1-42^ and [tau] Proteins as Alzheimer Disease Biomarkers." Clinical Chemistry **59**(6): 903-916.

Over the past 2 decades, clinical studies have provided evidence that cerebrospinal fluid (CSF) amyloid β^sub 1-42^ (Aβ^sub 1-42^), total τ (t-τ), and τ phosphorylated at Thr181 (p-τ^sub 181^) are reliable biochemical markers of Alzheimer disease (AD) neuropathology. In this review, we summarize the clinical performance and describe the major challenges for the analytical performance of the most widely used immunoassay platforms [based on ELISA or microbead-based multianalyte profiling (xMAP) technology] for the measurement of CSF AD biomarkers (Aβ^sub 1-42^, t-τ, and p-τ^sub 181^). With foundational immunoassay data providing the diagnostic and prognostic values of CSF AD biomarkers, the newly revised criteria for the diagnosis of AD include CSF AD biomarkers for use in research settings. In addition, it has been suggested that the selection of AD patients at the predementia stage by use of CSF AD biomarkers can improve the statistical power of clinical trial design. Owing to the lack of a replenishable and commutable human CSF-based standardized reference material (SRM) and significant differences across different immunoassay platforms, the diagnostic-prognostic cutpoints of CSF AD biomarker concentrations are not universal at this time. These challenges can be effectively met in the future, however, through collaborative ongoing standardization efforts to minimize the sources of analytical variability and to develop reference methods and SRMs. Measurements of CSF Aβ^sub 1-42^, t-τ, and p-τ^sub 181^ with analytically qualified immunoassays reliably reflect the neuropathologic hallmarks of AD in patients at the early predementia stage of the disease and even in presymptomatic patients. Thus these CSF biomarker tests are useful for early diagnosis of AD, prediction of disease progression, and efficient design of drug intervention clinical trials.

Kang, J.-H., et al. (2015). "Potential Threat of Microplastics to Zooplanktivores in the Surface Waters of the Southern Sea of Korea." Archives of Environmental Contamination & Toxicology **69**(3): 340-351.

The potential impact of microplastic to zooplanktivores was assessed by measuring a ratio of neustonic microplastics to zooplankton by abundance in the southern sea of Korea. Neustonic microplastics and zooplankton (0.33-2 mm) were collected using a 330-μm mesh Manta trawl in Geoje eastern Bay and Jinhae Bay before and after the rainy season in 2012 and 2013. The mean microplastic to zooplankton ratios were 0.086 (May) and 0.022 (July) in 2012, and 0.016 (June) and 0.004 (July) in 2013, indicating that zooplanktivores could be more likely to feed on microplastics than natural preys before the rainy season in 2012 and 2013. In particular, the relatively high ratio occurred in a semi-enclosed bay characterized by a shipyard and a beach resort in Geoje Bay, and at stations close to a wastewater treatment plant and an aquaculture facility in Jinhae Bay before the rainy season. Among dominant microplastics and zooplankton before the rainy season, meroplankton of macrobenthos could be confused with paint particles in Geoje Bay, 2012, whereas Styrofoam could be mistaken as immature copepods by predators in Jinhae Bay, 2013. These observations suggest that zooplanktivores could be more likely to feed on microplastics than natural preys around Geoje and Jinhae Bays before the rainy season. [ABSTRACT FROM AUTHOR]

Kannahi, M. and P. Sudha (2013). "Screening of polythene and plastic degrading microbes from Muthupet mangrove soil." Journal of Chemical and Pharmaceutical Research **5**(8): 122-127.

Polythene and plastic waste accumulating in the environment are posing an ever increasing ecological threat. Biodegradable plastics are environment friendly; they have an expanding range of potential application and are driven by the growing use of plastics in packaging. In this study, soil sample were collected from polythene and plastic dumped site waste in the area of

Muthupet Mangrove. The physico-chemical parameters of the soil were studied. The isolated microbial strains were identified based on their cultural morphological and biochemical study. Degradation of polythene bag and plastic cup were analyzed 35, 45 and 55days of incubation in liquid culture method. Pot culture of Vigna radiata was performed. The morphological parameters such as Germinating ability, root length, shoot length and chlorophyll content were analyzed. Waste management was the important process to protect the environment from pollution. Polythene and plastic cup waste materials cause serious environment problems, so the waste materials removed by using the microorganism. This method was cheap and effective, so that it can be used widely for the treatment of polythene and plastic cup.

Kantak, C., et al. (2012). "Utilizing microfluidics to synthesize polyethylene glycol microbeads for Forster resonance energy transfer based glucose sensing." Biomicrofluidics **6**(2): 22006-220069.

Here, we utilize microfluidic droplet technology to generate photopolymerizeable polyethylene glycol (PEG) hydrogel microbeads incorporating a fluorescence-based glucose bioassay. A microfluidic T-junction and multiphase flow of fluorescein isothiocyanate dextran, tetramethyl rhodamine isothiocyanate concanavalin A, and PEG in water were used to generate microdroplets in a continuous stream of hexadecane. The microdroplets were photopolymerized mid-stream with ultraviolet light exposure to form PEG microbeads and were collected at the outlet for further analysis. Devices were prototyped in PDMS and generated highly monodisperse 72 +/- 2 mum sized microbeads (measured after transfer into aqueous phase) at a continuous flow rate between 0.04 ml/h-0.06 ml/h. Scanning electron microscopy analysis was conducted to analyze and confirm microbead integrity and surface morphology. Glucose sensing was carried out using a Forster resonance energy transfer (FRET) based assay. A proportional fluorescence intensity increase was measured within a 1-10 mM glucose concentration range. Microfluidically synthesized microbeads encapsulating sensing biomolecules offer a quick and low cost method to generate monodisperse biosensors for a variety of applications including cell cultures systems, tissue engineering, etc.

Kaposi, K. L., et al. (2014). "Ingestion of Microplastic Has Limited Impact on a Marine Larva." Environmental Science & Technology **48**(3): 1638-1645.

There is increasing concern about the impacts of microplastics (<1 mm) on marine biota. Microplastics may be mistaken for food items and ingested by a wide variety of organisms. While the effects of ingesting microplastic have been explored for some adult organisms, there is poor understanding of the effects of microplastic ingestion on marine larvae. Here, we investigated the ingestion of polyethylene microspheres by larvae of the sea urchin,Tripneustes gratilla. Ingestion rates scaled with the concentration of microspheres. Ingestion rates were, however, reduced by biological fouling of microplastic and in the presence of phytoplankton food. T. gratilla larvae were able to egest microspheres from their stomach within hours of ingestion. A microsphere concentration far exceeding those recorded in the marine environment had a small nondose dependent effect on larval growth, but there was no significant effect on survival. In contrast, environmentally realistic concentrations appeared to have little effect. Overall, these results suggest that current levels of microplastic pollution in the oceans only pose a limited threat to T. gratilla and other marine invertebrate larvae, but further research is required on a broad range of species, trophic levels, and polymer types. [ABSTRACT FROM AUTHOR]

Kapp, K. J. and E. Yeatman (2018). "Microplastic hotspots in the Snake and Lower Columbia rivers: A journey from the Greater Yellowstone Ecosystem to the Pacific Ocean." Environmental Pollution **241**: 1082-1090.

It is widely understood that microplastics (MPs) are ubiquitous in the marine environment yet less is known about MP abundance in freshwater rivers, particularly those of the western United States. This study documents MP pollution along the Snake River (~1735 km) and from its confluence with the Columbia River to the Pacific Ocean. Grab and plankton net samples (mesh size 100 mum) were collected from the top 25 cm of surface water every 80.5 river km. MPs were identified if they met visual criteria and were verified with the hot needle test. A small representative subset of MPs from the net samples (16.7%) were selected based on appearance for micro-Raman spectroscopy in effort to provide examples of polymer types found in this study. Seventy-five percent of grab samples and 92.8% of net samples contained MPs, with concentrations ranging from 0 to 5.405 MP L⁻¹ and 0 to 0.014 MP L⁻¹ (0 to 13.7 MP m⁻³), respectively. The majority of fragments, films and beads were between 100 mum and 333 mum. This study identifies potential hotspots of MP pollution along the Snake and Lower Columbia rivers and prioritizes areas where more intensive sampling is needed. Sites with low flow or those further down river had higher numbers and the top two hotspots were located in areas with low population density but high agricultural use. Monitoring MP abundance in freshwater systems is important for establishing baseline levels of MP pollution and can direct laboratory toxicology studies in using more environmentally relevant concentrations for a better indication of how MP pollution affects ecosystems. This study documents microplastic (MP) pollution in the Snake River using two sampling methods and identifies MP hotspots as the river flows through multi-use landscapes.

Kappler, A., et al. (2016). "Analysis of environmental microplastics by vibrational microspectroscopy: FTIR, Raman or both?" Analytical & Bioanalytical Chemistry **408**(29): 8377-8391.

The contamination of aquatic ecosystems with microplastics has recently been reported through many studies, and negative impacts on the aquatic biota have been described. For the chemical identification of microplastics, mainly Fourier transform infrared (FTIR) and Raman spectroscopy are used. But up to now, a critical comparison and validation of both spectroscopic methods with respect to microplastics analysis is missing. To close this knowledge gap, we investigated environmental samples by both Raman and FTIR spectroscopy. Firstly, particles and fibres >500 mum extracted from beach sediment samples were analysed by Raman and FTIR microspectroscopic single measurements. Our results illustrate that both methods are in principle suitable to identify microplastics from the environment. However, in some cases, especially for coloured particles, a combination of both spectroscopic methods is necessary for a complete and reliable characterisation of the chemical composition. Secondly, a marine sample containing particles <400 mum was investigated by Raman imaging and FTIR transmission imaging. The results were compared regarding number, size and type of detectable microplastics as well as spectra quality, measurement time and handling. We show that FTIR imaging leads to significant underestimation (about 35 %) of microplastics compared to Raman imaging, especially in the size range <20 mum. However, the measurement time of Raman imaging is considerably higher compared to FTIR imaging. In summary, we propose a further size division within the smaller microplastics fraction into 500-50 mum (rapid and reliable analysis by

FTIR imaging) and into 50-1 mum (detailed and more time-consuming analysis by Raman imaging). Graphical Abstract Marine microplastic sample (fraction <400 mum) on a silicon filter (middle) with the corresponding Raman and IR images.

Kara, A. and E. Demirbel (2012). "Kinetic, Isotherm and Thermodynamic Analysis on Adsorption of Cr(VI) Ions from Aqueous Solutions by Synthesis and Characterization of Magnetic-Poly(divinylbenzene-vinylimidazole) Microbeads." Water, Air, & Soil Pollution **223**(5): 2387-2403.

The magnetic-poly(divinylbenzene-1-vinylimidazole) [m-poly(DVB-VIM)] microbeads (average diameter 53-212 mum) were synthesized and characterized; their use as adsorbent in removal of Cr(VI) ions from aqueous solutions was investigated. The m-poly(DVB-VIM) microbeads were prepared by copolymerizing of divinylbenzene (DVB) with 1-vinylimidazole (VIM). The m-poly(DVB-VIM) microbeads were characterized by N(2) adsorption/desorption isotherms, ESR, elemental analysis, scanning electron microscope (SEM) and swelling studies. At fixed solid/solution ratio the various factors affecting adsorption of Cr(VI) ions from aqueous solutions such as pH, initial concentration, contact time and temperature were analyzed. Langmuir, Freundlich and Dubinin-Radushkvich isotherms were used as the model adsorption equilibrium data. Langmuir isotherm model was the most adequate. The pseudo-first-order, pseudo-second-order, Ritch-second-order and intraparticle diffusion models were used to describe the adsorption kinetics. The apparent activation energy was found to be 5.024 kJ mol(-1), which is characteristic of a chemically controlled reaction. The experimental data fitted to pseudo-second-order kinetic. The study of temperature effect was quantified by calculating various thermodynamic parameters such as Gibbs free energy, enthalpy and entropy changes. The thermodynamic parameters obtained indicated the endothermic nature of adsorption of Cr(VI) ions. Morever, after the use in adsorption, the m-poly(DVB-VIM) microbeads with paramagnetic property were separeted via the applied magnetic force. The magnetic beads could be desorbed up to about 97% by treating with 1.0 M NaOH. These features make the m-poly(DVB-VIM) microbeads a potential candidate for support of Cr(VI) ions removal under magnetic field.

Karaca, H. and C. Koyunoğlu (2010). "Co-liquefaction of Elbistan Lignite and Biomass. Part I: The Effect of the Process Parameters on the Conversion of Liquefaction Products." Energy Sources Part A: Recovery, Utilization & Environmental Effects **32**(6): 495-511.

In this study, the liquefaction of Elbistan lignite and the co-liquefaction of Elbistan lignite with the biomass were examined. The biomass type used in this study consists of waste plastic, waste paper, waste mud, and molasses. The dissolution reactions were carried out in tetralin at 350-425°C under nitrogen atmosphere. Mo(CO)6, Cr(CO)6, Fe2O3, and MoO3 were used as the added catalysts. The particle size ranged from 0.25 mm to 1.5 mm, the isothermal extraction periods ranged from 30 to 150 min, and the solvent/lignite ratio ranged from 1/1 to 9/1. The results indicated that total conversion and oil + gas conversion obtained during the liquefaction largely changed according to catalyst type, biomass type, and reaction temperature. It is understood that other process parameters, such as particle size and solvent/solid ratio, did not have any important effects. According to the obtained results, optimum process parameters were determined as particle size of 1.5 mm, solvent/solid ratio of 3/1, reaction time of 90 min, and reaction temperature of 400°C. Fe2O3 was selected as the most suitable catalyst type and waste paper as biomass type. In order to reduce liquefaction cost in liquefaction operations, results of the experimental studies showed that using coal + biomass instead of coal, nitrogen instead of hydrogen, and recycled solvent instead of fresh solvent would be more suitable.

[ABSTRACT FROM AUTHOR]

Karamata, B., et al. (2004). "Spatially incoherent illumination as a mechanism for cross-talk suppression in wide-field optical coherence tomography." Optics Letters **29**(7): 736-738.

Comparison of two illumination modes for wide-field optical coherence tomography has revealed that spatially coherent illumination generates coherent cross talk, causing significant image degradation, and that spatially incoherent illumination, with an adequate interferometer design, provides an efficient mechanism for suppression of coherent cross talk. This is shown by comparison of a pulsed laser with a thermal light source for a U.S. Air Force resolution target covered with a scattering solution made from microbeads as well as for an ex vivo tooth.

Karami, A. (2017). "Gaps in aquatic toxicological studies of microplastics." Chemosphere **184**: 841-848.

The contamination of aquatic environments with microplastics (MPs) has spurred an unprecedented interest among scientific communities to investigate their impacts on biota. Despite the rapid growth in the number of studies on the aquatic toxicology of MPs, controversy over the fate and biological impacts of MPs is increasingly growing mainly due to the absence of standardized laboratory bioassays. Given the complex features of MPs, such as the diversity of constituent polymers, additives, shapes and sizes, as well as continuous changes in the particle buoyancy as a result of fouling and defouling processes, it is necessary to modify conventional bioassay protocols before employing them for MP toxicity testings. Moreover, several considerations including quantification of chemicals on/in the MP particles, choice of test organisms, approaches for renewing the test solution, aggregation prevention, stock solution preparation, and units used to report MP concentration in the test solution should be taken into account. This critical review suggests some important strategies to help conduct environmentally-relevant MP bioassays.

Karami, A., et al. (2017). "A high-performance protocol for extraction of microplastics in fish." Science of the Total Environment **578**: 485-494.

So far, several classes of digesting solutions have been employed to extract microplastics (MPs) from biological matrices. However, the performance of digesting solutions across different temperatures has never been systematically investigated. In the first phase of the present study, we measured the efficiency of different oxidative agents (NaClO or H 2 O 2), bases (NaOH or KOH), and acids [HCl or HNO 3 ; concentrated and diluted (5%)] in digesting fish tissues at room temperature (RT, 25 °C), 40, 50, or 60 °C. In the second phase, the treatments that were efficient in digesting the biological materials (> 95%) were evaluated for their compatibility with eight major plastic polymers (assessed through recovery rate, Raman spectroscopy analysis, and morphological changes). Among the tested solutions, NaClO, NaOH, and diluted acids did not result in a satisfactory digestion efficiency at any of the temperatures. The H 2 O 2 treatment at 50 °C efficiently digested the biological materials, although it decreased the recovery rate of nylon-6 (NY6) and nylon-66 (NY66) and altered the colour of polyethylene terephthalate (PET) fragments. Similarly, concentrated HCl and HNO 3 treatments at RT fully digested the fish tissues, but also fully dissolved NY6 and NY66, and reduced the recovery rate of most or all of

the polymers, respectively. Potassium hydroxide solution fully eliminated the biological matrices at all temperatures. However, at 50 and 60 °C, it degraded PET, reduced the recovery rate of PET and polyvinyl chloride (PVC), and changed the colour of NY66. According to our results, treating biological materials with a 10% KOH solution and incubating at 40 °C was both time and cost-effective, efficient in digesting biological materials, and had no impact on the integrity of the plastic polymers. Furthermore, coupling this treatment with NaI extraction created a promising protocol to isolate MPs from whole fish samples. [ABSTRACT FROM AUTHOR]

Karami, A., et al. (2017). "The presence of microplastics in commercial salts from different countries." Scientific Reports **7**: 46173.
The occurrence of microplastics (MPs) in saltwater bodies is relatively well studied, but nothing is known about their presence in most of the commercial salts that are widely consumed by humans across the globe. Here, we extracted MP-like particles larger than 149 mum from 17 salt brands originating from 8 different countries followed by the identification of their polymer composition using micro-Raman spectroscopy. Microplastics were absent in one brand while others contained between 1 to 10 MPs/Kg of salt. Out of the 72 extracted particles, 41.6% were plastic polymers, 23.6% were pigments, 5.50% were amorphous carbon, and 29.1% remained unidentified. The particle size (mean +/- SD) was 515 +/- 171 mum. The most common plastic polymers were polypropylene (40.0%) and polyethylene (33.3%). Fragments were the primary form of MPs (63.8%) followed by filaments (25.6%) and films (10.6%). According to our results, the low level of anthropogenic particles intake from the salts (maximum 37 particles per individual per annum) warrants negligible health impacts. However, to better understand the health risks associated with salt consumption, further development in extraction protocols are needed to isolate anthropogenic particles smaller than 149 mum.

Karbalaei, S., et al. (2019). "Abundance and characteristics of microplastics in commercial marine fish from Malaysia." Marine Pollution Bulletin **148**: 5.
Plastic debris is widespread and ubiquitous in the marine environment and ingestion of plastic debris by marine organisms is well-documented. Viscera and gills of 110 individual marine fish from 11 commercial fish species collected from the marine fish market were examined for presence of plastic debris. Isolated particles were characterized by Raman spectroscopy, and elemental analysis was assessed using energy-dispersive X-ray spectroscopy (EDX). Nine (of 11) species contained plastic debris. Out of 56 isolated particles, 76.8% were plastic polymers, 5.4% were pigments, and 17.8% were unidentified. Extracted plastic particle sizes ranged from 200 to 34,900 μm (mean = 2600 μm ±7.0 SD). Hazardous material was undetected using inorganic elemental analysis of extracted plastic debris and pigment particles. The highest number of ingested microplastics was measured in Eleutheronema tridactylum and Clarias gariepinus, suggesting their potential as indicator species to monitor and study trends of ingested marine litter.

Karbalaei, S., et al. (2020). "Analysis and inorganic composition of microplastics in commercial Malaysian fish meals." Marine Pollution Bulletin **150**: 110687.

Presence of microplastics (MPs) in a broad range of wild and cultured marine organisms is well-documented, but transfer mechanisms by which cultured organisms are contaminated with MPs is poorly understood. MP loads in three Malaysian commercial brands of fish meal were investigated. Chemical composition of extracted MP-like particles was confirmed using micro-Raman spectroscopy. Inorganic composition of MPs and pigment particles were assessed through energy-dispersive X-ray spectroscopy (EDX). Out of 336 extracted particles, 64.3% were plastic polymers, 25% pigment particles, 4.2% non-plastic items, and 6.5% were unidentified. Fragments were the dominant form of MPs (78.2%) followed by filaments (13.4%) and films (8.4%). This study demonstrates that cultured organisms could be exposed to high levels of MPs via MP contaminated fish/shellfish used in fish meal production. Fish meal replacement with other sources of protein including meat meals and plant-based meals may mitigate MP exposure to cultured or farmed organisms.

Karbalaei, S., et al. (2018). "Occurrence, sources, human health impacts and mitigation of microplastic pollution." Environmental Science & Pollution Research **25**(36): 36046-36063.
The presence and accumulation of plastic and microplastic (MP) debris in the natural environment is of increasing concern and has become the focus of attention for many researchers. Plastic debris is a prolific, long-lived pollutant that is highly resistant to environmental degradation, readily adheres hydrophobic persistent organic pollutants and is linked to morbidity and mortality in numerous aquatic organisms. The prevalence of MPs within the natural environment is a symptom of continuous and rapid growth in synthetic plastic production and mismanagement of plastic waste. Many terrestrial and marine-based processes, including domestic and industrial drainage, maritime activities agricultural runoff and wastewater treatment plants (WWTPs) effluent, contribute to MP pollution in aquatic environments. MPs have been identified in food consumed by human and in air samples, and exposure to MPs via ingestion or inhalation could lead to adverse human health effects. Regulations in many countries have already been established or will soon be implemented to reduce MPs in aquatic environments. This review focuses on the occurrence, sources, and transport of MPs in terrestrial and aquatic environments to highlight potential human health effects, and applicable regulations to mitigate impacts of MPs. This study also highlights the importance of personality traits and cognitive ability in reducing the entry of MPs into the environment.

Karidis, A. (2019). "What Emerging Contaminants are on Whose Radar?" Waste360: N.PAG-N.PAG.
"Emerging contaminants of concern" is now a buzz term in the solid waste management arena. Three main leachate treatment technologies address the problems around emerging contaminants to a degree: reverse osmosis, activated carbon and ion exchange. "It means we will need to take steps to remove contaminants before they release to the environment ... And I think landfill owners need to look at whether leachate is a significant contributor to emerging contaminants entering wastewater treatment plants. [Extracted from the article]

Karidis, A. (2019). "Why EFS-Plastics is on the Chase for Mixed Bales." Waste360: N.PAG-N.PAG.

The article discusses Elastic File System (EFS) plastics on looking for making mixed bales of plastics. Topics include views of Eadaoin Quinn, EFS-Plastics director of business development and procurement on looking for plastics which working with materials; company which makes and sells pellets for automotive, construction and agricultural commodities; and offer reusable bags with least 20 percent of post consumer content.

Karidis, A. (2020). "Manufacturer Hub Labels Becomes Landfill Free." Waste360: N.PAG-N.PAG.

The Hagerstown, Md.-based label manufacturer has become landfill free, despite its place in an industry notorious for generating high volumes of hard-to-recycle and impossible-to-recycle materials. These are materials the recycling market often no longer accepts as it [unlike SRF manufacturers] has no market for them, says Dyson. [Extracted from the article]

Karisathan Sundararajan, N. and A. R. B. Ammal (2018). "Improvement studies on emission and combustion characteristics of DICI engine fuelled with colloidal emulsion of diesel distillate of plastic oil, TiO₂ nanoparticles and water." Environmental Science & Pollution Research **25**(12): 11595-11613.

Experimentation was conducted on a single cylinder CI engine using processed colloidal emulsions of TiO₂ nanoparticle-water-diesel distillate of crude plastic diesel oil as test fuel. The test fuel was prepared with plastic diesel oil as the principal constituent by a novel blending technique with an aim to improve the working characteristics. The results obtained by the test fuel from the experiments were compared with that of commercial petro-diesel (CPD) fuel for same engine operating parameters. Plastic oil produced from high density polyethylene plastic waste by pyrolysis was subjected to fractional distillation for separating plastic diesel oil (PDO) that contains diesel range hydrocarbons. The blending process showed a little improvement in the field of fuel oil-water-nanometal oxide colloidal emulsion preparation due to the influence of surfactant in electrostatic stabilization, dielectric potential, and pH of the colloidal medium on the absolute value of zeta potential, a measure of colloidal stability. The engine tests with nano-emulsions of PDO showed an increase in ignition delay (23.43%), and decrease in EGT (6.05%), BSNO_x (7.13%), and BSCO (28.96%) relative to PDO at rated load. Combustion curve profiles, percentage distribution of compounds, and physical and chemical properties of test fuels ascertains these results. The combustion acceleration at diffused combustion phase was evidenced in TiO₂ emulsion fuels under study.

Karkanorachaki, K., et al. (2018). "Plastic pellets, meso- and microplastics on the coastline of Northern Crete: Distribution and organic pollution." Marine Pollution Bulletin **133**: 578-589.

Plastic pollution in the marine environment is one of the foremost environmental problems of our time, as it affects wildlife and human health both directly and indirectly through the effects of contaminants carried by microplastics. This study investigates the temporal and spatial distribution of plastic pellets and fragments in sandy beaches along the coastline of Northern Crete, during 2013. Their densities varied throughout the year in each beach, with highest densities during the summer and towards the upper parts of the beaches. The concentrations of 16 polycyclic aromatic hydrocarbons (PAHs) sorbed on microplastics sampled from nine sandy

beaches of Northern Crete was quantified using Gas chromatography - Ion Trap Mass Spectrometry (GC-ITMS). PAHs concentrations ranged from non-detectable levels to 1592ng/g and fluctuated between sampling periods. Based on the observed patterns of meso- and microplastics distribution, practical guidelines are proposed to minimize the entrance of microplastics into the seawater wherefrom they are exceptionally difficult to collect, if mitigation actions are to be applied.

Karlsson, T. M., et al. (2019). "Comparison between manta trawl and in situ pump filtration methods, and guidance for visual identification of microplastics in surface waters." Environmental Science & Pollution Research **18**: 18.

Owing to the development and adoption of a variety of methods for sampling and identifying microplastics, there is now data showing the presence of microplastics in surface waters from all over the world. The difference between the methods, however, hampers comparisons, and to date, most studies are qualitative rather than quantitative. In order to allow for a quantitative comparison of microplastics abundance, it is crucial to understand the differences between sampling methods. Therefore, a manta trawl and an in situ filtering pump were compared during realistic, but controlled, field tests. Identical microplastic analyses of all replicates allowed the differences between the methods with respect to (1) precision, (2) concentrations, and (3) composition to be assessed. The results show that the pump gave higher accuracy with respect to volume than the trawl. The trawl, however, sampled higher concentrations, which appeared to be due to a more efficient sampling of particles on the sea surface microlayer, such as expanded polystyrene and air-filled microspheres. The trawl also sampled a higher volume, which decreased statistical counting uncertainties. A key finding in this study was that, regardless of sampling method, it is critical that a sufficiently high volume is sampled to provide enough particles for statistical evaluation. Due to the patchiness of this type of contaminant, our data indicate that a minimum of 26 particles per sample should be recorded to allow for concentration comparisons and to avoid false null values. The necessary amount of replicates to detect temporal or spatial differences is also discussed. For compositional differences and size distributions, even higher particle counts would be necessary. Quantitative measurements and comparisons would also require an unbiased approach towards both visual and spectroscopic identification. To facilitate the development of such methods, a visual protocol that can be further developed to fit different needs is introduced and discussed. Some of the challenges encountered while using FTIR microspectroscopic particle identification are also critically discussed in relation to specific compositions found.

Karlsson, T. M., et al. (2017). "Screening for microplastics in sediment, water, marine invertebrates and fish: method development and microplastic accumulation." Marine Pollution Bulletin **122**(1/2): 403-408.

Measurements of microplastics in biota and abiotic matrices are key elements of exposure and risk assessments for this emerging environmental pollutant. We investigated the abundance of microplastics in field-collected biota, sediment and water. An improved sediment extraction method, based on density separation was developed. For analysis of microplastics in biota we found that an adapted enzymatic digestion protocol using proteinase K performed best, with a 97% recovery of spiked plastic particles and no observed degradation effects on the plastics in subsequent Raman analysis. Field analysis revealed that 8 of 9 tested invertebrate species from the North Sea and 68% of analyzed individuals of brown trout (Salmo trutta) from the Swedish West Coast had microplastics in them. Based on the number of plastic particles per kg d.w. the microplastic concentrations found in mussels were approximately a thousand-fold higher compared to those in sediment and surface water samples from the same location.

Karmana, E., et al. (1997). "The microsortation of high loadings of post-consumer mixed polyolefins using liquid carbon dioxide in a slightly agitated, batch apparatus." Resources, Conservation and Recycling **20**(3): 143-152.

The microsortation of clean, dry, mixed, shredded, post-consumer polyolefins can be accomplished using near-critical carbon dioxide as a float-sink medium. At high loadings of plastics, however, buoyant forces alone are not sufficient to break up the aggregates of interlocking shredded plastic particles. Therefore a close-clearance impeller must be used to agitate the mixed plastics during the batch separation. This slight agitation permits these irregularly shaped chips to either float or sink without being hindered by surrounding chips. The separation apparatus operates most efficiently when the plastics are charged to a level that corresponds to the top of the highest blade of a large-diameter multiple-pitched blade impeller that rotates at 15 rpm. A post-consumer flake mixture of 85% HDPE/15% PP can be sorted into HDPE and PP streams of 99 + % purity at loadings up to 56 volume per cent. In the absence of an impeller, high purity separations can be achieved at loadings of only two volume per cent. This dramatic increase in the loading reduces the estimated processing cost of mixed polyolefins to $ 0.03-0.05/lb, enhancing the economic feasibility of this high pressure, CO<inf>2</inf>-based microsortation process.

Karthick, T., et al. (2016). "Biodegradation of plastic by Bacillus subtilis isolated from polythene polluted soil." World Journal of Pharmaceutical Research **5**(4): 1148-1153.

Polyethylene is a commonly used raw material in manufacturing plastics, which are non-biodegradable substances that stay in the environment for an infinite period of time. According to the Central Pollution Control Board (CPCB), India generates nearly 56 lakh tonnes of plastic waste each year with only 60% of it being recycled and reused. The remaining 40% causes not just littering but it is hazardous to freshwater, marine and terrestrial ecosystems. Bacillus subtilis is the most efficient soil microbes which degrade polyethylene without the need of applying any external treatments and may provide an ecofriendly solution for management of plastic waste. Plastic degradation by microbes due to the activity of enzymes that cause cleavage of the polymer chains into monomers and oligomers. The degradation of plastic by Bacillus subtilis is analysed using liquid (shaker) culture method. Microbes degrade plastic more in 1 month period.

Karthik, R., et al. (2018). "Microplastics along the beaches of southeast coast of India." Science of the Total Environment **645**: 1388-1399.

Occurrence of microplastics (plastic debris <5mm) along the coast is a growing concern worldwide, due to increased input of discarded wastes from various sources. In order to evaluate the extent of microplastic pollution on the sandy beaches (25 locations) along Tamil Nadu coast (1076km), India, microplastic debris were quantified and categorized into four different size classes. The beaches were classified according to potential sources of pollution i.e. riverine, tourism and fisheries. Beach samples collected from the high tide line contained significantly higher abundance of microplastic than at the low tide line. Beaches adjacent to rivers exhibited relatively higher microplastic abundance compared to those influenced by tourism and fishing activities. Out of the total detected debris, plastic fragments were the maximum (47-50%), followed by line/fibres (24-27%) and foam (10-19%) materials. Fourier Transform Infrared Spectroscopy (FTIR) analysis revealed that polyethylene, polypropylene, and polystyrene were the main types of microplastics present in these beaches. Gut content analysis of commercially important fishes, collected from the coastal waters, revealed microplastics

ingestion in 10.1% of fishes. The results indicate that microplastics accumulation in the coastal environment, especially close to the river mouths, may be a serious concern, due to its ability to enter into the marine food web and highlights the necessity of microplastics screening from estuarine, coastal waters and other potential sources.

Karthik Raja, M., et al. (2012). "Formulation, characterization and evaluation of aceclofenac-alginate/potato starch micro beads." Indian Journal of Novel Drug Delivery **4**(2): 151-156.
Microencapsulation is a process by which very tiny droplets or particles of liquid or solid material are surrounded or coated with a continuous film of polymeric material. It means of converting liquids to solids, of altering colloidal and surface properties. The capsule protects the active ingredient from its surrounding environment until an appropriate time and material escapes through the capsule wall either by rupture, dissolution, melting or diffusion. In the view of converting the active pharmaceutical ingredients into dosage forms suitable for administration, the present study is an attempt to formulate a hydrogel bead of micron size by ionotrophic gelation technique using potato starch as a release retardant and thereby increasing the release time of the encapsulated drug and providing a delayed/controlled release formulation. It was observed that increase in polymer concentration, the drug release and particle size was gradually decreased. The formulation were investigated for various parameters life particle size, micrometric properties, surface morphology by SEM, incorporate efficiency and invitro release study. With the obtained results of mentioned parameter it reveals that microbeads with high potato starch concentration (F1 & F2) show delayed release of aceclofenac. Decrease in concentration of alginate results in reduced size of the microbeads along with high efficiency, thus satisfied the need of formulation of delayed release aceclofenac microbeads. © KESS All rights reserved.

Kase, J. A., et al. (2016). "Rapid identification of Shiga toxin-producing Escherichia coli O serogroups from fresh produce and raw milk enrichment cultures by Luminex bead-based suspension array." Journal of Food Protection **79**(9): 1623-1629.
The U.S. Food and Drug Administration's Bacteriological Analytical Manual (BAM) Chapter 4a describes a Luminex microbead-based suspension array used to screen colonies for 11 clinically relevant Shiga toxin-producing Escherichia coli (STEC) serogroups: O26, O45, O91, O103, O104, O111, O113, O121, O128, O145, and O157. We evaluated the usefulness of this method to identify STEC-positive enrichment samples before agar plating. Twelve E. coli strains were added to three types of fresh produce (bagged baby spinach, alfalfa sprouts, and cilantro) at levels near the detection limit of the test. A subset of these strains (six O serogroups) was similarly evaluated in raw milk. For comparison, portions of each of the 168 enrichment cultures were analyzed for serogroup by a real-time PCR assay and a Bio-Plex 200 assay with the bead-based suspensions. No falsepositive results were obtained. Of the 112 samples with a reported cycle threshold (C_T) value, 101 undiluted, diluted, or extracted enrichment cultures also produced ratios above 5.0 in the Bio-Plex assay. When PCR C_T values approached or were greater than 35, Bio-Plex detection became less reliable. Using undiluted or extracted enrichment cultures resulted in a significantly larger number of positive results. With the same enrichment material prepared for real-time PCR analysis as described in the BAM Chapter 4a, the STEC microbead-based suspension array can accurately screen food enrichment cultures.

Kasi, D., et al. (2017). "Cell-free translational screening of an expression sequence tag library of Clonorchis sinensis for novel antigen discovery." Biotechnology Progress **33**(3): 832-837.
The rapidly evolving cloning and sequencing technologies have enabled understanding of

genomic structure of parasite genomes, opening up new ways of combatting parasite-related diseases. To make the most of the exponentially accumulating genomic data, however, it is crucial to analyze the proteins encoded by these genomic sequences. In this study, we adopted an engineered cell-free protein synthesis system for large-scale expression screening of an expression sequence tag (EST) library of Clonorchis sinensis to identify potential antigens that can be used for diagnosis and treatment of clonorchiasis. To allow high-throughput expression and identification of individual genes comprising the library, a cell-free synthesis reaction was designed such that both the template DNA and the expressed proteins were co-immobilized on the same microbeads, leading to microbead-based linkage of the genotype and phenotype. This reaction configuration allowed streamlined expression, recovery, and analysis of proteins. This approach enabled us to identify 21 antigenic proteins. © 2017 American Institute of Chemical Engineers Biotechnol. Prog., 33:832-837, 2017

Kaske, M. and W. v. Engelhardt (1990). "The effect of size and density on mean retention time of particles in the gastrointestinal tract of sheep." British Journal of Nutrition **63**(3): 457-465.

The selective retention of particles in the reticulo-rumen and in the gastrointestinal tract distal to the reticulo-rumen was studied in fistulated sheep maintained on a roughage diet. Polyethylene glycol and plastic particles of different lengths (1 and 10 mm) and densities (0.92, 1.03, 1.22 and 1.44 g/ml) were given by mouth or into the omasum. The mean retention time in the reticulo-rumen (MRT_{RR}) of 1 mm long particles with a density of about 1.0 g/ml was about 67 h, that is eight times longer than the MRT_{RR} of fluid; the heavier particles were retained only 3 times longer than fluid. Particles with a length of 10 mm were retained in the reticulo-rumen 19 to 28 h longer than 1 mm long particles of the same density. Particles with a length of 10 mm were reduced to smaller particles (0.5 to 4 mm) due to rumination. Multiple regression analysis indicated that particle density and particle size accounted for 59 and 28% of the total variation of MRT_{RR}, respectively. The mean retention time distal to the reticulo-rumen of 1 and 10-mm long particles with a density near 1.0 g/ml was 18 to 19 h, similar to that of fluid (16 h). The heavier particles were retained about 3 to 8 h longer.

Kaske, M., et al. (1992). "The influence of density and size of particles on rumination and passage from the reticulo-rumen of sheep." British Journal of Nutrition **67**(2): 235-244.

Plastic particles with different densities (0.92, 1.03, 1.22 and 1.44 g/ml) and sizes (1, 10 and 20 mm) were introduced by cannula into the rumen of sheep fed on a roughage diet. The rumen was emptied 12 and 24 h after the introduction of particles, and the contents were replaced by the same amount of rumen contents without plastic particles. The proportions of particles which left the reticulo-rumen (RR) during the experimental period were estimated by collecting faeces during the following 5 days. Non-ruminated particles were separated from dried RR contents and faeces. Large particles were ruminated independently of particle size and density within the investigated range. After 12 and 24 h, 59 and 81%, respectively, of the particles initially introduced were comminuted due to rumination. During the 12 h period about 4 times as many particles with a density of 1.44 g/ml passed from the RR into the omasum compared with particles with a density of 0.92 or 1.03 g/ml. Three to 10 times more 1 mm particles were excreted than originally-large particles (10 and 20 mm). Particles introduced with an original size of 10 or 20 mm were recovered mostly comminuted in the faeces. In a further experiment the rumens of 8 sheep were emptied and filled with a buffer solution. Plastic particles (10 g) of each length (1, 5, 10 and 20 mm; all with a density of 1.03 g/ml) were introduced into the ventral rumen. Sedimentation of particles was prevented by gassing the solution in the RR. Of the initially introduced particles, 31.9, 25.4, 12.7 and 1.5% of the 1, 5, 10 and 20-mm long particles, respectively, left the RR within 4 h. It is concluded that rumination of particles is independent of particle density and size within the tested range. The probability of particles leaving the RR increases with the higher particle density and with the smaller size. If particle sedimentation is prevented in the RR even 10-mm long particles can leave the RR in considerable amounts.

Kaske, M. and A. Midasch (1997). "Effects of experimentally-impaired reticular contractions on digesta passage in sheep." British Journal of Nutrition **78**(1): 97-110.

Feed intake, mean retention time of luid and plastic particles in the reticulo-rumen, rumen fluid volume, forestomach motility and particle size distribution in the faeces were determined in 5 rumen-fistulated female Blackhead sheep fed on hay ad libitum (experiment 1). The same variables were determined when reticular movements were impaired for 10 days by introducing a silicone-covered lead weight (500 g) into the reticulum (experiment 2). As feed intake significantly decreased in experiment 2 by 27% compared with experiment 1, the sheep received in an additional experiment exactly the amount of feed which had been consumed during experiment 2 and measurements were repeated without impairing reticular movements (experiment 3). The introduction of the weight did not affect the frequency of A- or B-cycles, but elevation of the reticular floor in a cranio-dorsal direction during the biphasic contraction was significantly reduced. The pattern of marker excretion indicated a significantly changed composition of reticular outflow in experiment 2 compared with experiments 1 and 3. During experiment 2, rumen fluid volume was similar to that in experiment 1 but about 25% higher ($P<0.05$) than that in experiment 3; the amount of large feed particles in the faeces was increased ($P<0.05$) compared with experiment 1 (+49%) and experiment 3 (+7%). In at least 2 sheep, abomasal emptying was inhibited during experiment 2, as indicated by an enlarged impacted abomasum. It is concluded that the results emphasize the central role of reticular motility for the separation of particles in the forestomach, the outflow of digesta from the reticulo-rumen and transpyloric digesta flow.

Kaspersen, J. (2013). "One Word: Plastics." Stormwater **14**(8): 6-6.

The author expresses her concern over the growing problem of managing plastic trash. She describes how the nonbiodegradability of plastic enters the waters, gets ingested by animals and eventually by humans. She points out other sources of plastics such as microbeads in cosmetics. New suggestions include sifting the plastic residue by the stormwater management groups, imposing greater responsibility upon plastic producers and banning the use of plastic bags are included.

Kass, M. J. (2019). "Fishing for Plastic: EU Targets Marine Pollution." Natural Resources & Environment **34**(1): 58-59.

The article deals with the effort by the European Union (EU) to address plastic marine litter. The EU has made the move in response to the implications of plastics for the ocean environment, coastal biodiversity and human health. The European Commission's legislative proposal has been approved by the European Parliament to regulate common single-use plastic products.

Kass, W. (2004). "Geohydrological marking techniques. (Lehrbuch der Hydrogeologies Band 9) [German]." Geohydrologische Markierungstechnik **557**.

This book is divided into 5 chapters on definitions of artificial and natural markers (tracers); different tracers (such as paints, salts, smells, radio-active components, Lycopodium spores, fluorescent plastic particles, bacteria); preparation and implementation of tracer studies;

analysis of results. The last chapter provides many examples of the use of tracers in studies of groundwater, gletschers, surface water, deep water, infiltration, and drinking water.

Kassem, A. A., et al. (2015). "Development of mucoadhesive microbeads using thiolated sodium alginate for intrapocket delivery of resveratrol." International Journal of Pharmaceutics **487**(1-2): 305-313.

Resveratrol (Res), a polyphenolic phytoalexin, had shown a promising therapeutic efficacy towards treatment of periodontal disease in vitro. This work aims to develop Res microbeads with strong mucoadhesion using thiolated alginate (TA) for local treatment of periodontal pockets. TA was synthesized by conjugating sodium alginate (A) with thioglycolic acid. Product was evaluated by IR and DSC. Both A and A:TA Res microbeads with different ratios were prepared by ionotropic gelation method. Formulations were evaluated regarding their entrapment efficiency (%EE), swelling index (SI), in vitro drug release and kinetics. Selected formula was examined for its mucoadhesion by ex vivo wash-off method, surface morphology using scanning electron microscope (SEM) and stability against light. Clinical evaluation is running.Formation of TA was confirmed. %EE for all formulations ranged from 83.72 to 104.54%. Results revealed a significant lower SI for TA rich formulation (A/TA 1:1) along with slower release rate and zero-order kinetics, in addition to powerful mucoadhesion; 26% remaining of microbeads after 1 h, compared to 2% for A microbeads. SEM micrographs showed a rough surface with drug precipitation. The formula maintained its %EE after 5 h exposure to direct sunlight. A/TA 1:1 mucoadhesive Res microbeads could be exploited as a prolonged drug release devices for intrapocket application. Copyright © 2015 Published by Elsevier B.V.

Kassis, A. I., et al. (2019). "Immuno-genomic detection and prognostication of aggressive prostate cancer phenotypes by next-generation RNA sequencing." Cancer Research. Conference: American Association for Cancer Research Annual Meeting **79**(13 Supplement).

Prostate cancer (PC) is the most common non-cutaneous malignancy in men. The prediction of outcome based on multicore biopsy specimens is problematic, mainly due to tumor multifocality compounded by intratumoral heterogeneity. Since 1) cancer assays compare a patient's profile to that of individuals unknown to have PC, and 2) baseline signatures of the diseased man are specific to his genome while those of the controls are specific to theirs, such intrinsic inter-individual genomic differences have impeded valid disease signature identification. Thus, methods that filter out inter-individual "noise" not related to the disease should enhance the identification of a robust prognostic PC signature. OBJECTIVE(S): Assess the ability of a novel immuno-genomics blood-based RNA expression assay for PC prognosis. The method, which uses a proprietary algorithm to interrogate CD2 and CD14 cells, is a real-time surveillance of gene expression changes consequent to PC that filters out intrinsic inter-individual genomic signatures not related to PC. We expect this Subtraction-Normalized Expression of Phagocytes (SNEP) approach to be valuable in making apt clinical decisions and stratifying patients with aggressive PC (need life-saving treatments) from those with indolent disease (safe for active surveillance). PATIENTS: Men were eligible for enrollment if they 1) were determined by their physician to have a risk profile that warrants a prostate biopsy (Pre-Biopsy blood draw), 2) had a biopsy >90 d prior to but <1 yr of study entry and scheduled for but have not undergone therapy post biopsy blood draw, and 3) are on active surveillance such that a biopsy will be done within the next year. METHOD(S): Peripheral blood samples (n = 713) were collected in purpletop Vacutainer tubes. CD2 and CD14 cells were isolated 4 h later using Miltenyi's MACS Microbeads and mRNA was extracted using the Qiagen's miRNEasy Mini Kit. The raw (FASTQ) RNA-Seq data (Illumina) was trimmed (Trimmomatic), aligned (Bowtie2), and quantified (Express). Transcripts with quantifiable expression changes between samples from the two cell types were identified

following differential expression analysis using a linear model and cell type as endpoints. This resulted in the final set of 10,643 transcripts with <10% False Discovery Rate (FDR) and >1.5 absolute fold change. RESULT(S): We identified genomic signatures in biopsy-positive patients that are predictive of Gleason grade, Cores Positive (CP), Maximum Involvement (MI), and an Aggressiveness Index (AI - an aggregate of the 3 endpoints). The signature scores were significantly associated with GG (tau 0.427, p 1.3x10⁻²⁵), CP (tau 0.275, p3.3x10⁻¹¹), MI (tau 0.564, p 8.5x10⁻⁴⁴), and AI (tau 0.517, p 7.2x10³⁷). Interestingly, 1) certain transcripts were found to be specific to each endpoint (108 for GG, 88 for CP, 93 for MI, and 102 for AI), 2) some pairwise overlap was seen - highlighting the complementary of the three endpoints, and 3) no overall overlap was detected between all four endpoints. CONCLUSION(S): The multiple genomic signatures identified from CD2/CD14 RNA expression ratios - per SNEP assay - gives a prognostic summary that is comparable to prostate biopsy information including tumor grade, size/volume, and heterogeneity, and leads to the development of an aggressiveness signature that if validated will affect patient care decisions.

Kassouf, A., et al. (2014). "Rapid discrimination of plastic packaging materials using MIR spectroscopy coupled with independent components analysis (ICA)." Waste Management **34**(11): 2131-2138.

Plastic packaging wastes increased considerably in recent decades, raising a major and serious public concern on political, economical and environmental levels. Dealing with this kind of problems is generally done by landfilling and energy recovery. However, these two methods are becoming more and more expensive, hazardous to the public health and the environment. Therefore, recycling is gaining worldwide consideration as a solution to decrease the growing volume of plastic packaging wastes and simultaneously reduce the consumption of oil required to produce virgin resin. Nevertheless, a major shortage is encountered in recycling which is related to the sorting of plastic wastes. In this paper, a feasibility study was performed in order to test the potential of an innovative approach combining mid infrared (MIR) spectroscopy with independent components analysis (ICA), as a simple and fast approach which could achieve high separation rates. This approach (MIR-ICA) gave 100% discrimination rates in the separation of all studied plastics: polyethylene terephthalate (PET), polyethylene (PE), polypropylene (PP), polystyrene (PS) and polylactide (PLA). In addition, some more specific discriminations were obtained separating plastic materials belonging to the same polymer family e.g. high density polyethylene (HDPE) from low density polyethylene (LDPE). High discrimination rates were obtained despite the heterogeneity among samples especially differences in colors, thicknesses and surface textures. The reproducibility of the proposed approach was also tested using two spectrometers with considerable differences in their sensitivities. Discrimination rates were not affected proving that the developed approach could be extrapolated to different spectrometers. MIR combined with ICA is a promising tool for plastic waste separation that can help improve performance in this field; however further technological improvements and developments are required before it can be applied at an industrial level given that all tests presented here were performed under laboratory conditions.

Kataoka, T., et al. (2019). "Assessment of the sources and inflow processes of microplastics in the river environments of Japan." Environmental Pollution **244**: 958-965.

The numerical and mass concentrations of microplastics collected at 36 sites on the surfaces of 29 Japanese rivers were mapped and compared with four basin characteristics (basin area, population density, and urban and agricultural ratios) and six water quality parameters (pH, biochemical oxygen demand (BOD), suspended solids (SS), dissolved oxygen (DO), total nitrogen

(T-N), and total phosphorus (T-P)) in each river basin. Microplastics were found in 31 of the 36 sites, indicating that some plastics fragment into small pieces before reaching the ocean. The microplastic concentrations are significantly correlated with urbanisation and population density, indicating that the microplastic concentrations in the river depend on human activities in the river basin. Furthermore, we found a significant relationship between the numerical and mass concentrations and BOD, which is an environmental indicator of river pollution. This result demonstrates that microplastic pollution in river environments has progressed more in polluted rivers with poor water quality than in rivers with good water quality, leading to the conclusion that the sources and inflow processes of microplastics in river environments are similar to those of other pollutants. Our findings can help identify potential sources (i.e., point and non-point sources) of fragmented microplastics to improve waste management in Japan and model the transport fluxes of fragmented microplastics in Japanese rivers using water quality parameters and basin characteristics. Graphical abstract Image 1 Highlights • Microplastics (MPs) were collected at 36 sites on the surface of 29 Japanese rivers. • The concentrations of MPs in count and mass were investigated and mapped. • MPs concentrations are significantly correlated with biochemical oxygen demand (BOD). • The pollution by MPs has progressed in polluted rivers with poor water quality. • The outflow sources and processes of MPs are similar to those of pollutants. [ABSTRACT FROM AUTHOR]

Katare, R., et al. (2013). "Perivascular delivery of encapsulated mesenchymal stem cells improves postischemic angiogenesis via paracrine activation of VEGF-A." Arteriosclerosis, Thrombosis & Vascular Biology **33**(8): 1872-1880.

OBJECTIVE: To test the therapeutic activity of perivascular transplantation of encapsulated human mesenchymal stem cells (MSCs) in an immunocompetent mouse model of limb ischemia.

APPROACH AND RESULTS: CD1 mice underwent unilateral limb ischemia, followed by randomized treatment with vehicle, alginate microbeads (MBs), MB-encapsulated MSCs (MB-MSCs), or MB-MSCs engineered with glucagon-like peptide-1. Treatments were applied directly in the perivascular space around the femoral artery. Laser Doppler and fluorescent microsphere assessment of blood flow showed a marked improvement of perfusion in the MB-MSCs and MB-MSCs engineered with glucagon-like peptide-1 groups, which was associated with increased foot salvage particularly in MB-MSCs engineered with glucagon-like peptide-1-treated mice. Histological analysis revealed increased capillary and arteriole density in limb muscles of the 2 MSC groups. Furthermore, MB-MSCs engineered with glucagon-like peptide-1 and, to a lesser extent, MB-MSC treatment increased functional arterial collaterals alongside the femoral artery occlusion. Analysis of expressional changes in ischemic muscles showed that MB-MSC transplantation activates a proangiogenic signaling pathway centered on vascular endothelial growth factor A. In contrast, intramuscular MB-MSCs caused inflammatory reaction, but no improvement of reparative vascularization. Importantly, nonencapsulated MSCs were ineffective either by intramuscular or perivascular route.

CONCLUSIONS: Perivascular delivery of encapsulated MSCs helps postischemic reperfusion. This novel biological bypass method might be useful in patients not amenable to conventional revascularization approaches.

Katare, R., et al. (2012). "Perivascular delivery of microbead-encapsulated mesenchymal stem cells improves perfusion recovery after limb ischemia." Circulation. Conference: American Heart Association **126**(21 SUPPL. 1).

Objective: Stem cell therapy holds promise for the treatment of peripheral vascular disease. However, the optimal method for cell delivery to achieve maximum therapeutic effect, i.e. efficient collateralization, is still debated. We tested the feasibility and efficacy of perivascular application of mesenchymal stem cells (MSCs) as a novel method to bypass the artery blockage. Methods and Results: Ten week-old CD1 mice underwent unilateral limb ischemia by femoral artery occlusion, followed by randomized treatment with vehicle (V), microbead-encapsulated MSCs (MB-MSCs) or microbeads alone (MB) injected in the perivascular space around the femoral artery and vein (n=12 in each group) at the site of vascular occlusion. Laser Doppler showed a marked improvement of blood flow recovery in the MB-MSCs group (P<0.001 vs. V or MB, from day 7 to 21 after ischemia). Final measurement of muscular blood flow by fluorescent microspheres confirmed the improvement in MB-MSCs group (0.960.06 vs. 0.820.02 ml/gm of tissue in V and vs. 0.850.01 ml/gm in MB, P<0.001). Histological analysis at day 21 revealed increased capillary (88015 vs. 67316/mm2in V and vs. 73512/mm2in MB) and arteriole density (150.5 vs. 100.4/mm2 in V and vs. 100.3/mm2 in MB, P<0.001 for both comparisons). Whole mount IHC demonstrated numerous functional capillaries and arterioles bridging the space between MB-MSCs and the ischemic muscles at the site of femoral artery occlusion (Figure). These effects were absent in the group treated with microbeads alone. Cytometry bead array and RT-PCR profiler analysis showed activation of genes regulating angiogenesis pathway in the MB-MSCs group. Conclusion(s): We newly show the feasibility and efficacy of perivascular delivery of MSCs to enhance peri-occlusional collaterals and improve reperfusion following limb ischemia. This novel biological bypass method might be particularly useful in patients not amenable to conventional revascularization.

Katayama, M., et al. (2014). "Plasma pentraxin3 (PTX3) as a novel useful biomarker for infection in patients with rheumatoid arthritis (RA)." Annals of the Rheumatic Diseases. Conference: Annual European Congress of Rheumatology of the European League Against Rheumatism, EULAR **73**(SUPPL. 2).

Background Infection is a critical complication that occurs during the management of RA patients. High levels of serum C-reactive protein (CRP), is not easily distinguishable between the exacerbations of RA from infections. PTX3 is a novel biomarker which responds to local inflammation. The following study evaluates the diagnostic use of PTX3 in RA patients with high levels of CRP. Objectives To evaluate the diagnostic use of PTX3 in RA patients with high levels of CRP. Methods 18 RA patients with infections (infection RA: iRA), 20 with high disease activity of RA (flare RA: fRA) and 23 healthy controls (HC) were enrolled in this study. Patients whom pathogens were identified were designated as iRA (15 bacterial, 2 viral and 1 mycosis). We measured PTX3, CRP, procalcitonin (PCT) and neutrophil CD64 (nCD64), pre- and post-treatments (iRA and fRA) and at any time (HC). PTX3 levels were measured using an enzyme-linked immunoabsorbent assay (ELISA). mCD64 was measured by a quantitative flow cytometry using fluorescene microbeads. Levels of respective measurements at both pre- and post-treatment were analyzed using the Wilcoxon signed-rank test, and comparisons of levels within each group were analyzed using the Mann-Whitney's U-test. Results At pre-treatment, levels of PTX3 in iRA (15.1+/-20.7 ng/ml) are significantly higher compared with those in fRA (3.6+/-4.2 ng/ml). Both levels for iRA and fRA were significantly higher compared with those in HC (0.89+/-0.91 ng/ml). Additionally, levels of PCT (0.048+/-0.042 ng/ml) and nCD64 (1488+/-470 molecules per cell) at pre-treatment in fRA were <0.5 ng/ml and <2,000 molecules

per cell, respectively. After treatment, levels of PTX3 ($p<0.01$), CRP ($p<0.01$), PCT ($p<0.01$), nCD64 ($p<0.01$) were significantly decreased in iRA. In fRA, CRP ($p<0.01$), PCT ($p<0.01$), nCD64 ($p=0.02$) were significantly decreased after treatment, but PTX3 levels were not ($p=0.13$). Conclusions Plasma PTX3 levels may be a helpful tool in distinguishing worsening of RA from complications due to infection. (Table Presented).

Katija, K., et al. (2017). "From the surface to the seafloor: How giant larvaceans transport microplastics into the deep sea." Science Advances **3**(8): e1700715.

Plastic waste is a pervasive feature of marine environments, yet little is empirically known about the biological and physical processes that transport plastics through marine ecosystems. To address this need, we conducted in situ feeding studies of microplastic particles (10 to 600 mum in diameter) with the giant larvacean Bathochordaeus stygius. Larvaceans are abundant components of global zooplankton assemblages, regularly build mucus "houses" to filter particulate matter from the surrounding water, and later abandon these structures when clogged. By conducting in situ feeding experiments with remotely operated vehicles, we show that giant larvaceans are able to filter a range of microplastic particles from the water column, ingest, and then package microplastics into their fecal pellets. Microplastics also readily affix to their houses, which have been shown to sink quickly to the seafloor and deliver pulses of carbon to benthic ecosystems. Thus, giant larvaceans can contribute to the vertical flux of microplastics through the rapid sinking of fecal pellets and discarded houses. Larvaceans, and potentially other abundant pelagic filter feeders, may thus comprise a novel biological transport mechanism delivering microplastics from surface waters, through the water column, and to the seafloor. Our findings necessitate the development of tools and sampling methodologies to quantify concentrations and identify environmental microplastics throughout the water column.

Kato, K., et al. (2017). "Novel interferon-gamma enzyme-linked immunoSpot assay using activated cells for identifying hypersensitivity-inducing drug culprits." Journal of Dermatological Science **86**(3): 222-229.

BACKGROUND: The drug-induced lymphocyte stimulation test (DLST), also referred to as lymphocyte transformation test (LTT), is used to identify the culprit drug in cases of cutaneous adverse drug reactions (cADR). Although DLST is a widely used in vitro test, its sensitivity and specificity are unsatisfactory. Recent reports suggest that the detection of drug-induced interferon (IFN)-gamma production using enzyme-linked immunoSpot (ELISpot) assay (conventional IFN-gamma ELISpot) is useful for identifying culprit drugs in cADR cases.

OBJECTIVE: The aim of this study was to establish a novel method for identifying culprit drugs in patients with cADR by efficiently detecting drug-specific IFN-gamma production using activated cells.

METHODS: Sixteen patients with cADR, including drug-induced hypersensitivity syndrome, erythema multiforme-like eruption, maculopapular exanthema, Stevens-Johnson syndrome, and toxic epidermal necrolysis, caused by clinically convincing culprit drugs were enrolled in this study. In some cases, the blood samples were obtained at two or three different time points. Peripheral blood mononuclear cells (PBMCs) from total 20 samples were analyzed using both the DLST and drug-induced conventional IFN-gamma ELISpot. In addition, drug-induced IFN-gamma ELISpot was performed using PBMCs, which were stimulated with anti-cluster of differentiation (CD)-3/CD28 antibody-coated microbeads and interleukin (IL)-2 for 7 days before exposure to the culprit drugs (modified IFN-gamma ELISpot).

RESULTS: Among the culprit drugs tested in each patient, the modified IFN-gamma ELISpot was positive in 17 samples (13 patients) while DLST and conventional IFN-gamma ELISpot were positive in eight and four samples (six and three patients), respectively.

CONCLUSION: The modified IFN-gamma ELISpot using activated PBMCs was more sensitive than the conventional IFN-gamma ELISpot was for detecting drug-induced IFN-gamma production, which could be a useful in vitro tool for identifying culprit drugs in cADR cases.

Katodritou, E., et al. (2011). "Tumor-primed natural killer cells from patients with multiple myeloma lyse autologous, NK-resistant, bone marrow-derived malignant plasma cells." Haematologica **2)**: 119.

Background. Natural killer (NK) cells are cytotoxic lymphocytes able to kill tumor cells and virus-infected cells. Human resting NK cells can be activated by co-culture with NK-resistant CTV-1 cells. These tumoractivated cells (TaNK) are cytotoxic to a range of NK-resistant tumor cells in vitro. This potential, has not been explored in multiple myeloma (MM). Aim. The current study was design to assess the relative function in vitro of NK and TaNK cells from MM patients compared to normal controls in the lysis of tumor cell- lines and freshly isolated autologous and allogeneic MM cells. In addition we explored whether the ability to generate TaNK cells in vitro correlates with patients' characteristics, including the disease status and treatment, including novel agents. Methods. Freshly isolated CD56+ NK cells from normal donors and 21 MM patients, separated with CD56 immunomagnetic Microbeads were co-incubated with CTV-1 cells or lysates there from, overnight at 37oC, 5% CO2, to generate TaNK cells. For the cytotoxicity assay, the erythroleukemia cell-line K562 with known sensitivity to NK lysis was used as a positive control, the Burkitt's lymphoma cell-line Raji, known to be refractory to NK lysis was used as a negative control of NK killing. The Myeloma cell-line U266 as well as freshly isolated bone marrow (BM) autologous and allogeneic CD138+ plasma cells from MM patients were used to evaluate the sensitivity of plasma cells to MM patients' NK and TaNK lysis. Cytotoxicity was measured in a 4-h assay. Loss of membrane integrity was measured by ingress of To-Pro-3 iodide as determined by flow cytometry. Bone marrow plasma cells, were acquired after electronic gating on the CD138(+) cells, and the mean proportion of CD138 positive/To-Pro 3 iodide- positive cells from the samples was determined. Background. Target-cell death was determined from cells incubated in the absence of effector cells and the "percent lysis - CD138+"was calculated by subtraction of the background cell death. To determine the specificity of malignant plasma cell lysis, CD138-ve cells were gated in the same analysis and the "percent lysis - control cells"determined as above. This was subtracted from the "percent lysis - CD138+"to give a "percent specific lysis". Results. We have demonstrated that TaNK cells from MM patients lyse several myeloma targets, including autologous and allogeneic CD138+ myeloma cells whilst sparing CD138-ve BM cells. Myeloma patients' TaNK-induced lysis of the U266 cell-line was significantly higher compared to normal controls (median specific lysis 79.1% vs 69.5%) (p=0.003). In addition, TaNKs induced substantial lysis of autologous and allogeneic CD138+ myeloma cells (median specific lysis 52.5% and 37.4%, respectively). The percentage of specific lysis did not correlate with important disease characteristics, (ISS, age, high-risk cytogenetics), nor with the disease status and anti-myeloma treatment, including novel agents and dexamethasone. Summary/Conclusions. Tumorprimed NK cells are able to induce substantial lysis of myeloma targets including autologous and allogeneic CD138+ myeloma plasma cells and could be an additional therapeutic approach in MM, particularly in the era of novel agents.

Katsanevakis, S. and A. Katsarou (2004). "Influences on the Distribution of Marine Debris on the Seafloor of Shallow Coastal Areas in Greece (Eastern Mediterranean)." Water, Air & Soil Pollution **159**(1-4): 325-337.

The abundance and composition of marine benthic debris was investigated in shallow coastal areas of Greece (eastern Mediterranean). The mean total density of marine debris in the areas surveyed was 15 items per 1000 m2 and ranged from 0 to 251 items per 1000 m2, with plastics

dominating. Much higher marine debris densities were found in this study than those found in most studies surveying the continental shelf or the deep seafloor, indicating that pollution with marine debris is more intense in coastal areas. Greater abundance of marine debris was found in bays than in open areas. Artisanal fishing activities were found to significantly contribute to marine pollution with debris. In the Saronicos Gulf, a densely populated and highly industrialized area, the abundance of marine debris was higher than the rest of the Greek areas surveyed. [ABSTRACT FROM AUTHOR]

Katsifis, G. E., et al. (2009). "Systemic and local interleukin-17 and linked cytokines associated with Sjogren's syndrome immunopathogenesis." American Journal of Pathology **175**(3): 1167-1177.
Recently recognized as a distinct CD4(+) T helper (Th) lineage, Th17 cells have been implicated in host responses to infections and in pathogenesis associated with autoimmune diseases. This cytokine is implicated in primary Sjogren's syndrome (pSS) immunopathology because of the increased levels of circulating interleukin (IL)-17 in pSS. Plasma and minor salivary glands (MSGs) from patients with pSS were therefore evaluated for CD4(+) T cells, T regulatory cells, IL-17, and supporting cytokines by immunohistochemistry, RT-PCR, and microbead assays. MSGs from pSS patients contain IL-17-expressing cells as a dominant population within inflammatory lesions. IL-17 protein expression progressively increased with higher biopsy focus scores (P < 0.0001), in parallel with detection by RT-PCR. Transforming growth factor-beta, IL-6 and IL-23, which are requisite promoters of Th17 differentiation, were found in abundance compared with the amounts in control tissues. Although transforming growth factor-beta is also a pivotal differentiation factor for immunosuppressive Foxp3(+) T regulatory cells (Tregs), an increase in Foxp3(+) Tregs was evident in biopsy specimens with mild and moderate inflammation but this increase was disproportionate to escalating pro-inflammatory Th17 populations in advanced disease. Furthermore, the Th17-centric cytokines IL-17, IL-6, IL-23, and IL-12 were significantly elevated in pSS plasma. These data identify a profusion of IL-17-generating cells and supporting cytokines within diseased pSS MSGs without a compensatory increase in immunomodulatory Tregs; this imbalance seems to foster a pathogenic milieu that may be causative and predictive of infiltrative injury and amenable to therapeutic intervention.

Kaur, H., et al. (2010). "Transportation of drug-(polystyrene bead) conjugate by actomyosin motor system." Journal of Biomedical Nanotechnology **6**(3): 279-286.
The Nanorobotics and cargo transportation application of molecular motors is of recent intent. The present study explores the transportation of Mesalamine/5-aminosalicylic acid/5-ASA drug by molecular motors. Mesalamine is an anti-inflammatory drug used to treat Crohn's disease and ulcerative colitis. Conjugate of mesalamine and polystyrene (Dia.: 3 microm) beads was prepared by amide linkage between amine (-NH2) group of drug and carboxyl (-COOH) group of the bead. In Fourier Transform Infrared spectra, peaks were observed at 3428.1 and 1654.0 cm(-1) for N-H and C=O stretching bond respectively confirming the amide bond formation between drug and microbeads. Quantification of 5-ASA attached to polystyrene bead was done by UV-vis spectroscopy and it was ascertained that 93% of 5-ASA was loaded on polystyrene beads. Conjugate of drug-polystyrene beads were then covalently attached to actin filaments.

Velocity of actin filaments attached to drug loaded beads in in-vitro motility assay reduced to 0.89 microm/s as compared to free actin velocity (4.64 microm/s). This further ascertains the microcomposites formation. The present study provides an insight into the actin-myosin based molecular motor systems for an efficient tool for drug transportation.

Kaushal, R. K. and A. K. Nema (2013). "Strategic Analysis of Computer Waste Management Options: Game-Theoretic Approach." Journal of Environmental Engineering **139**(2): 241-249.

Computer waste has emerged as a critical issue globally because of the growing quantity of waste and problems arising out of its toxic nature. In India, it is estimated that 480,000 t of electronic waste (e-waste) is generated annually. Computer waste includes plastics and metals that have a good potential for recycling; however, if not managed properly, the additives and chemicals in plastic waste and traces of heavy metals raise concern for human health and the environment. Efficient e-waste management will require a strategy that offers a win-win situation for all the involved stakeholders. This paper uses a game-theoretic approach for analyzing the strategies by identifying the equilibrium points for various scenarios that can help in deciding the incentives and penalties for deriving the self-propelling market-based mechanism for efficient management of e-waste. Results suggest that applying take-back schemes with some incentives to the consumers and penalty to those who do not follow the prescribed procedure for discarding e-waste could be very useful to discourage the land disposal of computer waste. Nash-equilibrium implies that the recycler would prefer to collect the computer waste directly from the consumer only if the incentive return to the consumer is less than 15% of the price of the computer, the recycling fee is less than 5% of the price of the computer, and the price of the recycled material is more than 15% of the price of the computer; otherwise collect it through the producer. Also, for the producer, it would be preferable to take an extra fee from the consumer for end-of-life management of the desktop computer as an advance recovery fee (apparent fee) only up to 4.0% of the cost of the computer. If the producer had to take an extra fee more than 4.0%, it should be taken as an extended producer responsibility fee (hidden fee combined in the cost) so that computer sales are not affected. Kavakli, C., et al. (2002). "1,4,8,11-Tetraazacyclotetradecane bound to poly(p-chloromethylstyrene-ethylene glycol dimethacrylate) microbeads for selective gold uptake." Analytica Chimica Acta **464**(2): 313-322.

Poly(p-chloromethylstyrene-ethylene glycol dimethacrylate) (poly(p-CMS-EGDMA)) polymeric microbeads, with an average size of 186mum were synthesized by the suspension polymerization of p-CMS in an aqueous medium. To increase the rigidity of the polymeric microbeads EGDMA monomer was added to polymerization medium at 25% for cross-linking. 1,4,8,11-Tetraazacyclotetradecane (cyclam) was reacted with p-CMS under nitrogen atmosphere for 18h at 65degreeC. Fourier transform infrared (FT-IR) spectrophotometry, thermogravimetric analysis (TGA) and elemental analysis were used to characterize the plain and ligand-attached microbeads structures. The affinity of the cyclam-attached poly(p-CMS-EGDMA) microbeads for gold ions were used to test the adsorption/desorption behavior from aqueous media containing different concentrations of gold (0.05-10mM) at different pH values (2.5-5.0). The uptake of gold ions onto the poly(p-CMS-EGDMA) microbeads from solution was 6.18mmolg⁻¹. More than 95% of the adsorbed gold ion was desorbed over 48h in a desorption medium containing 0.8M thiourea in 3M HCl. Poly(p-CMS-EGDMA) co-polymeric microbeads containing the cyclam ligand were found to be suitable for repeated use without noticeable loss of adsorption capacity. The selective adsorption of gold onto the microbeads at pH 3.0 was very high compared to Cu(II), Ni(II), Co(II) and Zn(II). © 2002 Elsevier Science B.V. All rights reserved.

Kavet, R. I. and J. D. Brain (1977). "Phagocytosis: quantification of rates and intercellular heterogeneity." J.Appl.Physiol.Respir.Environ.Exercise Physiol **42**(3): 432-437.

The authors present a method which permits analysis of phagocytic behavior in small samples of macrophages. Both overall phagocytic kinetics and intercellular variability in particle uptake were measured. Macrophages lavaged from Syrian golden hamster lungs were incubated (5 min at 37degreeC) with 2 to 4 mum plastic particles at 4.6, 6.9, 9.1, and 16.0 x 10⁶ part./ml. Harvested macrophages ranged from 0.6 to 4.0 x 10⁶ cells per animal. To concentrate the cells and separate them from cell free substrate after termination of phagocytosis, 30 - 60% of each flask's contents were centrifuged (400 x g, 20 min) atop a Metrizamide subphase (34% wt/vol, p=1.18). Cells were collected from the interface, fixed, and visually scored for number of particles phagocytized. Phagocytic rates followed Michaelis Menten kinetics with Vmax= 0.63 +/- 0.18 (SEM) part./viable cell per min and Km= 8.5 +/- 2.7 (SEM) x 10⁶ part./ml. In every case (23/23 flasks from 6 animals) particle uptake exhibited greater (P<0.01) cell to cell variability in avidity for substrate than the Poisson distribution would predict from mean number of particles phagocytized per viable cell.

Kavitha, R., et al. (2014). "Biodegradation of low density polyethylene by bacteria isolated from oil contaminated soil." International Journal of Plant, Animal and Environmental Sciences **4**(3): 601-610.

Plastics are composed of petroleum based materials that are resistant to biodegradation. The widespread applications of plastics are not only due to their favourable mechanical and thermal properties but also mainly due to the stability and durability. The most commonly used non-degradable solid waste is polythene which is a linear hydrocarbon polymers consisting of long chains of the ethylene monomers. Most shopping bags are made from polyethylene a chemically inert compound consisting of carbon and hydrogen. Burning of this plastic waste and burying of the plastics releases harmful toxic material which is a major pollutant in environment. Degradation of waste plastics through microorganism use represents one of the alternatives to deal with such problems. The present study aims to investigate the biodegrading potentials of bacteria isolated from oil contaminated soil. The extents of biodegradability of the untreated low density polyethylene film by the isolated bacterial strains were assessed in vitro in the medium containing polyethylene film as the sole carbon source. After 30 days of incubation period, the biodegradation of the polyethylene film was measured in terms of weight loss and physicochemical analysis by scanning electron microscopy and Fourier transform infra red spectroscopy. The hydrophobicity of the bacterial isolates was evaluated by BATH test. The results depict that both the isolates were hydrophobic and were able to grow in a medium containing untreated polyethylene as a sole carbon source. Incubation of untreated polyethylene with bacterial isolate 1 and 2 (30 days, 37 degrees c) reduces its mass by 1.29% and 1.3% respectively. The smooth surface of the untreated polyethylene film became eroded as a result of biodegradation. The FTIR spectra showed changes in the chemical properties of the polyethylene film due to the biodegradation by the bacterial isolates.

Kawabe, K., et al. (2017). "Amphotericin B Increases Transglutaminase 2 Expression Associated with Upregulation of Endocytotic Activity in Mouse Microglial Cell Line BV-2." Neurochemical Research **42**(5): 1488-1495.

Amphotericin B (AmB), a polyene antibiotic, is reported to cause the microglial activation to induce nitric oxide (NO) production and proinflammatory cytokines expression, and change neurotrophic factors expression in cultured microglia (Motoyoshi et al. in Neurochem Int 52:1290-1296, 2008). On the other hand, tissue-type transglutaminase (TG2) is involved in connection to phagocytes with apoptotic cells. Engulfment of neurons by activated microglia is thought to cause neurodegenerative diseases but detail is unclear, and involvement of TG2 in phagocytosis has been reported in our previous study using lipopolysaccharide-stimulated BV-2 cells (Kawabe et al. in Neuroimmunomodulation 22(4):243-249, 2015). In the present study, we examined the changes of TG2 expression, phagocytosis and pinocytosis in BV-2 cells stimulated by AmB. AmB stimulation increased TG2 expression and TG activity. Phagocytosis of dead cells and pinocytosis of fluorescent microbeads were also up-regulated by AmB stimulation in BV-2 cells. Blockade of TG activity by cystamine, an inhibitor of TGs, suppressed AmB-enhanced TG2 expression, TG activity, NO production, phagocytosis and pinocytosis. Excessive NO production from microglia and/or facilitation of phagocytosis might be involved in neuronal death. To control TG activity might make possible to protect neurons and care for CNS diseases. Copyright © 2017, Springer Science+Business Media New York.

Kawakami, Y., et al. (1997). "Subcutaneous xenotransplantation of hybrid artificial pancreas encapsulating pancreatic B cell line (MIN6): functional and histological study." Cell Transplantation **6**(5): 541-545.

The biohybrid artificial pancreas is designed to enclose pancreatic tissues with a selectively permeable membrane that immunoisolates the graft from the host immune system, allowing those endocrine tissues to survive and control glucose metabolism for an extended period of time. The pancreatic B cell line MIN6 is established from a pancreas B cell tumor occurring in transgenic mice harbouring the human insulin promoter gene connected to the SV40 T-antigen hybrid gene. It has been proven that glucose-stimulated insulin secretion in MIN6 cells retains a concentration-dependent response similar to that of normal islets. In this study, we performed the histological and functional examination of three-layer microbeads employing MIN6 cells after subcutaneous xenotransplantation to evaluate this device as bioartificial pancreas. MIN6 cells were microencapsulated in three-layer microbeads formulated with agarose, polystyrene sulfonic acid, polybrene, and carboxymethyl cellulose. Microbeads were xenogenically implanted in the subcutaneous tissue of the back of Lewis rats with streptozotocin-induced diabetes. One week after implantation, microbeads were retrieved and cultured for 24 h before the static incubation. There was no evidence of adhesion to the graft and the fibrosis in the transplantation site as determined by gross visual inspection. Microscopic examination demonstrated that retrieved microbeads maintained normal shape, containing intact MIN6 cells. Histological study showed that these MIN6 cells in the microbeads appeared to be viable without cellular infiltration within or around the microbeads. Immunohistochemical analysis of the microbeads clearly revealed the intense staining of insulin in the cytoplasm of encapsulated MIN6 cells. Insulin productivity of MIN6 cells in the microbeads is strongly suggested to be preserved. In response to 16.7 mM glucose stimulation, static incubation of microbeads 1 wk after implantation caused the 2.3 times increase in insulin secretion seen after 3.3 mM glucose stimulation (84.3 +/- 10.0 vs. 37.4 +/- 10.7 microU/3 x 10(6) cells/hr, n = 5 each, p < 0.01). This study demonstrates that three-layer microbeads encapsulating MIN6 cells retain excellent biocompatibility and maintain good insulin secretion even after subcutaneous xenotransplantation, suggesting the possible future clinical application of this unique bioartificial pancreas to subcutaneous xenotransplantation.

Kawamoto, K. and H. Miyata (2015). "Dioxin formation and control in a gasification-melting plant." Environmental Science & Pollution Research **22**(19): 14621-14628.

We investigated dioxin formation and removal in a commercial thermal waste treatment plant employing a gasification and melting process that has become widespread in the last decade in Japan. The aim was to clarify the possibility of dioxin formation in a process operation at high temperatures and the applicability of catalytic decomposition of dioxins. Also, the possible use of dioxin surrogate compounds for plant monitoring was further evaluated. The main test parameter was the influence of changes in the amount and type of municipal solid waste (MSW) supplied to the thermal waste treatment plant which from day to day operation is a relevant parameter also from commercial perspective. Here especially, the plastic content on dioxin release was assessed. The following conclusions were reached: (1) disturbance of combustion by adding plastic waste above the capability of the system resulted in a considerable increase in dioxin content of the flue gas at the inlet of the bag house and (2) bag filter equipment incorporating a catalytic filter effectively reduced the gaseous dioxin content below the standard of 0.1 ng toxic equivalency (TEQ)/m(3) N, by decomposition and partly adsorption, as was revealed by total dioxin mass balance and an increased levels in the fly ash. Also, the possible use of organohalogen compounds as dioxin surrogate compounds for plant monitoring was further evaluated. The levels of these surrogates did not exceed values corresponding to 0.1 ng TEQ/m(3) N dioxins established from former tests. This further substantiated that surrogate measurement therefore can well reflect dioxin levels.

Kawamoto, T., et al. (2015). "Comparison of IgG against plastic resin in workers with and without chemical dermatitis." BMC Public Health **15**: 930.

BACKGROUND: There are many chemical sensitizers which cause allergy in the surrounding environment. However, the identification of substances causing allergy is difficult. We developed a new method to detect IgG which reacts against many kinds of chemical-human serum albumin (HSA) adducts at the same time. In this study, the diagnostic significance of the IgG was studied among workers of a company where a mass outbreak of chemical dermatitis had occurred after changing a plastic resin to a new one.

METHODS: Eleven workers who handled the new plastic resin and suffered from dermatitis (case) and 9 workers who also handled the same resin in the same company but were free from dermatitis (control) were the subjects. Immunological dot blotting was carried out to detect serum IgG using originally prepared diagnostic antigens, comprising a mixture of HSA and the plastic resin or its components under various conditions.

RESULTS: IgG against the plastic resin in use was detected in all workers who suffered from dermatitis. The prevalence of the IgG against the plastic resin was significantly higher in workers with than in those without dermatitis. On the other hand, IgG against its components (bisphenol A diglycidyl ether, m-xylylenediamine and butyl 2,3-epoxypropyl ether) was detected in a few workers with dermatitis.

DISCUSSION: This suggests that IgG against chemical-HSA adduct reflects not only exposure but also causative chemicals of dermatitis. Our method to use a material itself as a hapten is practical and useful in the occupational field.

CONCLUSION: It is suggested that IgG against chemicals is a useful marker of chemicals inducing dermatitis.

Kawase, Y. and N. Hashimoto (1996). "Gas hold-up and oxygen transfer in three-phase external-loop airlift bioreactors: Non-Newtonian fermentation broths." Journal of Chemical Technology and Biotechnology **65**(4): 325-334.

> The effects of solids loading on gas hold-up and oxygen transfer in external-loop airlift bioreactors with non-Newtonian fermentation media are discussed. Experiments were performed in two model external-loop airlift bioreactors with aqueous solutions of carboxymethyl cellulose (CMC) and xanthan gum representing non-Newtonian flows. Low-density plastic particles of 1030 and 1300 kg m⁻³ were used and the solids loading was varied in the range 0-20% (v/v). For the inelastic non-Newtonian CMC aqueous solutions, the presence of low-density solid particles slightly increased the riser gas hold-up, (gr), but decreased the volumetric mass transfer coefficient, k(L)a. On the other hand, (gr) decreased but k(L)a increased with solids loading in the viscoelastic non-Newtonian xanthan gum aqueous solution. The extent of these effects depended on non-Newtonian flow behavior. Theoretical models of riser gas hold-up and volumetric mass transfer coefficient have been developed. The capability of the proposed models was examined using the present experimental data obtained in the model external-loop airlift bioreactors and the available data in the literature. The data were successfully correlated by the proposed correlations except the results for k(L)a coefficient in the xanthan gum solution.

Kawecki, D. and B. Nowack (2019). "Polymer-Specific Modeling of the Environmental Emissions of Seven Commodity Plastics As Macro- and Microplastics." Environmental Science & Technology **53**(16): 9664-9676.

> Plastic has been identified as an emerging contaminant in aquatic and terrestrial ecosystems. Uncertainties remain concerning the amounts present in the environment and the main responsible sources. In this study, the emissions of macro- and microplastics have been mapped for seven polymers in Switzerland. The modeling is based on a complete analysis of the flows from production and use to end-of-life using probabilistic material flow analysis. We estimate that 94 +/- 34 g/capita/year of low-density polyethylene, 98 +/- 50 g/cap/a of high-density polyethylene, 126 +/- 43 g/cap/a of polypropylene, 24 +/- 13 g/cap/a of polystyrene, 16 +/- 12 g/cap/a of expanded polystyrene, 65 +/- 36 g/cap/a of polyvinyl chloride, and 200 +/- 120 g/cap/a of polyethylene terephthalate enter the Swiss environment. All polymers combined, 540 +/- 140 and 73 +/- 14 g/cap/a are emitted into soil as macroplastics and microplastics, respectively, and 13.3 +/- 4.9 and 1.8 +/- 1.1 g/cap/a are emitted into freshwater as macroplastics and microplastics, respectively. The leading emission pathway is littering for both terrestrial and aquatic environments. Construction, agriculture, and pre- and postconsumer processes cause important emissions of microplastics into soils, and postconsumer processes, textiles, and personal care products release most of the microplastics into waters. Because mass flows into soils are predicted to be 40 times larger than those into waters, more attention should be placed on this compartment. Our work also highlights the importance of referring to specific polymers instead of just "plastics".

Kay, P., et al. (2018). "Wastewater treatment plants as a source of microplastics in river catchments." Environmental Science & Pollution Research **25**(20): 20264-20267.

It is now well established that the oceans contain significant accumulations of plastic debris but only very recently have studies began to look at sources of microplastics (MPs) in river catchments. This work measured MPs up- and downstream of six wastewater treatment plants (WWTPs) in different catchments with varying characteristics and found that all led to an increase in MPs in rivers. Nevertheless, the data collected indicated that there were other important sources of MPs in the catchments studied and that these may include atmospheric deposition, agricultural land to which sewage sludge has been applied, and diffuse release of secondary MPs following the breakdown of larger plastic items. MPs were comprised mainly of fibres, fragments, and flakes with pellets and beads only dominating at one site. Variation in MP pollution occurred over time and this difference was greater at some sites than others. A key research need is the further study of MP sources in river catchments to facilitate management efforts to reduce their presence in freshwater and marine environments.

Kaynar, L., et al. (2016). "Immune recovery after transplantation of TCRalphabeta depleted allografts from haploidentical donors in adult patients." Bone Marrow Transplantation **1)**: S159.

Introduction: Haploidentical hematopoietic stem cell transplantation (HSCT) offers the advantage of being immediately applicable to virtually all patients who lack a HLA-matched donor. Graft manipulation with removal of all T lymphocyte subsets has been associated with an increased risk of lifethreatening infections and leukemia recurrence because of delayed immune reconstution. To improve the immune recovery, we have used a new T-cell depletion method that removes alphabeta+ T lymphocytes while retaining gammadelta+ T lymphocytes, NK cells and other cells in the graft. We report immune reconstitution data of acute leukemia patients transplanted with this approach. Material (or patients) and methods: We enrolled 34 acute leukemia patients. Median age was 28 years (range 18-60). The alphabeta+ T cells were depleted by using anti-TCRalphabeta- coated microbeads and the automated CliniMACS device (Miltenyi Biotec). B cell depletion was not performed. The conditioning regimen consisted of fludarabine (40 mg/m2, days -8 to -5), thiotepa (2 x 5 mg/kg, day -4) and melphalan (70 mg/m2, days -3, -2). Anti-thymocyte globulin (ATG-Fresenius) 15-30 mg/kg starting on days -12 to -9 was used to deplete remaining host T cells, avoiding graft rejection. Mycophenolate sodium was given as prophylactic immune suppression, if residual T cells in the graft exceeded 25 x104/ kg BW. Result(s): All patients received HSCT with alphabeta+ T cell depleted haploidentical grafts. The patients received a median number of ?12.69 x 106 CD 34+ progenitor cells per kg body weight (BW). In addition, grafts contained a median number of 4.58 x 10⁶ per kg BW gammadelta T cells. The median residual alphabeta T cells was 11.72 x 10³ cells per kg BW All but 3 patients engrafted with full donor chimerism and one of them died due to bacterial infection.The others were re-transplanted. Engraftment eventually occurred in 31 patients (91.2%). The median time to reach an absolute neutrophil count 40.5 x 10⁹/L and a platelet count >20 x 10⁹/L was 12 days (10-15) and 11 days (10-12). Five pts developed acute GVHD. Eleven pts (30%) experienced grade I-VI acute GVHD. Two pts developed gut and liver grade IV acute GVHD (6%). Only 2 pts developed chronic GVHD. Four pts died because of disease relapse 7 pts died due to transplantation related mortality. Median follow-up is 191 days (range 35-933). The immune reconstitution were given Table. All patients and donor were CMV seropositive. CMV reactivaiton was seen every patients but CMV disease or EBV related post transplant lymhpoproliferatif disease were not seen. Conclusion(s): These data indicate that a selective graft manipulation results into effective prevention of both acute and chronic GVHD, high engraphmant rates, rapid recovery of neutrophil and platelet counts and low TRM. The use of TCRalphabeta-depleted stem cells together with a melphalan-based regimen resulted in improving immune recovery. (Table

Presented).

Kazmiruk, T. N., et al. (2018). "Abundance and distribution of microplastics within surface sediments of a key shellfish growing region of Canada." PLoS ONE **13**(5).

The abundance and distribution of microplastics within 5 sediment size classes (>5000 micro m, 1000-5000 micro m, 250-1000 micro m, 250-0.63 micro m and <0.63 micro m) were determined for 16 sites within Lambert Channel and Baynes Sound, British Columbia, Canada. This region is Canada's premier growing area for the Pacific oyster (Crassostrea gigas). Microplastics were found at all sampling locations indicating widespread contamination of this region with these particles. Three types of microplastics were recovered: microbeads, which occurred in the greatest number (up to 25000/kg dry sediment) and microfibers and microfragments, which were much less in number compared with microbeads and occurred in similar amounts (100-300/kg dry sediment). Microbeads were recovered primarily in the <0.63 micro m and 250-0.63 micro m sediment size class, whereas microfragments and microfibers were generally identified in all 5 sediment size classes. Abundance and distribution of the three types of microplastics were spatially dependent with principal component analysis (PCA) indicating that 84 percent of the variation in abundance and distribution was due to the presence of high numbers of microbeads at three locations within the study region. At these sites, microbeads expressed as a percent component of the sediment by weight was similar to key geochemical components that govern trace metal behavior and availability to benthic organisms. Microbeads have been shown to accumulate metals from the aquatic environment, hence in addition to the traditional geochemical components such as silt and organic matter, microplastics also need to be considered as a sediment component that can influence trace metal geochemistry. Our findings have shown that BC's premier oyster growing region is highly contaminated with microplastics, notably microbeads. It would be prudent to assess the degree to which oysters from this region are ingesting microplastics. If so, it would have direct implications for Canada's oyster farming industry with respect to the health of the oyster and the quality of product that is being farmed and sets an example for other shellfish growing regions of the world.

Kazour, M. and R. Amara (2019). "Is blue mussel caging an efficient method for monitoring environmental microplastics pollution?" Science of the Total Environment: 135649.

The effectiveness of mussel caging for active microplastics (MPs) biomonitoring was investigated for the first time by comparing abundance and characteristics (shape, size, color and type of polymers) of MPs ingested by caged depurated blue mussels with those ingested by native mussels collected at the same sites and with those found in their surrounding environment (surface water and sediments). Mussels were exposed along a pollution gradient originating from a wastewater treatment plant discharge and near an abandoned coastal landfill. After 6 weeks of deployment, the majority (93%) of clean transplanted mussels had ingested MPs with a mean number of items ranging from 0.61 to 1.67 items/g. The occurrence, abundance and properties of MPs ingested by caged mussels were similar to those found in native mussels. Among the debris items detected in caged and native mussels, fragments were the most predominant type, consistent with the MPs found in their surrounding environment. MPs sizes were very similar whether in the water, sediments and both caged and native mussels, with a dominance of items <150 mum. Although some polymers were under-represented or totally absent in the caged mussels compared to overlying seawater or surrounding sediment, there was a good overlap in polymer types proportion being found between caged mussels and sediments (Morisita's index of similarity = 0.93) or seawater (0.86). Polystyrene dominated all samples in all the different matrices. Our study suggests that blue mussels caging may be a promising tool for MPs biomonitoring making monitoring more reliable with an accurate assessment of the biological effects of MPs over a predetermined exposure period. However, further methodological improvements should be considered to define a uniform protocol for blue mussels caging to allow spatial and temporal microplastics active biomonitoring.

Kazour, M., et al. (2018). "Juvenile fish caging as a tool for assessing microplastics contamination in estuarine fish nursery grounds." Environmental Science & Pollution Research **15**: 15.

Estuaries serve as nursery grounds for many marine fish species. However, increasing human activities within estuaries and surrounding areas lead to significant habitat quality degradation for the juveniles. In recent years, plastic pollution has become a global environmental issue as plastic debris are found in all aquatic environments with potential adverse impacts on marine biota. Given the important ecological role of estuaries and implications of microplastics (MP) in ecosystems, here we assess the occurrence, number, size, and polymer types of MP ingested by wild and caged juvenile European flounder (Platichthys flesus). We deployed caged fish for 1 month at five sites in three estuaries in the eastern English Channel. The Seine estuary, heavily impacted by manmade modifications and one of the most contaminated estuaries in Europe, was compared to two smaller estuaries (Canche and Liane) less impacted by industrial activities. We found that juvenile flounders (7-9 cm) were vulnerable to plastic ingestion. Seventy-five percent of caged fish and 58% of wild caught fish had the presence of MP items in their digestive tract. Fibers (69%) dominated in the fish's digestive tract at all sites. An average of 2.04 +/- 1.93 MP items were ingested by feral juvenile flounder and 1.67 +/- 1.43 by caged juvenile flounder. For the caged fish, the three sites impacted by wastewater treatment plant (Liane, Le Havre harbor, and Rouen) were those with the highest percentage of individuals that has ingested MP items. Most of the isolated items were fibers and blue in color. Polymers identified by micro Raman spectroscopy were polycaprolactam, polyethylene terephthalate, and polyurethane. Although other environmental factors may have affected caged fish condition and mortality, we found no significant correlation with the number of ingested MP. However, the high occurrence of MP ingested by juvenile fish on nursery grounds raises concerns on their potential negative effects for fish recruitment success and population renewal. Finally, this study describes, for the first time, the feasibility of using caged juvenile fish as an assessing tool of MP contamination in estuarine nursery grounds.

Kazour, M., et al. (2019). "Microplastics pollution along the Lebanese coast (Eastern Mediterranean Basin): Occurrence in surface water, sediments and biota samples." Science of the Total Environment **696**: 133933.

The Mediterranean Sea is the largest semi-enclosed sea and one of the worst affected regional seas with sub-basin scale heterogeneity in plastics concentration. Few studies on microplastics (MPs) pollution have been conducted in the Eastern part of the Mediterranean basin. This study aims to evaluate, for the first time, the MPs pollution of the Lebanese coast (Levantine Basin) as well as the most common polymers found, and to assess the potential role of coastal landfills in this pollution. Two important seafood species that are wholly consumed by the Lebanese community: the European anchovy, Engraulis encrasicolus, and the spiny oysters, Spondylus spinosus, were sampled in three different sites englobing the littoral (Tripoli, Beirut and Sidon). Sea water and sediment samples were also collected from the same sites.

Kazumi, K. K., et al. (2015). "High fidelity antibody immobilized microbead technology for blood typing." Vox Sanguinis **1)**: 267.

Background: Donated blood samples undergo blood typing, biochemical/infectious disease tests, and nucleic acid amplification tests at Japanese Red Cross Society Blood Centers before being provided to clinical institutions as blood products for transfusion. ABO and RhD typing is technologically based on agglutination of red cells by IgM antibodies, and generally performed by automated systems. However, testing for rare blood groups is difficult in obtaining those antibodies, forcing alternative use of IgG antibodies and the accompanied laborious manual processing. Aim(s): One of these rare blood groups is JR blood group. Jr antigen that belongs to JR blood group is high frequency in general population, and frequency of Jr antigen- negative in Japanese population is 1 in 1600. Since hemolytic transfusion reaction might occur to patients with anti- Jr if they are transfused with Jr antigenpositive blood, the Jr antigen-negative blood transfusion is crucial for these patients. Currently the Jr typing is performed on only a part of blood products, and an increased number of testing by a simpler, more accurate method is long sought. Method(s): We developed a simple method for testing Jr antigen using highly sensitive antibody-immobilized microbead technology. This system utilizes human monoclonal anti- Jr antibody (IgG) that were immobilized on the surface of micro-beads while maintaining its high antibody activity. The test result can be observed with or without agglutination of red cells by mixing a reagent including the microbeads and red cell suspension. This microbead reagent is able to be adapted to the automated blood typing analyzer PK7300 (Beckman Coulter); by pre-setting the reagent into a specialized bottle, and the Jr typing is determined in 30 min. Result(s): We validated the test performance using more than three thousand blood samples and confirmed accuracy, simultaneous reproducibility, and day-to-day reproducibility of this test. Our bead technology could accurately determine Jr type (positive, weak positive, negative). [IMAGE PRESENTED] Summary/Conclusions: We've developed a highly sensitive IgG antibody-immobilized micro-bead technology. By using the bead technology, we made the one step automate Jr blood typing possible. We are expecting this automate blood typing system is also applicable to other rare blood type determination tests and more.

Ke, A., et al. (2019). "Impacts of leachates from single-use polyethylene plastic bags on the early development of clam Meretrix meretrix (Bivalvia: Veneridae)." Marine Pollution Bulletin **142**: 54-57.

Plastic debris in the oceans is a major and growing problem in global environmental pollution. There are increasing concerns that plastic debris is a source of contaminant, either added during manufacturing or adsorbed from the environment. However, there is little information about the acute toxicity of leachates from plastic debris on marine organisms. In this study, we conducted experiments to evaluate the toxicity of leachates from two single-use polyethylene plastic bags (PB1 and PB2) with the embryo and larvae of the commercial clam Meretrix meretrix. Results showed that fertilization of the embryos was not affected by plastic leachates, but the developments of D-veliger larvae, including survival, deformity, and shell height, were significantly affected by plastic leachates from both PB1 and PB2 compared to the controls of filtered seawater. We speculate that compounds leaching from plastic bags are responsible for the observed toxicity. Therefore, leaching toxicity from plastic debris should be considered when assessing the risks of plastic pollution in the oceans.

Ke, T. and X. S. Sun (2003). "Starch, Poly(lactic acid), and Poly(vinyl alcohol) Blends." Journal of Polymers & the Environment **11**(1): 7-14.

Research on biodegradable materials has been stimulated due to concern regarding the persistence of plastic wastes. Blending starch with poly(lactic acid) (PLA) is one of the most promising efforts because starch is an abundant and cheap biopolymer and PLA is biodegradable with good mechanical properties. Poly(vinyl alcohol) (PVOH) contains unhydrolytic residual groups of poly(vinyl acetate) and also has good compatibility with starch. It was added to a starch and PLA blend (50:50, w/w) to enhance compatibility and improve mechanical properties. PVOH (MW 6,000) at 10%, 20%, 30%, 40%, 50% (by weight) based on the total weight of starch and PLA, and 30% PVOH at various molecular weights (MW 6,000, 25,000, 78,000, and 125,000 dalton) were added to starch/PLA blends. PVOH interacted with starch. At proportions greater than 30%, PVOH form a continuous phase with starch. Tensile strength of the starch/PLA blends increased as PVOH concentration increased up to 40% and decreased as PVOH molecular weight increased. The increasing molecular weight of PVOH slightly affected water absorption, but increasing PVOH concentration to 40% or 50% increased water absorption. Effects of moisture content on the starch/PLA/PVOH blend also were explored. The blend containing gelatinized starch had higher tensile strength. However, gelatinized starch also resulted in increased water absorption. [ABSTRACT FROM AUTHOR]

Keane, M. A. (2007). "Catalytic conversion of waste plastics: Focus on waste PVC." Journal of Chemical Technology and Biotechnology **82**(9): 787-795.

Effective waste management must address waste reduction, reuse, recovery/ recycling and, as the least progressive option, waste treatment. The increase in plastic waste production is a serious environmental issue. Plastics consumption continues to grow and while plastic recycling has seen a significant increase since the early 1990s, consumption still far exceeds recycling. Waste plastic can, however, serve as a potential resource and, with the correct treatment, can be reused or serve as hydrocarbon raw material or as a fuel. PVC, highly versatile with many applications, is non-biodegradable and has a high C1 content (56% of the total weight). Waste PVC incineration is highly energy demanding and can result in the formation of toxic chloro-emissions with adverse ecological, environmental and public health impacts. The Cl component must be removed from any waste PVC derived gas or oil before it can be used. An overview of the existing waste plastic treatment technologies is provided with an analysis of the available literature on thermal and catalytic PVC degradation. Thermal degradation results in random scissioning of the polymer chains generating products with varying molecular weights and uncontrolled Cl content. There is a dearth of literature dealing with the catalytic dechlorination of PVC. A case study is presented to illustrate the role heterogeneous catalysis can play in PVC waste treatment. The efficacy of Pd/Al<inf>2</inf>O<inf>3</inf> to promote PVC dechlorination is demonstrated, where a significant decrease (by up to a factor of 560) in the liquid fraction Cl content is recorded in addition to differences (relative to thermal degradation) in the gas phase product, i.e. higher C<inf>1</inf>-C<inf>4</inf> content with preferential alkane formation. © 2007 Society of Chemical Industry.

Keane, M. A. (2009). Catalytic processing of waste polymer composites, Elsevier Inc.**:** 122-151.

The increase in plastic waste represents a serious environmental issue. Plastics consumption continues to grow and while plastic recycle has seen a significant increase since the early 1990s, consumption still far exceeds recycle. Waste plastic can, however, serve as a potential resource and, with the correct treatment, can be reused or serve as hydrocarbon raw material or as a fuel. An overview of the existing waste plastic treatment technologies is provided with an analysis of the available literature on thermal degradation. Thermal pyrolysis results in a random scissioning of the polymer chains generating products with varying molecular weights. Catalytic degradation provides control over the product composition/distribution and serves to lower significantly the degradation temperature. Fundamental aspects of catalysis are presented with a discussion of the correlation of catalyst structure with performance, placing a particular emphasis on the role of zeolites as catalytic materials that have been widely used to promote polymer degradation. Polyvinyl chloride (PVC), highly versatile with manifold applications, is non-biodegradable and bears a high Cl content (56% of the total weight). Waste PVC incineration is very energy demanding and can result in the formation of toxic chloro-emissions with adverse ecological, environmental and public health impacts. The Cl component must be removed from any waste PVC-derived gas or oil before it can be used. The potential of a catalytic dechlorination unit operation to facilitate PVC recycle is discussed with reference to the pertinent, albeit limited, available literature. 2010 Woodhead Publishing Limited All rights reserved..

Keane, M. A. (2009). "Catalytic transformation of waste polymers to fuel oil." ChemSusChem **2**(3): 207-214.

Waste not, want not: The increase in waste polymer generation, which continues to exceed recycle, represents a critical environmental burden. However, plastic waste may be viewed as a potential resource and, with the correct treatment, can serve as hydrocarbon raw material or as fuel oil, as described in this Minireview.Effective waste management must address waste reduction, reuse, recovery, and recycle. The consumption of plastics continues to grow, and, while plastic recycle has seen a significant increase since the early 1990s, consumption still far exceeds recycle. However, waste plastic can be viewed as a potential resource and can serve, with the correct treatment, as hydrocarbon raw material or as fuel oil. This Minireview considers the role of catalysis in waste polymer reprocessing and provides a critical overview of the existing waste plastic treatment technologies. Thermal pyrolysis results in a random scissioning of the polymer chains, generating products with varying molecular weights. Catalytic degradation provides control over the product composition/distribution and serves to lower significantly the degradation temperature. Incineration of waste PVC is very energy demanding and can result in the formation of toxic chloro emissions. The efficacy of a catalytic transformation of PVC is also discussed. [References: 110]

Kearns, J., et al. (2011). "Discrepant reactivity of anti-dqa/dqb antibody with single antigen beads versus peripheral blood B cells: Implications for the assessment of donor specific antibody and donor selection." Human Immunology **72 (SUPPL.1)**: S43.

Aim: Factors that can affect anti-DQ antibody reactivity may include amino acid variability of the DQA1 and DQB1 alleles at surface exposed residues as well as structural variations secondary to the nature of the peptide displayed by the HLA DQA/DQB heterodimer molecules. In addition, cryptic epitopes may be displayed by the HLA-DQ coated microbeads used in Luminex Single Antigen bead (SAB) assay. We compared reactivity of anti-DQ antibodies using SAB assay to reactivity with B cells using flow cytometric analysis. Method(s): The reactivity of 12 anti-DQ specific sera were evaluated by SAB and flow cytometry using a cell panel of 21 unrelated donors who were typed for HLA class I and class II alleles using SSO methods. All sera were non reactive with other HLA class I or class II antigens. Result(s): We found that the correlation between the strength of antibody reactivity with DQ alleles assessed by Luminex beads versus reactivity with B cells varied significantly with different DQA/DQB allele combinations. The reactivity of 4 anti-DQ specific sera that reacted strongly with DQB1*05:01, DQA1*01:01 SAB was discrepant when compared with their reactivity with B cells from a single individual carrying the DQB1*05:01, DQA1*01:01 alleles. Despite a high level of expression of the DQB1*05:01 molecules on these cells (assessed by Serum AS, Table 1), one of these sera (TE) did not react with B cells; and serum AA reacted very weakly. (Table Presented) Conclusion(s): These results indicate that the level of reactivity of anti-DQ antibody with SAB do not consistently correlate with reactivity with B cells. The assessment of donor specific antibody and donor selection by Luminex SAB assays alone may be inadequate.

Keating, F. (2005). "PLASTIC FANTASTIC." Materials Recycling Week **186**(11): 64-64.
The article focuses on the recycling of waste plastics. With plastics taking up to 400 years to break down in a landfill, it is an area that needs urgent attention. Even more worryingly, it is a problem which is growing, with research by Great Britain's Department for Environment, Food and Rural Affairs finding that consumers use more than eight billion plastic carrier bags a year. However, an innovative solution by a North Yorkshire farmer could help address the problem of the mountains of plastic generated in Great Britain. John Gaskarth, a farmer, has developed a process which converts any type of waste plastic into a drainage system called Aquadyne.

Kedzierski, M., et al. (2016). "Microplastics elutriation from sandy sediments: A granulometric approach." Marine Pollution Bulletin **107**(1): 315-323.
Although relatively easy to extract in the marine environment, microplastics are very difficult to recover when they are trapped in sediments. The elutriation column is one of the best tools currently available for extracting plastics from sediment, but with a high sand recovery yield. This study aims to address the following questions: (i) is it possible to use a sedimentological approach to limit the sand recovery? (ii) does the extraction velocity of the sand and plastic particles vary according to density and granulometry? (iii) what is the relative recovery efficiency obtained for dense polymer particles mixed with marine sand? Based on a new granulometric classification, different plastic particle-size fractions are defined. Their extraction velocities are experimentally determined on particles of sediment and different plastics (PA, PVC). The particle recovery experiments indicate that it is possible to extract > 90% of dense plastic particles in cases of negligible sand recovery. Copyright © 2016 Elsevier Ltd.

Kedzierski, M., et al. (2017). "Microplastics elutriation system. Part A: Numerical modeling." Marine Pollution Bulletin **119**(2): 151-161.
The elutriation process has shown its efficiency to extract microplastics from sand and began to spread in the scientific community. This extraction technic requires knowing with accuracy the extraction velocities of particles. This study aims to test whether numerical modeling could help to calculate these velocities. From hydrodynamic equations, a numerical model has been developed and the outputs are compared to experimental extraction data. The results show, for the calculated velocities, the experimental plastic extraction yields will be higher than 90% for <10% of sand contamination. The model also allows determining that, with the actual protocol, the maximum plastic density which can be extracted is about 1450kg.m⁻³ whereas the detrimental resuspension, which may occur during the column filling step, is highlighted. From model calculations, it arises that changes in the column dimensioning and the protocol operations need to be considered.

Kedzierski, M., et al. (2019). "Microplastics in Mediterranean Sea: A protocol to robustly assess contamination characteristics." PLoS ONE [Electronic Resource] **14**(2): e0212088.
The study of microplastic pollution involves multidisciplinary analyses on a large number of microplastics. Therefore, providing an overview of plastic pollution is time consuming and,

despite high throughput analyses, remains a major challenge. The objective of this study is to propose a protocol to determine how many microplastics must be analyzed to give a representative view of the particle size distribution and chemical nature, and calculate the associated margin error. Based on microplastic data from Tara Mediterranean campaign, this approach is explained through different examples. In this particular case, the results show that only 3% of the collected microplastics need to be analyzed to give a precise view on the scale of the North West Mediterranean Basin (error <5%), and 17.7% to give an overview manta per manta (error <10%). This approach could be an important practical contribution to microplastic studies.

Keisling, C., et al. (2020). "Low concentrations and low spatial variability of marine microplastics in oysters (Crassostrea virginica) in a rural Georgia estuary." Marine Pollution Bulletin **150**: 110672.

Microplastics are an emerging concern for the health of marine ecosystems. In the southeastern US, the filter-feeding Eastern oyster, Crassostrea virginica, is susceptible to microplastic ingestion. We quantified the distribution of microplastics within adult oysters (harvestable size >7.5cm) from 28 reefs throughout a rural estuary with limited riverine inputs (St. Catherines Sound, Georgia). To determine which variables best predict microplastic concentration in oysters, we also quantified oyster recruitment, distance to ocean, fetch, and water body width. Oysters averaged 0.72 microplastic particles per individual (0.18 particles per gram wet mass); microfragments and microplastics were equally abundant. Although microplastic concentrations were low, multivariate models identified a positive effect of water body width on the site-level concentration of plastic microfibers; average microfragment length was affected by fetch. Our work informs a growing understanding of microplastic distribution in coastal estuaries, providing an important rural contrast to the urbanized estuaries that have been examined.

Keith, J. I. (2015). "A Taste of Plastic." Orion Magazine **34**(4): 12-13.

The article offers the author's insights on the effects of plastic garbages in mussels and oysters. Topics discussed include the effects of plastics in the health of humans, the study by researchers in Belgium at Ghent University which reveals that microplastics were found in foods consumed by humans, and the number of plastic particles that are consumed by some Europeans.

Kelkar, V. P., et al. (2019). "Chemical and physical changes of microplastics during sterilization by chlorination." Water Research **163**: 114871.

Wastewater treatment plants are known to release microplastics that have been detected in aquatic and terrestrial organisms constituting part of the human diet. Chlorination of wastewater-borne microplastics was hypothesized to induce chemical and physical changes detectable by Raman spectroscopy and differential scanning calorimetry (DSC). In the laboratory, virgin plastics (~0.05x2x2mm) were exposed to differing sterilization conditions representative of dosages used in the disinfection of drinking water, wastewater, and heavily contaminated surfaces. Polypropylene (PP) was most resistant to chlorination, followed by high density polyethylene (HDPE) and polystyrene (PS). Polystyrene showed degradation, indicated by changes in Raman peak widths, at concentration-time regimes (CT values) as low as 75mgmin/L, whereas HDPE and PP remained unaltered even at chlorine doses characteristic of wastewater disinfection (150mgmin/L). However, HDPE and PS were not completely resistant to oxidative attack by chlorination. Under extremely harsh conditions, shifts in Raman peaks and the formation of new bonds were observed. These results show that plastics commonly used in consumer products can be chemically altered, some even under conditions prevailing during wastewater treatment. Changes in polymer properties, observed for HDPE and PP under extreme exposure conditions only, are predicted to alter the risk microplastics pose to aquatic and terrestrial biota, since an increase in carbon-chlorine (C-Cl) bonds is known to increase toxicity, rendering the polymers more hydrophobic and thus more prone to adsorb, accumulate, and transport harmful persistent pollutants to biota in both aquatic and terrestrial environments.

Kellar, K. L. (2003). "Applications of Multiplexed Fluorescent Microsphere-Based Assays to Studies of Infectious Disease." Journal of Clinical Ligand Assay **26**(2): 76-86.

The study of infectious diseases has advanced as technology has developed beyond the use of culture and microscopy to detect pathologic organisms. Polymerase chain reaction (PCR) and immunoassay are currently the basis of most microbiologic procedures, but more rapid, sensitive, automated and high throughput methods are expanding the repertoire of techniques available to discover, diagnose and clinically manage the common and newly emerging infectious diseases that traverse the world today. Fluorescent microsphere-based assays take advantage of the multiparametric resolving power of flow cytometry and the surface-binding characteristics of microbeads. Multiplexed fluorescent microsphere arrays can replace the one sample, one analyte assay with a multiple sample, multiple analyte approach needed to unravel the complexity of biomolecular interactions and meet the requirements for rapid analysis platforms in the post-genomic era. These assays are applicable to any ligand-ligand binding format and have the potential to revolutionize the analytical methods that dominant laboratory protocols.

Keller, A. S., et al. (2020). "Transport of Nano- and Microplastic through Unsaturated Porous Media from Sewage Sludge Application." Environmental Science & Technology **09**: 09.

Wastewater treatment plants have been identified as important hubs for small particulate plastic, down to the nanometer scale, from urban areas to the environment. The reuse of sludge as fertilizer in agricultural practices can lead to accumulation of plastic in the soil. In this study, nanoplastic particles and microplastic fibers were synthesized with a passive inorganic tracer to aid in faster and more quantitative analysis using inductively coupled plasma mass spectrometry (ICP-MS). Using the anaerobic digestate of a pilot wastewater treatment plant spiked with metal-doped plastic, the excess sludge was dewatered, ensuring realistic associations between sludge and plastic. The resulting sludge cake was affixed atop an unsaturated porous-medium column of glass beads to assess: (i) the release of particulate plastic from the sludge, and (ii) the accumulation and mobility of plastic and organic matter through the column (analogous to a soil). A total of three particulate plastic treatments were assessed, in triplicate, where the plastic and mobile organic fractions were monitored for 14 pore water volumes. Due to size-limited transport, low deattachment from the sludge and reduced mobility through the column were found for microplastic fibers (>95% retention). However, cotransport between the mobile organic fraction and nanoplastic particles was observed, with 50% of both retained in the column. These results contribute to the understanding of the fate of particulate plastics and to assessing the associated environmental risks of particle mobility and percolation, particularly for nanoplastics.

Kelly, M. R., et al. (2019). "Importance of Water-Volume on the Release of Microplastic Fibers from Laundry." Environmental Science & Technology **53**(20): 11735-11744.

The influence of laundry washing parameters on the release of microfibers (MF) from polyester textiles was studied. These fibers are an important type of microplastic pollution. However, the factors which affect MF release during laundry are poorly understood and more rigorous

methods for quantifying this release are needed. A novel method was therefore developed using a tergotometer with eight 1000 mL washing vessels and the CIELab color space measure of lightness (L*). L* was related to the mass of released MFs by creating a calibration curve to quantify the amounts of MFs released from textiles during washing. This method was used to investigate the effect of water-volume, agitation, temperature, and duration of the wash on MF release. Counterintuitively, increased water-volume, characteristic of European "delicate" cycles, resulted in the greatest release of MFs. Full-scale testing was then carried out using domestic washing machines with real consumer cycles to determine the effect of cycle type on MF release. In the first wash, delicate wash cycles released 800 000 more MFs (94 mg/kg) per wash than a lower water-volume standard wash and also increased MF release in subsequent washing cycles ($P < 0.05$). These results indicate that a high water-volume-to-fabric ratio is the most influential factor for MF release, rather than agitation as previously thought. Therefore, consumers can reduce MF release by avoiding high water-volume washes (delicate cycles), transitioning to appliances that use a lower water-volume (North American high-efficiency washing machines), and ensuring that full wash loads are used.

Kendall, W. F., Jr., et al. (2004). "Effect of alginate composition and purity on alginate microspheres." Journal of Microencapsulation **21**(8): 821-828.

BACKGROUND: Alginate is commonly used to microencapsulate islets in experiments with islet allografts and xenografts for the treatment of Type I diabetes. The purpose of the present study is to determine the effects of alginate composition and purity on the morphology and size of microspheres.

METHODS: Microcapsules produced with the impure alginate types, medium-viscosity high-guluronic acid (IMVG), low-viscosity high-G (ILVG), low-viscosity high-mannuronic acid (ILVM) and medium-viscosity high-M (IMVM) were compared with one another and others generated with a highly purified LVM (HPLVM) alginate. Droplets of 1.5% alginate from an air-syringe pump were gelled in 1.1% CaCl2 solution. While leaving the alginate pressure and needle recess constant, the air-jacket pressure was varied between 9.5-10.5 PPSI to enhance stable microcapsule generation and different batches of microbeads were made from each alginate type.

RESULTS: The sizes of the high-guluronic acid alginate microbeads were consistently bigger than those of the corresponding high-mannuronic acid alginate beads at all air-jacket settings. At the optimal air-jacket pressure of 9.0 PPSI, the mean+SD diameter of the IMVG microbeads was 780 + 20 microm, while that of IMVM was 607 + 44 microm ($p < 0.0001$, $n=30$). Similarly, the mean ILVG microbead diameter was 816+28 microm compared to 656+26 microm for ILVM capsules ($p<0.0001$, $n=30$). Less polymorphism was found with the HPLVM microspheres than with the ILVM microbeads.

CONCLUSION: Highly purified high-mannuronic acid alginate will provide smaller, spherical microcapsules suitable for islet cell transplantation.

Kennedy, P. M., et al. (1992). "Intake and digestion in swamp buffaloes and cattle. 1. The digestion of rice straw (Oryza sativa)." Journal of Agricultural Science **119**(2): 227-242.

Swamp buffaloes and Bos indicus X B. taurus cattle, with ruminal and abomasal or duodenal fistulae were fed on rice straw with mineral supplements in 2 experiments. In experiment 1, the straw was supplemented with 5% of leaf of Leucaena leucocephala, and in experiment 2 with urea or urea with sunflower meal and rice grain. Intake of supplements of urea or urea/sunflower/rice respectively was 935 and 681 g/kg given to buffaloes and 566 and 789 in cattle. Buffaloes ruminated longer than cattle (experiment 1, 635 vs. 452; experiment 2, 626 vs. 466 min/day, $P<0.01$). In experiment 1, intake and frequency of 'A' sequence forestomach

contractions of both species was not different, but buffaloes had a greater (P<0.05) contraction force in the rumen and omasum, lower rate of 'B' sequence rumen contractions, and faster (P<0.001) rate of gastrointestinal passage than cattle. In experiment 2, intake of both species was similar, and concentrates did not affect voluntary roughage intake, nor in situ rate of digestion of rice straw. Digestion of dietary materials did not differ between species in experiment 1, despite lower concentrations of ammonia in rumen fluid in cattle than buffaloes; however in experiment 2, the rate of digestion of rice straw was higher (P<0.05) and predicted extent of digestion was 14-20% (P<0.05) lower in buffaloes. Digestibility of cell wall constituents was lower (P<0.05) in buffaloes than in cattle, but in experiment 2, concentrates reduced (P<0.01) the proportion of digestible cell wall constituents digested in the forestomach of buffaloes, but not of cattle. Plasma urea was higher (P<0.05) and transfer of urea to the rumen was higher (7.4 vs. 3.7 g N/day; P<0.10) in buffaloes. Faster fractional outflow rates of microbes and of small digesta particles from the rumen were seen in buffaloes in experiment 1. In experiment 1, more microbial N left the abomasum (35 vs. 30 g/kg organic matter apparently digested in the forestomach; P<0.05) of buffaloes than cattle, and in experiment 2 more non-ammonia N (43 vs. 31 g/kg organic matter apparently digested in the forestomach) flowed into the intestines of buffaloes. In experiment 1 microbial retention time was shorter (26 vs. 47 h; P<0.01) in the rumen of buffaloes. Appearance of plastic particles with time after dosing indicated faster escape from the rumen of buffaloes of non-chewed particles, and a greater proportion of particles subjected to ruminative chewing, than in cattle. Ruminative chewing of plastic particles in buffaloes was more efficient than in cattle with increasing particle length and decreasing specific gravity. Analysis of faecal particle distribution indicated buffaloes excreted smaller particles than cattle. It is concluded that the adaptive significance of faster digesta passage in the buffaloes appeared to derive from a more balanced supply of absorbed protein relative to digestible energy.

Kennedy, P. M., et al. (1992). "Influence of dietary particle size on intake, digestion, and passage rate of digesta in goats and sheep fed wheaten (Triticum aestivum) hay." Small Ruminant Research **9**(2): 125-138.

Castrated goats and Merino sheep about 1 year old and 26 and 35 kg liveweight, respectively, were fed on wheat hay diets, with urea and minerals. The diets were chopped (1 cm) hay, pellets, and 2 mixtures of chopped/pellets in the ratio 2:1 and 1:2. Goats selected more pellets from the mixed diets than did sheep. DM digestibility was similar in both species, but decreased with increasing pellet content. Feed intake and digestible DM intake per kilogram metabolic liveweight by goats were lower than for sheep. Reticulorumen fill increased from 166 g for goats fed on chopped or pelleted diets to 250-280 g/kg body weight (BW) when fed mixtures of chopped and pelleted diets. Fill in sheep was relatively constant at 221-237 g/kg BW for all diets. DM content of reticulorumen digesta was higher (P<0.01) in goats than in sheep (13.2 vs. 11.3%), whereas the mean particle size of digesta was smaller (P<0.01) in goats. Five varieties of plastic particles of defined length and specific gravity, were inserted into the reticulorumen via cannula, and unchewed plastic particles were recovered in faeces. Cumulative recovery of plastic particles over 120 h after dosing was greater for sheep. Kinetic analysis of the excretion patterns of the plastic particles indicated that in goats the rate of passage from the reticulorumen was lower, and the rate of reduction of particle size was higher, than in sheep. Apparent fractional passage rates of digesta from the reticulorumen and of small particles labelled with chromium, were also lower in goats than in sheep, but DM flows per volume of fluid were similar between species. The significant variability in degree of fill in the reticulorumen in goats appeared to be not to be due to particle size, and substantially contributed to lower rates of passage in goats.

Kent, S. (1996). "ENVIRONMENTAL HUSBANDRY." Recycling Textile & Plastic Waste: 173-178.
The article focuses on the attention given to pollution and environmental issues in Great Britain through the development of water laws and the demands of textile retailing chains that their suppliers be environmentally-friendly. Companies have to respond to the challenges of maintaining growth, improved flexibility and optimization of cost and efficiency and should find solutions to environmental issues. At Parkland Manufacturing, they address environmental issues by developing an environmental strategy where they find out what law requires, find a partner, assign a person who is responsible for such matters. Next, they start to examine all stages of the manufacturing process and identify the areas affected if solvent process will be eliminated and lastly, source reduction.

Kentin, E. and H. Kaarto (2018). "An EU ban on microplastics in cosmetic products and the right to regulate." Review of European Comparative & International Environmental Law **27**(3): 254-266.
In January 2018, the European Commission initiated a restriction procedure on microplastics in cosmetic products. This article deals with the legal implications of a European Union (EU) restriction under the Regulation on the Registration, Evaluation, Authorisation and Restriction of Chemicals (REACH) in relation to the right to regulate in the EU and in the context of the World Trade Organization (WTO). The article argues that in the aftermath of harmonization, the legal scope for EU Member States is dependent on the definition that will be adopted as regards microplastics under REACH: the wider the scope of the restriction, the more probable it is that Member States' action is restrained. In the context of WTO rules, similar considerations apply as regards the scope of the definition: the wider the scope of an EU ban, the more demanding it will be to satisfy the requirements under the Agreement on Technical Barriers to Trade. Providing scientific evidence is instrumental, as there is little room for the precautionary principle in both regimes. [ABSTRACT FROM AUTHOR]

Kerby, M. B., et al. (2006). "Measurements of kinetic parameters in a microfluidic reactor." Analytical Chemistry **78**(24): 8273-8280.
Continuous flow microfluidic reactors that use immobilized components of enzymatic reactions present special challenges in interpretation of kinetic data. This study evaluates the difference between mass-transfer effects and reduced efficiencies of an enzyme reaction. The kinetic properties of immobilized alkaline phosphatase (AP) were measured by the dephosphorylation of 6,8-difluoro-4-methylumbelliferyl/phosphate to a fluorescent 6,8-difluoro-4-methylumbelliferone. A glass microfluidic chip with an in-channel weir was created for the capture of solid silica microbeads functionalized with enzyme. The input substrate concentrations and flow rates across the bed were varied to probe the flow-dependent transport and kinetic properties of the reaction in the microreactor bed. Unlike previous reactors, substrate was titrated directly over the fixed enzyme bed by controlling the air pressure over the chip reservoirs. The reactor explored substrate conversions from near zero to 100%. The average bed porosity, residence time, and bed resistance were measured with dye

pulses. A simple criterion was derived to evaluate the importance of flow-dependent mass-transfer resistances when using microreactors for calculating kinetic rate constants. In the absence of mass-transfer resistances, the Michaelis-Menten kinetic parameters are shown to be flow independent and are appropriately predicted using low substrate conversion data. A comparison of the kinetic parameters with those obtained using solution-phase enzymatic reactions shows a significant decrease in enzyme activity in the immobilized conformation. The immobilized Km of AP is approximately 6 times greater while the kcat is reduced by approximately 28 times. Contradictions found in literature on the evaluation of Michaelis-Menten kinetic parameters for immobilized enzymes in microfluidic reactors are addressed. When product molecules occupy a significant number of enzymatic sites or modify the enzyme activity, the assumed Michaelis-Menten mechanism can no longer be valid. Under these conditions, the calculations of "apparent" kinetic rate constants, based on Michaelis-Menten kinetics, can superficially show a dependence on flow rate conditions even in the absence of mass-transfer resistances. High substrate conversions are shown to depend on flow rate. A kinetic model based on known mechanisms of the alkaline phosphatase enzyme reaction is tested to predict the measurements for high substrate conversion. The study provides a basis for appropriate use of mass-transfer and reaction arguments in successful application of enzymatic microreactors.

Keren, A., et al. (2018). "Innate lymphoid cells 3 induce psoriasis in xenotransplanted healthy human skin." Journal of Allergy and Clinical Immunology **142**(1): 305-308.e306.

To the Editor: Recent studies have demonstrated that the number of group 3 innate lymphoid cells (ILC3s) is increased in peripheral blood, lesional skin, and nonlesional skin of patients with psoriasis.1,E1,E2 However, definitive evidence is as yet entirely missing that these innate immunocytes, which produce IL-22 and IL-17, but not TNF-α or IFN-γ, and lack cytotoxic effectors,E2 are functionally involved in the induction of psoriatic lesions in human skin. [...]the present study aimed to determine whether human ILC3s (ie, CD3− RORγt+ NKp44+ cells)E1 suffice to induce psoriatic lesions in healthy human skin in vivo. Flow cytometric analysis documented the absence of γδ T cells and natural killer (NK) cells in the ILC3 preparation, while 5% γδ T cells and NK cells were present in the TH17/Tc17 cell cultures (Fig E2, D).6 The purified ILC3s were associated with the expected intracellular cytokine expression pattern5,7,E9: 78% of ILC3s showed IL-22 expression, and 10% ± 3% of these cells were double-positive for both IL-17 and IL-22 (Fig E3, B). Animal handling was in accordance with the national guidelines and approved by the Technion Animal Care and Use Committee.Culture of cells with IL2 and AhR agonist To obtain an enriched RORγt + cell culture, PBMCs from 8 normal volunteers were incubated with a high dose of IL-2 (100 U/mL) and AhR agonistE12,E13 200 nM (6-formylindolo carbazole, Enzo) for 14 days.E7Magnetic isolation of TH17-cell and ILC subsets from IL2+AhR-activated PBMC cultures Separation was performed using anti-CD3 antibodies conjugated to ferromagnetic microbeads (Miltenyi Biotec, Bergisch Gladbach, Germany) and directed through a cell separation column containing a magnetic field (Miltenyi Biotec).

Kergaravat, S. V., et al. (2012). "Biotin determination in food supplements by an electrochemical magneto biosensor." Talanta **97**: 484-490.

An electrochemical magneto biosensor for the rapid determination of biotin in food samples is reported. The affinity reaction was performed on streptavidin-modified magnetic microbeads as a solid support in a direct competitive format. The biotinylated horseradish peroxidase enzyme (biotin-HRP) competes with free biotin in the sample for the binding sites of streptavidin on the magnetic microbeads. The modified magnetic beads were then easily captured by a magneto

graphite-epoxy composite electrode and the electrochemical signal was based on the enzymatic activity of the HRP enzyme under the addition of H(2)O(2) as the substrate and o-phenilendiamine as cosubstrate. The response was electrochemically detected by square wave voltammetry. The limit of detection was 8.4x10(-8) mol L(--1) of biotin (20 mug L(--1)) with a dynamic range from 0.94 to 2.4x10(-7) mol L(--1). Biotin-fortified commercial dietary supplement and infant formula samples were evaluated obtaining good performances in the results. Total time of analysis was 40 min per 20 assays.

Kershaw, P. J. (2011). "BEWARE MERMAID'S TEARS." Our Planet **22**(1): 26-27.
The article discusses increasing marine pollution due to plastics. There are several types of plastics which are buoyant and very durable, and their debris is common on coastlines worldwide. Plastic particles are known to damage or block an animal's digestive tract or other organs, depending on its lifestyle and the quantities involved. Plastic pollution may gradually decline as a problem if waste is considered a valuable resource.

Keserue, H. A., et al. (2011). "Rapid detection and enumeration of Giardia lamblia cysts in water samples by immunomagnetic separation and flow cytometric analysis." Applied & Environmental Microbiology **77**(15): 5420-5427.
Giardia lamblia is an important waterborne pathogen and is among the most common intestinal parasites of humans worldwide. Its fecal-oral transmission leads to the presence of cysts of this pathogen in the environment, and so far, quantitative rapid screening methods are not available for various matrices, such as surface waters, wastewater, or food. Thus, it is necessary to establish methods that enable reliable rapid detection of a single cyst in 10 to 100 liters of drinking water. Conventional detection relies on cyst concentration, isolation, and confirmation by immunofluorescence microscopy (IFM), resulting in low recoveries and high detection limits. Many different immunomagnetic separation (IMS) procedures have been developed for separation and cyst purification, so far with variable but high losses of cysts. A method was developed that requires less than 100 min and consists of filtration, resuspension, IMS, and flow cytometric (FCM) detection. MACS MicroBeads were used for IMS, and a reliable flow cytometric detection approach was established employing 3 different parameters for discrimination from background signals, i.e., green and red fluorescence (resulting from the distinct pattern emitted by the fluorescein dye) and sideward scatter for size discrimination. With spiked samples, recoveries exceeding 90% were obtained, and false-positive results were never encountered for negative samples. Additionally, the method was applicable to naturally occurring cysts in wastewater and has the potential to be automated.

Kesimer, M. and J. K. Sheehan (2008). "Analyzing the functions of large glycoconjugates through the dissipative properties of their absorbed layers using the gel-forming mucin MUC5B as an example." Glycobiology **18**(6): 463-472.
Glyconjugates such as mucins, proteoglycans, and polysaccharides form the structural basis of protective cell-surface layers. In particular gel-forming mucins define a zone between the epithelial cell layer and the environment. Such molecules are of extreme molecular weight 5-100 x 10(6) and size (Rg 20-300 nm). On this account their biochemistry is inseparable from their physical biochemistry. Combining laser light scattering and quartz crystal mass balance with dissipation methods (QCM-D) we have investigated the properties of the MUC5B mucin and its cognate fragments when bound to a hydrophobic surface. MUC5B forms the basis of gels responsible for the protection of the oral cavity, lung, and cervical canal surfaces. Here we show, by analyzing dissipative interactions of hydrophobic, gold, and polystyrene surfaces, with the

intact MUC5B molecule, its reduced subunits, and glycosylated tryptic fragments (obtained after reduction), the formation of 40- to 100-nm-thick highly structured, hydrated interfaces. These interfaces are dominated in their geometry and dissipative properties by the negatively charged carbohydrate-rich domains of the molecule, the naked protein domains being responsible for attachment. These carbohydrate-rich surfaces have well-defined absorptive properties and permit the entry and entrapment of albumin-coated micro-beads into the absorbed layer at and below a size of 60 nm. However beads larger than 100 nm are completely excluded from the surfaces. These absorptive phenomena correlate with large changes in film dissipation and thus may not only be important in biological functions, e.g. binding viruses, but could also be informative to the surfaces (often ciliated) onto which such mucus films are attached.

Kessel, A., et al. (2005). "Increased plasma levels of matrix metalloproteinase-9 are associated with the severity of chronic urticaria." Clinical & Experimental Allergy **35**(2): 221-225.

BACKGROUND: Matrix metalloproteinase (MMP)-9 is produced by many inflammatory cells such as macrophages, neutrophils, mast cells, eosinophils and T lymphocytes. Activated T cells are capable, through cell-cell contact, of inducing MMP-9 expression in human mast cells.

OBJECTIVE: To investigate the activation status of peripheral CD4+ T cells and the level of MMP-9 in the plasma of patients with chronic urticaria (CU), and whether MMP-9 levels are in association with CU severity.

METHODS: Study subjects included 29 patients with CU and 30 healthy control subjects. At the time of assessment, patients were divided into subgroups according to urticarial severity. Plasma levels of total MMP-9 (free pro-MMP-9 and free MMP-9) were determined by ELISA. CD4+ lymphocytes were positively selected with magnetic microbeads. After 48 h of activation, CD4+ T cells were assayed for both nuclear factor-kappa B (NF-kappa B) expression and proliferation.

RESULTS: Plasma levels of MMP-9 were found to be significantly higher in 29 CU patients compared with 18 healthy controls (186 +/- 174 vs. 31 +/- 21 ng/mL, P<0.0001). We also found a significant correlation between MMP-9 levels and urticarial severity (r = 0.92, P<0.001). In addition, CD4+ T cells from CU patients expressed higher levels of NF-kappa B than CD4+ T cells from healthy controls (82 +/- 30 vs. 69 +/- 20 optical density, P = 0.007). Finally, as compared with seven healthy individuals, DNA synthesis in CD4+ T cells from seven CU patients was found to be significantly elevated (1000 +/- 240 vs. 751 +/- 166 counts per minute, P = 0.01).

CONCLUSION: Increased levels of MMP-9 are found in CU patients, and particularly among those with severe disease. We also demonstrated that CD4+ T cells from such patients are highly activated.

Keswani, A., et al. (2016). "Microbial hitchhikers on marine plastic debris: Human exposure risks at bathing waters and beach environments." Marine Environmental Research **118**: 10-19.

Marine plastic debris is well characterized in terms of its ability to negatively impact terrestrial and marine environments, endanger coastal wildlife, and interfere with navigation, tourism and commercial fisheries. However, the impacts of potentially harmful microorganisms and pathogens colonising plastic litter are not well understood. The hard surface of plastics provides an ideal environment for opportunistic microbial colonisers to form biofilms and might offer a protective niche capable of supporting a diversity of different microorganisms, known as the "Plastisphere". This biotope could act as an important vector for the persistence and spread of pathogens, faecal indicator organisms (FIOs) and harmful algal bloom species (HABs) across beach and bathing environments. This review will focus on the existent knowledge and research gaps, and identify the possible consequences of plastic-associated microbes on human health, the spread of infectious diseases and bathing water quality.

Kesy, K., et al. (2016). "Polystyrene influences bacterial assemblages in Arenicola marina-populated aquatic environments in vitro." Environmental Pollution **219**: 219-227.

Plastic is ubiquitous in global oceans and constitutes a newly available habitat for surface-associated bacterial assemblages. Microplastics (plastic particles <5 mm) are especially susceptible to ingestion by marine organisms, as the size of these particles makes them available also to lower trophic levels. Because many marine invertebrates harbour potential pathogens in their guts, we investigated whether bacterial assemblages on polystyrene are selectively modified during their passage through the gut of the lugworm Arenicola marina and are subsequently able to develop pathogenic biofilms. We also examined whether polystyrene acts as a vector for gut biofilm assemblages after subsequent incubation of the egested particles in seawater. Our results showed that after passage through the digestive tract of A. marina, the bacterial assemblages on polystyrene particles and reference glass beads became more similar, harbouring common sediment bacteria. By contrast, only in the presence of polystyrene the potential symbiont Amphritea atlantica was enriched in the investigated biofilms, faeces, and water. Thus, especially in areas of high polystyrene contamination, this polymer may impact the bacterial composition of different habitats, with as yet unknown consequences for the respective ecosystems.

Kettenmann, S. (2016). "Nationwide Ban on Plastic Microbeads in Cosmetics." Natural Resources & Environment **31**(1): 58-59.

The article examines the features of the U.S. Microbead-Free Waters Act of 2015 aimed to ban bans plastic microbeads that are produced for exfoliates in cosmetic consumer products and causing damage to marine environments, including rivers, lakes, and oceans.

Kettner, M. T., et al. (2019). "The Eukaryotic Life on Microplastics in Brackish Ecosystems." Frontiers in Microbiology **10**: 538.

Microplastics (MP) constitute a widespread contaminant all over the globe. Rivers and wastewater treatment plants (WWTP) transport annually several million tons of MP into freshwaters, estuaries and oceans, where they provide increasing artificial surfaces for microbial colonization. As knowledge on MP-attached communities is insufficient for brackish ecosystems, we conducted exposure experiments in the coastal Baltic Sea, an in-flowing river and a WWTP within the drainage basin. While reporting on prokaryotic and fungal communities from the same set-up previously, we focus here on the entire eukaryotic communities. Using high-throughput 18S rRNA gene sequencing, we analyzed the eukaryotes colonizing on two types of MP, polyethylene and polystyrene, and compared them to the ones in the surrounding water and on a natural surface (wood). More than 500 different taxa across almost all kingdoms of the eukaryotic tree of life were identified on MP, dominated by Alveolata, Metazoa, and Chloroplastida. The eukaryotic community composition on MP was significantly distinct from wood and the surrounding water, with overall lower diversity and the potentially harmful dinoflagellate Pfiesteria being enriched on MP. Co-occurrence networks, which include prokaryotic and eukaryotic taxa, hint at possibilities for dynamic microbial interactions on MP. This first report on total eukaryotic communities on MP in brackish environments highlights the complexity of MP-associated biofilms, potentially leading to altered microbial activities and hence changes in ecosystem functions.

Kettner, M. T., et al. (2017). "Microplastics alter composition of fungal communities in aquatic ecosystems." Environmental Microbiology **19**(11): 4447-4459.

Summary Despite increasing concerns about microplastic (MP) pollution in aquatic ecosystems, there is insufficient knowledge on how MP affect fungal communities. In this study, we explored the diversity and community composition of fungi attached to polyethylene (PE) and polystyrene (PS) particles incubated in different aquatic systems in north-east Germany: the Baltic Sea, the River Warnow and a wastewater treatment plant. Based on next generation 18S rRNA gene sequencing, 347 different operational taxonomic units assigned to 81 fungal taxa were identified on PE and PS. The MP-associated communities were distinct from fungal communities in the surrounding water and on the natural substrate wood. They also differed significantly among sampling locations, pointing towards a substrate and location specific fungal colonization. Members of Chytridiomycota, Cryptomycota and Ascomycota dominated the fungal assemblages, suggesting that both parasitic and saprophytic fungi thrive in MP biofilms. Thus, considering the worldwide increasing accumulation of plastic particles as well as the substantial vector potential of MP, especially these fungal taxa might benefit from MP pollution in the aquatic environment with yet unknown impacts on their worldwide distribution, as well as biodiversity and food web dynamics at large.

Khadijah Husna, A. H., et al. (2019). "Semi-refined carrageenan film incorporated with alpha -tocopherol: application in food model." Journal of Food Processing and Preservation **43**(5).

Semi-refined carrageenan (SRC) film plasticized with glycerol and incorporated with alpha -tocopherol was prepared for food packaging application. Functional characterization, thermal stability, and microstructure of SRC-based films were analyzed. The effects of antioxidant alpha -tocopherol from SRC-based film were studied based on thiobarbituric acid-reactive substance assay, metmyoglobin assay, and pH value in food model (meat patties) for 12 days of storage. The development of lipid oxidation was delayed in the meat patties wrapped with antioxidant films during the storage with the final value of 0.68-0.37 mg malondialdehyde/kg sample. A less than 50% brown color development (metmyoglobin) of the meat patties wrapped with antioxidant film was observed in the first nine days of storage. Hence, the incorporation of alpha -tocopherol into the SRC-based film could be an alternative way to prolong the shelf life of food product, reducing the use of synthetic preservative directly into food product. Practical applications: Recent strategy on the development of biodegradable film for food packaging is important as an alternative to the petrochemical-derived plastic that is harmful to the environment. SRC is one of the potential biopolymers that has the ability to form a strong gel and provides efficient barrier against gas, lipids, and oils, and addition of plasticizer glycerol into SRC enhanced mechanical and barrier properties of the films. The present study showed the potential of alpha -tocopherol within the SRC film plasticized with glycerol as active packaging on the film characteristics and increased the shelf life of meat patties. Hence, the active packaging film developed is not only contributes to reduce plastic waste discharged to environment but can be a potential substitute of synthetic preservative in food.

Khaiboullina, S., et al. (2017). "Zika virus infection activates proinflammatory cytokines and triggers monocyte differentiation." Blood. Conference: 59th Annual Meeting of the American Society of Hematology, ASH **130**(Supplement 1).

In 2015, Zika virus (ZIKV) outbreak in several countries of South America was linked to microcephaly in newborns. Microcephaly, a severe clinical presentation, was first diagnosed in association with ZIKV, which primarily considered self-limiting infection. From infected keratinocytes, virus disseminates crossing blood-tissue barriers and is detected in various tissues including brain, muscles and placenta. One of the mechanisms utilized by viruses to cross tissue barriers involves leukocytes, where monocytes are often identified as the carriers. Recently, circulating monocytes were shown to harbor ZIKV, suggesting that these leukocyte populations

could serve as vehicle to transport ZIKV to the fetus. We speculate that ZIKV infection could promote monocyte activation and release of cytokines causing tissue damage. However, little is known about monocyte susceptibility to ZIKV infection. Also, effect of ZIKV infection on transcriptional activation and production remains unclear. Materials and methods. Monocytes were isolated from cord blood buffy coats (University of Colorado Cord Blood Bank, Aurora) using Miltenyi magnetic bead separation kit (CD14 Microbeads; Miltenyi, Auburn, CA). Monocytes were infected with two ZIKV strains, PRVABC59 (South America) and IBH30656 (Nigeria), ATCC (Manassas, VA). Total RNA was extracted and used for Next generation Sequencing (Illustra RNAspin Mini kit (GE Healthcare, Marlborough, MA)). FastQ data generated by the MiSeq (Illumina, San Diego CA) was annotated and the sequence reads were analyzed by CLC workbench 9.0.1 (Qiagen, Germantown, MD) for the detection of viral and cellular genes. Differential expressions of cellular genes based on the Reads Per Kilobase of transcript per Million mapped reads were determined by comparing with mock-infected cells using RNA-seq analysis tool of CLC Workbench. Differentially regulated genes due to ZIKV infection, identified by CLC Workbench, were subjected for determining the deregulated pathways using IPA Ingenuity Pathways analysis tool (Qiagen Germantown, MD). Viral replication was determined by qPCR, Western blot and immunofluorescence. Cytokine activation was analyzed using Bio-Plex Pro Human Cytokine 27-plex Panel (Bio-Rad, Hercules, CA, USA) following manufacturer's instructions. Results. We have shown that South American and Nigerian strains of ZIKV can infect monocytes and actively replicate. Presence of capsid protein and accumulation of viral transcripts was demonstrated in vitro. Infection with PRVABC59 strain changes transcriptional activity of 332 cellular genes, while the Nigerian strain affected the transcription of 521 cellular genes compared to the mock-infected controls. Interestingly, 195 genes were commonly deregulated in cells infected with both strains. Analysis of these commonly affected genes identified multiple pathways including apoptosis, chemotaxis, cell proliferation, inflammation, acute phase response, mitochondria activation. The most amazing observation was upregulation of mitochondrial and inflammasome genes. Mitochondrial genes (MT-ND2, MT-ND5 and MT-ATP8) activated in ZIKV infected monocytes were shown to play a key role in pathogenesis of other neurodegenerative disease. Analysis of cytokine production revealed early activation of proinflammatory cytokines (IL-1beta, IL-6 and IL-8) (Table 1). Upregulation of IL-1beta by ZIKV infected monocytes is evident for inflammasome activation. Upregulation of IL-6, IL-10 and IL-17alpha suggested an activation of Th17 pathway in ZIKV infected monocytes. Besides only Nigerian ZIKV strain increased the production of IL-4 in monocytes. IL-4 together with IL-10 could promote Th2 type immune response to ZIKV. Finally, both strains increased production of FGF, while levels of VEGF were increased only in supernatants of PRVABC59 infected monocytes. Conclusion(s): Human monocytes are susceptible to infection with ZIKV strains, PRVABC59 and IBH30656 and support viral replication. ZIKV infection affects cellular pathways, including mitochondrial and inflammasome ones that could play significant role in pathogenesis. ZIKV infection of monocytes upregulates cytokine production, which can trigger inflammation and leukocyte migration. Analysis of cytokine production by ZIKV infected monocytes suggests activation of Th2 and Th17 leukocytes, supporting the role of this signaling in ZIKV pathogenesis.

Khajuria, D. K., et al. (2020). "Ionic Diffusion and Drug Release Behavior of Core-Shell-Functionalized Alginate-Chitosan-Based Hydrogel." ACS Omega **5**(1): 758-765.

This paper reports the core-shell structure effects in calcium alginate (CaALG) microbeads due to the threshold water level for phase transition and correlates these properties with respect to pH and electrical conductivity. Further, in this study, we used a novel microfluidic device for drug release testing to study the programmed release of risedronate (RIS-anti-osteoporotic drug) encapsulated in pH-responsive CaALG-chitosan (CHT) microbeads. Our microfluidic device contains a single straight microchannel containing a steplike barrier design used to restrict the mobility of the microbeads at the sample detection zone. For optical and fluorescence microscopy, single fluorescently labeled CaALG-CHT microbead containing RIS was placed in the sample detection zone by flowing through the inlet port with ultrapure water. The RIS release behavior from the microbeads at different pH (2.1, 4, 6.8, and 7.4) conditions was determined by using a spectrophotometer connected to the outlet port of the device.

Khalida, J., et al. (2018). "Effects of virgin microplastics on goldfish (Carassius auratus)." Chemosphere **213**: 323-332.

Microplastics (MPs) are abundant in freshwater and marine environments. They are diverse shape and size and are ingested by organisms. In this study, goldfish (Carassius auratus) were exposed via diet to three types of virgin MPs material types and shapes including fibers, fragments, and pellets. After six weeks of exposure, various sub-lethal effects, but no mortality, was observed. Fish exposed to plastic showed significant weight loss compared with the control. Fibers were found in the gills, gastrointestinal tract (GIT), and feces were not likely to accumulate in the GIT. Pronounced and severe alterations were found in the livers of fish exposed to fibers. The distal intestine showed more pronounced and severe changes compared to the proximal intestine, likely due to an intake of fibers. The ingestion of fibers caused the highest frequencies of progressive and inflammatory changes in the livers and intestines. This is in accordance with the higher organ index in these organs compared to other texa. Conversely, fragments and pellets were not ingested but chewed and expelled. Chewing process resulted in damages to the jaws as ranging from slight exfoliation to deep incisions. The highest frequency of regressive and circulatory (e.g., dilated sinusoids) changes was found in fish exposed to fragments, specifically in the upper and lower jaw, and in lower jaw and liver, respectively. Together, these results demonstrate that ingestion and chewing of MPs lead to damages in various organs and tissues of the gastrointestinal system, and suggest that different materials can have drastically different impacts on fish.

Khalik, W. M. A. W. M., et al. (2018). "Microplastics analysis in Malaysian marine waters: A field study of Kuala Nerus and Kuantan." Marine Pollution Bulletin **135**: 451-457.

The first report on the emergence of microplastic in Malaysian marine waters was documented in this study. Water samples were collected from two regions, namely Kuala Nerus and Kuantan port, as the representatives of different anthropogenic activities. Identification of microplastic was performed based on physical characteristics (colour, shape, density) and chemical characterisation (ATR-FTIR analysis) for a functional group of polymers. Fragment type, black or grey colour and high density (>1.02 g cm⁻³) of microplastic were the most prevalent characteristics found in both areas. Two principal components (density and colour) rendered explained about 95.3% (Kuantan) and 95.6% (Kuala Nerus) of the total variance. Six possible polymer materials were identified, namely polyester, polystyrene, polyamide, polyvinyl chloride, polypropylene, and polyethylene. The findings of the study provided good baseline information on marine debris issue in Malaysia. Copyright © 2018 Elsevier Ltd

Khaliq, A., et al. (2017). "Field evaluation of a blood based test for active tuberculosis in endemic settings." PLoS ONE **12 (4) (no pagination)**(e0173359).

Over 9 million new active tuberculosis (TB) cases emerge each year from an enormous pool of 2 billion individuals latently infected with Mycobacterium tuberculosis (M. tb.) worldwide. About

3 million new TB cases per year are unaccounted for, and 1.5 million die. TB, however, is generally curable if diagnosed correctly and in a timely manner. The current diagnostic methods for TB, including state-of-the-art molecular tests, have failed in delivering the capacity needed in endemic countries to curtail this ongoing pandemic. Efficient, cost effective and scalable diagnostic approaches are critically needed. We report a multiplex TB serology panel using microbead suspension array containing a combination of 11 M.tb. antigens that demonstrated overall sensitivity of 91% in serum/plasma samples from TB patients confirmed by culture. Group wise sensitivities for sputum smear positive and negative patients were 95%, and 88%, respectively. Specificity of the test was 96% in untreated COPD patients and 91% in general healthy population. The sensitivity of this test is superior to that of the frontline sputum smear test with a comparable specificity (30-70%, and 93- 99%, respectively). The multiplex serology test can be performed with scalability from 1 to 360 patients per day, and is amenable to automation for higher (1000s per day) throughput, thus enabling a scalable clinical work flow model for TB endemic countries. Taken together, the above results suggest that well defined antibody profiles in blood, analyzed by an appropriate technology platform, offer a valuable approach to TB diagnostics in endemic countries. Khamput, P. and K. Suweero (2014). "Using of Para-rubber to develop properties of concrete block mixed with Ethylene Vinyl Acetate plastic in masonry." International Journal of Environmental and Rural Development **5**(2): 86-92.

The aim of this research is to use Para-rubber (vulcanized latex) as an admixture for improving the properties of EVA plastic waste concrete block. In mix design, cement per EVA plastic waste per quarry dust per water ratio is 1:0.5:4:1.6 by weight, vulcanized latex per cement ratios are 0.00, 0.05, 0.10, 0.15, 0.20, 0.25, 0.30, 0.35, 0.40, and 0.45 respectively (by weight of cement), no charge surfactant is 4% (by weight of vulcanized latex). The suitable ratio of vulcanized latex per cement in this testing is 0.15 (by weight of cement). The properties are obtained as follows. (1) The average density in 14 days is 1,169.59 kg/m³. (2) The average water absorption in 14 days is 9.33%. (3) The average compressive strength in 28 days is 25.74 ksc. (4) The coefficient of thermal conductivity is 0.1527 W/m.K. (5). The sound absorption coefficient at 2,000 hertz is 0.38. (6) The noise reduction coefficient is 0.3. It can be seen that many properties are better than normal EVA plastic waste concrete blocks.

Khan, A. A., et al. (2009). "Human hepatic epithelial progenitor cell transplantation to the patients with end stage liver cirrhosis." Hepatology International **3 (1)**: 216.

A late stage of progressive hepatic fibrosis characterized by distortion of the hepatic architecture, necrosis of hepatocytes and the formation of regenerative nodules contributes to cirrhosis. Limitations like organ donors shortage, high cost, absence of proliferation in cultured hepatocytes, inherent risks of infection, rejection in xenogenic cells and other socio-economical complications emerges advanced regenerative Human hepatic stem cells(hHpSCs) transplantation. hHpSCs are located in the ductal plates in fetal and Canals of Hering in adult livers[Schmelzer et al.(2006)]. Hepatoblasts, in turn, give rise to the hepatocytic and biliary lineages, the hepatocytes and cholangiocytes[SchmelzerE etal(2006)].hHpSCs express CD326(EpCAM)marker. Scjelzer etal demonstrated that during embryogenesis 90% of the EpCAM positive cells had hepatoblast phenotype. In animal study, on transplantation of freshly isolated hHpSCs in SCID mice results in mature liver tissue expressing human-specific proteins.

Recently, we(Aleem etal 2008)have shown clinical improvement in study in patients with Crigler-Najjar syndrome, Biliary atresia using hHpSCs infusion. In the present study we transplanted hepatic progenitors to five subjects of end stage liver cirrhosis with MELD score >30. hHpSCs were sorted using MACS with CD326 antibody microbeads and infused through hepatic artery via femoral artery catheterization, a safe procedure provided portal pressure to monitor cell infusion route in order to prevent vascular thrombosis. All the patients showed improvement clinical and functional biochemical parameters after first month of cell infusion. Ascites was decreased and changed Encephalopathy grade into normal level was observed. MELD score system falling to normal level from >30 to <22 after infusion.

Khan, A. A., et al. (2000). "Dam-Break Surges with Floating Debris." Journal of Hydraulic Engineering **126**(5): 375-380.

The effect of floating debris on dam-break surges is studied experimentally. Hexahedron plastic particles having a specific gravity of 0.92 are used as debris. In addition to qualitative investigation of the surge behavior, the speed and height of the surges are plotted for various downstream to upstream depth ratios and debris concentration. The results are compared with the clear-water surges. Deceleration and the increase in height of the surge are more pronounced for smaller initial depths downstream of the gate. In general, the speed of the surge is found to be a function of downstream to upstream depth ratio, the ratio of the mass of the debris per unit surface area to the mass of the water per unit surface area upstream of the gate, and the particle size relative to the upstream depth. The wave height, on the other hand, is found to be a function of the depth and concentration ratios for smaller initial downstream depths. For higher initial downstream depths, the wave height is a function of the depth ratio only.

Khan, D., et al. (2016). "Impact of socioeconomic status on municipal solid waste generation rate." Waste Management **49**: 15-25.

The solid waste generation rate was expected to vary in different socioeconomic groups due to many environmental and social factors. This paper reports the assessment of solid waste generation based on different socioeconomic parameters like education, occupation, income of the family, number of family members etc. A questionnaire survey was conducted in the study area to identify the different socioeconomic groups that may affect the solid waste generation rate and composition. The average waste generated in the municipality is 0.41kg/capita/day in which the maximum waste was found to be generated by lower middle socioeconomic group (LMSEG) with average waste generation of 0.46kg/capita/day. Waste characterization indicated that there was no much difference in the composition of wastes among different socioeconomic groups except ash residue and plastic. Ash residue is found to increase as we move lower down the socioeconomic groups with maximum (31%) in lower socioeconomic group (LSEG). The study area is a coal based city hence application of coal and wood as fuel for cooking in the lower socioeconomic group is the reason for high amount of ash content. Plastic waste is maximum (15%) in higher socioeconomic group (HSEG) and minimum (1%) in LSEG. Food waste is a major component of generated waste in almost every socioeconomic group with maximum (38%) in case of HSEG and minimum (28%) in LSEG. This study provides new insights on the role of various socioeconomic parameters on generation of household wastes.

Khan, F., et al. (2019). "Understanding consumers' behavior intentions towards dealing with the plastic waste: Perspective of a developing country." Resources, Conservation and Recycling **142**: 49-58.

Plastic consumption has been increasing globally, creating large amount of litter and posing threat to the environment. The recycling of the plastic waste can help in reducing it and its environmental threat. The purpose of this paper is to identify the factors that influence the consumer's return/recycling intention regarding plastic waste. Moreover, recycling behavior of consumer was explored in detail. The theory of planned behavior was adapted and extended to measure the determinants of recycling behavior. Survey research design was employed whereas data includes valid 243 households, collected through survey questionnaire, by employing purposive sampling. PLS-SEM was applied on the collected data for hypotheses testing. The finding of this study indicates that subjective norms, awareness consequences and convenience are major predictors of return/recycling intention. Whereas, hypothesis for the attitude, perceived behavioral control and moral norms were rejected and they all have insignificant impact on return/recycling intention. Moreover, return intention have positive significant impact on resell, reuse, dispose and donate. Reuse was the most predicted by the return intention. This study enriches the literature of reverse logistics helping to understand the consumers' perspective. Provides the insights that will help government and organizations to understand consumers' return/recycling intention and formulate such strategies that will increase the involvement of consumers in recycling activities. Copyright © 2018 Elsevier B.V.

Khan, F., et al. (2019). "Managing plastic waste disposal by assessing consumers' recycling behavior: the case of a densely populated developing country." Environmental Science & Pollution Research **26**(32): 33054-33066.

The rapid increase in urbanization has given rise to the need of proper waste management. Within municipal waste, the plastic waste is a growing concern which is causing severe harm to our ecosystem. If ignored, this problem will have harmful effects on both human and wildlife. Therefore, this study aims to find out the factors that influence the recycling behavior patterns of consumers regarding plastic waste. The variables from the theory of planned behavior were adopted to study the behavior of consumers toward recycling plastic waste. The data was collected from 243 residents of Karachi-metropolitan city of Pakistan. The partial least square-structural equation modelling was applied to analyze the data. The findings of the current study reveal that different consumers' attributes and attitudes trigger different types of recycling behavior when it comes to waste disposal. Pressure from family and friends and perceived behavioral control trigger the behavior of reselling the waste plastic products while consumer's awareness of consequences and personal attitude toward proper waste disposal leads to reuse or donating that product to someone who can use that plastic product. The understanding of these consumer attributes may help to shape the behavioral outcomes in order to manage waste disposal. This study will be beneficial for business managers looking to improve reverse logistics as well as government/municipal policy makers and academics/researchers who are interested in a solution-oriented study.

Khan, F., et al. (2009). "Nasal epithelial cells of donor origin after allogeneic Hematopoietic Cell Transplantation (HCT): Result of cell fusion, transdifferentiation of hematopoietic stem cells or transfer of epithelial cell precursors with the graft?" Journal of Allergy and Clinical Immunology **1)**: S147.

RATIONALE: Epithelial cells (ECs) of respiratory mucosa are generally believed to originate from epithelial stem cells and not from hematopoietic stem cells (HSC). However, donor origin ECs have occasionally been detected in HCT recipients, suggesting an HSC origin. Transfer of ECs or their precursors with the graft, or epithelial-hematopoietic cell fusion may represent an alternative explanation. Here we evaluated the frequency of donor nasal epithelial cells in posttransplant patients, and the underlying mechanism. METHOD(S): We collected nasal scrapings and blood from 23 HCT survivors, early (2-3 months, n = 5) or late (4-22 years, n = 18) posttransplant. Nasal cells were cytospinned and stained with cytokeratin (CK) and CD45 antibodies. DNA extracted from laser-captured ECs (CK + CD45-) and blood leukocytes was PCR amplified for 16 short tandem repeat chimerism markers. FISH for two autosomes was performed in 8 patients to assess cell fusion. Magnetic separation using CD36-microbeads and CK staining was utilized to identify ECs in 3 PBSC graft specimens. RESULT(S): In all 23 HCT survivors, ECs of donor origin were identified; 2-12% nasal epithelial cells were of donor-type. The percentage of donor ECs was significantly higher in late (mean = 7%) compared to early (mean = 4%) posttransplants (p = 0.004). None of the nasal ECs in all HCT survivors studied exhibited cell fusion. CD36 + CK + ECs were identified in all graft specimens studied. CONCLUSION(S): Donor-origin nasal ECs can be found in all transplant recipients. This appears to be due to transdifferentiation of HSC into ECs or the transfer of ECs (or their precursors) with the graft, but not due to cell fusion.

Khan, F. R., et al. (2017). "Do polyethylene microplastic beads alter the intestinal uptake of Ag in rainbow trout (Oncorhynchus mykiss)? Analysis of the MP vector effect using in vitro gut sacs." Environmental Pollution **231**(Part 1): 200-206.

Microplastic (MP) vector effects have been well described in the literature but surprisingly little is in known about the impact of MPs on the intestinal uptake of contaminants. The present study aimed to determine whether the intestinal fate of Ag was affected by the presence of polyethylene MP beads. Ag (added as ^{110 m}Ag) was introduced into the lumen of rainbow trout (Oncorhynchus mykiss) anterior/mid-intestine gut sac preparations as Ag only, Ag and MPs (co-exposure) and Ag-incubated MPs (where Ag was adsorbed to the MP). Results show that after 3 h exposure the distribution of accumulated Ag between the four intestinal compartments (mucus layer, mucosal epithelium, muscle layer and serosal saline) was not affected by either MP condition when compared to Ag alone (p >0.05, One way ANOVA). Across all treatment groups mucus layer binding dominated (54.2-72.6%) whereas relatively little Ag was transported to the blood compartment (i.e. combined muscle layer and serosal saline compartments, 8.5-15.0%). Accompanying adsorption/desorption studies were performed in relevant media. Over 24 h, 60.6+or- 2.9% of the available Ag in artificial freshwater adhered to the surface of the PE MPs. In pH adjusted luminal fluids (pH 2.2, 4.1, 7.4 and 9.8) that span the range of conditions encountered within the rainbow trout digestive tract, there was almost complete dissociation at acidic pHs within 3 h (<2% remaining on MPs at both pH 2.2 and pH 4.1). Such pHs are typical of piscine stomach. Based on our finding we suggest that following the ingestion of MPs with adsorbed pollutants, desorption would occur prior to entering the site of uptake. The MPs themselves have no impact on the trans-epithelial transport of the contaminant, but the net result of the MP vector effect is to potentially introduce labile contaminant forms into the intestine.

Khan, F. R., et al. (2015). "Influence of polyethylene microplastic beads on the uptake and localization of silver in zebrafish (Danio rerio)." Environmental Pollution **206**: 73-79.

This study aimed to determine whether the uptake and localization of Ag in zebrafish was affected by the presence of polyethylene microplastic beads (PE MPBs). Zebrafish were exposed to 1 micro g Ag L⁻¹ (radiolabelled with ^{110 m}Ag) for 4 and 24 h in the presence or absence of PE MPBs (10, 100 or 1000 MPBs mL⁻¹), and one treatment in which MPBs (1000 MPBs mL⁻¹) were incubated with Ag to promote adsorption. The presence of MPBs, at any of the tested doses, had no effect on the uptake or localization of Ag. However, exposure to the Ag-incubated MPBs (~75% of the Ag bound to MPBs) significantly reduced Ag uptake at both time points and also significantly increased the proportion of

intestinal Ag. This study demonstrates that microplastics can alter the bioavailability and uptake route of a metal contaminant in a model fish species.

Khan, I. H., et al. (2005). "Simultaneous serodetection of 10 highly prevalent mouse infectious pathogens in a single reaction by multiplex analysis." Clinical and Diagnostic Laboratory Immunology **12**(4): 513-519.

Under current practices of mouse colony maintenance, sera from mice are analysed for antibodies against several widespread infectious pathogens by conventional immunoassays, generally enzyme-linked immunosorbent assay (ELISA). To test for multiple agents, these methods consume large volumes of mouse serum and are laborious and time-consuming. More efficient immunoassays, using small amounts of sample, are therefore needed. Accordingly, we have developed a novel multiplex diagnostic system that employs fluorescent microbeads, coated with purified antigens, for simultaneous serodetection of 10 mouse infectious agents. Individually identifiable, fluorescent microbeads were coated with antigens from Sendai virus, mouse hepatitis virus, Theiler's mouse encephalomyelitis virus/GDVII strain, mouse minute virus, mouse cytomegalovirus, respiratory enteric orphan virus (Reo-3 virus), mouse parvovirus, calf rotavirus for epizootic diarrhoea virus of infant mice, vaccinia virus for ectromelia virus, and Mycoplasma pulmonis. Standard sera, singly positive for antibodies to individual infectious agents, were generated by inoculation of BALB/cj and C57BL/6j mice. Sera from these experimentally infected mice, as well as sera from naturally infected mice, were analysed using a mixture of microbeads coated with antigens of the 10 infectious agents listed above. Results demonstrated that the multiplex assay was at least as sensitive and specific as ELISA for serodetection. Importantly, the multiplex assay required only 1 microliter of serum for simultaneous serodetection of the 10 mouse infectious agents in one reaction vessel. Thus, this multiplex microbead assay is a reliable, efficient, and cost-effective diagnostic modality that will impact serosurveillance of mice used in research.

Khan, I. H., et al. (2011). "Plasma antibody profiles as diagnostic biomarkers for tuberculosis." Clinical & Vaccine Immunology: CVI **18**(12): 2148-2153.

Two billion people are infected with Mycobacterium tuberculosis, the etiological agent of tuberculosis (TB), worldwide. Ten million to 20 million of the infected individuals develop disease per year. TB is a treatable disease, provided that it is diagnosed in a timely manner. The current TB diagnostic methods are subjective, inefficient, or not cost-effective. Antibody-based blood tests can be used efficiently and cost-effectively for TB diagnosis. A major challenge is that different TB patients generate antibodies against different antigens. Therefore, a multiplex immunoassay approach is needed. We have developed a multiplex panel of 28 M. tuberculosis antigen-coated microbeads. Plasma samples were obtained from over 300 pulmonary TB patients and healthy controls in a country where TB is endemic, Pakistan. Multiplex data were analyzed using computational tools by multivariate statistics, classification algorithms, and cluster analysis. The results of antibody profile-based detection, using 16 selected antigens, closely correlated with those of the sputum-based diagnostic methods (smear microscopy and culture) practiced in countries where TB is endemic. Multiplex microbead immunoassay had a sensitivity and specificity of approximately 90% and 80%, respectively. These antibody profiles could potentially be useful for the diagnosis of nonpulmonary TB, which accounts for approximately 20% of cases of disease. Since an automated, high-throughput version of this multiplex microbead immunoassay could analyze thousands of samples per day, it may be useful for the diagnosis of TB in millions of patients worldwide.

Khan, I. H., et al. (2008). "Profiling antibodies to Mycobacterium tuberculosis by multiplex microbead suspension arrays for serodiagnosis of tuberculosis." Clinical & Vaccine Immunology: CVI **15**(3): 433-438.
Tuberculosis (TB) is a serious global disease. The fatality rate attributed to TB is among the highest of infectious diseases, with approximately 2 million deaths occurring per year worldwide. Identification of individuals infected with Mycobacterium tuberculosis and screening of their immediate contacts is crucial for controlling the spread of TB. Current methods for detection of M. tuberculosis infection are not efficient, in particular, for testing large numbers of samples. We report a novel and efficient multiplex microbead immunoassay (MMIA), based on Luminex technology, for profiling antibodies to M. tuberculosis. Microbead sets identifiable by unique fluorescence were individually coated with each of several M. tuberculosis antigens and tested in multiplex format for antibody detection in the experimental nonhuman primate model of TB. Certain M. tuberculosis antigens, e.g., ESAT-6, CFP-10, and HspX, were included to enhance the specificity of the MMIA, because these antigens are absent in nontuberculous mycobacteria and the vaccine strain Mycobacterium bovis bacillus Calmette-Guerin. The MMIA enabled simultaneous detection of multiple M. tuberculosis plasma antibodies in several cohorts of macaques representing different stages of infection and/or disease. Antibody profiles were defined in early and latent/chronic infection. These proof-of-concept findings demonstrate the potential clinical use of the MMIA. In addition, the MMIA serodetection system has a potential for mining M. tuberculosis open reading frames (about 4,000) to discover novel target proteins for the development of more-comprehensive TB serodiagnostic tests.

Khan, I. U., et al. (2013). "Continuous-flow encapsulation of ketoprofen in copolymer microbeads via co-axial microfluidic device: influence of operating and material parameters on drug carrier properties." International Journal of Pharmaceutics **441**(1-2): 809-817.
Microchannels based microfluidic systems are able to obtain monodispersed microparticles but are limited by cost, time and channel clogging. We succeeded in on the fly encapsulation of high ketoprofen contents in acrylate-based copolymer microbeads by environment friendly UV induced free radical polymerization in off-the-shelf co-axial microfluidic device. FTIR shows complete polymerization of acrylate monomers and interaction between carboxylic group of ketoprofen and ester group of monomers. DSC and XRD confirm amorphous nature of drug in microbeads. Different comonomer content formulations show limited drug release at low pH, a helpful properties to avoid gastric irritating effect of ketoprofen associated with conventional dosage forms. At pH 6.8 microbeads release higher content of drug by a non-Fickian diffusion mechanism. Their drug release rate depends upon the weight content of ethyl acrylate in the formulation as well as their size, increasing by increasing the former and decreasing the later.

Khan, M. B. and R. S. Prezant (2018). "Microplastic abundances in a mussel bed and ingestion by the ribbed marsh mussel Geukensia demissa." Marine Pollution Bulletin **130**: 67-75.
Human activities have generated large quantities of microplastics that can be consumed by filter-feeding organisms as potential food sources. As a result, organisms may experience marked reductions in growth and/or health. To date there has been no investigations connecting microplastics (MPs) with the critically important ribbed mussel Geukensia demissa. Here we examined MP abundances within a bed of G. demissa in New Jersey.

Khan, M. S., et al. (2010). "Development and evaluation of pH-dependent micro beads for colon targeting." Indian Journal of Pharmaceutical Sciences **72**(1): 18-23.
The purpose of this research was to develop and evaluate multiparticulates of alginate and chitosan hydrogel beads exploiting pH sensitive property for colon-targeted delivery of

theophylline. Alginate and chitosan beads were prepared by ionotropic gelation method followed by enteric coating with Eudragit S100. All formulations were evaluated for particle size, encapsulation efficiency, swellability and in vitro drug release. In vitro dissolution studies performed following pH progression method demonstrated that the drug release from coated beads depends on coat weights applied and pH of dissolution media. Mechanism of drug release was found to be swelling and erosion-dependent. The studies showed that formulated alginate and chitosan beads can be used effectively for the delivery of drug to colon and a coat weight of 20% weight gain was sufficient to impart an excellent gastro resistant property to the beads for effective release of drug at higher pH values.

Khandagale, A. B., et al. (2012). "Neutrophil-dependent cleavage of Tissue Factor Pathway Inhibitor (TFPI) supports blood coagulation in arterial and microvessel thrombosis." Hamostaseologie **32 (1)**: A8.

Aim: Role of neutrophil elastase and cathepsin G in fibrin formation via cleavage of tissue factor pathway inhibitor (TFPI) , the physiological inhibitor of tissue factor. Method(s): We prepared human platelets and isolated human neutrophils using microbeads or Ficoll gradients. eNuc were prepared using nuclei of HeLa cells. We performed site-directed mutagenesis of human TFPI to get T87F/L89A mutant. Confocal imaging was used to detect arterial thrombi, externalised nucleosomes and neutrophils. TFPI degradation was anlysed using Western blot technique. Whole-blood coagulation was measured by thrombelastography. Result(s): We found that in suspension of human neutrophils and platelets, neutrophil elstase (NE) was exposed together with externalised nucleosomes (eNuc) on the surface of neutrophils. NE induced cleavage of the endogenous anticoagulant TFPI was enhanced by eNuc. which is resistant to cleavage by NE and cathepsin G (CG). T87F/L89A mutant reduced fibrin formation in human whole blood more effectively than native TFPI. An inhibitor of NE reduced fibrin formation to the same extend as the T87F/L89A mutant. Western blot analysis showed cleavage of TFPI by NE was increased more than 2-fold by e-Nuc. This effect could be inhibited with anti H2A-H2B-DNA antibody. In arterial thrombi recovered from wt mice, TFPI was strongly degraded. In contrast, TFPI remained largely intact in mice lacking NE and CG (NE^{-/-}/CG^{-/-}) supporting NE-dependent TFPI cleavage. In parallel, fibrin formation and thrombus sizes were reduced in the carotid artery (FeCl<inf>3</inf>) and in liver microvessels of NE^{-/-}/CG^{-/-} mice. The anti H2A-H2B-DNA antibody also diminished intravascular thrombus formation in the carotid artery and in liver microvessels. Conclusion(s): Our study shows that neutrophil serine proteases propagate and stabilize nascent thrombi in arterial vessels and microvessels by cleavge of TFPI an physiological inhibitor of coagulation activator.

Kharat, V. T., et al. (2017). "Studies on development of probiotic chocolate by using microencapsulated Lactobacillus strains." Trends in Biosciences **10**(20): 3832-3836.

The popularity of chocolate around the world combined with high level of health related awareness of the contemporary consumer, imposed the idea of enriching chocolate with probiotic bacterial strains. The main objective of this work was to obtain a potentially probiotic chocolate by using microencapsulated Lactobacillus strains. The Lactobacillus strains were encapsulated as micro-beads by using sodium alginate and guar gum and these beads were incorporated into chocolate suspension. This probiotic milk chocolate displayed the same sensory properties as the reference, probiotic-free chocolate. The number of live bacterial cells was maintained at the functional level of 107-109 Cfu/g after keeping for 4 weeks at 40 C. Neither the texture nor the total and volatile acidity of chocolate masses were changed by addition of the microencapsulated Lactobacillus cells.

Kharya, D. G., et al. (2015). "Haploidentical paternal TCRAB and CD 19 depleted stem cell transplant for severe combined immunodeficiency with pneumocystis jiroveci pneumonia." Bone Marrow Transplantation **1)**: S341.

Introduction: In haploidentical hematopoietic stem cell transplant (HSCT), in vitro T-cell depletion of the graft is effective at preventing graft versus host disease (GVHD). Various T-cell depletion strategies have been used over time to minimize GVHD and maximize sustained engraftment and early immune reconstitution in alternative donor transplants with variable success rates. Depletion of T cell receptor alpha and beta (TCRab) and CD 19+ cells, with selection of TCRgd T-cells is a new technique with promising results in haploidentical HSCT. We report a child with Severe Combined Immunodeficiency (SCID) with pneumocystis jiroveci pneumonia (PCP) treated successfully using this method. Materials (or patients) and methods: Five months old male baby with SCID (T-B-NK+) with PCP requiring ventilator support was shifted to BLK SSH for further management. PCP was managed with septran and clindamycin. In the absence of suitably matched family or unrelated donor he was taken up for haploidentical paternal HSCT. He was conditioned using Fludarabine 30 mg/m² (D-7 to D-3), Treosulfan 12gm/m² (D-7 to D-5), Thymoglobulin 2.5 mg/kg (D-9 to D-6). GVHD prophylaxis included cyclosporine. Stem cells were mobilized using GCSF and peripheral blood stem cells were harvested. In vitro TCRab T cells were depleted using bioitnylated anti ab antibody followed by antibiotin antibody conjugated to magnetic microbeads. B cells were depleted using CD19 conjugated microbeads. He received 8.5x10^8/kg total nucleated cells, 14.7x10^6/kg CD34 cells, 1.7x10^4/kg TCRab T cells (3.91 log reduction), 11.8x10^6/kg TCRgd T cells, 3.7x10^4 CD19 cells (3.07 log reduction). Result(s): Polymorphonuclear cell and platelet engraftment were seen on D+10 and D+12 respectively. Chimerism on day +15 showed 100% donor cells. There is no evidence of acute or chronic GVHD. He was discharged on D+28 in good clinical condition. He is currently D+75 post HSCT clinically well, on tapering doses of cyclosporine. His immune reconstitution assay shows he has good numbers of NK cells but T cells have yet not appeared. Conclusion(s): Successful Haploidentical Paternal TCRab and CD19 Depleted Stem Cell Transplant for SCID despite PCP Infection. This appears to be a promising technique in haploidentical or MMUD HSCT with early and sustained engraftment, early immune recovery and less risk of GVHD. This is the first reported case of haploidentical HSCT using this technique for primary immunodeficiency in India.

Khawaja, X. Z. (2007). "Development of a scintillation proximity assay for human insulin-like growth factor-binding protein 4 compatible with inhibitor high-throughput screening." Analytical Biochemistry **366**(1): 80-86.

The insulin-like growth factor-binding protein 4 (IGFBP-4), which exists in many different tissues and biological fluids, modulates insulin-like growth factor 1 (IGF-1) bioavailability in part by competitive sequestration and prevention of interaction with cell membrane IGF-1 receptors. Accordingly, small molecules that inhibit the ability of IGF-1 to associate with IGFBP-4 may have clinical utility as regulators of cellular proliferation, survival, and differentiation. Currently, a polyethylene glycol-based precipitation of [(125)I]IGF-1 bound to IGFBP-4 is used to quantify selective IGFBP-4 ligand interactions. We have developed a novel 96-well plate scintillation proximity assay (SPA) for measuring small molecule interactions at IGFBP-4 using a biotinylated form of IGFBP-4 coupled to streptavidin-coated polyvinyltoluene (PVT) SPA microbeads and using [(125)I]IGF-1 as the endogenous ligand. Dose-displacement curves with unlabeled IGF-1 exhibited a mean K(d) value of 0.46 nM. Parallel studies using the nonselective IGFBP inhibitor, NBI-31772, generated a K(i) value of 47 nM. Under optimized conditions, the IGFBP-4 SPA was stable for up to 24h at room temperature and was unaffected by dimethyl sulfoxide (DMSO,<0.5%). This homogeneous binding assay is simple, stable, sensitive, and amenable to automation. The good signal/noise ratio (10:1) and Z' factor (0.7-0.8) make it compatible with high-throughput screening platforms for the identification of IGFBP-4 inhibitors. The IGFBP-4 binding assay may be expanded to other IGFBP members, in biotinylated form, to provide a powerful tool amenable to drug screening and the design of therapeutics to treat a variety of IGF-responsive diseases.

Khim, J. S., et al. (2018). "A comparative review and analysis of tentative ecological quality objectives (EcoQOs) for protection of marine environments in Korea and China." Environmental Pollution **Part B. 242**: 2027-2039.

Ecological quality objectives (EcoQOs), as tools for implementing ecosystem approach, have long been acknowledged to protect the marine ecosystems and fisheries in regional seas through joint efforts by surrounding countries over the past decade. The present review analyzed the best available meta-data relating to the five ecosystem elements that were recently proposed by the Northwest Pacific Action Plan to evaluate the current status of coastal ecosystem health in marine environment of the Yellow Sea. We suggested the six tentative EcoQOs among five ecological quality elements including: 1) biological and habitat diversity; 2) invasive species; 3) eutrophication; 4) pollutants; and 5) marine litters. Environmental status was assessed, depending on the EcoQOs targets, by comparison to the world average values, existing environmental standards, or reported values of other regional seas. Results of analysis revealed that among the six tentative EcoQOs, two target objectives to marine biodiversity and concentrations of nutrients (viz., DIN and DIP) were met towards good environmental status. Whilst, three EcoQOs relating to hypoxia and red-tide, pollutants (persistent toxic substances and metals), and marine litters (including microplastics) did not meet and one relating to invasive species could not be judged due to insufficient data sets. The biggest weak point for developing suitable EcoQOs and assessing status of ecosystem health could be insufficient meta-data sets available and/or discrepancy in methodological details cross the data-sets or between the two targeted countries. Thus, the cooperation of neighboring countries, viz., Korea and China for the Yellow Sea, is necessary for the ecosystem based management of our regional sea in the future. Overall, this first time review for the assessment of target tentative EcoQOs in the Yellow Sea region encompassing coasts of Korea and China would provide a better understanding of the current status of environmental pollution and ecosystem health. "Six tentative EcoQOs developed to assess current status of ecosystem health in the marine environments of the Yellow Sea with comparative review and analysis for selected ecosystem elements". Kholidah, N., et al. (2018). "Polystyrene plastic waste conversion into liquid fuel with catalytic cracking process using Al₂O₃ as catalyst." Science and Technology Indonesia **3**(1): 7-13.

The increase in energy consumption and an increase in plastic waste generation are two major problems that arise along with economic growth and the increase of population. Styrofoam is one type of polystyrene plastic waste that can be processed into liquid fuels by cracking process. In this study, the cracking process of polystyrene plastic waste into liquid fuel carried by the catalytic cracking process using Al₂O₃ as catalyst. This study aimed to determine the effect of the catalyst weight, length of cracking time and range of temperature in the catalytic cracking process of polystyrene plastic waste into liquid fuel toward the mass and characteristics of liquid fuels produced and to determine the composition of liquid fuels produced. The catalytic cracking process of polystyrene plastic waste with catalyst was done in

the fixed bed type reactor by heating the reactor with a heater, where the process took place at temperature of 150 degrees C, 200 degrees C, 250 degrees C and 300 degrees C and the length of the process was varied into 20, 40, and 60 minutes and the catalyst weight was also varied, which were 4%, 6% and 8%, while the styrofoam weight was 250 grams. From the research, the highest mass of liquid fuel derived from polystyrene catalytic cracking process was in the amount of 48.8 grams and liquid yield percentage of 19.5% at temperature of 250 degrees C, cracking time of 60 minutes and weight of 8% catalyst, while the characteristics of liquid fuel that were approaching the characteristics of gasoline was at temperatures of 250 degrees C, cracking time of 60 minutes and weight of 6% catalyst, in which each value of density of 0.763 g/ml, specific gravity of 0.778 and oAPI gravity of 50.2. While other liquid fuels obtained from the cracking of polystyrene were still within the tolerance range characteristic properties of gasoline. Liquid fuels produced from the catalytic cracking process was analyzed using a GC-MS, in which the analysis results indicated that liquid fuels were included into the gasoline fraction.

Khoramnejadian, S. (2011). "Converting non-biodegradable plastic to biodegradable by using natural polymer to help environment conservation." Journal of Food, Agriculture and Environment **9**(2): 477-479.

Plastic waste cause a problem for environmental conservation, plastic materials are resistant against degradation by microorganisms and remain in the environment for many years. Biodegradable polymers could solve this problem. In this article, biodegradability of Linear Low Density Polyethylene (LLDPE) with chitosan was studied. Polyethylene grafted maleic anhydride (PE-g-MA) was used as a compatibilizer. Samples with different levels of chitosan (3.7%, 7.4%, 10%, 15% and 20%) with constant amount of PE-g-MA were prepared. In all samples amount of compatibilizer was same. The biodegradation of blends was studied with soil burial and exposure to mould growth. Biodegradation was determined by weight loss, change in mechanical properties of the sheets, mould growth and SEM test. The results showed that with increasing chitosan content biodegradability of blends increased. Biodegradation of the samples due to soil burial after 11 months revealed that the weight of the blends was decreased by increasing the chitosan level.

Khordagui, H. K. and A. H. Abu-Hilal (1994). "Industrial plastic on the southern beaches of the Arabian Gulf and the western beaches of the Gulf of Oman." Environmental Pollution **84**(3): 325-327.

The increasing production and use of plastic in the Arabian Gulf combined with shipping and waste disposal practices, have increased the concentration of plastic particles on the sea's surface and beaches. The objective of this investigation was to provide an assessment of the abundance, distribution, potential sources and significance of industrial plastic on the western beaches of the United Arab Emirates on the Arabian Gulf and on the eastern beaches on the Gulf of Oman. The abundance of stranded plastic pellets was highly uneven. By early 1992 alarming levels of fresh plastic pellets were noticed on the Arabian Gulf beaches of the UAE. Large numbers of 25 kg sacks of white plastic spherules manufactured by (SABIC) in Jubail, Saudi Arabia were washed ashore. When compared to the west coast on the Arabian Gulf, the east coast on the Gulf of Oman exhibited much lower levels of plastic pellets. When compared to other parts of the world, the beaches of the UAE on the Arabian Gulf are considered to be heavily polluted with industrial plastic.

Khosrovyan, A. and A. Kahru (2019). "Evaluation of the hazard of irregularly-shaped co-polyamide microplastics on the freshwater non-biting midge Chironomus riparius through its life cycle." Chemosphere **244**: 125487.

Plastics pollution is increasingly attracting societal and political attention. However, despite extensive research effort recently dedicated to the hazard of plastics in the environment, the data obtained are often redundant and essential knowledge gaps exist: available freshwater ecotoxicity data mostly concern Daphnia magna and are derived from acute exposure to spherical particles. In this paper, we address this gap by exploring the biological effects of irregularly-shaped co-polyamide (PA, 10-180 mum) on Chironomus riparius - a very versatile organism that during its life-stages inhabits both sediment and water column - relevant compartments for microplastics (MP) pollution. C. riparius represents an important part of the freshwater food chain and is also a standard OECD test organism. Different toxicity endpoints along the life cycle of C. riparius (28 days) were used as described in OECD 218: emergence, time to emergence, sex ratio of imagoes and the number of egg clutches per female. Chironomid larvae were exposed to 100 mg PA kg⁻¹ (i.e., 10,100 particles kg⁻¹) sediment throughout. Soluble Zn-salt (1 mg Zn L⁻¹) was used as a positive control and as a co-pollutant in combination with PA. We demonstrated that the tested concentrations of PA and Zn alone as well in combination showed no adverse effects for C. riparius in chronic exposures. 100 mg PA kg⁻¹ also did not affect the life cycle traits of the offspring of PA-exposed parent Chironomids. The data obtained will be useful for environmental risk assessment of PA when actual environmental concentrations of PA will be available.

Khoury, H., et al. (2004). "Correlation between karyotype and quantitative immunophenotype in acute myelogenous leukemia with t(8;21)." Modern Pathology **17**(10): 1211-1216.

Acute myelogenous leukemia with t(8;21) is a distinct clinicopathologic entity in which the malignant myeloblasts display a characteristic pattern of surface antigen expression. Quantitative analysis of surface marker expression in patients with this chromosomal abnormality compared to acute myelogenous leukemia patients with a different karyotype has not been reported. From 305 consecutive newly diagnosed acute myelogenous leukemia patients underwent immunophenotyping and cytogenetic analysis at our center; 16 patients (5.2%) had a t(8;21). Fluorescence intensity values were obtained, using a set of reference microbeads, by conversion of mean channel fluorescence to molecular equivalent of soluble fluorochrome. Patients with t(8;21) displayed higher levels of CD34, HLA-DR and MPO expression ($P < 0.001$ for each) and lower levels of CD13 ($P = 0.03$) and CD33 ($P = 0.02$) expression. In order to study the sensitivity, specificity and predictive value of these markers, molecular equivalent of soluble fluorochrome thresholds were statistically determined. The statistically established threshold for each of the individual markers (CD34 > 60.5 x 10(3), HLA-DR > 176.1 x 10(3), MPO > 735.1 x 10(3), CD13 < 24.3 x 10(3) and CD33 < 17.3 x 10(3)) had a sensitivity of 100%, a specificity of 62-92% and a positive predictive value of 7-45%. In multivariate analysis, two quantitative patterns (CD34 > 60.5 x 10(3) and MPO > 176.1 x 10(3); CD33 < 17.3 x 10(3) and MPO > 176.1 x 10(3)) had a sensitivity, specificity and positive predictive value of 100%. These aberrant phenotypic patterns might help identify patients with t(8;21) at diagnosis and could be useful in minimal residual disease monitoring.

Khraishi, N. M. and Y. Tabaza (1997). "Recycling of plastic waste from protected agriculture into novel multilayered greenhouse covers." 14th International congress on plastics in agriculture, Tel Aviv, Israel, March.

The international and national activities of the Royal Scientific Society in the field of plastic waste management, in particular recycling of plastic waste from protected agriculture and its utilization in the development of multilayered greenhouse covers, are highlighted. Novel greenhouse polyethylene films were developed utilizing recycled degraded and weathered films.

The outdoor performance of these films was investigated in comparison with virgin traditional covers. The mechanical and physical properties of the films were monitored versus accelerated and natural aging. The results had excellent stability against weathering effects for films developed under very controlled processing conditions, blend composition, history of recycled waste and structure of the films. The cumulative fruit yield and plant growth under these covers was monitored over 2 growing seasons by examining 2 actual size greenhouses covered with the standard commercial film and the recycled film respectively. The developed film was as effective as the environmental requirements for a tomato crop.

Kikuchi, H. and T. Yajima (1992). "Correlation between water-holding capacity of different types of cellulose in vitro and gastrointestinal retention time in vivo of rats." Journal of the Science of Food and Agriculture **60**(2): 139-146.

Rats were fed on a fibre-free basal diet (BD) or basal diet including 7% of 1 of 3 indigestible and poorly fermentable food components: cellulose powder (CEL), microfibril cellulose (MCEL), or plastic particles (PLS). Faecal moisture was highest in MCEL and lowest in PLS rats. Mean gut retention times (MRT) of solid and liquid phases, respectively, were 9.4, 11.1, 13.6 and 17.8, and 12.9, 15.0, 14.2 and 13.9 h in MCEL, CEL, PLS and BD, respectively. There was an inverse relationship ($r = 0.74$, $P<0.01$) between MRT of solid phase and settling volume whereas MRT of liquid phase was not significantly affected by diet. Relationship between organic acid content and settling volume was significant ($r = 0.61$, $P<0.01$).

Kim, A. R., et al. (2013). "On-chip immunoassay of a cardiac biomarker in serum using a polyester-toner microchip." Talanta **109**: 20-25.

An on-chip immunoassay to detect C-reactive protein (CRP) was performed using a polyester-toner (PT) microchip. CRP is a highly conserved plasma protein responding to inflammation and is used for clinical purposes to diagnose an inflammatory state. For rapid analysis and specific interactions in immunoassays, extensive studies using microfluidic chips have been carried out. Recently, a simple technique to fabricate a disposable PT microchip by a direct printing process was developed and several applications were introduced. One major drawback of the PT microchip, however, is the poor separation performance due to the quality of the microfluidic structures. This problem for a PT microchip can be overcome using a cleavable tag immunoassay, which requires minimal separation performance. After analytes are conjugated onto antibodies which are immobilized on the surface of microbeads placed on the PT microchip, a second group of fluorescently tagged antibodies are added and complexed with the analytes. The tag is then cleaved and the solution containing the cleaved tag is analyzed by electrophoresis. The time needed for the complete analysis to be carried out on a PT microchip was less than 35 min. The dynamic range of the CRP in 10-fold diluted serum was 0.3-100 mg/L and the limit of detection was 0.3 mg/L, which demonstrated the possibility of a quantitative analysis of CRP in serum in clinical trials.

Kim, B. J., et al. (2015). "Control of Microbial Growth in Alginate/Polydopamine Core/Shell Microbeads." Chemistry, An Asian Journal **10**(10): 2130-2133.

Microbial microencapsulation not only protects microorganisms from harmful environments by physically isolating them from the outside media but also has the potential to tailor the release profile of the encapsulated cells. However, the microbial release has not yet been controlled tightly, leading to undesired detrimental exposure of microorganisms to the outside. In this work, we suggest a simple method for controlling the cell release by suppressing the microbial growth in the microbeads. Alginate microbeads, encapsulating yeast cells, were coated with

ultrathin but robust polydopamine shells, and the resulting core/shell structures effectively reduced the growth rate, while maintaining the cell viability.

Kim, C., et al. (2012). "Microarray-based mutation detection and phenotypic characterization in Korean patients with retinitis pigmentosa." Molecular Vision **18**: 2398-2410.

PURPOSE: To evaluate microarray-based genotyping technology for the detection of mutations responsible for retinitis pigmentosa (RP) and to perform phenotypic characterization of patients with pathogenic mutations.

METHODS: DNA from 336 patients with RP and 360 controls was analyzed using the GoldenGate assay with microbeads containing 95 previously reported disease-associated mutations from 28 RP genes. Mutations identified by microarray-based genotyping were confirmed by direct sequencing. Segregation analysis and phenotypic characterization were performed in patients with mutations. The disease severity was assessed by visual acuity, electroretinography, optical coherence tomography, and kinetic perimetry.

RESULTS: Ten RP-related mutations of five RP genes (PRP3 pre-mRNA processing factor 3 homolog [PRPF3], rhodopsin [RHO], phosphodiesterase 6B [PDE6B], peripherin 2 [PRPH2], and retinitis pigmentosa 1 [RP1]) were identified in 26 of the 336 patients (7.7%) and in six of the 360 controls (1.7%). The p.H557Y mutation in PDE6B, which was homozygous in four patients and heterozygous in nine patients, was the most frequent mutation (2.5%). Mutation segregation was assessed in four families. Among the patients with missense mutations, the most severe phenotype occurred in patients with p.D984G in RP1; less severe phenotypes occurred in patients with p.R135W in RHO; a relatively moderate phenotype occurred in patients with p.T494M in PRPF3, p.H557Y in PDE6B, or p.W316G in PRPH2; and a mild phenotype was seen in a patient with p.D190N in RHO.

CONCLUSIONS: The results reveal that the GoldenGate assay may not be an efficient method for molecular diagnosis in RP patients with rare mutations, although it has proven to be reliable and efficient for high-throughput genotyping of single-nucleotide polymorphisms. The clinical features varied according to the mutations. Continuous effort to identify novel RP genes and mutations in a population is needed to improve the efficiency and accuracy of the genetic diagnosis of RP.

Kim, D., et al. (2017). "Mixture Toxicity of Nickel and Microplastics with Different Functional Groups on Daphnia magna." Environmental Science & Technology **51**(21): 12852-12858.

In recent years, discarded plastic has become an increasingly prevalent pollutant in aquatic ecosystems. These plastic wastes decompose into microplastics, which pose not only a direct threat to aquatic organisms but also an indirect threat via adsorption of other aquatic pollutants. In this study, we investigated the toxicities of variable and fixed combinations of two types of microplastics [one coated with a carboxyl group (PS-COOH) and the other lacking this functional group (PS)] with the heavy metal nickel (Ni) on Daphnia magna and calculated mixture toxicity using a toxic unit model. We found that toxicity of Ni in combination with cither of the two microplastics differed from that of Ni alone. Furthermore, in general, we observed that immobilization ofD. magna exposed to Ni combined with PS-COOH was higher than that of D. magna exposed to Ni combined with PS. Collectively, the results of our study indicate that the toxic effects of microplastics and pollutants may vary depending on the specific properties of the pollutant and microplastic functional groups, and further research on the mixture toxicity of various combinations of microplastics and pollutants is warranted. Kim, D., et al. (2002). "Waste plastics as supplemental fuel in the blast furnace process: Improving combustion efficiencies." Journal of Hazardous Materials **94**(3): 213-222.

The possibility of using waste plastics as a source of secondary fuel in a blast furnace has been of recent interest. The success of this process, however, will be critically dependent upon the optimization of operating systems. For instance, the supply of waste plastics must be reliable as well as economically attractive compared with conventional secondary fuels such as heavy oil, natural gas and pulverized coal. In this work, we put special importance on the improvement of the combustibility of waste plastics as a way to enhance energy efficiency in a blast furnace. As experimental variables to approach this target, the effects of plastic particle size, blast temperature, and the level of oxygen enrichment were investigated using a custom-made blast model designed to simulate a real furnace. Lastly, the combustion efficiency of the mixture of waste plastics and pulverized coal was tested. The observations made from these experiments led us to the conclusion that with the increase of both blast temperature and the level of oxygen enrichment, and with a decrease in particle size, the combustibility of waste polyethylene could be improved at a given distance from the tuyere. Also it was found that the efficiency of coal combustion decreased with the addition of plastics; however, the combustion efficiency of mixture could be comparable at a longer distance from the tuyere. © 2002 Elsevier Science B.V. Kim, D.-H., et al. (2016). "Microbead-based immunoassay using the outer membrane layer of Escherichia coli combined with autodisplayed Z-domains." Applied Surface Science **362**: 146-153.

The Z-domain has the potential to control the orientation of immobilized antibodies because of its binding affinity to the F c regions of antibodies (IgGs). In this work, Z-domains were autodisplayed on the outer membrane (OM) of Escherichia coli. OM particles were isolated and coated onto microbeads with positive, neutral, or negative surface charges. Other conditions such as incubation time and initial OM concentration were also optimized for the OM coating to obtain maximum antibody-binding. Using three kinds of model proteins with different isoelectric points (pI), streptavidin (pI=5, negative charge at pH 7), horseradish peroxidase (pI=7, neutral charge at pH 7), and avidin (pI=10, positive charge at pH 7), protein immobilization onto the microbeads was carried out through physical adsorption and electrostatic interactions. Using fluorescently labeled antibodies and fluorescence-activated cell sorting, it was determined that the neutral and the positively charged microbeads effectively bound antibodies while minimizing non-specific protein binding. The OM-coated microbeads with autodisplayed Z-domains were applied to C-reactive protein immunoassay. This immunoassay achieved 5-fold improved sensitivity compared to conventional immunoassay based on physical adsorption of antibodies at the cutoff concentration of medical diagnosis of inflammatory diseases (1000ng/ml) and cardiovascular diseases (200ng/ml).

Kim, D. N., et al. (2009). "Fabrication of microfluidic devices incorporating bead-based reaction and microarray-based detection system for enzymatic assay." Sensors and Actuators B: Chemical **137**(1): 305-312.

In this study, we developed a novel microfluidic device for enzyme-based assays that incorporates heterogeneous reaction and microarray-based detection systems. The microfluidic device had two serial chambers connected through microchannels; one for the reaction between analytes and enzymes, and the other for the quantitative detection of analytes. The reaction chamber was filled with glass microbeads covalently bound to enzymes via aminopropyltriethoxysilane (APTES). Enzyme-immobilized microbeads 70km in diameter were retained within the reaction chamber using a microfilter composed of micropillars with 30km interspaces. In the detection chamber, a poly(ethylene glycol)-based hydrogel microarray was fabricated using photolithography, which could immobilize other protein molecules or fluorescent dyes for the optical analysis of enzyme-catalyzed reaction. Different concentrations of glucose were detected within the microfluidic system where the reaction chamber was filled with glucose oxidase (GOX)-immobilizing glass microbeads, and a horseradish peroxidase (POD)-entrapping hydrogel microarray was placed in the detection chamber. A sequential bienzymatic reaction resulted in the conversion of non-fluorescent Amplex Red into fluorescent resorufin within the hydrogel microarray and glucose concentrations ranging from 1 to 10mM were successfully detected by measuring the change of emission intensity of resorufin inside the hydrogel microarray.

Kim, H. and J. Kim (2014). "A microfluidic-based dynamic microarray system with single-layer pneumatic valves for immobilization and selective retrieval of single microbeads." Microfluidics and Nanofluidics **16**(4): 623-633.

A simple yet effective dynamic bead-based microarray is necessary for multiplexed high-throughput screening applications in the fields of biology and chemistry. This paper introduces a microfluidic-based dynamic microbead array system using pneumatically driven elastomeric valves integrated with a microchannel in a single polydimethylsiloxane (PDMS) layer that performs the following functions: single-microbead arraying with loading and trapping efficiencies of 100 %, sequential microbead release for selective retrieval of microbeads of interest, and rapid microarray resettability (<1 s). The key feature is the utilization of an elastomeric membrane as a valve for trapping and releasing single microbeads; this membrane is deformable depending on the applied pneumatic pressure, thereby simply providing a dual trap-and-release function. We propose an effective single-microbead-trapping mechanism based on a dynamic flow-change network and a mathematical model as the design criterion of a trapping site. A sequential microbead release technique via a multistep "release-retrap-and-repeat" method was developed for the selective retrieval of trapped microbeads with a simple configuration consisting of a single PDMS layer and a simple macro-to-micro connection. The proposed dynamic microbead array could be a powerful tool for high-throughput multiplex bead-based drug screening or disease diagnosis.

Kim, H., et al. (2019). "Uptake of nanopolystyrene particles induces distinct metabolic profiles and toxic effects in Caenorhabditis elegans." Environmental Pollution **246**: 578-586.

Nanoplastics are widely used in modern life, for example, in cosmetics and daily use products, and are attracting concern due to their potential toxic effects on environments. In this study, the uptake of nanopolystyrene particles by Caenorhabditis elegans (C. elegans) and their toxic effects were evaluated. Nanopolystyrene particles with sizes of 50 and 200 nm were prepared, and the L4 stage of C. elegans was exposed to these particles for 24 h. Their uptake was monitored by confocal microscopy, and various phenotypic alterations of the exposed nematode such as locomotion, reproduction and oxidative stress were measured. In addition, a metabolomics study was performed to determine the significantly affected metabolites in the exposed C. elegans group. Exposure to nanopolystyrene particles caused the perturbation of metabolites related to energy metabolism, such as TCA cycle intermediates, glucose and lactic acid. Nanopolystyrene also resulted in toxic effect including induction of oxidative stress and reduction of locomotion and reproduction. Collectively, these findings provide new insights into the toxic effects of nanopolystyrene particles.

Kim, H., et al. (2004). "Quantitative analysis of the number of antigens immobilized on a glass surface by AFM." Ultramicroscopy **100**(3-4): 203-210.
To develop force measurements using an atomic force microscope (AFM) in a quantitative manner, it is necessary to estimate the number density of target molecules on a sample surface, and for this, the sensitivity of detection should be known. In this study, the AFM was used as a mechanical detector and an antigen and its antibody were used as a model to evaluate the sensitivity of detection. Antigens were immobilized on a glass surface and number density was estimated by monitoring optical absorbance due to product formation by the reaction of crosslinkers. The concentration of antigen was controlled by mixing control peptides. A microbead was used as a probe and antibodies were immobilized on the bead. AFM force measurements were then made for a range of number densities in the order of 10-10(6) antigen molecules per square micrometer of surface and were compared to evaluate the sensitivity of detection. Our result establishes the reliability of estimating a number of molecules like receptors on the cell surface, and indicates that the AFM is useful as a mechanical detector with high sensitivity.

Kim, I.-S., et al. (2015). "Factors Influencing the Spatial Variation of Microplastics on High-Tidal Coastal Beaches in Korea." Archives of Environmental Contamination & Toxicology **69**(3): 299-309.
The presence and distribution characteristics of microplastics become a big issue due to the adverse effects on marine organisms caused by not only microplastics but any incorporated and/or adsorbed pollutants. Distribution of microplastics (50- to 5000-µm size) was determined for three sandy beaches on an isolated island in a high-tidal costal region to elucidate spatial distributions in relation to beach locations. The abundances of microplastics (n = 21) measured were 56-285,673 (46,334 ± 71,291) particles/m corresponding to the highest level globally. Out of observed polymer types, expanded polystyrene was overwhelmingly dominant. Although lying toward the estuary of the largest river in the country, the north-side beach contained a 100-fold lower abundance than two south-side beaches that faced southerly wind and currents that were prevalent throughout the study season. In addition, distinct differences between the beaches on either side were also present in terms of size distribution and spatial homogeneity of microplastics on the same beach. Winds and currents are therefore considered to be the driving forces in the distribution of microplastics. [ABSTRACT FROM AUTHOR]

Kim, J., et al. (2006). "Hybridization of DNA to bead-immobilized probes confined within a microfluidic channel." Langmuir **22**(24): 10130-10134.
We report the factors influencing the capture of DNA by DNA-modified microbeads confined within a microfluidic channel. Quantitative correlation of target capture efficiency to probe surface concentration, solution flow rate, and target concentration are discussed. The results indicate that the microfluidic system exhibits a limit of detection of approximately 10(-10) M

(approximately 10(-16) mol) DNA and a selectivity factor of approximately 8 x 10(3). Typical hybridization times are on the order of minutes.

Kim, J., et al. (2012). Electrokinetically integrated isolation and amplification of protein-binding nucleic acids on a microchip. Proceedings of the 16th International Conference on Miniaturized Systems for Chemistry and Life Sciences, MicroTAS 2012.

This paper presents a microchip that integrates the isolation and amplification of target-binding DNA strands in a randomized DNA mixture. Target-binding strands are isolated in the chip via binding with human immunoglobulin E (IgE) immobilized on microbeads, electrophoretically transported through a gel-filled microchannel, captured onto microbead-tethered reverse primers, and amplified using polymerase chain reaction (PCR). Integration of isolation and amplification is achieved using electrophoretic transport through the gel-filled microchannel, which prevents contamination of buffers or reactants while transferring the desired target-binding DNA. Experimental results show that our microchip can isolate and amplify target-binding DNA strands with increased binding affinity to IgE protein.

Kim, J., et al. (2013). "Potentiometric multichannel cytometer microchip for high-throughput microdispersion analysis." Analytical Chemistry **85**(1): 362-368.

The parallelization of microfluidic cytometry is expected to lead to considerably enhanced throughput enabling point-of-care diagnosis. In this article, the development of a microfluidic potentiometric multichannel cytometer is presented. Parallelized microfluidic channels sharing a fluid path inevitably suffer from interchannel signal crosstalk that results from electrical coupling within the microfluidic channel network. By employing three planar electrodes within a single detection channel, we electrically decoupled each channel unit, thereby enabling parallel analysis by using a single cytometer microchip with multiple microfluidic channels. The triple-electrode configuration is validated by analyzing the size and concentration of polystyrene microbeads (diameters: 1.99, 2.58, 3, and 3.68 mum; concentration range: ~2 x 10(5) mL(-1) to ~1 x 10(7) mL(-1)) and bacterial microdispersion samples (Bacillus subtilis, concentration range: ~4 x 10(5) CFU mL(-1) to ~3 x 10(6) CFU mL(-1)). Crosstalk-free parallelized analysis is then demonstrated using a 16-channel potentiometric cytometer (maximum cross-correlation coefficients

r

: < 0.13 in all channel combinations). A detection throughput of ~48,000 s(-1) was achieved; the throughout can be easily increased with the degree of parallelism of a single microchip without additional technical complexities. Therefore, this methodology should enable high-throughput and low-cost cytometry.

Kim, J., et al. (2016). "Integrated Microfluidic Isolation of Aptamers Using Electrophoretic Oligonucleotide Manipulation." Scientific Reports **6**: 26139.

We present a microfluidic approach to integrated isolation of DNA aptamers via systematic evolution of ligands by exponential enrichment (SELEX). The approach employs a microbead-based protocol for the processes of affinity selection and amplification of target-binding oligonucleotides, and an electrophoretic DNA manipulation scheme for the coupling of these processes, which are required to occur in different buffers. This achieves the full microfluidic integration of SELEX, thereby enabling highly efficient isolation of aptamers in drastically reduced times and with minimized consumption of biological material. The approach as such also offers broad target applicability by allowing selection of aptamers with respect to targets that are either surface-immobilized or solution-borne, potentially allowing aptamers to be developed as readily available affinity reagents for a wide range of targets. We demonstrate the utility of this approach on two different procedures, respectively for isolating aptamers against a surface-immobilized protein (immunoglobulin E) and a solution-phase small molecule (bisboronic acid in the presence of glucose). In both cases aptamer candidates were isolated in three rounds of SELEX within a total process time of approximately 10 hours.

Kim, J., et al. (2018). "CD14+CD16+ monocyte subpopulation is dominant in the inflammation of osteoarthritis synovial fluid." Annals of the Rheumatic Diseases **77 (Supplement 2)**: 896.

Background: In osteoarthritis (OA), the activation of inflammation response involving the interaction of cartilage and synovial hyperplasia may contribute to disease progression. However, inflammatory cells in OA synovial fluid (OASF) have been rarely studied. Objective(s): To investigate the phenotype of CD14 +cells and the secretion of proinflammatory cytokines by these cells Methods: Immunohistochemistry staining in OA synovium was performed using anti-CD14, anti-CD16 and anti-CD56 antibody. The OASF was obtained through arthrocentesis. Mononuclear cells from OASFs were stained with anti-CD3, anti- CD4, anti-CD14, anti-CD16, anti-TLR4 or anti-TLR2 and analysed using flow cytometry. CD14 +CD16+and CD14+CD16 mononuclear cells in OASF were selected with magnetic microbeads. In the supernatant of these cells culture, the concentration of IL-1beta, IL-6, IL-8, TNFalpha, MMP-1,-3 were measured by Luminex. Result(s): In OA synovium, CD14 or CD16 was stained, but CD56 was not expressed. In OASF, there was a substantial number of CD14 +cells (36.6% +/-25.2%), CD3 +cells (37.4%+/-12.9%), with a rarity of CD90 +cells (1.7%+/-1.3%). The proportion of CD14 +cells was increased significantly in recurred synovial fluid, compared with the proportion in initial synovial fluid. Among CD14 +cells in OASF, CD14 +CD16+monocyte subpopulation (21.2%+/-21.8%) was more abundant than CD14 +CD16- monocyte subpopulation (10.9%+/-10.0%). TLR4 and TLR2 expressions were higher in CD14 +CD16+cells than in CD14 +CD16- cells. The concentration of IL-8 and MMP-3 was more increased in the supernatant of CD14 +CD16+cells than in that of CD14 +CD16- cells. Conclusion(s): In OASF, the proportion of CD14 +cells was increased in recurred synovial effusion. Compared to CD14 +CD16- monocyte subpopulation, CD14 +CD16+monocyte subpopulation released more cytokine such as IL-8 and MMP-3, and had higher expressions of TLR4 and TLR2.

Kim, J. H. K., et al. (2013). "Characterizations of the energy balance and circulating inflammation makers in a polygenic mouse model of obesity and type 2 diabetes." Obesity Facts **1)**: 49.

Introduction: TALLYHO/JngJ (TH) mice are a polygenic model for type 2 diabetes characterized by obesity, hyperlipidemia, hyperinsulinemia, impaired glucose uptake and tolerance, and hyperglycemia. In this study, we characterized the energy balance and circulating cytokine/ chemokine profile in TH mice. Method(s): To investigate energy balance, Comprehensive Laboratory Animal Monitoring System was used to measure heat production, respiratory exchange ratio (RER), locomotor activity, food intake, and water drinking in TH mice and non-obese and non-diabetic C57BL/6J (B6) mice at young (6-10 week) and old (16-25 week) ages. Plasma cytokine/chemokine profile was examined using multiplex fluorescent microbead immunoassay in 22-plex set up consisting of Eotaxin, GCSF, GM-CSF, IFNgamma, IL-10, IL-12(p70), IL-13, IL-17, IL-1alpha, IL-1beta, IL-2, IL-5, IL-6, IP-10, KC, KIX, M-CSF, MCP-1, MIG, MIP-1alpha, RANTES, and TNFalpha. Result(s): A significant hypoactivity was observed in TH mice during the dark period at both ages compared to B6 mice. However, energy expenditure, assessed by heat production (kcal/hour) calculated from VO2, was largely increased in TH mice with age. So did water drinking. Fuel source preference, as RER, or food intake (g consumed/day) was not significantly different between TH and B6 mice. Compared with B6, the

levels of plasma IL-1alpha and IL-6 concentrations exhibited a significant rise in TH mice at young and old, respectively. There was a significant reduction in circulating G-CSF levels in TH mice at both ages. Conclusion(s): Our data revealed the metabolic characteristics and alterations of circulating inflammatory cytokines in TH mice that encompass many aspects of polygenic human diabetes and obesity.

Kim, J.-S., et al. (2018). "Global Pattern of Microplastics (MPs) in Commercial Food-Grade Salts: Sea Salt as an Indicator of Seawater MP Pollution." Environmental Science & Technology **52**(21): 12819.

Previous studies have identified microplastics (MPs) in commercial table salts but could not exactly address the origin of the MPs because of several limitations. The present study is based on the hypothesis that commercial sea salts can act as an indicator of MP pollution in the surrounding environment unless the MPs are filtered out during the manufacturing process. A total of 39 different salt brands produced at geospatially different sites, including 28 sea salt brands from 16 countries/regions on six continents, were investigated. A wide range of MP content (in number of MPs per kg of salt; n/kg) was found: 0–1674 n/kg (excluding one outlier of 13 629 n/kg) in sea salts, 0–148 n/kg in rock salt, and 28–462 n/kg in lake salt. Relatively high MP content was identified in sea salts produced in Asian countries/regions. The abundance of MPs in unrefined sea salts (n = 25) exhibited significant linear correlations with plastic emissions from worldwide rivers (r^2= 0.33; p = 0.003) and with the MP pollution levels in surrounding seawater (r^2= 0.46; p = 0.021) in the published literature. The results indicate that not only is Asia a hot spot of global plastic pollution, as previous studies have suggested, but also that sea salt can be a good indicator of the magnitude of MP pollution in the surrounding marine environment.

Kim, K. B., et al. (2009). Microfluidic chip based hematoanalyzer using polyelectrolytic gel electrodes. Progress in Biomedical Optics and Imaging - Proceedings of SPIE.

We reports on a novel microfluidic chip with polyelectrolytic gel electrodes (PGEs) used to rapidly count the number of red blood cells in diluted whole blood. The number and amplitude of dc impedance peaks provide the information about the number and size of red blood cells, respectively. This system features a low-voltage dc detection method and noncontact condition between cells and metal electrodes. The performance of this PGEs-based system was evaluated in three steps. First, in order to observe the size-only dependence of the impedance signal, three different sizes of fluorescent microbeads were used in the experiment. Second, the cell counting performance was evaluated by using 7.2 µm fluorescent microbeads, similar in size to red blood cells, in various concentrations and comparing the results with an animal hematoanalyzer. Finally, in human blood sample tests, intravenously collected whole blood was just diluted in a phosphate buffered saline without centrifuge or other pretreatments. The PGEs-based system produced almost identical numbers of red blood cells in over 800-fold diluted samples to the results from a commercialized human hematoanalyzer. © 2009 SPIE.

Kim, K. H., et al. (1995). "Seasonal differences of feed digestibility and particulate passage rate in gastro-intestinal tract of sika deer." Korean Journal of Animal Science **37**(4): 371-378.

Digestibility of nutrients and rate of passage of digesta were estimated in sika deer [Cervus nippon] in summer and winter. The diet given to deer included a commercial concentrate feed, lucerne hay cubes, oak leaves and mixed feeds. Digestibilities of organic matter, DM, CP and NDF were slightly higher in summer than in winter. Faecal excretion of chromium-mordanted fibre did not differ between seasons. Recovery of plastic particles (PP) of density 0.91 to 2.10 g/ml and given by mouth did not differ between seasons, but was critically dependent on

gravity. At 0.91 g/ml density, PP decreased rate of passage through the digestive tract by about 6%; at density of 1.2 or 1.55 g/ml, gravity was less important. With PP at density above 2.10 g/ml, particle recovery rate was 75%. As gravity of PP increased, rumination frequency decreased and digesta passage was faster.

Kim, K. J., et al. (2018). "Subtyping of Magnetically Isolated Breast Cancer Cells Using Magnetic Force Microscopy." Biotechnology Journal **13**(6): e1700625.

Circulating tumor cell (CTC) which recently arisen as potential sources for monitoring and characterizing non-haematologic cancers and their metastatic derivatives. Immunomagnetic microbeads and magnetic nanoparticles (MNPs) have been extensively explored to isolate CTCs from blood samples. However, MNPs attached on the membrane protein are interrupted further analysis to distinguish the cancer subtype by consumption or blocking the target surface marker. Here, an MNP-mediated analysis method for surface marker expression profile by magnetic force microscopy (MFM) is described. Two MNPs, zinc ferrite and iron oxide, are showed distinct phase shift (-16.5degree and -3.7degree, respectively) signal on the MFM images. The antibody conjugated MNPs are successfully isolated target cells without giving damage to the cell. The MFM image of MNP decorated cells show clear differences between two breast cancer cell lines, MCF-7 and SK-BR-3, which proof the cancer subtyping property using MFM method. To confirmation of the surface marker consumption during the cell isolation, antibody-conjugated quantum dots and drug-loaded oleosome are treated on the cells, thereby MNP decorated cells are survived. This newly developed MFM analysis method provides a new direction to utilize the MNP for the surface marker expression phenotypes.

Kim, K. S. and J. K. Park (2005). "Magnetic force-based multiplexed immunoassay using superparamagnetic nanoparticles in microfluidic channel." Lab on a Chip **5**(6): 657-664.

This paper describes a novel microfluidic immunoassay utilizing binding of superparamagnetic nanoparticles to beads and deflection of these beads in a magnetic field as the signal for measuring the presence of analyte. The superparamagnetic 50 nm nanoparticles and fluorescent 1 mum polystyrene beads are immobilized with specific antibodies. When target analytes react with the polystyrene beads and superparamagnetic nanoparticles simultaneously, the superparamagnetic nanoparticles can be attached onto the microbeads by the antigen-antibody complex. In the poly(dimethylsiloxane) (PDMS) microfluidic channel, only the microbeads conjugated with superparamagnetic nanoparticles by analytes consequently move to the high gradient magnetic fields under the specific applied magnetic field. In this study, the magnetic force-based microfluidic immunoassay is successfully applied to detect the rabbit IgG and mouse IgG as model analytes. The lowest concentration of rabbit IgG and mouse IgG measured over the background is 244 pg mL⁻¹ and 15.6 ng mL ⁻¹, respectively. The velocities of microbeads conjugated with superparamagnetic nanoparticles are demonstrated by magnetic field gradients in microfluidic channels and compared with the calculated magnetic field gradients. Moreover, dual analyte detection in a single reaction is also performed by the fluorescent encoded microbeads in the microfluidic device. Detection range and lower detection limit can be controlled by the microbeads concentration and the higher magnetic field gradient. © The Royal Society of Chemistry 2005.

Kim, M., et al. (2015). "Estimation of the Environmental Load of High- and Low-Density Polyethylene From South Korea Using a Mass Balance Approach." Archives of Environmental Contamination & Toxicology **69**(3): 367-373.

The accumulation of marine plastic debris is one of the main emerging environmental issues of the twenty first century. Numerous studies in recent decades have reported the level of plastic particles on the beaches and in oceans worldwide. However, it is still unclear how much plastic debris remains in the marine environment because the sampling methods for identifying and quantifying plastics from the environment have not been standardized; moreover, the methods are not guaranteed to find all of the plastics that do remain. The level of identified marine plastic debris may explain only the small portion of remaining plastics. To perform a quantitative estimation of remaining plastics, a mass balance analysis was performed for high- and low-density PE within the borders of South Korea during 1995-2012. Disposal methods such as incineration, land disposal, and recycling accounted for only approximately 40 % of PE use, whereas 60 % remained unaccounted for. The total unaccounted mass of high- and low-density PE to the marine environment during the evaluation period was 28 million tons. The corresponding contribution to marine plastic debris would be approximately 25,000 tons and 70 g km of the world oceans assuming that the fraction entering the marine environment is 0.001 and that the degradation half-life is 50 years in seawater. Because the observed concentrations of plastics worldwide were much lower than the range expected by extrapolation from this mass balance study, it is considered that there probably is still a huge mass of unidentified plastic debris. Further research is therefore needed to fill this gap between the mass balance approximation and the identified marine plastics including a better estimation of the mass flux to the marine environment. [ABSTRACT FROM AUTHOR]

Kim, M. K., et al. (2017). "Calcium-Triggered Pulsatile Delivery of Parathyroid Hormone from Microbeads for Osteoporosis Treatment." Biomacromolecules **18**(10): 3099-3105.

Recombinant human parathyroid hormone 1-34 (rhPTH 1-34) is the most potent anabolic drug recommended for patients with osteoporosis who do not respond to conventional treatment. However, subcutaneous intermittent injection is the only effective regimen due to its unusual action of mechanism. This regimen is inconvenient and is a big hurdle in clinical applications. In this study, we designed polyelectrolyte microbeads that can deliver rhPTH 1-34 in response to Ca²⁺ concentration, which indicates the osteoporotic status. Dextran photopolymer was synthesized, mixed with anionic monoacrylate, and photopolymerized by passing through capillary microfluidics to obtain the microbeads. The anionic property of microbeads was confirmed by toluidine blue staining. One microbead, loaded with a 1 day dose of rhPTH 1-34 (23.4 +/- 0.9 mug), released rhPTH 1-34 in a triggered manner following the addition of Ca²⁺ ion. In vitro cell study demonstrated that rhPTH 1-34 released in a pulsatile manner from the microbeads induced osteogenic markers (ALP, RUNX2, and OPN) and precipitated mineral disposition more effectively. Kim, R., et al. (2019). "Generation of phenotype-stable alveolar epithelial type ii cell from human induced pluripotent stem cells." American Journal of Respiratory and Critical Care Medicine. Conference **199**(9).

Alveolar epithelial type II cells (AECIIs) are resident stem cells that can proliferate and are able to differentiate into alveolar epithelial type I cells. The turnover time of AECIIs is very slow in a normal lung but is accelerated after experimental pneumonectomy in otherwise a healthy lung.

However, the regeneration capacity of AECIIs seems to be impaired in injured lung conditions. Induced pluripotent stem cells (iPSCs) are directly derived from adult somatic tissues. Once reprogrammed to pluripotency, iPSCs can be differentiated into specific target cells. iPSCs have been previously shown to differentiate into lung lineage cells. However, their long-term phenotypes and behaviors are yet to be examined as a reliable cell source for lung regeneration. We aimed to optimize published differentiation protocols to achieve iPSC-derived AECIIs and maintain their phenotypes for future in vivo application. iPSC lines, HDF-SV and HDF-mRNA were first cultured and differentiated into definitive endoderm, then specified into the anterior foregut endoderm fate, and finally differentiated into lung progenitor cells as identified by the expression of NK2 homeobox 1 and forkhead box protein A2 using immunocytochemistry approach. The lung progenitors were then matured to transform into AECIIs expressing prosurfactant protein C (ProSPC) and epithelial adhesion molecule (EpCAM) by using small molecules and growth factors including a WNT activator, fibroblast growth factors, a phosphodiesterase inhibitor and etc. The AECIIs were purified by undergoing immunomagnetic enrichment using anti-EpCAM microbeads and then passaged at 80% confluency every 5 -7 days for up to 7 passages. Doubling time of the AECIIs was about 4 days, and approximately ~94% of the cells were positive for EpCAM and ~98% positive for ProSPC at the 7th passage. Functional assessment of the AECIIs is underway. Our results suggest the plausibility of generating stable AECIIs from iPSCs serving as a powerful tool for regenerative research in lung injury.

Kim, S. and Y. An (2019). "Soil microplastics inhibit the movement of springtail species." Environment International **126**: 699-706.

Previous studies have indicated the means by which micro-sized plastic particles may affect the soil environment, and this could be linked to the behavior of plastics in the soil system and how these particles are influenced by biological responses. Soil-dwelling organisms play a key role in modifying the soil system by constructing bio-pores, and these structural changes are potentially related to the behavior of plastic particles. In this study, we found that micro-sized plastic particles moved into bio-pores within seconds, and that this influx disrupted the movement of springtails (Lobella sokamensis). The springtails moved to avoid becoming trapped, and this behavior created bio-pores in the soil system. The influx of plastic particles into these cavities subsequently immobilized the springtails within. This phenomenon was observed at low a concentration of plastic particles (8 mg/kg), and it likely occurs in actual soil environments. The findings of this study indicate that the behavior of plastic particles in the soil not only disrupts the movement of springtails but also has wider implications for effective management of soils.

Kim, S., et al. (2019). "Zebrafish can recognize microplastics as inedible materials: quantitative evidence of ingestion behavior." Science of the Total Environment **649**: 156-162.

This study investigated the ingestion behavior of zebrafish exposed to microplastic particles (MPs) at different concentrations, presented alone or in a mix with food particles. Zebrafish showed spitting behavior after ingesting micro-sized (247.5 micro m) polyethylene particles (i.e., MPs), with prey-capture time increasing when food and MPs were supplied simultaneously. Fish were compelled to ingest MPs with food, and the accumulation percentage (ingested particles/supplied particles) was quantified as 0.5 to 9.4% with increasing food volume. However, the accumulation percentage was determined as 0.0 to 1.0% under exposure to MPs only, and as 3.8 to 4.3% at high MP concentrations when the food concentration was fixed. Overall, these results demonstrate that small freshwater organisms can recognize that MPs are not food items. Under laboratory conditions, zebrafish rarely discriminate between food and MPs when both are presented together, and the indiscriminate feeding behavior becomes

clearer as more food is available.

Kim, S., et al. (2018). "Dietary uptake, biodistribution, and depuration of microplastics in the freshwater diving beetle Cybister japonicus: effects on predacious behavior." Environmental Pollution **242**(Part A): 839-844.

Microplastics (MPs) have adverse effects on aquatic organisms in marine environments; however, there is a lack of information on freshwater environments. This study investigated the dietary uptake, and biodistribution and depuration of MPs in the freshwater diving beetle Cybister japonicus (Coleoptera: Dytiscidae) after consumption of zebrafish (Danio rerio) exposed to MPs. The transfer of MPs in diving beetles after consumption of zebrafish was assessed to determine whether the presence of MPs affected diving beetle behavior and predation. We found that diving beetles that consumed MP-exposed fish had a significantly lower ingestion rate than the control. In addition, the trophic transfer rate of MPs was 13-18%. However, MPs were found only in the crop and proventriculus of the beetles, and all particles were depurated within 48 h, likely via regurgitation. As diving beetle is a top predator in freshwater ecosystems and could facilitate transfer from aquatic to terrestrial ecosystems via predation, its behavior towards indigestible MPs in its digestive organs (i.e., filtering and vomiting) could represent a meaningful phenomenon as a potential vector for MP transport. This is the first report of the trophic transfer of MPs from fish to dytiscid species, which helps clarify the effects and mechanisms of MPs in freshwater systems.

Kim, S., et al. (2019). "Fluorescence Enhancement from Nitro-Compound-Sensitive Bacteria within Spherical Hydrogel Scaffolds." Acs Applied Materials & Interfaces **11**(15): 14354-14361.

For the safety of both production and life, it is a very significant issue to detect explosive nitro compounds in a remote way or over a long distance. Here, we report that nitro compounds were detected by the bacterial sensor based on hydrogel microbeads as a platform. Green fluorescent protein-producing Escherichia coli, which was genetically engineered to be sensitive to nitro compounds, was loaded within poly(2-hydroxyethyl methacrylate) [poly(HEMA)]-based hydrogel beads, in which fluorescent signals from bacteria were concentrated and strong enough to be easily detected. For efficient loading of negatively charged bacteria, the surface charge of poly(HEMA)-based beads was controlled by copolymerization with 2-(methacryloyloxy)ethyltrimethylammonium chloride (MAETC) as a cationic monomer. With the addition of MAETC, the cell affinity was nine times enhanced by the interaction between the positively charged poly(HEMA- co-MAETC) beads and negatively charged bacteria. The increased cell affinity resulted in an enhancement of a sensing signal. After exposure to 2,4,6-trinitrotoluene, a typical explosive nitro compound, the fluorescence intensity of bacterial sensors using poly(HEMA- co-MAETC) beads having 80 wt % MAETC was five times increased compared to those based on poly(HEMA) beads. This amplification of the fluorescent signal enables easier detection of explosives efficiently by a remote detection, even over a long distance.

Kim, S. J., et al. (2013). "Optical immunosensor for quantifying C-telopeptide fragments of type II collagen as an osteoarthritis biomarker in urine." Biochip Journal **7**(4): 399-407.

A fluorescence-based biosensor for measuring the quantity of C-telopeptide fragments of type II collagen (CTX-II) was developed as an osteoarthritis biomarker in urine. During osteoarthritis progression, joint components such as cartilage collagen are degraded by collagenase-protease and secreted into the serum as CTX-II. To detect CTX-II in urine (uCTX-II) having structural heterogeneity, conventional sandwich format assay does not provide sufficient accuracy. As an alternative, a competitive immunoassay was developed for the quantification of uCTX-II, which uses antibody-conjugated fluoro-microbeads to generate an optical signal. After preparing the biosensing surface, the uCTX-II sample and antibody-optical probe conjugates were reacted on the PEG<inf>4</inf>-EKGPDP exposed biosensing surface. The optical probes competed with the uCTX-II in the sample for binding to the immobilized PEG<inf>4</inf>-EKGPDP. This assay was able to detect uCTX-II concentrations between 200 ng/mmol (corrected value vs. creatinine) and 1,400 ng/mmol, encompassing the clinical detection ranges required for osteoarthritis diagnosis. The competitive immunoassay developed for uCTX-II detection was rapid and exhibited good correlation with conventional ELISA methods. This novel competition assay is a promising tool for the diagnosis and monitoring of osteoarthritis using urine samples. © 2013 The Korean BioChip Society and Springer-Verlag Berlin Heidelberg.

Kim, S. M., et al. (2010). "Exposure to environmental toxins in mothers of children with autism spectrum disorder." Psychiatry Investigation **7**(2): 122-127.

Objective: Environmental pollutants, especially environmental toxins (ET), may have the potential to disrupt neurodevelopmental pathways during early brain development. This study was designed to test our hypothesis that mothers with autism spectrum disorder (ASD) children would have less knowledge about ET and more chance to be exposed to ET than mothers with healthy children (MHC). Methods: One hundred and six biologic mothers with ASD children (MASD) and three hundred twenty four biologic mothers with healthy children MHC were assessed using two questionnaires asking about ET. Results: The total score in response to questions related to knowledge about ET in MHC was higher than that in MASD. The possibility of exposure to ET was higher in MASD than MHC. MASD showed higher sub-scale scores in terms of exposures to canned food, plastics, waste incinerators, old electronics, microwavable food, and textiles. Conclusion: The current results show that reduced knowledge about ET and greater exposure to ET may be associated with autism spectrum disorder. Copyright © 2010 Korean Neuropsychiatric Association.

Kim, S. M., et al. (2018). "Genetic characteristics of senescent CD8 T cells in the peripheral blood mononuclear cells of Behcet's disease patients." Clinical and Experimental Rheumatology **36 (6 Supplement 115)**: S160-S161.

Introduction. Behcet's disease (BD) is a chronic inflammatory disease characterized by recurrent mucocutaneous ulceration and complications such as blindness and large vessel inflammation. Immunosenescence, aging of the immune system, is related to increased susceptibility to infectious diseases, vaccine failure, and chronic low-grade systemic inflammation. Our previous study showed an increased frequency of immunosenescent cells in the peripheral blood of patients with BD. Aims. The aim of this study was to investigate the differences in RNA expression in immunosenescent cells in the peripheral blood of BD patients and controls, and to find its role in autoimmune/autoinflammatory pathogenesis of BD. Methods. Peripheral blood mononuclear cells (PBMCs) were extracted from BD patients (n=18) and healthy controls (HC, n=18). CD8⁺ T cells were isolated through CD8 microbeads, and those were labeled with conjugated monoclonal antibodies as follows: FITC anti-CD8, allophycocyanin (APC)-H7 anti-CD27 and APC anti-CD28. Using fluorescence-activated cell sorting (FACS), senescent CD8⁺ T cells (CD8⁺ CD27-CD28-cells) and non-senescent CD8⁺ T cells (CD8⁺ CD27⁺ CD28⁺ cells) were sorted. After sorting, each group of cells was pooled together and cultured in medium (RPMI 1640). Cells were stimulated with anti-CD3 (500ng/ml, clone OKT3) for 72 hours. Total RNA was extracted from anti-CD3-stimulated cells with the RNA isolation kit. We performed

transcriptome analysis on those RNA samples and analyzed the differentially expressed genes from the four different groups (BD patients vs. controls, senescent CD8⁺ T cells (CD8⁺ CD27-CD28-) vs. non-senescent CD8⁺ T cells (CD8⁺ CD27⁺ CD28⁺)). Results. A large number of differentially expressed genes of each group were found out through total RNA transcriptome analysis. Gene Ontology (http://geneontology.org/) was used for the significant differentially expressed genes to conduct the gene set enrichment analysis according to gene ontology's functional classifications, biological process (BP), molecular function(MF), and cellular component(CC). As a result of the analysis, it was found that that the gene set list, which showed the significance, appears differently for each categories. Conclusion. Through next-generation sequencing, we could find that the gene expression of the senescent CD8⁺ T cells differs from that of nonsenescent CD8⁺ T cells. These differentially expressed genes of senescent immune cells can be thought of as having an effect on the occurrence and activation of the disease. Therefore, functional changes in cells caused by immunosenescence are likely to be responsible for the pathogenesis of BD.

Kim, S. W. and Y.-J. An (2019). "A simple and efficient method for separation of low-density polyethylene films into different micro-sized groups for laboratory investigation." Science of the Total Environment **668**: 84-89.

Microplastics are abundant in both aquatic and terrestrial environments. While they have received much recent attention because of their effects on ecosystems, their true impact on natural environments remains difficult to assess because of the problems associated with processing them in the laboratory. In this study, we designed and implemented a new, vacuum-based method of separating different sizes of low-density polyethylene films. Using multiple sieve sizes, we achieved consistent recovery of the desired size fractions using this method. The vacuum suction (VS) system consisted of two differently sized cylindrical sieves of 500 μm (or 200 μm) and 65 μm, allowing film samples between 65 and –500 μm and 65–200 μm to be collected. The VS systems successfully separated microplastic film samples into small area ranges of 0.015–0.065 mm2, and the film areas showed different distributions for each sample from the different VS systems. This system provided an easy, rapid, and low-labor means of processing different sizes of microplastics via an innovative method. Further research into the effects of microplastics on natural environments is critically needed, and the laboratory separation of different size fractions of microplastics facilitates such endeavors. Graphical abstract Unlabelled Image Highlights • The vacuum suction (VS) system is developed to prepare microplastic films. • The method can separate microplastic films into different size groups. • The desired size fractions using the method can be recovered. • The method can improve the efficiency of microplastic film processing. [ABSTRACT FROM AUTHOR]

Kim, S. W., et al. (2019). "Size-dependent effects of polystyrene plastic particles on the nematode Caenorhabditis elegans as related to soil physicochemical properties." Environmental Pollution **258**: 113740.

Plastic polymers are widely used in various applications and are thus prevalent in the environment. Over time, these polymers are slowly degraded into nano- and micro-scale particles. In this study, the free-living nematode, Caenorhabditis elegans, was exposed to polystyrene particles of two different sizes (42 and 530 nm) in both liquid and soil media. The number of offspring significantly (p < 0.05) decreased at polystyrene concentrations of 100 mg/L and 10 mg/kg in liquid and soil media, respectively. In soil media, but not liquid media, C. elegans was more sensitive to the larger particles (530 nm) than the smaller particles (42 nm), and the median effective concentration (EC₅₀) values of the 42 and 530 nm-sized particles were found to be > 100 and 14.23 (8.91-22.72) mg/kg, respectively. We performed the same toxicity bioassay on five different field-soil samples with different physicochemical properties and found that the size-dependent effects were intensified in clay-rich soil samples. A principal component analysis showed that the bulk density, cation exchange capacity, clay content, and sand content were the dominant factors influencing the toxicity of the 530 nm-sized polystyrene particles. Therefore, we conclude that the soil composition has a significant effect on the toxicity induced by these 530 nm-sized polystyrene particles.

Kim, T. G., et al. (2018). "Hydrometallurgical recycling of surface-coated metals from automobile-discarded ABS plastic waste." Waste Management **80**: 414-422.

The ammoniacal leaching of surface-coated metals from automobile-discarded ABS plastics followed by their recovery through solvent extraction has been investigated. The leaching of ABS (typically containing 4.1% Cu, 1.3% Ni, and 0.03% Cr) could efficiently dissolve the ammine complexes of Cu and Ni, leaving Cr unleached as fine particles. The optimization studies for achieving the maximum efficiency revealed that the leaching of metal ions in different ammoniacal solutions follows the order CO₃²⁻>Cl⁻>SO₄²⁻. The leaching carried out in a carbonate medium by maintaining the total NH₃ concentration 5.0M at a NH₄OH/(NH₄)₂CO₃ ratio of 4:1, pulp density of 200g/L, agitation speed of 400rpm, temperature of 20degreeC, and time of 120min yielded the optimum efficiency of >99% Cu and Ni (i.e., 8.14g/L and 2.57g/L, respectively, in the leach liquor). Subsequently, the solvent extraction of metals from ammoniacal leach liquor as a function of extractant (LIX 84-I) concentration and organic-to-aqueous (O:A) phase ratio was examined. Based on the extraction data, a three-stage counter-current extraction at O:A=1:1 was validated using 0.8M LIX 84-I, yielding the quantitative extraction of both metals into the organic phase. Thereafter, the stripping of metals in acid solutions indicated that 0.5M H₂SO₄ could quantitatively strip Ni from the loaded organic phase; however, ~27% Cu was also co-stripped. The rest of Cu from the Ni-depleted organic phase was separately stripped with 1.0M H₂SO₄ that can be directly sent to the electrowinning process. On the other hand, the co-stripped metals from the acidic solution can be easily separated, again using LIX 84-I as the extractant, by adopting the pH-swing method. Finally, a process has been proposed for the hydrometallurgical recovery of surface-coated metals from waste ABS plastics; that does not affect the physicochemical characteristics of the polymer substances for their reuse.

Kim, Y., et al. (2019). "Identification of adverse outcome pathway related to high-density polyethylene microplastics exposure: Caenorhabditis elegans transcription factor RNAi screening and zebrafish study." Journal of Hazardous Materials: 121725.

To gain insight into the human health implications of microplastics, in this study, we investigated the possible mechanisms affecting the toxicity of high-density polyethylene (HDPE) in the

nematode Caenorhabditis elegans using RNAi screening and a bioinformatics-based unbiased approach. The candidate pathways identified from C. elegans study were also confirmed using vertebrate model, zebrafish, Danio rerio and human relevance was then inferred using Comparative Toxicogenomics Database (CTD) analysis. Prior to evaluating the toxicity, label-free Raman mapping was conducted to investigate whether or not the organisms could uptake HDPE. C. elegans transcription factor RNAi screening results showed that the nucleotide excision repair (NER) and transforming growth factor-beta (TGF-beta) signaling pathways were significantly associated with HDPE exposure, which was also confirmed in zebrafish model. Gene-disease interaction analysis using the CTD revealed the possible human health implications of microplastics. Finally, based on this finding, related AOPs were identified from AOP Wiki (http://aopwiki.org), which are "Peroxisome proliferator-activated receptors gamma inactivation leading to lung fibrosis" and "AFB1: Mutagenic Mode-of-Action leading to Hepatocellular Carcinoma". Further studies are needed for the validation of these AOPs with various microplastics.

Kim, Y. J., et al. (2014). "A microchip filter device incorporating slit arrays and 3-D flow for detection of circulating tumor cells using CAV1-EpCAM conjugated microbeads." Biomaterials **35**(26): 7501-7510.
Circulating tumor cells (CTCs) are rare cells and the presence of these cells may indicate a poor prognosis and a high potential for metastasis. Despite highly promising clinical applications, CTCs have not been investigated thoroughly, due to many technical limitations faced in their isolation and identification. Current CTC detection techniques mostly take the epithelial marker epithelial cell adhesion molecule (EpCAM), however, accumulating evidence suggests that CTCs show heterogeneous EpCAM expression due to the epithelial-to-mesenchymal transition (EMT). In this study, we report that a microchip filter device incorporating slit arrays and 3-dimensional flow that can separate heterogeneous population of cells with marker for CTCs. To select target we cultured breast cancer cells under prolonged mammosphere culture conditions which induced EMT phenotype. Under these conditions, cells show upregulation of caveolin1 (CAV1) but down-regulation of EpCAM expression. The proposed device which contains CAV1-EpCAM conjugated bead has several tens of times increased throughput. More importantly, this platform enables the enhanced capture yield from metastatic breast cancer patients and obtained cells that expressed various EMT markers. Further understanding of these EMT-related phenotypes will lead to improved detection techniques and may provide an opportunity to develop therapeutic strategies for effective treatment and prevention of cancer metastasis. © 2014 Elsevier Ltd.

Kim, Y. S., et al. (2010). "Investigation of thermodynamic parameters in the thermal decomposition of plastic waste-waste lube oil compounds." Environmental Science & Technology **44**(13): 5313-5317.
Thermal decomposition properties of plastic waste-waste lube oil compounds were investigated under nonisothermal conditions. Polyethylene (PE), polypropylene (PP), polystyrene (PS), and polyethylene terephthalate (PET) were selected as representative household plastic wastes. A plastic waste mixture (PWM) and waste lube oil (WLO) were mixed with mixing ratios of 33, 50, and 67 (w/w) % on a PWM weight basis, and thermogravimetric (TG) experiments were performed from 25 to 600 degrees C. The Flynn-Wall method and the Ozawa-Flynn-Wall method were used for analyses of thermodynamic parameters. In this study, activation energies of PWM/WLO compounds ranged from 73.4 to 229.6 kJ/mol between 0.2 and 0.8 of normalized mass conversions, and the 50% PWM/WLO compound had lower activation energies and enthalpies among the PWM/WLO samples at each mass conversion. At the point of maximum differential mass conversion, the analyzed activation energies, enthalpies, entropies, and Gibbs

free energies indicated that mixing PWM and WLO has advantages in reducing energy to decrease the degree of disorder. However, no difference in overall energy that would require overcoming both thermal decomposition reactions and degree of disorder was observed among PWM/WLO compounds under these experimental conditions.

Kinjo, A., et al. (2019). "Size-dependent elimination of ingested microplastics in the Mediterranean mussel Mytilus galloprovincialis." Marine Pollution Bulletin **149**: 110512.

Filter feeding organisms have been reported to ingest microplastics (MP) in marine environments. However, information regarding how long the ingested MPs are retained in their digestive tracts remains limited. Here, we report the gut retention time (GRT₉₀) and the long-term egestion time of three different sized polystyrene microspheres (1, 10, and 90mum) in the Mediterranean mussel Mytilus galloprovincialis. We found significant differences in GRT₉₀ with respect to MP size. With respect to the long-term egestion of MPs, most of the smaller MPs were excreted immediately, although some were detected intermittently until day 40. In comparison, larger MPs were slowly excreted in bulk, after which they were not detected. The results indicate that different sized MPs are retained differently in the digestive tract of mussels. The size-dependent effects of MPs should thus be considered when evaluating the effects of MPs in mussels.

Kinman, R. N., et al. (1990). "Analysis of 20-Year-Old Refuse from the Mallard North Landfill in Chicago, Illinois." Proceedings of the 44th Purdue Industrial Waste Conference. May 9-11 1989, Purdue Univ., West Lafayette, Indiana. CRC Press, Inc., Boca Raton, Florida. 1990. p 527-536, 5 fig, 9 tab, 4 ref.

A dig was performed in 1988 by the University of Arizona Anthropology Department with the aim of finding 20-yr old garbage in the Mallard North Landfill in Chicago, Illinois. Using newspapers and other sources, the age of the waste recovered was confirmed as at least 17, 18, or 19 yr old. Moisture is a key environmental variable affecting degradation. Many artifacts, including paper, plastics, metal, wood, garden, food, and other items were easily identified. Paper was the main component (32.7% by weight). All materials, including paper, plastics, metal, wood, garden, food, and other materials, were observed to be under different degrees of attack by microorganisms. Microorganism levels were within the range found in other landfill studies; most organisms ranged from 10,000 to 10 billion MPN/100 g. The presence of methane bacteria was confirmed. No viruses were recovered from any samples. Moisture and pH were observed to influence the microorganisms in the landfill. Many pieces of plastic waste showed signs of deterioration. Twenty-eight of 30 polyethylene samples tested by bomb calorimetry showed significant deterioration. The percent degradation of polyethylene plastics, as calculated from bomb calorimetry, ranged from 0.19 to 54.28%. (See also W90-10965) (Rochester-PTT)

Kirby, D., et al. (2015). "Rapid and cost-efficient enumeration of rare cancer cells from whole blood by low-loss centrifugo-magnetophoretic purification under stopped-flow conditions." Cytometry Part A **87**(1): 74-80.

We present a substantially improved design and functionality of a centrifugo-magnetophoretic platform which integrates direct immunoseparation and cost-efficient, bright-field detection of cancer cells in whole blood. All liquid handling takes place in a disposable cartridge with geometry akin to a conventional compact disc (CD). The instrumentation required to process such a "lab-on-a-disc" cartridge can be as simple and cost-efficient as the rotor on a common optical disc drive. In a first step, target cells in a blood sample are specifically bound to paramagnetic microbeads. The sample is then placed into the disc cartridge and spun. In the second step, magnetically tagged target cells are separated by a co-rotating, essentially lateral magnetic field from the background population of abundant blood cells, and also from unbound magnetic beads. A stream of target cells centrifugally sediments through a stagnant liquid phase into a designated detection chamber. The continuous, multiforce immunoseparation proceeds very gently, i.e. the mechanical and hydrodynamic stress to the target cells is minimized to mitigate the risk of cell loss by collective entrapment in the background cells or vigorous snapping against a wall. We successfully demonstrate the extraction of MCF7 cancer cells at concentrations as low as 1 target cell per mu l from a background of whole blood, with capture efficiencies of up to 88%. Its short time-to-answer is a notable characteristic of this system, with 10% of target cells collected in the first minute after their loading to the system and the remainder captured within the following 10 min. All the above-mentioned factors synergetically combine to leverage the development of a prospective point-of-care device for CTC detection. copyright 2014 International Society for Advancement of Cytometry

Kirschbaum, M., et al. (2009). "Correlating short-term Ca(2+) responses with long-term protein expression after activation of single T cells." Lab on a Chip **9**(24): 3517-3525.

In order to elucidate the dynamics of cellular processes that are induced in context with intercellular communication, defined events along the signal transduction cascade and subsequent activation steps have to be analyzed on the level of individual cells and correlated with each other. Here we present an approach that allows the initiation of cell-cell or cell-particle interactions and the analysis of cellular reactions within various regimes while the identity of each individual cell is preserved. It utilizes dielectrophoresis (DEP) and microfluidics in a lab-on-chip system. With high spatial and temporal precision we contacted single T cells with functionalized microbeads and monitored their immediate cytosolic Ca(2+) response. After this, the cells were released from the chip system and cultivated further. Expression of the activation marker molecule CD69 was analyzed the next day and correlated with the previously recorded Ca(2+) signal for each individual cell. We found a significant difference in the patterns of Ca(2+) traces between activated and non-activated cells, which shows that Ca(2+) signals in T cells can provide early information about a later reaction of the cell. Although T cells are non-excitable cells, we also observed irregular Ca(2+) transients upon exposure to the DEP field only. These Ca(2+) signals depended on exposure time, electric field strength and field frequency. By minimizing their occurrence rate, we could identify experimental conditions that caused the least interference with the physiology of the cell.

Kirstein, I. V., et al. (2016). "Dangerous hitchhikers? Evidence for potentially pathogenic Vibrio spp. on microplastic particles." Marine Environmental Research **120**: 1-8.

The taxonomic composition of biofilms on marine microplastics is widely unknown. Recent sequencing results indicate that potentially pathogenic Vibrio spp. might be present on floating microplastics. Hence, these particles might function as vectors for the dispersal of pathogens. Microplastics and water samples collected in the North and Baltic Sea were subjected to selective enrichment for pathogenic Vibrio species. Bacterial colonies were isolated from CHROMagar^{TM}Vibrio and assigned to Vibrio spp. on the species level by MALDI-TOF MS (Matrix Assisted Laser Desorption/Ionisation-Time of Flight Mass Spectrometry). Respective polymers were identified by ATR FT-IR (Attenuated Total Reflectance Fourier Transform-Infrared Spectroscopy). We discovered potentially pathogenic Vibrio parahaemolyticus on a number of microplastic particles, e.g. polyethylene, polypropylene and polystyrene from North/Baltic Sea. This study confirms the indicated occurrence of potentially pathogenic bacteria on marine microplastics and highlights the urgent need for detailed biogeographical analyses of marine microplastics.

Kisley, L., et al. (2014). "High ionic strength narrows the population of sites participating in protein ion-exchange adsorption: a single-molecule study." Journal of Chromatography. A **1343**: 135-142.

The retention and elution of proteins in ion-exchange chromatography is routinely controlled by adjusting the mobile phase salt concentration. It has repeatedly been observed, as judged from adsorption isotherms, that the apparent heterogeneity of adsorption is lower at more-eluting, higher ionic strength. Here, we present an investigation into the mechanism of this phenomenon using a single-molecule, super-resolution imaging technique called motion-blur Points Accumulation for Imaging in Nanoscale Topography (mbPAINT). We observed that the number of functional adsorption sites was smaller at high ionic strength and that these sites had reduced desorption kinetic heterogeneity, and thus narrower predicted elution profiles, for the anion-exchange adsorption of alpha-lactalbumin on an agarose-supported, clustered-charge ligand stationary phase. Explanations for the narrowing of the functional population such as inter-protein interactions and protein or support structural changes were investigated through kinetic analysis, circular dichroism spectroscopy, and microscopy of agarose microbeads, respectively. The results suggest the reduction of heterogeneity is due to both electrostatic screening between the protein and ligand and tuning the steric availability within the agarose support. Overall, we have shown that single molecule spectroscopy can aid in understanding the influence of ionic strength on the population of functional adsorbent sites participating in the ion-exchange chromatographic separation of proteins.

Kitamoto, H., et al. (2018). "Enzymatic degradation of poly-butylene succinate-co-adipate film in rice husks by yeast Pseudozyma antarctica in indoor conditions." Journal of Bioscience & Bioengineering **125**(2): 199-204.

Agricultural mulch films made from biodegradable polymers (BP) have been used to decrease the burden of plastic waste recovery and recycling. However, their degradations depend largely on environmental conditions and sometimes do not proceed as desired. Yeast strains of Pseudozyma antarctica often isolated from rice husks were found to secrete an esterase to degrade BP films. Poly-butylene succinate-co-adipate (PBSA) films buried in unsterilized rice husks with 60% (w/w) moisture degraded rapidly compared to that buried in field soil. The type strain of P. antarctica JCM 10317 added as cell suspension onto sterilized rice husks with PBSA film grew rapidly forming filamentous growth on the surface of rice husks and films. BP-degrading enzyme secreted by the growing cells was adsorbed on the surface of film and decomposed the film. Addition of rice husk-derived P. antarctica strains also showed BP film degradation activity in sterilized rice husks. In the light of these findings, we suggest that techniques for disposal of used BPs which combine plastics with unutilized residual plant materials piled at the side of agricultural fields be developed.

Kitani, T., et al. (2014). "Direct human mitochondrial transfer: a novel concept based on the endosymbiotic theory." Transplantation Proceedings **46**(4): 1233-1236.

Mitochondria play an essential role in eukaryotes, and mitochondrial dysfunction is implicated in several diseases. Therefore, intercellular mitochondrial transfer has been proposed as a mechanism for cell-based therapy. In addition, internalization of isolated mitochondria cells by simple coincubation was reported to improve mitochondrial function in the recipient cells. However, substantial evidence for internalization of isolated mitochondria is still lacking, and its precise mechanism remains elusive. We tested whether enriched mitochondria can be internalized into cultured human cells by simple coincubation using fluorescence microscopy and flow cytometry. Mitochondria were isolated from endometrial gland-derived mesenchymal

cells (EMCs) or EMCs stably expressing mitochondrial-targeted red fluorescent protein (EMCs-DsRed-mito), and enriched by anti-mitochondrial antibody-conjugated microbeads. They were coincubated with isogeneic EMCs stably expressing green fluorescent protein (GFP). Live fluorescence imaging clearly showed that DsRed-labeled mitochondria accumulated in the cytoplasm of EMCs stably expressing GFP around the nucleus. Flow cytometry confirmed the presence of a distinct population of GFP and DsRed double-positive cells within the recipient cells. In addition, transfer efficiency depended on mitochondrial concentration, indicating that human cells may possess the inherent ability to internalize mitochondria. Therefore, this study supports the application of direct transfer of isogeneic mitochondria as a novel approach for the treatment of diseases associated with mitochondrial dysfunction.

Kitsongsermthon, J., et al. (2017). "In vivo cleansing efficacy of biodegradable exfoliating beads assessed by skin bioengineering techniques." Skin Research & Technology **23**(4): 525-530.

BACKGROUND/PURPOSE: The plastic microbeads, used in many cleansers, will be banned in cosmetic and personal care products within 2017 since they are non-degradable and can disturb the living organisms in water reservoirs. Various choices of biodegradable beads are commercially available, but their efficacy has not been proven yet. This study aimed to compare the cleansing efficacy in dirt and sebum removal aspects of three types of exfoliating beads.

METHODS: The gel scrubs with polyethylene (PE) beads, mannan beads or wax beads, were formulated and evaluated for their stability. The in vivo evaluation was done in 38 healthy volunteers and the skin irritation, efficacy for dirt and sebum removal were measured by Mexameter , Colorimeter , and Sebumeter , respectively.

RESULTS: The selected gel scrubs did not cause an irritation in any volunteers. The differences in dirt residues between before and after scrubbing were not statistically significant among three gel scrubs and the similar result was also reported in the sebum removal study.

CONCLUSION: All gel scrubs demonstrated the comparable cleansing efficacy in term of dirt and sebum removal. Thus, mannan beads and wax beads may be replaced non-biodegradable PE beads to achieve the similar cleansing effect.

Kitsongsermthon, J., et al. (2018). "In vivo exfoliating efficacy of biodegradable beads and the correlation with user's satisfaction." Skin Research & Technology **24**(1): 26-30.

BACKGROUND/PURPOSE: By the end of 2017, non-biodegradable microbeads will be prohibited in USA, UK and Europe, due to their environmental issue. There are biodegradable beads available, but their effect on skin desquamation has not been evaluated yet. This study aimed to understand the skin renewal time, moisturizing effect and user's satisfaction of gel scrubs containing different exfoliating beads.

METHODS: Gel scrubs, containing polyethylene, mannan or wax beads, were used in this study. The stratum corneum turnover time (SCTT) and skin hydration were evaluated by dansyl chloride staining technique and Corneometer , respectively. The self-assessment was also performed after a 3-week home use trial.

RESULTS: The SCTTs of three different gel scrubs were not significantly different. A numerical increase in the skin hydration level was found in all groups. Satisfaction scores for the appearance and usability attributes were similar, but scores for improvement in the skin hydration and skin smoothness were higher in the gel scrubs with mannan or wax beads.

CONCLUSION: All three gel scrubs provided a similar effect on the SCTT and skin hydration, but gel scrubs with mannan or wax beads were more favorable. Thus, these two biodegradable exfoliating beads may be good substitutes in scrubbing products.

Klaeger, F., et al. (2019). "Residual Monomer Content Affects the Interpretation of Plastic Degradation." Scientific Reports **9**(1): 2120.

Plastic degradation rates in the marine environment are essential to understand. This study demonstrates that in plastic-microbial interaction experiments, residual monomeric and oligomeric content of PA6 significantly influences the development of dissolved organic carbon. While it is well recognized that additives in plastics should be considered during the inception of plastic-exposure experiments, residual monomers have yet to be prominently considered in the same light. As such, in degradation studies where residual contents of monomers and/or oligomers are not considered, degradation of synthetic polymers could be significantly overestimated. The substantial conversion of these monomeric and oligomeric leachates also has implications for plastic-biofilm development studies and microplastic-biota-based ingestion experiments.

Klein, M. and E. K. Fischer (2019). "Microplastic abundance in atmospheric deposition within the Metropolitan area of Hamburg, Germany." Science of the Total Environment **685**: 96-103.

Only few studies investigated the input of microplastic particles via the atmosphere, so far. Here, we present results on microplastic concentrations in the atmospheric deposition in the metropolitan region of Hamburg. In total, six investigation sites were equipped with three bulk precipitation samplers each and sampled biweekly over 12weeks (12/17-03/18). Three sites were located in a rural area south of Hamburg comprising one open field site and two throughfall sites under beech/oak and Douglas fir forest canopy, respectively. Three further sites were selected within the city following a transect from north to south representing urban sites of varying degrees concerning population, traffic and industrial pressures. Particles and fibers were counted under UV light within a photo box and under a fluorescence microscope (Axio Lab A.1, Zeiss).

Kleinteich, J., et al. (2018). "Microplastics Reduce Short-Term Effects of Environmental Contaminants. Part II: Polyethylene Particles Decrease the Effect of Polycyclic Aromatic Hydrocarbons on Microorganisms." International Journal of Environmental Research & Public Health [Electronic Resource] **15**(2): 07.

Microplastic particles in terrestrial and aquatic ecosystems are currently discussed as an emerging persistent organic pollutant and as acting as a vector for hydrophobic chemicals. Microplastic particles may ultimately deposit and accumulate in soil as well as marine and freshwater sediments where they can be harmful to organisms. In this study, we tested the sensitivity of natural freshwater sediment bacterial communities (by genetic fingerprint) to exposure to microplastics (polyethylene, 2 and 20 mg/g sediment) and microplastics loaded with polycyclic aromatic hydrocarbons (PAHs, phenanthrene and anthracene), using a laboratory-based approach. After two weeks of incubation, the bacterial community composition from an unpolluted river section was altered by high concentrations of microplastics, whereas the community downstream of a wastewater treatment plant remained unchanged. Low microplastic concentrations loaded with phenanthrene or anthracene induced a less pronounced response in the sediment communities compared to the same total amount of phenanthrene or anthracene alone. In addition, biodegradation of the PAHs was reduced. This study shows, that microplastic can affect bacterial community composition in unpolluted freshwater sediments. Moreover, the results indicate that microplastics can serve as a vehicle

for hydrophobic pollutants but bioavailability of the latter is reduced by the sorption to microplastics.

Klener Jr, P., et al. (2012). "Mouse models of human mantle cell lymphoma for the study of disease biology and for pre-clinical assessment of experimental treatment approaches." Blood. Conference: 54th Annual Meeting of the American Society of Hematology, ASH **120**(21).

Mantle cell lymphoma (MCL) is an aggressive type of B-cell non-Hodgkin lymphoma associated with poor prognosis. MCL animal models for the study of disease biology and for the testing of novel agents are scarce. We established and characterized various in vivo models of metastatic blastoid human MCL by tail vein injection of five MCL cell lines (Jeko-1, HBL-2, Mino, Rec-1, Granta-519) into the NOD.Cg-Prkdcscid Il2rgtm1Wjl/SzJ immunodeficient mice. Untreated animals were then observed to evaluate differences in the pattern of lymphoma growth and overall survival (OS) between different cell lines. We analyzed infiltration of selected murine organs (i.e. bone marrow [BM], spleen, liver, brain, kidneys, and enlarged lymph nodes [LN]) by immunohistochemistry (IHC) (CD20, Ki-67) at four different time-points related to OS. Extent of organ infiltration with human MCL cells was estimated using the Image-Pro Plus 5.1 software within 20 samples from different organ areas. Subsequently, we analyzed gene expression of Jeko-1 and Mino cells obtained from the xenografted animals (in vivo growing cells) compared to the cells cultured in vitro (controls).MCL cells isolated from various murine organs (the BM, liver, spleen, and LN) or in vitro cultured cells were magnetically sorted by CD45-microbeads. Gene expression analyses were carried out using Illumina BeadChips, and the data were functionally clustered with DAVID Bioinformatics tool. In addition, differences in surface expression of selected antigens were compared between in vivo vs. in vitro grown MCL cells by flow cytometry. Finally, we evaluated the anti-tumor activity of single-agent chemotherapy agents (cytarabine, fludarabine, bendamustine, and cisplatin), monoclonal antibodies (rituximab, ofatumumab, bevacizumab) or targeted agents (bortezomib, temsirolimus) in Jeko-1 and Mino bearing mice. Tumor engraftment was achieved in all the cell lines tested. The median overall survival (OS) of mice xenografted with 1-10x10⁶ MCL cells ranged from 22 to 55 days depending on the cell line used. The principal site of engraftment and proliferation niche for all MCL cell lines was the bone marrow. MCL cells disseminated to other murine organs including the spleen, liver and brain. Development of enlarged lymph nodes (peripheral, intraabdominal) and/or extranodal MCL masses (subcutaneous tumors) were associated with Mino, while infiltration of the ovaries was inconstant finding in Jeko-1 xenografted mice. Mice xenografted with Jeko-1, HBL-2 and Granta-519 showed leukemization of peripheral blood before death. Gene expression studies of Jeko-1 and Mino in vivo growing cells revealed that the genes from the "B-cell receptor signaling" and the "oxidative-phosphorylation" pathways were the most upregulated or downregulated, respectively. In vivo growing Jeko-1 cells showed upregulation of CD31/PECAM, CD37, CD38, CD44, CD164, and downregulation of podoplanin and CXCR4. In vivo growing Mino cells had upregulation of CD23, but downregulation of CD37, CD40, CD44, CD54, CD138, CXCR4, CCR7 and podoplanin. Both Jeko-1 and Mino cells isolated from the BM (but not from the spleen, liver or LN) were significantly more sensitive to cytarabine (2-4 fold) and cisplatin (2 fold) than in vitro growing controls. Single-agent therapy of Jeko-1 and Mino bearing mice with either a chemotherapy agent, monoclonal antibody, or targeted agent resulted in significant prolongation of OS compared to untreated controls. Treatment of Jeko-1 and HBL2 bearing mice with single-agent cisplatin, single-agent cytarabine or combination of both agents revealed that the therapy with single-agent cisplatin was associated with the longest prolongation of OS. Moreover, IHC analyses of the BM, spleen and liver of the treated animals confirmed the most profound suppression of both MCL infiltration

(CD20) and proliferation rate (Ki-67) in the single-agent cisplatin cohort compared to the other cohorts. In summary, the mouse models can be used for the study of MCL biology, as well as for preclinical assessment of experi ental therapy of MCL including agents that cannot be properly tested in vitro (e.g. monoclonal antibodies, pro-drugs, anti-angiogenic agents, inhibitors of B-cell receptor signaling etc.).

Klika, K. D. (2013). "Waste Plastic and Pharmaceuticals, Could an Integrated Solution Help?" Environmental Science & Technology **47**(18): 10111-10112.

The article focuses on the use of plastic waste in removing pharmaceutical and personal care products (PPCP) from wastewater. It states that low concentrations of PPCPs can result in behavioral changes and physiological effects and comments on the use of adsorbents such as porous boron nitride nanosheets in removing pollutants. It speculates on the use of plastics in absorbing toxins and PPCPs from wastewater which could then be disposed of through incineration.

Klingberg, F., et al. (2014). "Prestress in the extracellular matrix sensitizes latent TGF-beta1 for activation." Journal of Cell Biology **207**(2): 283-297.

Integrin-mediated force application induces a conformational change in latent TGF-beta1 that leads to the release of the active form of the growth factor from the extracellular matrix (ECM). Mechanical activation of TGF-beta1 is currently understood as an acute process that depends on the contractile force of cells. However, we show that ECM remodeling, preceding the activation step, mechanically primes latent TGF-beta1 akin to loading a mechanical spring. Cell-based assays and unique strain devices were used to produce a cell-derived ECM of controlled organization and prestrain. Mechanically conditioned ECM served as a substrate to measure the efficacy of TGF-beta1 activation after cell contraction or direct force application using magnetic microbeads. The release of active TGF-beta1 was always higher from prestrained ECM as compared with unorganized and/or relaxed ECM. The finding that ECM prestrain regulates the bioavailability of TGF-beta1 is important to understand the context of diseases that involve excessive ECM remodeling, such as fibrosis or cancer.

Klocker, N., et al. (2018). "From troublesome materials to fluid technologies: Making and playing with plastic-bag footballs." Cultural Geographies **25**(2): 301-318.

The material recalcitrance of plastic bags – evident in their refusal to decompose and their capacity to evade neat disposal – is a widespread source of environmental concern and frustration. Yet throughout the Majority (developing) World, the incessant materiality of plastic affords boys and young men an opportunity to make footballs (soccer balls) out of waste. Made in situ, plasticbag footballs are uniquely suited to local contexts and landscapes – a resourceful technology assembled from otherwise troublesome materials. Plastic-bag footballs are also fluid: perpetually in-the-making and characterized by diverse states of working order. Insights garnered from discussions with young Tanzanian football-makers and players position plastic-bag footballs against neocolonial discourses of poverty and precarity. Meanwhile attentiveness to the socio-material relations of plastic-bag footballs makes plain that they are not inferior technologies. Plastic-bag footballs invite consideration of how humans live, materially, in the Anthropocene. Plastic bags typify the ecological crises of throwaway consumerism and malignant toxicity. Yet, we ask: could it be that plastic-bag footballs exemplify the material resourcefulness, skill, care for things – and even playfulness – needed to cope with these very crises?. © The Author(s) 2017.

Klockner, P., et al. (2019). "Tire and road wear particles in road environment - Quantification and assessment of particle dynamics by Zn determination after density separation." Chemosphere **222**: 714-721.

In this study, a method for the determination of tire and road wear particle (TRWP) contents in particulate samples from road environment was developed. Zn was identified as the most suitable elemental marker for TRWP, due to its high concentration in tire tread and the possibility of separation from other Zn sources. The mean concentration of 21 tire samples was 8.7 +/- 2.0 mg Zn/g. Before quantification in samples from road environment, TRWP were separated from the particulate matrix by density separation. Method development was conducted using shredded tread particles (TP) as a surrogate for TRWP. Recovery of TP from spiked sediment was 95 +/- 17% in a concentration range of 2 - 200 mg TP/g. TP determination was not affected by other Zn containing solids or spiked Zn-salts. By adjusting the density of the separation solution to 1.9 g/cm3, more than 90% of total TRWP were separated from the sample matrix. TRWP concentrations in particulate matter collected in two road runoff treatment systems ranged from 0.38 to 150 mg TRWP/g. Differences in quantified TRWP contents of the two systems indicate changes in particle dynamics due to ageing and aggregation processes. The developed method allows TRWP determination in road runoff and in environments that are influenced by road traffic. The validated separation procedure can also be applied for TRWP characterization in future studies.

[ABSTRACT FROM AUTHOR]

Klonoff, D. C. (2012). "Overview of fluorescence glucose sensing: a technology with a bright future." Journal of Diabetes Science & Technology **6**(6): 1242-1250.

Fluorescence represents a promising alternative technology to electrochemistry and spectroscopy for accurate analysis of glucose in diabetes; however, no implanted fluorescence glucose assay is currently commercially available. The method depends on the principle of fluorescence, which is the emission of light by a substance after absorbing light. A fluorophore is a molecule that will absorb energy of a specific wavelength and reemit energy at a different wavelength. A fluorescence glucose-sensing molecule can be constructed to increase or decrease in fluorescence from baseline according to the ambient concentration of glucose. A quantum dot is a semiconductor crystal that can serve as a sensor by fluorescing at a desired wavelength or color, depending on the crystal size and materials used. If receptor molecules for glucose can be adsorbed to single-wall carbon nanotubules, then the resulting binding of glucose to these receptors will alter the nanotubes' fluorescence. Fluorescence glucose sensors can provide a continuous glucose reading by being embedded into removable wire-shaped subcutaneous or intravenous catheters as well as other types of implanted structures, such as capsules, microcapsules, microbeads, nano-optodes, or capillary tubes. Fluorescence glucose-sensing methods, which are under development, offer four potential advantages over commercially used continuous glucose monitoring technologies: (1) greater sensitivity to low concentrations of glucose, (2) the possibility of constructing sensors that operate most accurately in the hypoglycemic range by using binding proteins with disassociation constants in this range, (3) less need to recalibrate in response to local tissue reactions around the sensor, and (4) no need to implant either a transmitter or a power source for wireless communication of glucose data. Fluorescence glucose sensors also have four significant disadvantages compared with commercially used continuous glucose monitoring technologies: (1) a damaging foreign body response; (2) a sensitivity to local pH and/or oxygen, which can affect the dye response; (3) potential toxicity of implanted dyes, especially if the implanted fluorophore cannot be fully removed; and (4) the necessity of always carrying a dedicated light source to interrogate the implanted sensor. Fluorescence sensing is a promising method for measuring glucose continuously, especially in the hypoglycemic range. If currently vexing technical and engineering and biocompatibility problems can be overcome, then this approach could lead to a new family of continuous glucose monitors.

Klotoe, B. J., et al. (2020). "NTF-RINT, a new method for the epidemiological surveillance of MDR Mycobacterium tuberculosis L2/Beijing strains." Tuberculosis **120 (no pagination)**(101894).

The most widely discussed antibiotic-resistant tuberculosis strains ("W" and "B0/W148", "CAO") belong to L2/Beijing Lineage and are characterized by IS6110 insertion sequences at the NTF locus. We present a high-throughput, microbead-based method, called NTF-RINT for detection of IS in NTF and Rifampicin and Isoniazid Typing. This method provides tuberculosis diagnostic confirmation, screens for the so-called modern L2/Beijing sublineage and detects mutations involved in resistance to Rifampicin (RIF) and Isoniazid (INH). Klyuchnikov, E., et al. (2011). "CD34+-selected stem cell boost for poor graft function after allogeneic haematopoietic stem cell transplantation." Bone Marrow Transplantation **1)**: S338.

About 5-27% of patients (pts) experience a poor graft function (PGF) defined as hemoglobin (Hb) <10.0 g/dL and/or neutrophils (Neu) <1,500/muL and/or plateletes (Plt) <30,000/muL with complete donor chimerism on day 30 after HSCT. This complication is associated with considerable morbidity and mortality due to infections and hemorrhagic complications. Some reports showed the potential of CD34+-selected stem cell boost (SCB) in this setting. However, this approach might also exacerbate GvHD. To further assess the safety and efficacy of this approach, 28 patients (m/21, f/7; median age, 49 y; 34 - 64) with PGF received SCB without conditioning at University Medical Center Hamburg and at Institut Paoli Calmettes, Marseille. Pts were transplanted (related, n=11; unrelated: matched, n=12; mismatched, n=5) initially for myelofibrosis (n=11), AML/MDS (n=3), CML (n=3), ALL (n=2), NHL (n=3), multiple myeloma (n=2), or aplastic anemia (n=4). At the time of the SCB (median 5 mo (1-228) post-transplant) the median numbers of Neu and Plt for evaluable pts were 945/ mkl (840 - 4,160) and 16,000/mkl (10,000 - 94,000), respectively. The 17/25 (68%) pts required red blood (n=10), platelet (n=1) transfusions or both (n=6); 22/28 (79%) pts experienced PGF in 2, while 6 (21%) in 3 hematopoietic lines. The pts received a median of 3.3x10⁶ CD34+/kg bw (1-14) and of 8x10³ CD3+/kg bw (2-70). All SCBs were performed by MicroBeads-based cell selection (Miltenyi Biotec). At a median follow-up of 25 mo (10-107) from SCB 11 pts (39%) had expired (relapse, n=3; GvHD, n=4; severe infection, n=3; severe hemorrhage, n=1). GvHD after SCB developed in 6/28 pts (acute, 21%) and 8/27 pts (chronic, 30%), respectively. Of those, 4 pts already had GvHD after HSCT. We have not observed any significant correlations between the GvHD rate and CD3+ cell count. Also, there was no significant difference in GvHD rates between pts who received SCB before a median of 5 mo (6/11, 55%) and after it (8/17, 47%). The 20/24 evaluable pts (83%) resolved from PGF at day 30 after SCB (25% increase in Neu/Plt counts and/or transfusionindependence). Of 17 alive pts, 12 (71%) were in CR, 4 (24%) in PR, and 1 (5%) had progressive disease. The 2-year overall survival after SCB for all 28 pts was 60%. In conclusion, SCB represents an effective strategy to improve the function of graft in cases of PGF, however, despite the T-depleted approach, there is still a risk of GvHD.

Klyuchnikov, E., et al. (2011). "CD34+-selected stem cell boost without further conditioning for poor graft function after allogeneic hematopoietic stem cell transplantation." Onkologie **6)**: 280-281.

Introduction: About 5 - 27% of patients (pts) experience a poor graft function (PGF) defined as Hb< 10.0 g/dL and/or Neu< 1,500/muL and/or Plt< 30,000/muL with complete donor chimerism after allogeneic hematopoietic stem cell transplantation (HSCT). This complication is associated with considerable morbidity and mortality due to infections and hemorrhagic complications. Some reports showed the potential of CD34+-selected stem cell boost (SCB) in this setting. However, this approach might also exacerbate graftversus-host disease (GvHD). Patients and Methods: To further assess the safety and efficacy of this approach, 28 patients (m/21, f/7; median age, 49 y; 34 - 64) with PGF received SCB without further conditioning at University Medical Center Hamburg and at Institut Paoli Calmettes, Marseille. Pts were transplanted (related, n=11; unrelated: HLA-matched, n=12; HLA-mismatched, n=5) initially for myelofibrosis (n=11), AML/MDS (n=3), CML (n=3), ALL (n=2), NHL (n=3), multiple myeloma (n=2), or severe aplastic anemia (n=4). At the time of the SCB (median 5 month (mo; range, 1-228) post-transplant) the median numbers of Neu and Plt for evaluable pts were 945/muL (range, 840 - 4,160) and 16,000/muL (range, 10,000 - 94,000), respectively. The 17/25 (68%) pts required red blood (n=10), platelet (n=1) transfusions or both (n=6); 22/28 (79%) pts experienced PGF in 2, while 6 (21%) in 3 hematopoietic lines. The pts received a median of 3.3x106 CD34+/kg bw (1-14) and of 8.0x103 CD3⁺/kg bw (2-70). All SCBs were performed by MACS MicroBeads-based cell selection (Miltenyi). Result(s): At a median follow-up of 25 mo (range, 2-107) from SCB 11 pts (39%) had expired (relapse, n=3; GvHD, n=3; severe infection, n=4; severe hemorrhage, n=1). GvHD after SCB developed in 3/28 pts (7%; Grade II, n=1; Grade III, n=1; Grade IV, n=1), one of whom had died. All those pts initially experienced GvHD post-transplant. We have not observed any significant correlations between the GvHD rate and CD3⁺ cell count. The 24/28 pts (86%) resolved from PGF after SCB (at least 25% increase in Neu/Plt count and/or transfusion-independence). The 2-year overall survival after SCB for all 28 pts was 60%. Conclusion(s): SCB represents an effective strategy to improve the graft function in PGF cases. However, options to reduce the toxicity of this approach (e.g. decrease of interval between HSCT and SCB, adequate anti-infectious and GvHD prophylaxis) need to be further investigated.

Knapp, J., et al. (2017). "Methods to estimate the transfer of contaminants into recycling products - A case study from Austria." Waste Management **69**: 88-100.

Recycling of waste materials is desirable to reduce the consumption of limited primary resources, but also includes the risk of recycling unwanted, hazardous substances. In Austria, the legal framework demands secondary products must not present a higher risk than comparable products derived from primary resources. However, the act provides no definition on how to assess this risk potential. This paper describes the development of different quantitative and qualitative methods to estimate the transfer of contaminants in recycling processes. The quantitative methods comprise the comparison of concentrations of harmful substances in recycling products to corresponding primary products and to existing limit values. The developed evaluation matrix, which considers further aspects, allows for the assessment of

the qualitative risk potential. The results show that, depending on the assessed waste fraction, particular contaminants can be critical. Their concentrations were higher than in comparable primary materials and did not comply with existing limit values. On the other hand, the results show that a long-term, well-established quality control system can assure compliance with the limit values. The results of the qualitative assessment obtained with the evaluation matrix support the results of the quantitative assessment. Therefore, the evaluation matrix can be suitable to quickly screen waste streams used for recycling to estimate their potential environmental and health risks. To prevent the transfer of contaminants into product cycles, improved data of relevant substances in secondary resources are necessary. In addition, regulations for material recycling are required to assure adequate quality control measures, including limit values.

Knappich, F., et al. (2018). "A new approach to metal- and polymer-recovery from metallized plastic waste using mechanical treatment and subcritical solvents." The Journal of Material Cycles and Waste Management **20**(3): 1541-1552.

Galvanized or “chromium-plated” plastics are well known to the consumer from the automotive sector and sanitary area. Polymers such as acrylonitrile butadiene styrene (ABS) are typically coated with a layer system of chromium, nickel and copper to obtain the characteristic optical surface and resistance properties. Due to the complex manufacturing process and high quality requirements, the production of these plastic metal composites generates 10–30% of rejects. We, therefore, developed an innovative process cascade for the recovery of both components (metal and polymer) applying established technologies (mechanical pre-treatment, classification, melt filtration, CreaSolv® Process) and were able to obtain ABS regranulate having excellent properties regarding the characteristic values for strength but slight compromises in impact characteristics. Blends with different amounts of virgin ABS, virgin PC and recycled ABS material as well as the pure cases were successfully re-metallized, all of them passing adhesion test, thermal shock resistance and CASS test. The high purity of the recovered materials led to increased redemption prices for metal and polymer by a factor of 6 and 2.5, respectively. Thus, the value added of metallized plastic waste is maximized, revealing a highly positive economic prognosis of a commercial implementation of the developed process—even at moderate scale.

Knezevic-Jugovic, Z. D., et al. (2016). "An approach for the improved immobilization of penicillin G acylase onto macroporous poly(glycidyl methacrylate-co-ethylene glycol dimethacrylate) as a potential industrial biocatalyst." Biotechnology Progress **32**(1): 43-53.

The use of penicillin G acylase (PGA) covalently linked to insoluble carrier is expected to produce major advances in pharmaceutical processing industry and the enzyme stability enhancement is still a significant challenge. The objective of this study was to improve catalytic performance of the covalently immobilized PGA on a potential industrial carrier, macroporous poly(glycidyl methacrylate-co-ethylene glycol dimethacrylate) [poly(GMA-co-EGDMA)], by optimizing the copolymerization process and the enzyme attachment procedure. This synthetic copolymer could be a very promising alternative for the development of low-cost, easy-to-prepare, and stable biocatalyst compared to expensive commercially available epoxy carriers such as Eupergit or Sepabeads. The PGA immobilized on poly(GMA-co-EGDMA) in the shape of microbeads obtained by suspension copolymerization appeared to have higher activity yield compared to copolymerization in a cast. Optimal conditions for the immobilization of PGA on poly(GMA-co-EGDMA) microbeads were 1 mg/mL of PGA in 0.75 mol/L phosphate buffer pH 6.0 at 25degreeC for 24 h, leading to the active biocatalyst with the specific activity of 252.7 U/g dry beads. Chemical amination of the immobilized PGA could contribute to the enhanced stability of the biocatalyst by inducing secondary interactions between the enzyme and the carrier, ensuring multipoint attachment. The best balance between the activity yield (51.5%), enzyme loading (25.6 mg/g), and stability (stabilization factor 22.2) was achieved for the partially modified PGA.

Kniess, C. T. and D. d. M. Conti (2019). "SUSTAINABILITY RESEARCH: THEMES AND METHODS." Revista de Gestão Ambiental e Sustentabilidade **8**(3): 406-407.

The Journal of Environmental Management & Sustainability (GeAS Journal) is a scientific Brazilian publishing which the mission is to contribute to the dissemination of the Environmental Management & Sustainability knowledge and it's three dimensions (environmental, social and economic). Since 2012, twenty-one editions of the journal have been published. The works that are present here speak of other relevant themes for sustainable development, as methods to manage plastic waste on the Commodity Chain, geophysic methodologies in the investigation of underground contamination and, also, a work that speaks of applied research to increase the production of biogas for the fortifi cation of renewable energy mix. The solutions for sustainable development go through innovation and the capacity for planning ahead. [...]this edition shares a work about patents, which contribute to the propagation of studies and applications of network theory for interorganizational innovations.

Kniggendorf, A. K., et al. (2019). "Microplastics Detection in Streaming Tap Water with Raman Spectroscopy." Sensors **19**(8): 18.

Microplastic particles have been found in drinking water sources worldwide and, thus, also in our food and beverages. Especially small microplastics, with sizes of 1 mm and less, cannot be identified reliably without spectroscopic means such as Fourier transform infrared spectroscopy (FTIR) or Raman spectroscopy, usually applied to the particles extracted from the samples. However, for drinking and tap water, with its comparatively low biological loads, direct observation may be possible and allows a point-of-entry monitoring for beverages and food to ensure uncontaminated drinking water is being used. In a proof of concept, we apply Raman spectroscopy to observe individual microplastic particles in tap water with added particulate and fluorescent contaminants streaming with 1 L/h through a custom-made flow cell. We evaluated several tubing materials for compatibility with microplastic suspensions containing three different polymers widely found in microplastic surveys worldwide. The experiment promises the monitoring of streaming tap water and even clear surface waters for microplastics smaller than 0.1 mm.

Knoll, S., et al. (2017). "Microplastics: Minuscule particles with big consequences?. [Dutch]." Vlaams Diergeneeskundig Tijdschrift **86**(4): 203-212.

Since the mass production of plastics, contamination of the marine environment with these persistent synthetic materials has become an ever-increasing problem. Lately, it has become clear that microplastics play a big part in this. These small plastic particles (< 5mm) are ubiquitous in seawater and sediments. There are various entryways, such as fragmentation of macroplastics and drainage of primary microplastic via wastewater. Recent studies have shown that microplastics may be ingested by numerous marine organisms. This could result in diverse health effects, including mechanical injury and cellular toxicity. Adverse effects of microplastics are possibly enhanced by the contamination of these plastic particles with toxic chemicals. Furthermore, microplastics and microplastic contaminants could accumulate in the food chain, eventually affecting humans. Despite the growing number of publications on microplastics, there are still many unanswered questions regarding this topic. In this article, the contemporary knowledge of microplastics in the marine environment is provided.

Knopper, M. (2008). "Bottled water backlash: environmental concerns are sending people back to their taps." E: The Environmental Magazine **19**(3): 36-39.

Call it reverse snob appeal. These days, it's the tap water enthusiasts, concerned about the growing mountains of plastic waste, who get to act self-righteous.

Knor, S., et al. (2008). "Efficient factor VIII affinity purification using a small synthetic ligand." Journal of Thrombosis & Haemostasis **6**(3): 470-477.

BACKGROUND: Hemophilia A is currently treated by infusions of the coagulation factor (F) VIII, of which production and purification remain a challenging task. Current purification procedures using immunoaffinity chromatography are cumbersome, expensive, and suffer from the instability of the applied antibody ligands, which elute along with the product and contaminate it. Recently, FVIII was purified using octapeptide ligands, but their use is limited due to the low resistance to proteases.

OBJECTIVE: Our goal was to develop and evaluate a novel ligand for FVIII purification, overcoming the drawbacks of current procedures.

METHODS: Peptide ligands were screened for binding of (125)I-plasma-derived-FVIII (pdFVIII) in a microbead assay. A selected ligand-coated Toyopearl resin was then used for pdFVIII purification from cell-conditioned Delbucco's modified Eagle's medium (DMEM) containing fetal bovine serum. The proteolytic stability of ligand was measured by incubating with human serum and proteinase K, and its cytotoxicity towards human OV-MZ-6 cells was assayed.

RESULTS: A high-affinity octapeptidic FVIII ligand was modified into the small, highly stable and non-toxic peptidomimetic ligand L4 by rational and combinatorial design without affecting its affinity for FVIII. Using ligand L4-coated Toyopearl resin, pdFVIII was isolated from cell-conditioned medium with high purity and 89% column retention after elution with a mild buffer containing 0.6 m NaCl at pH 6.8.

CONCLUSIONS: Ligand L4 offers a valuable alternative to antibody-based procedures for laboratory and industrial production. Its synthesis by established solid-phase procedures is straightforward and considerably cheaper than the biotechnological production of antibodies, and safety concerns associated with the use of biological material are overcome.

Knutter, I., et al. (2013). "Aklides-a highly versatile imaging platform for detection of ANCA." Presse Medicale **42 (4 PART 2)**: 686.

Introduction.- Here we describe a highly versatile microscopy platform - Aklides - (A) for the automated pattern analysis of ANCA with neutrophils combined with (B) multiplex microbead-based detection of Proteinase 3 (PR3), Myeloperoxidase (MPO), and glomerular basement membrane (GBM) autoantibodies (aab). The manual interpretation of ANCA patterns is very subjective and prone to high variability. EIA results are objective but EIA have their limit in multiplex detection of specific ANCA such as PR3 and MPO. Methods.- (A) ANCA were automatically analysed with ethanol (ethN) or formalin (formN) fixed neutrophils. Sera from 342 patients with AAV and other systemic rheumatic and infectious diseases were tested for ANCA patterns with Aklides and results were compared to those of conventional fluorescence microscopy. (B) Overall, n = 214 patient sera with prefindings for PR3 aab, n = 222 for MPO aab, and n = 65 for GBM aab were analyzed with microbead-based immunoassay (Aklides ANCA BA) and results were compared to those of conventional routine ELISA. Results.- (A) An interpretation software employing pattern recognition algorithms was developed enabling positive/negative discrimination and classification of cytoplasmic ANCA (C-ANCA) and

perinuclear ANCA (P-ANCA) pattern. Comparison of visual reading with automated interpretation revealed Cohens's kappa (kappa) values of 0.955 on ethN and 0.929 on formN for positive/negative discrimination. Analysis of the set with regard to the pattern discrimination showed a high agreement for ethN (k = 0.746) and formN (k = 0.847). There was no significant difference between visual and automated interpretation (P > 0.05). (B) For Aklides ANCA BA the following relative sensitivities and specificities were determined: anti-PR3 (98%; 95%), anti-MPO (97%; 99%), and anti-GBM (90%; 100%). Conclusion.-Aklides is suitable for automated ANCA pattern analysis and detection of PR3, MPO, and GBM aab and shows a high concordance to results of conventional fluorescence microscopy and routine ELISA.

Ko, C., et al. (1995). "In vitro slow release profile of endothelial cell growth factor immobilized within calcium alginate microbeads." Artificial Cells, Blood Substitutes, & Immobilization Biotechnology **23**(2): 143-151.

Although a variety of angiogenic growth factors have been isolated, its appropriate in vivo delivery remains problematic due to nonspecific, uncontrolled delivery by conventional methods. We have investigated calcium alginate microbeads as a vehicle for the controlled slow-release of endothelial cell growth factor (ECGF). Three different microbead compositions, dependent on ECGF amount and alginate percentage were studied. Microbeads were incubated in a 1.5% calcium chloride solution and release of ECGF into solution was measured spectrophotometrically at specific timepoints. Our results show release rate and amount released after the first 2 hours are dependent on initial quick delivery of ECGF in the first 2 hours after which a sustained controlled release occurred for 4-5 days. Beyond this point, release at a slower rate was noted for at least approximately 2 weeks. Calcium alginate microbeads demonstrated a controlled and predictable rate of release and that the amount of ECGF delivered can be varied by varying the initial concentration of ECGF in the microbeads. Based on these observations we conclude that calcium alginate microbeads are a convenient and practical vehicle for sustained ECGF delivery.

Ko, C. Y., et al. (2001). "Alginate microbead release assay of angiogenesis." Methods in Molecular Medicine **46**: 53-57.

Recently, the acceleration (and retardation) of blood vessel growth has been an increasingly frequent subject of study. With its potential application to a wide range of clinical disease processes, investigation certainly remains essential and promising. While in vitro investigation is traditional, well-controlled, and objective, studying angiogenesis in vivo can be quite difficult for a number of reasons. One major reason is the inherent tissue differences associated with blood vessel growth. Because all tissues are different, certain tissues tend to be inherently more vascular than others. As such, the growth (and concentration) of blood vessels occurs at different rates and proportions depending on that specific tissue. In the past several years, most in vivo angiogenesis work has been performed in the sclera as it allows for relatively easy access and the possibility of repeated observation. The sites to which investigation of angiogenesis might be applied, however, are invariably quite different and therefore additional tissues such as solid organs, fascia, muscle, and skin need to be studied as well. How can this be performed?

Ko, Y. J., et al. (2008). "Real-time immunoassay with a PDMS-glass hybrid microfilter electro-immunosensing chip using nanogold particles and silver enhancement." Sensors and Actuators B: Chemical **132**(1): 327-333.

This paper presents the development of a PDMS-glass hybrid electro-immunosensing chip for real-time measurement of an antigen-antibody reaction through an electrical signal. Using a microfilter and microbeads, the antigen was easily immobilized in the detection zone where the microelectrodes were located. The immuno-reaction was detected by measuring the electrical resistance between microelectrodes using gold nanoparticles with silver enhancement. An immunoassay test with the developed chip was performed for the antigen of protein A, the specific first antibody of anti-protein A, the nonspecific first antibody of HBsAg monoclonal IgG, and the second antibody anti-rabbit IgG. The electro-immunosensing chip reduced the antigen-antibody reaction time to 10min, thus reducing the overall assay time to about 1h. The electrical resistance varied according to the concentration of the specific first antibody, the detection limit of which was 10ng /ml. Compared to conventional enzyme-linked immunosorbent assays (ELISAs), the process of performing an immunoassay using the electro-immunosensing chip was relatively simple and required less time to complete. In addition, the electro-immunosensing chip required less sample volume.

Kochupurakkal, N., et al. (2012). "Trophoblast cells can induce regulatory T cells." Journal of Reproductive Immunology **94 (1)**: 11.

BACKGROUND: Fetomaternal tolerance consists of several mechanisms to protect the developing embryo/fetus from the maternal immune system, as it is considered part foreign. One of the mechanisms in place is the higher numbers of regulatory T cells (Treg cells) found in a pregnantwoman, especially in the uterus, where approximately 25% of all CD4+ T cells are Tregs. Trophoblast cells are developing from the outer layer of the blastocyst and are connecting the embryo to the uterus of the mother. Here we investigate if trophoblast cells play a role in inducing naive T cells at the fetomaternal interface into Tregs. MATERIALS AND METHODS: Mouse cell line and spleen cell preparation: We used the mouse trophoblast cell line TSras2 (a kind gift of A.Erlebacher, NYU), which was cultured in DMEM:F12 supplemented with 15mMHepes, 20% FCS, glutamine, Penicillin/Streptomycin, 2-bME. TSras2 originated from FVB mice and is expressing H2Kq. CD4+ T cells and dendritic cells were isolated from collagenasedigested spleens of C57BL6/J female mice aged 6-12 weeks (Jackson, Bar Harbor, Maine). Cells were magnetically separated using CD4 microbeads and CD11c microbeads (Miltenyi) respectively, cells were isolated with LS columns 2 times to ensure high purity. Purity of isolated cells was analyzed byflowcytometry and was >95%. For experiments with CD4+ CD25- T cells, CD25+ cells were depleted with anti-CD25 hybridoma supernatant and rabbit complement. Co-culture: One million CD4+ T cells were co-cultured with varying amounts of DCs and/or trophoblast cells in 96- well plates at 37 degreeC in a humidified incubator with 5% CO2, with RPMI 1640-10% FCS complete medium. Trophoblast cells were irradiated with 3000 rad from a Cs-137 source when stated. Recombinant TNF-a, recombinant mouse IFNg and recombinant human IL-2 were used at the 10 ng/ml, 100 ng/ml and 50 units/ml respectively (from Peprotech). Recombinant human TGF-b (Miltenyi) was used at a concentration of 1 ng/ml. Flow Cytometry: Cells were stained with CD4, CD25 and FoxP3 by using the Mouse Regulatory T cell staining kit from ebioscience according to the manufacturers instructions. RESULT(S): Mouse trophoblast cells upregulate PD-L1 upon in vitro stimulation with TNFa and IFNg, while PD-L2 and other costimulatory molecules (CD80, CD86, ICOS-L) are not expressed by these cells (data not shown). By co-culturing naive CD4+ CD25- T cells with trophoblast cells in the presence of TGF-b and IL-2, a population of CD4+ CD25+ FoxP3+ regulatory T cells emerges, similar in percentage to regulatory T cells induced by co-culture with DCs. By absolute cell numbers the trophoblast induced cells are approx. 50% less than Treg induced by DCs, which is due to an overall decrease in viability and less CD25 upregulation in the trophoblast cocultured CD4. CONCLUSION(S): We have shown here for the first time that naive T cells co-cultured with a trophoblast cell line can be induced into regulatory T cells. The mechanism by which this

conversion occurs and if the induced Tregs are functional, is currently under investigation.

Kocincova, A. S., et al. (2007). "Fiber-optic microsensors for simultaneous sensing of oxygen and pH, and of oxygen and temperature." Analytical Chemistry **79**(22): 8486-8493.

Fiber-optic microsensors with a tip diameter of approximately 140 microm have been developed that enable simultaneous measurement of dissolved oxygen (DO) and pH, and of DO and temperature (T), respectively. The tip of the optical fiber was covered with sensor compositions based on luminescent microbeads that respond to the respective parameters by a change in the decay time, intensity of their luminescence, or both. The use of microbeads enables the ratio of the signals to be easily varied, reduces the risk of fluorescence energy transfer between indicator dyes, and reduces the adverse effect of singlet oxygen that is produced in the oxygen-sensitive beads. The sensor chemistry for DO/pH was modified.

Kocincova, A. S., et al. (2008). "Multiplex bacterial growth monitoring in 24-well microplates using a dual optical sensor for dissolved oxygen and pH." Biotechnology & Bioengineering **100**(3): 430-438.

Non-invasive, simultaneous optical monitoring of oxygen and pH during bacterial cultivation in 24-well microplates is presented using an integrated dual sensor for dissolved oxygen and pH values. The dual sensor is based on oxygen-sensitive organosilica microparticles and pH-sensitive microbeads from a polymethacrylate derivative embedded into a polyurethane hydrogel. The readout is based on a phase-domain fluorescence lifetime-based method referred to as modified frequency domain dual lifetime referencing using a commercially available detector system for 24-well microplates. The sensor was used for monitoring the growth of Pseudomonas putida bacterial cultures. The method is suitable for parallelized, miniaturized bioprocessing, and cell-based high-throughput screening applications.

Kodama, Y. and M. Fujishima (2012). "Characteristics of the digestive vacuole membrane of the alga-bearing ciliate Paramecium bursaria." Protist **163**(4): 658-670.

Cells of the ciliate Paramecium bursaria harbor symbiotic Chlorella spp. in their cytoplasm. To establish endosymbiosis with alga-free P. bursaria, symbiotic algae must leave the digestive vacuole (DV) to appear in the cytoplasm by budding of the DV membrane. This budding was induced not only by intact algae but also by boiled or fixed algae. However, this budding was not induced when food bacteria or India ink were ingested into the DVs. These results raise the possibility that P. bursaria can recognize sizes of the contents in the DVs. To elucidate this possibility, microbeads with various diameters were mixed with alga-free P. bursaria and traced their fate. Microbeads with 0.20mum diameter did not induce budding of the DVs. Microbeads with 0.80mum diameter produced DVs of 5-10mum diameter at 3min after mixing; then the DVs fragmented and became vacuoles of 2-5mum diameter until 3h after mixing. Each microbead with a diameter larger than 3.00mum induced budding similarly to symbiotic Chlorella. These observations reveal that induction of DV budding depends on the size of the contents in the DVs. Dynasore, a dynamin inhibitor, greatly inhibited DV budding, suggesting that dynamin might be involved in DV budding.

Koelmans, A. A., et al. (2016). "Microplastic as a Vector for Chemicals in the Aquatic Environment: Critical Review and Model-Supported Reinterpretation of Empirical Studies." Environmental Science and Technology **50**(7): 3315-3326.

The hypothesis that 'microplastic will transfer hazardous hydrophobic organic chemicals (HOC) to marine animals' has been central to the perceived hazard and risk of plastic in the marine environment. The hypothesis is often cited and has gained momentum, turning it into paradigm status. We provide a critical evaluation of the scientific literature regarding this hypothesis. Using new calculations based on published studies, we explain the sometimes contrasting views and unify them in one interpretive framework. One explanation for the contrasting views among studies is that they test different hypotheses. When reframed in the context of the above hypothesis, the available data become consistent. We show that HOC microplastic-water partitioning can be assumed to be at equilibrium for most microplastic residing in the oceans. We calculate the fraction of total HOC sorbed by plastics to be small compared to that sorbed by other media in the ocean. We further demonstrate consistency among (a) measured HOC transfer from microplastic to organisms in the laboratory, (b) measured HOC desorption rates for polymers in artificial gut fluids (c) simulations by plastic-inclusive bioaccumulation models and (d) HOC desorption rates for polymers inferred from first principles. We conclude that overall the flux of HOCs bioaccumulated from natural prey overwhelms the flux from ingested microplastic for most habitats, which implies that microplastic ingestion is not likely to increase the exposure to and thus risks of HOCs in the marine environment. Koelmans, A. A., et al. (2017). "Risks of Plastic Debris: Unravelling Fact, Opinion, Perception, and Belief." Environmental Science & Technology **51**(20): 11513-11519.

Researcher and media alarms have caused plastic debris to be perceived as a major threat to humans and animals. However, although the waste of plastic in the environment is clearly undesirable for aesthetic and economic reasons, the actual environmental risks of different plastics and their associated chemicals remain largely unknown. Here we show how a systematic assessment of adverse outcome pathways based on ecologically relevant metrics for exposure and effect can bring risk assessment within reach. Results of such an assessment will help to respond to the current public worry in a balanced way and allow policy makers to take measures for scientifically sound reasons. [ABSTRACT FROM AUTHOR]

Koelmans, A. A., et al. (2014). "Leaching of plastic additives to marine organisms." Environmental Pollution **187**: 49-54.

It is often assumed that ingestion of microplastics by aquatic species leads to increased exposure to plastic additives. However, experimental data or model based evidence is lacking. Here we assess the potential of leaching of nonylphenol (NP) and bisphenol A (BPA) in the intestinal tracts of Arenicola marina (lugworm) and Gadus morhua (North Sea cod). We use a biodynamic model that allows calculations of the relative contribution of plastic ingestion to total exposure of aquatic species to chemicals residing in the ingested plastic. Uncertainty in the most crucial parameters is accounted for by probabilistic modeling. Our conservative analysis shows that plastic ingestion by the lugworm yields NP and BPA concentrations that stay below the lower ends of global NP and BPA concentration ranges, and therefore are not likely to constitute a relevant exposure pathway. For cod, plastic ingestion appears to be a negligible pathway for exposure to NP and BPA.

Koelmans, A. A., et al. (2013). "Plastic as a carrier of POPs to aquatic organisms: a model analysis."

Environmental Science & Technology **47**(14): 7812-7820.

It has been hypothesized that persistent organic pollutants (POPs) in microplastic may pose a risk to aquatic organisms. Here we develop and analyze a conceptual model that simulates the effects of plastic on bioaccumulation of POPs. The model accounts for dilution of exposure concentration by sorption of POPs to plastic (POP "dilution"), increased bioaccumulation by ingestion of plastic-containing POPs ("carrier"), and decreased bioaccumulation by ingestion of clean plastic ("cleaning"). The model is parametrized for the lugworm Arenicola marina and evaluated against recently published bioaccumulation data for this species from laboratory bioassays with polystyrene microplastic. Further scenarios include polyethylene microplastic, nanosized plastic, and open marine systems. Model analysis shows that plastic with low affinity for POPs such as polystyrene will have a marginal decreasing effect on bioaccumulation, governed by dilution. For stronger sorbents such as polyethylene, the dilution, carrier, and cleaning mechanism are more substantial. In closed laboratory bioassay systems, dilution and cleaning dominate, leading to decreased bioaccumulation. Also in open marine systems a decrease is predicted due to a cleaning mechanism that counteracts biomagnification. However, the differences are considered too small to be relevant from a risk assessment perspective.

Koelmans, A. A., et al. (2014). "Plastics in the marine environment." Environmental Toxicology & Chemistry **33**(1): 5-10.

The authors discuss the risks associated with the presence of plastic in the marine environment and its affect on marine populations and ecosystem. They discussed topics including lack of standardization associated with the quantification of plastics in the environment, impact of plastic debris on marine population. and plastics as a vector for persistent bioaccumulative and toxic (PBT) chemical. The authors further discuss toxicological implications of microplastic particle ingestion.

Koelmans, A. A., et al. (2019). "Microplastics in freshwaters and drinking water: Critical review and assessment of data quality." Water Research **155**: 410-422.

Microplastics have recently been detected in drinking water as well as in drinking water sources. This presence has triggered discussions on possible implications for human health. However, there have been questions regarding the quality of these occurrence studies since there are no standard sampling, extraction and identification methods for microplastics. Accordingly, we assessed the quality of fifty studies researching microplastics in drinking water and in its major freshwater sources. This includes an assessment of microplastic occurrence data from river and lake water, groundwater, tap water and bottled drinking water. Studies of occurrence in wastewater were also reviewed. We review and propose best practices to sample, extract and detect microplastics and provide a quantitative quality assessment of studies reporting microplastic concentrations. Further, we summarize the findings related to microplastic concentrations, polymer types and particle shapes. Microplastics are frequently present in freshwaters and drinking water, and number concentrations spanned ten orders of magnitude (1x10⁻² to 10⁸ #/m³) across individual samples and water types. However, only four out of 50 studies received positive scores for all proposed quality criteria, implying there is a significant need to improve quality assurance of microplastic sampling and analysis in water samples. The order in globally detected polymers in these studies is PE=PP>PS>PVC>PET, which probably reflects the global plastic demand and a higher tendency for PVC and PET to settle as a result of their higher densities. Fragments, fibres, film, foam and pellets were the most frequently reported shapes. We conclude that more high quality data is needed on the occurrence of microplastics in drinking water, to better understand potential

exposure and to inform human health risk assessments.

Kogel, T., et al. (2019). "Micro- and nanoplastic toxicity on aquatic life: Determining factors." Science of the Total Environment **709**: 136050.

Plastic pollution has become a major environmental concern due to its omnipresence and degradation to smaller particles. The potential toxicological effects of micro- and nanoplastic on biota have been investigated in a growing number of exposure studies. We have performed a comprehensive review of the main determining factors for plastic particle toxicity in the relevant exposure systems, from publications until including the year 2018. For a focused scope, effects of additives or other pollutants accumulated by the plastic particles are not included. In summary, current literature suggests that plastic particle toxicity depends on concentration, particle size, exposure time, particle condition, shape and polymer type. Furthermore, contaminant background, food availability, species, developmental stage and sex have major influence on the outcome of plastic particles exposures. Frequently reported effects were on body and population growth, energy metabolism, feeding, movement activity, physiological stress, oxidative stress, inflammation, the immune system, hormonal regulation, aberrant development, cell death, general toxicity and altered lipid metabolism. Several times reported were increased growth and food consumption, neuro-, liver- or kidney pathology and intestinal damage. Photosynthesis disruption was reported in studies investigating effects on phytoplankton. For the currently unquantified plastic particles below 10mum, more toxic effects were reported in all aquatic life, as compared to plastic particles of larger size.

Koh, H. W., et al. (2018). "Advanced Recycled Polyethylene Terephthalate Aerogels from Plastic Waste for Acoustic and Thermal Insulation Applications." Gels **4**(2): 17.

This work presents for the first time, a simple, practical and scalable approach to fabricating recycled polyethylene terephthalate (rPET) aerogels for thermal and acoustic insulation applications. The rPET aerogels were successfully developed from recycled PET fibers and polyvinyl alcohol (PVA) and glutaraldehyde (GA) cross-linkers using a freeze-drying process. The effects of various PET fiber concentrations (0.5, 1.0 and 2.0 by wt.%), fiber deniers (3D, 7D and 15D) and fiber lengths (32 mm and 64 mm) on the rPET aerogel structures and multi-properties were comprehensively investigated. The developed rPET aerogels showed a highly porous network structure (98.3-99.5%), ultra-low densities (0.007-0.026 g/cm3), hydrophobicity with water contact angles of 120.7-149.8degree, and high elasticity with low compressive Young's modulus (1.16-2.87 kPa). They exhibited superior thermal insulation capability with low thermal conductivities of 0.035-0.038 W/m.K, which are highly competitive with recycled cellulose and silica-cellulose aerogels and better than mineral wool and polystyrene. The acoustic absorption results were also found to outperform a commercial acoustic foam absorber across a range of frequencies.

Kojima, S., et al. (2008). "Implementation of HACCP in the risk management of medical waste generated from endoscopy." Journal of Risk Research **11**(7): 925-936.

Medical waste poses health hazards, increases the environmental load and is costly to dispose of. To solve the above problems, we applied the hazard analysis and critical control point system (HACCP) to the management of wastes generated from endoscopy. First, the wastes in three hospitals were quantified. The number and weight of waste per case differed significantly among the three hospitals. Second, HACCP was applied to the endoscopy unit of Hospital X for a year. Wastes were segregated into five types and weighed. We found that 25.8% of 'infectious waste' was in fact 'non-infectious waste' and 'non-infectious plastic waste'. The numbers of needles and needle caps did not correspond in two occasions (needle-loss rate: 0.42%). Bacterial counts of the waste container were determined to investigate infection hazard. The counts were 0 cfu/cm super(2) in all examinations except one occasion. The waste control manifests were reviewed, and all entries were consistent with the waste sent for disposal. In Hospital X where implementation of HACCP was attempted, reduction of environmental load and cutting of disposal cost are anticipated by changing the categories of waste segregation. The results suggest that hospital wastes should be managed more safely by HACCP.

Kokalj, A. J., et al. (2018). "Plastic bag and facial cleanser derived microplastic do not affect feeding behaviour and energy reserves of terrestrial isopods." Science of the Total Environment **615**: 761-766.

Current data regarding the effects of microplastic (MP) on terrestrial organisms are very scarce. Isopods play an important role in plant litter decomposition processes and are commonly used test species in terrestrial ecotoxicity studies. Their altered feeding behaviour and energy reserves are established biomarkers of adverse effects upon stressor exposure. For this study we assessed the effects of MP derived from plastic bag film (mean size 183+or-93 micro m) and particles from a facial cleanser (mean size 137+or-51 micro m) on the terrestrial isopod, Porcellio scaber. Isopods were exposed to MP via feeding on food pellets (4 mg g⁻¹ dry weight; 0.4% w w⁻¹) for 14 days under laboratory conditions. A control group was exposed to food pellets with no MP added. In line with previously suggested modes of MP action on animal ingestion, we assessed the food ingestion rate, defecation rate, food assimilation rate and efficiency, body mass change, mortality and energy reserves (proteins, carbohydrates, and triglycerides) in the digestive glands (hepatopancreas) of individual isopods. Contrary to our expectations, no effects on either end-point were observed under the given exposure conditions. Further work should be carried out to investigate the potential longer-term effects of such exposure. We conclude that 14 days exposure to plastic bag and facial cleanser MP is not severely hazardous to isopods.

Kokalj, A. J., et al. (2018). "Screening study of four environmentally relevant microplastic pollutants: uptake and effects on Daphnia magna and Artemia franciscana." Chemosphere **208**: 522-529.

This study investigated four different environmentally relevant microplastic (MP) pollutants which were derived from two facial cleansers, a plastic bag and polyethylene textile fleece. The mean size range of the particles (according to number distribution) was 20-250 micro m when measured as a powder and 0.02-200 micro m in suspension. In all MP exposures, plastic particles were found inside the guts of D. magna and A. franciscana, but only in the case of daphnids a clear exponential correlation between MP uptake in the gut and the size of the MP was identified. Exposure tests in which the majority of the MP particles were below 100 micro m in size also had higher numbers of daphnids displaying evidence of MP ingestion. As the average MP particle size increased, the percentage of daphnids which had MP in their gut decreased. Using a number distribution value to measure particle size when in a suspension is more experimentally relevant as it provides a more realistic particle size than when samples are measured as a powder. Generally, artemias had fewer MP particles in the gut, than the

daphnids, which could be explained by their different food size preferences. No acute effects on D. magna were found, but the growth of A. franciscana was affected. We conclude that zooplankton crustacean can ingest various MPs but none of the exposures tested were highly acutely hazardous to the test species. In addition, no delayed lethal effects in a 24 h post-exposure period were found.

Kolandhasamy, P., et al. (2018). "Adherence of microplastics to soft tissue of mussels: a novel way to uptake microplastics beyond ingestion." Science of the Total Environment **610**(611): 635-640.

Microplastic pollution is recognized as an emerging threat to aquatic ecosystems. One of the main environmental risks associated with microplastics is their bioavailability to marine organisms. Up to date, ingestion has been widely accepted as the sole way for the animals to uptake microplastics. Nevertheless, microplastics have also been found in some organs which are not involved in the process of ingestion. We hypothesize that the animal might uptake microplastics through adherence in addition to ingestion. To test this hypothesis, we collected mussels from the fishery farms, conducted exposure/clearance experiments and analyzed the accumulation of microplastics in specific organ of mussels. Our studies clearly showed the uptake of microplastic in multiple organs of mussels. In the field investigations, we found that the abundance of microplastic by weight but not by individual showed significant difference among organs, and the intestine contained the highest level of microplastics (9.2 items/g). In the uptake and clearance experiment, the accumulation and retention of microfibers could also be observed in all tested organs of mussels including foot and mantle. Our results strongly suggest that adherence rather than ingestion led to the accumulation of microplastics in those organs which are not involved in ingestion process. To our best knowledge, it is the first time to propose that adherence is a novel way for animals to uptake microplastics beyond ingestion. This new finding makes us rethink about the bioavailability, accumulation and toxicity of microplastics to aquatic animals.

Kolatorova, L., et al. (2018). "Endocrine disruptors." Diabetologie Metabolismus Endokrinologie Vyziva **21**(3): 142-149.

The increasing evidence of hormonal and endocrine diseases observed over the last decade has been linked to the occurrence of chemicals in the environment and the food chain. Many chemicals have the ability to disrupt the endocrine system and have been named endocrine disruptors (EDs). Actually, thousands of substances are considered as EDs, which, like hormones, can act in very small amounts. The human organism is exposed to the simultaneous action of various EDs that can interact with each other, have an antagonistic, additive or even synergistic effect. One of the well-known EDs is estrogen active bisphenol A (BPA), released from plastics, resins or cash receipts. Its use is regulated and even prohibited in some countries. Instead of BPA, however, the manufacturers use so-called alternative bisphenols, the use of which is not regulated yet. Parabens used as preservatives in the manufacture of cosmetics and pharmaceuticals or phthalates used as plasticizers of PVC plastics are another widespread ones. EDs also include natural substances, such as phytoestrogens estrogen active plant substances predominately found in soybeans. In addition to its positive effects, global soybean spread has also begun to increase knowledge about the role of phytoestrogens such as EDs. Due to the major estrogen activity od EDs, their effect on reproductive function is of interest. Current topics also include the effect of EDs on obesity, diabetes mellitus, bone metabolism and others. Investigating EDs and their effects on the human organism is currently one of the hot topics of the European Commission or the European Endocrine Society. © 2018 TIGIS Spol. s.r.o. Kole, P. J., et al. (2017). "Wear and Tear of Tyres: A Stealthy Source of Microplastics in the Environment." International Journal of Environmental Research & Public Health [Electronic Resource] **14**(10): 20.

Wear and tear from tyres significantly contributes to the flow of (micro-)plastics into the environment. This paper compiles the fragmented knowledge on tyre wear and tear characteristics, amounts of particles emitted, pathways in the environment, and the possible effects on humans. The estimated per capita emission ranges from 0.23 to 4.7 kg/year, with a global average of 0.81 kg/year. The emissions from car tyres (100%) are substantially higher than those of other sources of microplastics, e.g., airplane tyres (2%), artificial turf (12-50%), brake wear (8%) and road markings (5%). Emissions and pathways depend on local factors like road type or sewage systems. The relative contribution of tyre wear and tear to the total global amount of plastics ending up in our oceans is estimated to be 5-10%. In air, 3-7% of the particulate matter (PM_{2.5}) is estimated to consist of tyre wear and tear, indicating that it may contribute to the global health burden of air pollution which has been projected by the World Health Organization (WHO) at 3 million deaths in 2012. The wear and tear also enters our food chain, but further research is needed to assess human health risks. It is concluded here that tyre wear and tear is a stealthy source of microplastics in our environment, which can only be addressed effectively if awareness increases, knowledge gaps on quantities and effects are being closed, and creative technical solutions are being sought. This requires a global effort from all stakeholders; consumers, regulators, industry and researchers alike.

Kolle, W. (2017). "Water analyses - correctly assessed: basics, parameters, sources, and contents." Wasseranalysen richtig beurteilt: Grundlagen, Parameter, Wassertypen, Inhaltsstoffe **4**(500).

For a safe and sustainable drinking water supply, the quality of drinking water as well as of raw water must be constantly monitored by means of increasingly complex water analyses. Based on numerous sample analyses, this book once again offers a comprehensive overview of the fundamentals of water chemistry, the relevance of different parameters for the different types of water, the occurrence of natural and anthropogenic water constituents, as well as practical tips on how to use this completely revised and updated drinking water regulation calculation and analysis of data. The limit values in Germany and in the EU in accordance with the Drinking Water Ordinance and the European Drinking Water Directive are taken into account throughout. Numerous parameters have been added, such as drugs, construction chemicals, sweeteners, phthalates and microplastics. Special attention is paid to calcite saturation and its importance for the use of drinking water and its calculation according to the recast DIN standard. The associated website offers the reader with extensive supplementary image material to the reactants of water in aquifers, for water treatment, biofilms, corrosion products and asbestos. This book will be an indispensable and well-proven guide for anyone working professionally in monitoring water quality.

Komatsu, M., et al. (2015). "Maturation of human iPS cell-derived dopamine neuron precursors in alginate-Ca(2+) hydrogel." Biochimica et Biophysica Acta **1850**(9): 1669-1675.

BACKGROUND: Pluripotent stem cells (embryonic stem/induced pluripotent stem cells) have been widely studied as a potential cell source for cell transplantation therapy of Parkinson's disease. However, some difficulties remain to be overcome. These include the need to prepare a large number of dopamine (DA) neurons for clinical use and to culture the cells for a long period to allow their functional maturation and the removal of undifferentiated cells.

METHODS: In this study, aggregates of DA neuron precursors were enclosed in alginate-Ca(2+) microbeads, and the encapsulated aggregates were cultured for 25days to induce cell

maturation.
RESULTS: More than 60% of cells in the aggregates differentiated into tyrosine hydroxylase-positive DA neurons. The aggregates could release DA at the same level as aggregates maintained on culture dishes without encapsulation. In addition, by exposure to a citrate solution, the alginate-Ca(2+) gel layer could be easily removed from aggregates without damaging the DA neurons. When the aggregates were transplanted into rat brain, viable cells were found in the graft at one week post-transplantation, with cells extending neurites into the host tissue.
CONCLUSIONS: Cell aggregates encapsulated in alginate-Ca(2+) beads successfully differentiated into mature DA neurons.
GENERAL SIGNIFICANCE: The alginate-Ca(2+) microbead is suitable for maintaining DA precursor aggregates for a long period to allow their functional maturation.

Konagaya, S. and H. Iwata (2015). "Microencapsulation of dopamine neurons derived from human induced pluripotent stem cells." Biochimica et Biophysica Acta **1850**(1): 22-32.
BACKGROUND: Dopamine neurons derived from induced pluripotent stem cells have been widely studied for the treatment of Parkinson's disease. However, various difficulties remain to be overcome, such as tumor formation, fragility of dopamine neurons, difficulty in handling large numbers of dopamine neurons, and immune reactions. In this study, human induced pluripotent stem cell-derived precursors of dopamine neurons were encapsulated in agarose microbeads. Dopamine neurons in microbeads could be handled without specific protocols, because the microbeads protected the fragile dopamine neurons from mechanical stress.
METHODS: hiPS cells were seeded on a Matrigel-coated dish and cultured to induce differentiation into a dopamine neuronal linage. On day 18 of culture, cells were collected from the culture dishes and seeded into U-bottom 96-well plates to induce cell aggregate formation. After 5 days, cell aggregates were collected from the plates and microencapsulated in agarose microbeads. The microencapsulated aggregates were cultured for an additional 45 days to induce maturation of dopamine neurons.
RESULTS: Approximately 60% of all cells differentiated into tyrosine hydroxylase-positive neurons in agarose microbeads. The cells released dopamine for more than 40 days. In addition, microbeads containing cells could be cryopreserved.
CONCLUSION: hiPS cells were successfully differentiated into dopamine neurons in agarose microbeads.
GENERAL SIGNIFICANCE: Agarose microencapsulation provides a good supporting environment for the preparation and storage of dopamine neurons.

Kong, X. and A. A. Koelmans (2019). "Modeling Decreased Resilience of Shallow Lake Ecosystems toward Eutrophication due to Microplastic Ingestion across the Food Web." Environmental Science and Technology **53**(23): 13822-13831.
The discovery of microplastic (MP) being present in freshwaters has stimulated research on the impacts of MP on freshwater organisms. To date, research has focused on primary effects, leaving questions with respect to secondary effects at the level of freshwater food webs unanswered. Here, we use a theoretical modeling approach to investigate the hypothesis that MP imposes negative impacts on the level of freshwater shallow lake food webs. We find that increasing MP levels have the potential to affect the critical phosphorus loading (CPL), which is defined as the threshold for regime shifts between clear and turbid states of the water column. The possible occurrence of catastrophic cascades due to MP pollution is predominantly driven by the negative effects of MP on zooplankton. We explore the possible states of the food web by scenario analysis and show that the secondary effects of MP at current concentrations are likely to be negligible. However, at the current rate of MP production, a 20-40% reduction in the

CPL would occur by the end of this century, suggesting a loss of resilience in shallow lakes that would be subject to abrupt changes in the food web under lower nutrient loading. Copyright © 2019 American Chemical Society.

Konigsberg, R., et al. (2010). "Circulating tumor cells in metastatic colorectal cancer: efficacy and feasibility of different enrichment methods." Cancer Letters **293**(1): 117-123.

Comprehensive in vitro and in vivo studies comparing EpCAM-based methods with other cytometric CTC enrichment technologies in metastatic colorectal cancer (mCRC) patients are lacking. We compare four manual cytometric methods to detect CTCs in vitro and in mCRC patients. The EpCAM-based technology, MACS HEA MicroBeads((R)), showed a significant better tumor cell recovery rate compared to other cytometric methods (p-value<0.0001). CTCs of 38 mCRC patients were enriched with MACS HEA MicroBeads(R). Progression-free survival did significantly differ between mCRC patients without detectable and with >or= 1 CTCs (p=0.007). CTC enrichment with EpCAM coupled antibodies is superior to other cytometric methods and is a feasible method for CTC detection in mCRC patients.

Kooi, M., et al. (2017). "Ups and Downs in the Ocean: Effects of Biofouling on Vertical Transport of Microplastics." Environmental Science & Technology **51**(14): 7963-7971.

Recent studies suggest size-selective removal of small plastic particles from the ocean surface, an observation that remains unexplained. We studied one of the hypotheses regarding this size-selective removal: the formation of a biofilm on the microplastics (biofouling). We developed the first theoretical model that is capable of simulating the effect of biofouling on the fate of microplastic. The model is based on settling, biofilm growth, and ocean depth profiles for light, water density, temperature, salinity, and viscosity. Using realistic parameters, the model simulates the vertical transport of small microplastic particles over time, and predicts that the particles either float, sink to the ocean floor, or oscillate vertically, depending on the size and density of the particle. The predicted size-dependent vertical movement of microplastic particles results in a maximum concentration at intermediate depths. Consequently, relatively low abundances of small particles are predicted at the ocean surface, while at the same time these small particles may never reach the ocean floor. Our results hint at the fate of "lost" plastic in the ocean, and provide a start for predicting risks of exposure to microplastics for potentially vulnerable species living at these depths.

Koongolla, J. B., et al. (2019). "Occurrence of microplastics in gastrointestinal tracts and gills of fish from Beibu Gulf, South China Sea." Environmental Pollution **258**: 113734.

Microplastics are widespread across the global oceans, yet the potential risks of the ubiquitous environmental contaminant to marine organisms has been less known. Accumulation of microplastics and associated contaminants in marine fish, may pose adverse impacts to human health via seafood consumption. This study evaluated microplastic contamination in 24 fish species collected from Beibu Gulf, one of the world's largest fishing grounds in South China Sea. Microplastics were detected in 12 fish species at an abundance of 0.027-1.000 items individual⁻¹ and found in fish stomach, intestines and gills with the count percentage of 57.7%, 34.6% and 7.7%, respectively. Transparent fibers were observed as the predominant microplastics, which might be ingested accidently by fish or transferred through other animals at lower trophic levels. Majority of microplastics were identified as polyester

(44%) and nylon (38%), whereas polypropylene (6%), polyethylene (6%), and acrylics (6%) were also found. Relatively, higher microplastic abundances were found in demersal fish compared to the pelagic species. Overall, the abundance of microplastics was documented as relatively low in the commercial fish collected from the open water of Beibu Gulf, South China Sea.

Kor, K. and A. Mehdinia (2020). "Neustonic microplastic pollution in the Persian Gulf." Marine Pollution Bulletin **150**: 110665.

Currently, microplastics are a major challenge threatening marine environment. Given little information on their prevalence in the Persian Gulf, the present study as the first comprehensive study was conducted to evaluate microplastics abundance in surface waters. Neustonic samples were collected from 15 stations along the Persian Gulf. Visually separated microplastics were categorized according to their size, shape, and color. ATR-FTIR method was used to identify the composition of polymers. Microplastics were found in all sampling stations and their density varied from 1.5x10³ to 4.6x10⁴ particle.km⁻² with a mean density of 1.8x10⁴ particle.km⁻². Fibers were the most dominant shape of microplastics (44.1%). Approximately 76% of the analyzed microplastics were polyethylene and polypropylene and the predominant colors of the microplastics were white and blue.

Kord, S. and A. Naji (2019). "Study of micro-plastic contamination in five species of prevailing fishes of Chabahar Bay, (Sistan and Baluchestan Province)." Iranian Scientific Fisheries Journal **28**(3): 113-123.

The global demand for plastics is increasing due to its wide applications. Approximately 60 to 80 percent of the waste in the marine environment are plastics. There is a lack of information and research on the presence of plastic and micro-plastic contamination in aquatic animals. The present study, therefore examined the frequency, distribution, size, colour and type of micro-plastic (MPS) in the gastrointestinal tract of 5 species (n= 10) from the coasts of the Chabahar Bay, the Oman Sea, in spring. The total number of MPS found in the studied species varied and highest percentage of MPS in the gastrointestinal tract of the fish were fibre (55%), fragments (26%) and pellets (18%). The results of the Fourier transform infrared spectroscopy (FT-IR) analysis from suspect samples shown microplastics. The most commonly detected polymers were polyethylene (PE), polyethylene terephthalate (PET) and nylon. The results

showed that all fish sampled from Chabahar Bay contained MPS. Considering the importance of MPS pollution, it is suggested that monitoring the release of plastics on the shores with tourism and fishing in the Bay of Chabahar, can be a subject of future studies.

Korez, S., et al. (2019). "Feeding and digestion of the marine isopod Idotea emarginata challenged by poor food quality and microplastics." Comparative Biochemistry & Physiology **Toxicology & Pharmacology**: Cbp. 226:108586.

Ingestion of microplastics can impair nutrition of marine invertebrates. In a laboratory study, we tested whether microplastics affect ingestion rates and gastrointestinal enzyme activities in the marine isopod Idotea emarginata. Isopods were fed for eight days with one out of four different food formulations: natural food (the brown alga Fucus vesiculosus) or synthetic diet consisting of freeze-dried algal powder embedded in agarose, both, with or without microplastic particles (fluorescent polymethyl methacrylate, 10-100mum) at a concentration of 40 items per mg of food. The isopods accepted both types of food but consumed significantly more (average 3.1-fold) of the agar based synthetic food. I. emarginata responded to the reduced content of digestible organic matter in the synthetic food by a compensatory adjustment of the ingestion rates. Addition of microplastics had no effect on ingestion rates in natural food whereas the feeding rates for synthetic food varied in response to microplastics. Similarly, activity patterns of digestive enzymes, particularly those of esterases, changed significantly in the treatment with synthetic food. Isopods fed with synthetic food alone showed elevated esterase activities in the gut while those isopods fed with synthetic food and microplastics showed elevated esterase activities in the midgut gland but not in the gut. Apparently, not the exposure to microplastic alone, but the combined effects of reduced nutrient availability and microplastic ingestion caused considerable biochemical reactions in the digestive organs of the isopods.

Koroleva, A. V., et al. (2013). "LDPE COMPOSITES WITH WOOD FLOUR AND RUBBER." Advances in Sustainable Petroleum Engineering Science **5**(3): 141-145.

Currently the world's consumption of plastics is growing in this regard there are difficulties in disposing of large amounts of household plastic waste. The solution is to develop biodegradable polymers with a specific expiration date. This work is dedicated to the creation of biodegradable composite material based on LDPE, wood flour and rubbers of different nature.

Koroneos, C. J. and E. A. Nanaki (2012). "Integrated solid waste management and energy production - a life cycle assessment approach: the case study of the city of Thessaloniki." Journal of Cleaner Production **27**: 141-150.

Innovative strategies are needed to deal with the waste we produce today to prevent it from causing problems for future generations. As waste management issues gain public awareness, concern has risen about the appropriateness of various disposal methods. The objective of this work is the environmental assessment of different municipal solid waste treatment strategies for the city of Thessaloniki, within the methodological frameworks of Life Cycle Assessment (LCA) and the Integrated Solid Waste Management strategy, taking into account social, environmental and economic effects. The waste management methods in this study include: landfill of all waste fractions, recycling of paper, and anaerobic digestion of food waste in a biological treatment plant. The waste fractions considered are the total amount of food, paper and plastic waste produced in Thessaloniki during the period of one year. Environmental impacts are decreased when the solid waste management methods include some kind of recovery from waste. The results of this work indicate that paper recycling and anaerobic digestion of food waste is preferable compared to landfilling. It is also shown that landfilling of food waste utilizing the biocells method is more attractive than anaerobic digestion in a separate plant; nevertheless, energy recovery is about 45% lower.

Kosmider, B., et al. (2017). "DNA damage in human alveolar type II cells in emphysema." American Journal of Respiratory and Critical Care Medicine. Conference: American Thoracic Society International Conference, ATS **195**(no pagination).

Rationale Emphysema is caused by the destruction of alveolar wall septa. The major risk factor for this disease is cigarette smoke and effective therapies are very limited. Alveolar type II (ATII) cells are in the gas exchange portion of the lung. They make and secrete pulmonary surfactant, and proliferate to restore the epithelium after damage to the more sensitive alveolar type I cells. Methods Control ATII cells were isolated from deidentified control non-smoker and smoker organ donors whose lungs were not suitable for transplantation and donated for medical research. Furthermore, as a unique approach, we have developed a new method on how to isolate ATII cells from excess tissue from lung transplants obtained from patients with emphysema using magnetic microbeads. We determined DNA damage, DNA repair, oxidative stress, injury, and inflammation in human primary ATII cells isolated from these individuals in comparison with controls. Results Our data indicates high oxidative stress in human ATII cells induced by cigarette smoke extract in vitro as measured by 4-HNE staining by immunocytofluorescence. We also observed DNA double strand breaks, high DNA damage, and low DNA repair in these cells. Moreover, we found greater proinflammatory response as determined by IL-8 and IL-6 levels by ELISA. Furthermore, ATII cells obtained from patients with emphysema had greater injury compared to cells obtained from control non-smokers and smokers. Conclusion Our results indicate oxidative ATII cell damage induced by cigarette smoke and in emphysema. Observed DNA damage/repair imbalance may contribute to cell death in this disease. The study of ATII cell injury may improve our knowledge on this disease pathogenesis and may lead to novel therapeutic strategies to slow the progression of emphysema.

Kosmider, B., et al. (2017). "Impairment of DNA double strand break repair in human primary alveolar type II cells in emphysema." Cancer Research. Conference: American Association for Cancer Research Annual Meeting **77**(13 Supplement 1).

Kosore, C., et al. (2018). "Occurrence and ingestion of microplastics by zooplankton in Kenya's marine environment: first documented evidence." African Journal of Marine Science **40**(3): 225-234.

Microplastics can be ingested by marine organisms and may lead to negative impacts at the base of marine food chains. This study investigated the occurrence and composition of microplastics in the sea-surface water and sought evidence of ingestion by zooplankton. Surface seawater was collected using a stainless-steel bucket and sieved directly through a stainless-steel sieve (250-µm mesh), while a 500-µm mesh net was towed horizontally to collect zooplankton, at 11 georeferenced stations off the Kenyan coast in February 2017, on board the national research vessel RV Mtafiti. Microplastic particles were sorted and characterised using an Optika dissecting microscope. Polymer types were identified using an ALPHA Platinum attenuated total reflection-Fourier-transform infrared (ATR-FTIR) spectrometer. A total of 149 microplastic particles, with an average abundance of 110 particles m-3, were found in the surface seawater. A total of 129 particles were found ingested by zooplankton groups, where Chaetognatha, Copepoda, Amphipoda and fish larvae ingested 0.46, 0.33, 0.22 and 0.16 particles ind.-1, respectively. Filaments dominated both the surface-water microplastics and the ingested microplastics, contributing 76% and 97% to those compositions, respectively. White particles were prevalent in the water (51%), whereas black was the colour found most commonly (42%) across the zooplankton groups. The sizes of particles that were in the water were in the range of 0.25-2.4 mm, and those ingested ranged between 0.01 and 1.6 mm. Polypropylene was predominant in the surface water, whereas low-density polyethylene was the most-ingested polymer type. The results provide the first documented evidence of the occurrence, composition and ingestion of microplastics by zooplankton in Kenya's marine environment, indicating that microplastics have the potential to enter pelagic food webs and cause pollution in the study area.

Kostic, D., et al. (2019). "Multifunctional ternary composite films based on PLA and Ag/alginate microbeads: Physical characterization and silver release kinetics." Materials Science & Engineering. C, Materials for Biological Applications **98**: 1159-1168.

Novel multifunctional composite poly(lactic acid) (PLA) films with alginate microbeads containing silver nanoparticles (AgNPs) were developed for potential antimicrobial food packaging applications. AgNPs, 10-20nm in size, were synthesized in a Na-alginate solution by a hydrothermal method yielding a sterile, pH neutral colloid solution of low viscosity that was electrostatically extruded to produce Ag/alginate microbeads (190mum in size) with retained AgNPs. Dried microbeads were uniformly dispersed in PLA films with retained AgNPs as confirmed by UV-Vis spectroscopy and scanning electron microscopy. The films were characterized regarding thermal and mechanical properties as well as silver release in different food simulants.

Kosuth, M., et al. (2018). "Anthropogenic contamination of tap water, beer, and sea salt." PLoS ONE [Electronic Resource] **13**(4): e0194970.

Plastic pollution has been well documented in natural environments, including the open waters and sediments within lakes and rivers, the open ocean and even the air, but less attention has been paid to synthetic polymers in human consumables. Since multiple toxicity studies indicate

risks to human health when plastic particles are ingested, more needs to be known about the presence and abundance of anthropogenic particles in human foods and beverages. This study investigates the presence of anthropogenic particles in 159 samples of globally sourced tap water, 12 brands of Laurentian Great Lakes beer, and 12 brands of commercial sea salt. Of the tap water samples analyzed, 81% were found to contain anthropogenic particles. The majority of these particles were fibers (98.3%) between 0.1-5 mm in length. The range was 0 to 61 particles/L, with an overall mean of 5.45 particles/L. Anthropogenic debris was found in each brand of beer and salt. Of the extracted particles, over 99% were fibers. After adjusting for particles found in lab blanks for both salt and beer, the average number of particles found in beer was 4.05 particles/L with a range of 0 to 14.3 particles/L and the average number of particles found in each brand of salt was 212 particles/kg with a range of 46.7 to 806 particles/kg. Based on consumer guidelines, our results indicate the average person ingests over 5,800 particles of synthetic debris from these three sources annually, with the largest contribution coming from tap water (88%).

Kotaskova, J., et al. (2017). "Treatment with BCR inhibitors increases ROR1 expression in CLL cells." Haematologica **102 (Supplement 2)**: 414.

Background: Receptor Tyrosine Kinase-Like Orphan Receptor-1 (ROR1) expression on malignant B-cells is considered a promising target for therapy of CLL and other lymphoproliferative disorders. Recently published data suggest that combination of BCR inhibitor ibrutinib with ROR1 antibody cirmtuzumab can enhance treatment efficacy in CLL. Nevertheless, the variability in ROR1 expression during disease progression, therapy administration and relapse remains unknown. Aim(s): In our study we aimed to i) detect ROR1 in CLL cells during different stages of the disease using flow cytometry and qRT-PCR with focus on patients undergoing therapy; ii) analyse changes in ROR1 expression within individual patients during the disease course. Method(s): CLL cohort consisted of 96 CLL patients (152 samples): 23 patients with stable disease, 16 patients with active disease prior first therapy intervention, 6 patients during first therapy, 13 patients in progression before second line treatment, 3 patients in complete remission, 10 refractory patients, 9 patients treated with ibrutinib, 16 patients treated with idelalisib. To monitor changes in ROR1 expression we tested serial samples from 5 CLL patients (median follow up 76 months (66-131), median number of sampling points 12 (5-18)). For surface ROR1 protein analysis we used 8-colour flow cytometry (modified MRD protocol: CD45/CD3/CD19/CD5/CD81/CD79b/CD22/ROR1) in all samples. To quantify ROR1 mRNA expression changes within individual patients we performed qRT-PCR in separated CLL cells (>95% CD19+CD5+). CLL cells from samples in remission were separated immunomagneticaly (Whole Blood Anti-ROR1 MicroBead Kit, Miltenyi Biotec). Result(s): Using multicolour flow cytometry we confirmed ROR1 antigen/protein presence on CLL cells in each analysed sample. The ROR1 antigen was detectable on residual CLL cells during disease remission with the ability to distinguish malignant population from healthy B-cells. Using qRT-PCR we detected significantly higher levels of ROR1 mRNA in samples of treated patients ($p<0.01$). This observation was supported by analysis of ROR1 mRNA expression in five patients tested consecutively in several time-points. We detected ROR1 mRNA expression increase in disease progression before therapy and further increase during therapy administration. In case of remission induction we observed decrease of ROR1 mRNA level. In patients treated with ibrutinib or idelalisib we observed steep increase of ROR1 expression compared to patients treated with FCR regimen. Summary/Conclusions: ROR1 protein remains detectable on CLL cells during disease course even in complete remission. ROR1 mRNA levels are highly influenced by therapy administration especially in the case of treatment with BcR inhibitors.

Kottaridis, P., et al. (2011). "Results of a phase 1 clinical trial of allogeneic tumor-primed natural killer cells in AML." Blood. Conference: 53rd Annual Meeting of the American Society of Hematology, ASH **118**(21).

We have previously reported that resting human NK cells can be primed to lyse NK-resistant tumor cells, including AML, by co-incubation with membrane preparations from the leukemia cell line CTV-1. Tumor-primed NK cells can be cryopreserved and remain in a primed state when thawed. Following translation of this production method to GMP-compliance we designed a phase 1 trial for AML patients. PROTOCOL: AML patients meeting the inclusion criteria were enrolled and they and their children HLA-typed and screened for medical suitability for apheresis. KIR mismatched donors in the GvL direction were preferred when available. PATIENT INCLUSION CRITERIA: >60 years in PR (blasts >5<20% in BM) after 2nd course of induction chemotherapy; >60 years in CR2 after re-induction chemotherapy; >60 years in PR or CR after 2 courses of chemotherapy with poor risk disease by conventional cytogenetic criteria; <60 years beyond CR2 but unsuitable for transplantation. CONDITIONING: Fludarabine 25mg/m2/day for 3 days plus a single fraction (2Gy) TBI on day 4. MANUFACTURE OF Tumor-primed NK: T-pNK cells were generated from single 2hr apheresis from haploidentical related donors in 14 cases; 1 donor declined and the patient was not treated. NK cells were isolated with anti-CD56 microbeads (CliniMACS, Miltenyi Biotec) with (n=2) or without (n=12) prior depletion of CD3+ cells. Purified NK cells were co-incubated with a lysate of CTV-1 cells (DSMZ repository) overnight. Lysate was removed by density gradient separation on day 2 and cells were cryopreserved in dosed aliquots and released for infusion within 15 days of manufacture. TREATMENT: Three groups of 5 patients were to receive 1x10^6/kg, 5x10^6/kg or 1x10^7/kg haploidentical related donor T-pNK as a single i.v. infusion 24 hours after completion of TBI. RESULT(S): 15 patients were enrolled between July 2008 and Dec 2009-Table 1. Mean donor T-pNK yield was 6.73x10^9 and CD56 purity 99.3%. T cell contamination was <10^4/kg. All products achieved QC release criteria. Median time from enrolment to product release was 46 days. 8/15 patients received the T-pNK therapy; 7 untreated due to relapse during product manufacture or failure to remit (6) and donor refusal (1). No infusional toxicity was observed. 7/8 patients experienced profound bone marrow suppression with median time of neutrophil recovery 55 days (19-101). Two patients who previously had an allogeneic transplant were salvaged with a CD34+ top up stem cell transfusion from their original donors. All experienced neutropenic fevers requiring antibiotic support with 2 of them requiring ICU admission. Due to the toxicities observed the dose escalation was abandoned and all treated patients received 1x10^6 cell/kg. The median duration of CR post T-pNK was 222 days (55-845) compared to previous CR median of 47 days (0-90)-Table 1. 7/8 patients experienced a longer CR post T-pNK than their previous CR; median increase in duration of CR was 242 days (range 54-815). CONCLUSION(S): T-pNK can be easily generated and administered with acceptable toxicity which was easily managed. In this non-controlled trial there was evidence of clinical efficacy but delays in donor screening and processing led to 40% attrition of enrolled patients prior to drug administration. [Table Presented].

Kottke, B. A. and N. D. Bren (1994). "A particle concentration fluorescence immunoassay for Lp(a)." Chemistry & Physics of Lipids **67-68**: 249-256.

The quantitation of Lp(a) by immunoassay presents a major technical problem, because the molecular mass of the (a) protein of Lp(a) can vary between 419,000 and 838,000 Da (Gaubatz et al. (1990) J. Lipid Res. 31, 603-612), and this variability is determined by at least 24 alleles of the (a) gene. In an attempt to overcome this problem, we have developed an assay that is independent of variation of the size of (a). The assay utilizes a mixture of monoclonal antibodies to (a) which do not react to plasminogen or to apolipoprotein (apo) B. These antibodies are bound to inert microscopic beads to capture the Lp(a) particles. Subsequently, a fluorescein-labeled monoclonal antibody to apo B is used for detection and quantitation. The assay is done with special microtiter plates containing filters so that the particles can be thoroughly washed after capture on the microbeads. Because Lp(a) particles contain only one apo B particle and the molecular weight of apo B is constant, the assay is not affected by variation in the size of apo(a). By binding the mixture of monoclonal antibodies to inert beads, it is possible to greatly increase the amount of antibody bound to an exposed surface and thus increase the sensitivity of the assay. A mixture of monoclonal antibodies can be used to increase the affinity of the capture step of the assay. The assay can be completed in 4 h and has a wide working range.(ABSTRACT TRUNCATED AT 250 WORDS)

Kousaiti, A., et al. (2019). "Assessment of tetrabromobisphenol-A (TBBPA) content in plastic waste recovered from WEEE." Journal of Hazardous Materials: 121641.

Due to the variability of additives and polymer types used in electrical and electronic equipment (EEE), and in accordance with the European Directive 2012/19/EU, an implementation of sound management practices is necessary. This work focuses on assessing the content of tetrabromobisphenol-A (TBBPA) in acrylonitrile-butadiene-styrene (ABS), polypropylene (PP), polycarbonate (PC) and their polymer blends (i.e. PC/ABS). A total of 36 plastic housing samples originating from microwave ovens, electric irons, vacuum cleaners and DVD/CD players were subjected to microwave-assisted-extraction (MAE) and/or ultrasound-assisted-extraction (UAE). Maximum mean concentration values of TBBPA measured in DVD/CD players and vacuum cleaners ranged between 754-1146mug/kg, and varied per polymer type, as follows: 510-2515mug/kg in ABS and 55-3109mug/kg in PP. The results indicated that MAE was more sufficient than UAE in the extraction of TBBPA from ABS. To optimize the UAE procedure, various solvents were tested. Higher amounts of TBBPA were obtained from ABS and PP using a binary mixture of a polar-non-polar solvent, isopropanol:n-hexane (1:1), whereas the sole use of isopropanol exhibited incomplete extraction.

Kowalski, K., et al. (1972). "Stimulatory effects of induced phagocytosis on the function of isolated thyroid cells." Journal of Clinical Investigation **51**(11): 2808-2819.

Stimulation of endocytosis is a very early effect of thyrotropin on thyroid. However, the relationship of the endocytotic process to the many other thyrotropin effects on thyroid is not clearly defined. Since phagocytosis in isolated thyroid cells is a presumed model for in vivo endocytosis of colloid, phagocytosis was induced in isolated thyroid cells by incubating them at 37C with 0.109 mu diameter polystyrene microbeads; phagocytosis was confirmed in each experiment by electron microscopy and/or spectrophotometric analysis of dioxane cell extracts. Cells incubated with 50-100 mu diameter polystyrene macrobeads (too large to ingest) served as controls. Microbead induced phagocytosis in isolated thyroid cells was consistently accompanied by increases in: (a) cyclic 3,5 adenosine monophosphate 14C formation from adenine 8 14C (661/); (b) iodide I trapping (40i); (c) protein and RNA synthesis (30'i); (d) phospholipogenesis (50V); (e) a aminoisobutyric acid 1 14C uptake (15t). 50 to 100 p diameter polystyrene macrobeads did not influence cell function in any of these experiments. Aminotriazole, 5 x 10 3 M, a peroxidase inhibitor, blocked the stimulatory effect of microbead induced phagocytosis on phospholipogenesis only. These studies indicate that in isolated thyroid cells the phagocytotic process, per se, may alter activity of the membrane bound adenyl cyclase enzyme. The resultant increase in cyclic 3,5 adenosine monophosphate may be a triggering

mechanism for (some) subsequent metabolic changes occurring during phagocytosis. Since these changes mimic those induced by thyrotropin, it is suggested that a variety of thyrotropin effects on thyroid may be secondary to stimulation of colloid resorption and hormone secretion.

Kozlowska, J., et al. (2019). "Microparticles based on natural and synthetic polymers for cosmetic applications." International Journal of Biological Macromolecules **129**: 952-956.

Most peeling products (exfoliators) available on the market, used in cosmetic and aesthetic dermatology applications, contain synthetic microbeads as abrasive agents. After being released into the natural environment, these non-biodegradable microparticles have an adverse impact on it, especially on aquatic ecosystems. Cosmetics consisting of solid plastic particles will be prohibited in the European Union from 2020. Therefore, there is a great need to develop effective abrasive substances for cosmetic industry. An alternative to synthetic beads may be beads based on biopolymers. Spherical microparticles of sodium alginate and mixture of sodium alginate and starch were obtained using encapsulator BUCHI B-395 Pro. The obtained microparticles were added to the developed peeling formulation. Subsequently, the evaluation of skin condition after application of peelings with alginate, alginate-starch and synthetic microparticles was made, including topography, skin's barrier quality, hydration, colour, and the level of sebum. The peeling containing sodium alginate and sodium alginate with starch beads does not irritate the skin - redness of skin, itching and dryness did not appear. Microparticles of sodium alginate and sodium alginate with starch act on the skin as effectively as commercial synthetic particles, therefore they may be successfully used as abrasive ingredients in the developed recipe.

Kraines, S., et al. (2003). "A system tradeoff model for processing options for household plastic waste." Clean Technologies and Environmental Policy **4**(4): 204-216.

With the "Containers and Packaging Recycling Law", Japan has shown a firm conviction towards the promotion of recycling. Waste can be "recycled", i.e. resource value of waste material can be recovered, in many ways, from material recycling to energy recycling. Alternatively, waste can be reduced or disposed of in landfills. A system tradeoff model is developed from component process technology models of six different recycling and disposal options for household plastic waste processing: plastic pellet production, refuse derived fuel production, oil production, waste incineration to produce electricity, use of waste plastic as a coke substitute, and incineration for volume reduction. These technologies are compared with the case where all waste plastic is land filled. Models based on plant data, laboratory experiments, and theoretical considerations of scale effects and mass balances are developed to calculate the cost, energy consumption, CO 2 emission, and land fill occupancy. The models also calculate the valued products of each technology and convert them into cost, energy, CO 2 , and landfill occupancy using life cycle inventory data. These values are subtracted from the outputs of the waste processing models to obtain overall performances for each technology. The overall tradeoff system model is then used to evaluate several scenarios of plastic recycling and disposal technologies in Tokyo. [PUBLICATION ABSTRACT]

Kraines, S. B., et al. (2004). "Development of an internet-based collaboration platform and application to household waste plastic processing." International Journal of Technology Transfer and Commercialisation **3**(2): 129-146.

Object-based model integration using the internet combines aspects of modularisation and network technology approaches to address large-scale, complex, multi-disciplinary system problems. As a prototype application of this approach to holistic system analysis of

environmental sustainability issues, we are developing a decision support system that uses an object-based modeling framework for examining the various trade offs between costs, pollution emissions, resource consumption, and land fill use for different recycling and disposal options. The framework is applied to household plastic waste processing. The overall system of plastic waste processing is divided into three stages: generation of waste plastic from households, collection using different kinds of garbage collection vehicles and plant processing for recycling or disposal. The framework is used to examine several scenarios for different combinations of waste plastic recycling and disposal technologies in Tokyo, Japan. Plans are outlined for implementing the framework using network modelling technologies so that the trade off modelling system can be accessed over the internet by stakeholders and decision makers.

Kraitchman, D., et al. (2012). "In vivo biocompatibility and efficacy of an x-ray-visible, uniform, alginate microsphere for embolic therapy." Molecular Imaging and Biology **1)**: S1858.

Introduction Embolization is a minimally invasive approach frequently used in combination with X-ray angiography to deploy small particles to block or occlude vessels feeding tumors. The majority of embolic particles are composed of polymers that are radiolucent. Thus, embolic microsphere visibility is enhanced by co-injection with radiopaque contrast agent. We have recently developed a method to create highly uniform, X-ray-visible, alginate-based embolic beads (XEB) and sought to test the effectiveness and biocompatibility of this new embolic device. Method(s): Using a pressure-controlled, microfluidic device, barium sulfate impregnated alginate microbeads were crosslinked in a calcium-rich, oleic acid solution and further separated and crosslinked in a calcium-rich, isopropyl alcohol solution to generate XEBs with optimal 50 mum diameters. Radiopacity of the XEBs was determined in phantoms on an X-ray flat-panel angiographic system (Axiom Artis dFA, Siemens). In vivo imaging visibility, handling characteristics, and biocompatibility was evaluated in normal, anesthetized swine (n=5 acute; n=2 chronic). Using a femoral artery approach, a baseline aortic digital subtraction angiogram (DSA, hand contrast injection, 3 frames/s) was obtained followed by a non-contrast c-arm CT (8s DR Body DynaCT preset, Artis Zee, Siemens). Superselective catheterization of the kidney pole was then performed followed by a DSA during hand injection of contrast. XEBs were then injected intra-arterially, without the addition of iodinated contrast, into the selected kidney pole during suspended respiration while acquiring a DSA (3 frames/second). C-arm CTs were obtained to document XEB visibility and retention. Serial c-arm CTs were obtained in chronic animals. Endotoxin assays of XEBs were performed in all chronic studies. Histopathology was performed on the kidneys in all animals. Result(s): Radiopacity in the phantom on c-arm CT was equivalent to bone for 5 mul XEB (2774 +/- 1595 HU), 50 mul XEB (2809 +/- 1208 HU), and 10% iohexal (1482+/-354 HU) (Fig 1a). Transarterial delivery of XEBs was visualized by DSA in all pigs with total occlusion achieved after 0.05-0.1 ml of XEBs. Reflux or retrograde flow of XEBs was seen in 28% of the studies. The volume of radiopacity created by the XEBs on c-arm CT was reduced at 1 week follow-up with minimal presence of radiopacity at 3 weeks post-administration (Fig 1b-d). XEBs were intact acutely and at three weeks post injection with minimal inflammatory infiltrate and fibrosis consistent with renal infarction by XEBs (Fig 1e). All XEB samples were negative for endotoxin. Conclusion(s): X-ray-visible, uniform embolic beads allow confirmation of delivery success using conventional X-ray imaging systems without the addition of iodinated contrast agents. Biocompatibility of XEBs was high with no noted toxicities or adverse events. XEBs also offer the ability to see reflux of embolic nanoparticles to non-target locations. (Figure presented) .

Krakowska, B., et al. (2015). "Detection of discoloration in diesel fuel based on gas chromatographic

fingerprints." Analytical and bioanalytical chemistry **407**(4): 1159-1170.

Issue Title: A different way of looking at vibrational hyperspectral data/Micellar extraction for the analysis of Alzheimer's disease brain proteome/Quantification of polyolefin microplastics in personal-care products/Removal of Triton X-100 by microdialysis In the countries of the European Community, diesel fuel samples are spiked with Solvent Yellow 124 and either Solvent Red 19 or Solvent Red 164. Their presence at a given concentration indicates the specific tax rate and determines the usage of fuel. The removal of these so-called excise duty components, which is known as fuel "laundering", is an illegal action that causes a substantial loss in a government's budget. The aim of our study was to prove that genuine diesel fuel samples and their counterfeit variants (obtained from a simulated sorption process) can be differentiated by using their gas chromatographic fingerprints that are registered with a flame ionization detector. To achieve this aim, a discriminant partial least squares analysis, PLS-DA, for the genuine and counterfeit oil fingerprints after a baseline correction and the alignment of peaks was constructed and validated. Uninformative variables elimination (UVE), variable importance in projection (VIP), and selectivity ratio (SR), which were coupled with a bootstrap procedure, were adapted in PLS-DA in order to limit the possibility of model overfitting. Several major chemical components within the regions that are relevant to the discriminant problem were suggested as being the most influential. We also found that the bootstrap variants of UVE-PLS-DA and SR-PLS-DA have excellent predictive abilities for a limited number of gas chromatographic features, 14 and 16, respectively. This conclusion was also supported by the unitary values that were obtained for the area under the receiver operating curve (AUC) independently for the model and test sets.

Kratina, P., et al. (2019). "Interactive effects of warming and microplastics on metabolism but not feeding rates of a key freshwater detritivore." Environmental Pollution **255**(Part 2).

Microplastics are an emerging pollutant of high concern, with their prevalence in the environment linked to adverse impacts on aquatic organisms. However, our knowledge of these impacts on freshwater species is rudimentary, and there is almost no research directly testing how these effects can change under ongoing and future climate warming. Given the potential for multiple stressors to interact in nature, research on the combined impacts of microplastics and environmental temperature requires urgent attention. Thus, we experimentally manipulated environmentally realistic concentrations of microplastics and temperature to partition their independent and combined impacts on metabolic and feeding rates of a model freshwater detritivore. There was a significant increase in metabolic and feeding rates with increasing body mass and temperature, in line with metabolic and foraging theory. Experimental warming altered the effect of microplastics on metabolic rate, which increased with microplastic concentration at the lowest temperature, but decreased at the higher temperatures. The microplastics had no effect on the amount of litter consumed by the detritivores, therefore, did not result in altered feeding rates. These results show that the metabolism of important freshwater detritivores could be altered by short-term exposure to microplastics, with greater inhibition of metabolic rates at higher temperatures. The consequences of these metabolic changes may take longer to manifest than the duration of our experiments, requiring further investigation. Our results suggest little short-term impact of microplastics on litter breakdown by gammarid amphipods and highlight the importance of environmental context for a better understanding of microplastic pollution in freshwater ecosystems.

Krebs, C. R., et al. (2015). "A portable blood plasma clot micro-elastometry device based on resonant acoustic spectroscopy." Review of Scientific Instruments **86**(7): 075005.

Abnormal blood clot stiffness is an important indicator of coagulation disorders arising from a variety of cardiovascular diseases and drug treatments. Here, we present a portable instrument for elastometry of microliter volume blood samples based upon the principle of resonant acoustic spectroscopy, where a sample of well-defined dimensions exhibits a fundamental longitudinal resonance mode proportional to the square root of the Young's modulus. In contrast to commercial thromboelastography, the resonant acoustic method offers improved repeatability and accuracy due to the high signal-to-noise ratio of the resonant vibration. We review the measurement principles and the design of a magnetically actuated microbead force transducer applying between 23 pN and 6.7 nN, providing a wide dynamic range of elastic moduli (3 Pa-27 kPa) appropriate for measurement of clot elastic modulus (CEM). An automated and portable device, the CEMport, is introduced and implemented using a 2 nm resolution displacement sensor with demonstrated accuracy and precision of 3% and 2%, respectively, of CEM in biogels. Importantly, the small strains (<0.13%) and low strain rates (<1/s) employed by the CEMport maintain a linear stress-to-strain relationship which provides a perturbative measurement of the Young's modulus. Measurements of blood plasma CEM versus heparin concentration show that CEMport is sensitive to heparin levels below 0.050 U/ml, which suggests future applications in sensing heparin levels of post-surgical cardiopulmonary bypass patients. The portability, high accuracy, and high precision of this device enable new clinical and animal studies for associating CEM with blood coagulation disorders, potentially leading to improved diagnostics and therapeutic monitoring.

Krejcova, L., et al. (2012). "Paramagnetic particles coupled with an automated flow injection analysis as a tool for influenza viral protein detection." Electrophoresis **33**(21): 3195-3204.

Currently, the influenza virus infects millions of individuals every year. Since the influenza virus represents one of the greatest threats, it is necessary to develop a diagnostic technique that can quickly, inexpensively, and accurately detect the virus to effectively treat and control seasonal and pandemic strains. This study presents an alternative to current detection methods. The flow-injection analysis-based biosensor, which can rapidly and economically analyze a wide panel of influenza virus strains by using paramagnetic particles modified with glycan, can selectively bind to specific viral A/H5N1/Vietnam/1203/2004 protein-labeled quantum dots. Optimized detection of cadmium sulfide quantum dots (CdS QDs)-protein complexes connected to paramagnetic microbeads was performed using differential pulse voltammetry on the surface of a hanging mercury drop electrode (HMDE) and/or glassy carbon electrode (GCE). Detection limit (3 S/N) estimations based on cadmium(II) ions quantification were 0.1 micro g/mL or 10 micro g/mL viral protein at HMDE or GCE, respectively. Viral protein detection was directly determined using differential pulse voltammetry Brdicka reaction. The limit detection (3 S/N) of viral protein was estimated as 0.1 micro g/mL. Streptavidin-modified paramagnetic particles were mixed with biotinylated selective glycan to modify their surfaces. Under optimized conditions (250 micro g/mL of glycan, 30-min long interaction with viral protein, 25 degrees C and 400 rpm), the viral protein labeled with quantum dots was selectively isolated and its cadmium(II) content was determined. Cadmium was present in detectable amounts of 10 ng per mg of protein. Using this method, submicrogram concentrations of viral proteins can be identified.

Kresnawaty, I., et al. (2014). "Characterization of PHA from Pseudomonas aeruginosa and Bacillus subtilis inoculated in palm oil mill effluent media." Menara Perkebunan **82**(2): 57-63.

The difficulties in processing of petroleum-based plastic waste have encouraged the development of biodegradable plastics polyhydroxyalkanoate (PHA). Researchers isolated the PHA-producing microorganisms from various sources to obtain new species with high PHA production capability. In addition, the high cost of PHA production might be overcome by using carbon-rich waste, such as palm oil mill effluent (POME). This research conducted characterization of produced PHA and optimization of PHA production in POME. In previous research, three potential isolates were obtained, which are one Pseudomonas aeruginosa isolate and two Bacillus subtilis isolates. Analysis of Scanning Electron Microscopy (SEM) and Transmission Electron Microscopy (TEM) showed the presence of PHA accumulation within the bacterial cell. The results of Spectra of Fourier Transform Infra Red Spectroscopy (FT-IR) revealed differences in C-C and C-H alipathic regions of PHA produced by Pseudomonas aeruginosa and Bacillus subtilis. Optimum production of PHA was obtained using POME at concentration of 50-25% during 6 days of incubation time in an enriched media pretreatment.

Krishhan, V. V., et al. (2009). "Multiplexed microbead immunoassays by flow cytometry for molecular profiling: Basic concepts and proteomics applications." Critical Reviews in Biotechnology **29**(1): 29-43.

Flow cytometry was originally established as an automated method for measuring optical or fluorescence characteristics of cells or particles in suspension. With the enormous increase in development of reliable electronics, lasers, micro-fluidics, as well as many advances in immunology and other fields, flow cytometers have become user-friendlier, less-expensive instruments with an increasing importance for both basic research and clinical applications. Conventional uses of flow cytometry include immunophenotyping of blood cells and the analysis of the cell cycle. Importantly, methods for labeling microbeads with unique combinations of fluorescent spectral signatures have made multiplex analysis of soluble analytes (i.e. the ability to detect multiple targets in a single test sample) feasible by flow cytometry. The result is a rapid, high-throughput, sensitive, and reproducible detection technology for a wide range of biomedical applications requiring detection of proteins (in cells and biofluids) and nucleic acids. Thus, novel methods of flow cytometry are becoming important for diagnostic purposes (e.g. identifying multiple clinical biomarkers for a wide range of diseases) as well as for developing novel therapies (e.g. elucidating drug mechanisms and potential toxicities). In addition, flow cytometry for multiplex analysis, coupled with automated sample handling devices, has the potential to significantly enhance proteomics research, particularly analysis of post-translational modifications of proteins, on a large scale. Inherently, flow cytometry methods are strongly rooted in the laws of the physics of optics, fluidics, and electromagnetism. This review article describes principles and early sources of flow cytometry, provides an introduction to the multiplex microbead technology, and discusses its applications and advantages in comparison to other methods. Anticipated future directions, particularly for translational research in medicine, are also discussed. [References: 173]

Krishnakumar, S., et al. (2018). "A preliminary study on coastal debris in Nallathanni Island, Gulf of Mannar Biosphere Reserve, Southeast coast of India." Marine Pollution Bulletin **131**(Pt A): 547-551.

Nine sampling stations were fixed to carry out the preliminary investigation on coastal debris from Nallathanni island, Gulf of Mannar Biosphere Reserve, Southeast coast of India. The coastal debris were separated and identified using hand picking, visual identification and microscopic studies. The coastal areas of the study region were less dominated by micro plastic contamination. The coastal debris was dominated by polyethylene bottles and fibrous fishnet materials. The distribution of the coastal debris along the coastal region is chiefly controlled by winnowing action of sea waves and Aeolian action along the berm region.

Krishnan, A., et al. (2016). "Overexpression of Soluble Fas Ligand following Adeno-Associated Virus Gene Therapy Prevents Retinal Ganglion Cell Death in Chronic and Acute Murine Models of Glaucoma." Journal of Immunology **197**(12): 4626-4638.

Glaucoma is a multifactorial disease resulting in the death of retinal ganglion cells (RGCs) and irreversible blindness. Glaucoma-associated RGC death depends on the proapoptotic and proinflammatory activity of membrane-bound Fas ligand (mFasL). In contrast to mFasL, the natural cleavage product, soluble Fas ligand (sFasL) inhibits mFasL-mediated apoptosis and inflammation and, therefore, is an mFasL antagonist. DBA/2J mice spontaneously develop glaucoma and, predictably, RGC destruction is exacerbated by expression of a mutated membrane-only FasL gene that lacks the extracellular cleavage site. Remarkably, one-time intraocular adeno-associated virus-mediated gene delivery of sFasL provides complete and sustained neuroprotection in the chronic DBA/2J and acute microbead-induced models of glaucoma, even in the presence of elevated intraocular pressure. This protection correlated with inhibition of glial activation, reduced production of TNF-alpha, and decreased apoptosis of RGCs and loss of axons. These data indicate that cleavage of FasL under homeostatic conditions, and the ensuing release of sFasL, normally limits the neurodestructive activity of FasL. The data further support the notion that sFasL, and not mFasL, contributes to the immune-privileged status of the eye.

Krishnan, A., et al. (2019). "A small peptide antagonist of the Fas receptor inhibits neuroinflammation and prevents axon degeneration and retinal ganglion cell death in an inducible mouse model of glaucoma." Journal of Neuroinflammation **16**(1): 184.

BACKGROUND: Glaucoma is a complex, multifactorial disease where apoptosis, microglia activation, and inflammation have been linked to the death of retinal ganglion cells (RGCs) and axon degeneration. We demonstrated previously that FasL-Fas signaling was required for axon degeneration and death of RGCs in chronic and inducible mouse models of glaucoma and that Fas activation triggered RGC apoptosis, glial activation, and inflammation. Here, we investigated whether targeting the Fas receptor with a small peptide antagonist, ONL1204, has anti-inflammatory and neuroprotective effects in a microbead-induced mouse model of glaucoma.

METHODS: Intracameral injection of microbeads was used to elevate intraocular pressure (IOP) in Fas-deficient (Fas^{lpr}) mice and WT C57BL/6J mice that received an intravitreal injection of the Fas inhibitor, ONL1204 (2 mug/1 mul) (or vehicle only), on day 0 or day 7 after microbead injection. The IOP was monitored by rebound tonometry, and at 28 days post-microbead injection, Brn3a-stained RGCs and paraphenylenediamine (PPD)-stained axons were analyzed. The effects of ONL1204 on retinal microglia activation and the expression of inflammatory genes were analyzed by immunostaining of retinal flatmounts and quantitative PCR (qPCR).

RESULTS: Rebound tonometry showed equivalent elevation of IOP in all groups of microbead-injected mice. At 28 days post-microbead injection, the RGC and axon counts from microbead-injected Fas^{lpr} mice were equivalent to saline-injected (no IOP elevation) controls. Treatment with ONL1204 also significantly reduced RGC death and loss of axons in microbead-injected WT mice when compared to vehicle-treated controls, even when

administered after IOP elevation. Confocal analysis of Iba1-stained retinal flatmounts and qPCR demonstrated that ONL1204 also abrogated microglia activation and inhibited the induction of multiple genes implicated in glaucoma, including cytokines and chemokines (GFAP, Caspase-8, TNFalpha, IL-1beta, IL-6, IL-18, MIP-1alpha, MIP-1beta, MIP-2, MCPI, and IP10), components of the complement cascade (C3, C1Q), Toll-like receptor pathway (TLR4), and inflammasome pathway (NLRP3).

CONCLUSIONS: These results serve as proof-of-principal that the small peptide inhibitor of the Fas receptor, ONL1204, can provide robust neuroprotection in an inducible mouse model of glaucoma, even when administered after IOP elevation. Moreover, Fas signaling contributes to the pathogenesis of glaucoma through activation of both apoptotic and inflammatory pathways.

Krishnan, V. V., et al. (2014). "Multiplexed measurements of immunomodulator levels in peripheral blood of healthy subjects: Effects of analytical variables based on anticoagulants, age, and gender." Cytometry Part B, Clinical Cytometry **86**(6): 426-435.

Multiplex microbead immunoassay (MMIA) is a powerful technology for a wide range of biomedical and clinical applications. It is important to study the normal concentration ranges of immunomodulators under different sample preparation conditions and age groups of subjects in order to more precisely determine their reference values for use in assessing alterations of their levels in disease. The aim of this study was to determine the plasma concentrations of immunomodulators (cytokines, chemokines, and growth factors) in the peripheral blood from healthy subjects by the use of a large multiplex panel, and to determine the effects of different anticoagulants, age, and gender on the immunomodulator levels. In addition, the assay precision for these biomarker analytes was determined. Plasma samples from 107 healthy subjects, aged 18 to 85 years, were collected in three different anticoagulants (sodium citrate, EDTA, Heparin); corresponding serum samples were also obtained. Multiplex microbead immunoassays were performed for measuring a total of 23 analytes including chemokines, cytokines, and growth factors (IL-1beta, IL-1ra, IL-2, IL-6, IL-7, IL-8, IL-12 p70, IL-17, IFN-gamma, IP-10, MCP-1, PDGF-BB, RANTES, TNF-alpha, IL-1a, IL-16, HGF, MIG, TNF-beta, PDGF-ABBB, EGF, Flt-3 Ligand, VEGF). For these analytes, our results showed that the anticoagulant affected the concentration measurements and the coefficients of variation. However, the relative levels of the analytes (profiles) of samples collected in a particular anticoagulant are consistent. The analytes IL-1beta, IL-7, Flt-3 Ligand, and IL-12p70 show the largest variation (up to fourfold) between the age groups. In addition, no statistically significant differences in the level of the analytes were found between the sexes.

Krishnan, V. V., et al. (2018). "Proteomic profiles by multiplex microsphere suspension array." Journal of Immunological Methods **461**: 1-14.

Advances in high-throughput proteomic approaches have provided substantial momentum to novel disease-biomarker discovery research and have augmented the quality of clinical studies. Applications based on multiplexed microsphere suspension array technology are making strong in-roads into the clinical diagnostic/prognostic practice. Conventional proteomic approaches are designed to discover a broad set of proteins that are associated with a specific medical condition. In comparison, multiplex microsphere immunoassays use quantitative measurements of selected set(s) of specific/particular molecular markers such as cytokines, chemokines, pathway signaling or disease-specific markers for detection, metabolic disorders, cancer, and infectious agents causing human, plant and animal diseases. This article provides a foundation to the multiplexed microsphere suspension array technology, with an emphasis on the improvements in the technology, data analysis approaches, and applications to translational and

clinical research with implications for personalized and precision medicine.

Kritz, G. and T. Khaled (1995). "Method for measuring air space and moisture content at different pot depths." Acta Horticulturae **401**: 107-114.

A method was developed to characterize air and moisture distributions at different depths in pots using a PVC cylinder, 10 cm (height) and 15 cm (inner diameter). The lower part (height 8 cm; 12-20 cm from the top) comprised a solid phase above which, at 2 cm, was a secondary base perforated with holes to allow for passage of water which can be removed via a hose connection. This secondary base was covered with a filter of sintered polyethylene plastic particles. The upper part consisted of six consecutive detachable rings (each of height 2 cm). The substrate in the cylinder could be saturated and drained (to a depth 12 cm) by means of an adjustable water table connected to the base of the cylinder via a hose. During the first saturating and draining cycle, an extension collar (height 8 cm) was placed on the cylinder, but during the second similar cycle no collar was used. Bulk density, porosity, air space and moisture content were determined in each ring layer. The results showed that the air space decreased with an increase in pot depth and the degree of decomposition of the peat. The cylinder is now being used with Time Domain Reflectometry probes and mini-tensiometers to measure moisture content and pressure heads, respectively.

Kronekova, Z., et al. (2018). "Structural changes in alginate-based microspheres exposed to in vivo environment as revealed by confocal Raman microscopy." Scientific Reports **8**(1): 1637.

A next-generation cure for type 1 diabetes relies on immunoprotection of insulin-producing cells, which can be achieved by their encapsulation in microspheres made of non-covalently crosslinked hydrogels. Treatment success is directly related to the microsphere structure that is characterized by the localization of the polymers constituting the hydrogel material. However, due to the lack of a suitable analytical method, it is presently unknown how the microsphere structure changes in vivo, which complicates evaluation of different encapsulation approaches. Here, confocal Raman microscopy (CRM) imaging was tailored to serve as a powerful new tool for tracking structural changes in two major encapsulation designs, alginate-based microbeads and multi-component microcapsules. CRM analyses before implantation and after explantation from a mouse model revealed complete loss of the original heterogeneous structure in the alginate microbeads, making the intentionally high initial heterogeneity a questionable design choice. On the other hand, the structural heterogeneity was conserved in the microcapsules, which indicates that this design will better retain its immunoprotective properties in vivo. In another application, CRM was used for quantitative mapping of the alginate concentration throughout the microbead volume. Such data provide invaluable information about the microenvironment cells would encounter upon their encapsulation in alginate microbeads.

Kroon, F., et al. (2018). "A workflow for improving estimates of microplastic contamination in marine waters: A case study from North-Western Australia." Environmental Pollution **238**: 26-38.

Plastic pollution is ubiquitous throughout the marine environment, with microplastic (i.e. <5mm) contamination a global issue of emerging concern. The lack of universally accepted methods for quantifying microplastic contamination, including consistent application of microscopy, photography, an spectroscopy and photography, may result in unrealistic contamination estimates. Here, we present and apply an analysis workflow tailored to quantifying microplastic contamination in marine waters, incorporating stereomicroscopic visual sorting, microscopic photography and attenuated total reflectance (ATR) Fourier transform infrared (FTIR) spectroscopy. The workflow outlines step-by-step processing and associated decision making, thereby reducing bias in plastic identification and improving confidence in contamination estimates. Specific processing steps include (i) the use of a commercial algorithm-based comparison of particle spectra against an extensive commercially curated spectral library, followed by spectral interpretation to establish the chemical composition, (ii) a comparison against a customised contaminant spectral library to eliminate procedural contaminants, and (iii) final assignment of particles as either natural- or anthropogenic-derived materials, based on chemical type, a compare analysis of each particle against other particle spectra, and physical characteristics of particles. Applying this workflow to 54 tow samples collected in marine waters of North-Western Australia visually identified 248 potential anthropogenic particles. Subsequent ATR-FTIR spectroscopy, chemical assignment and visual re-inspection of photographs established 144 (58%) particles to be of anthropogenic origin. Of the original 248 particles, 97 (39%) were ultimately confirmed to be plastics, with 85 of these (34%) classified as microplastics, demonstrating that over 60% of particles may be misidentified as plastics if visual identification is not complemented by spectroscopy. Combined, this tailored analysis workflow outlines a consistent and sequential process to quantify contamination by microplastics and other anthropogenic microparticles in marine waters. Importantly, its application will contribute to more realistic estimates of microplastic contamination in marine waters, informing both ecological risk assessments and experimental concentrations in effect studies.

Kroon, F. J., et al. (2018). "Classification of marine microdebris: a review and case study on fish from the Great Barrier Reef, Australia." Scientific Reports **8**(1).

Marine debris, and in particular plastic pollution, is ubiquitous throughout global marine environments. Here, we present a classification of marine microdebris (i.e. debris between 0.1 micro m and <5 mm) tailored to represent synthetic, semi-synthetic and naturally-derived items. The specific aim of this classification is to introduce a level of consistency in the higher-level characterisation of marine microdebris, thereby improving the overall reporting on marine microdebris contamination. We first conducted an extensive literature review on the accumulation of ingested debris in fish to identify discrepancies in marine microdebris reporting as a basis for the new classification. The review reveals the diverse nature of ingested marine microdebris, including items that are non-plastic but often incorrectly reported on as microplastics. We then applied our classification to a case study on wild-caught juvenile coral trout, Plectropomus spp., from the Great Barrier Reef World Heritage Area, Australia. This first report on accumulation of ingested marine debris in commercial fish on the reef demonstrates a high frequency of occurrence and a prevalence of semi-synthetic and naturally-derived fibres. Based on our findings, we offer recommendations on potential improvements for the classification presented, ultimately contributing to a more realistic assessment of the ecological risks of marine microdebris.

Kubo, I., et al. (2014). Microfluidic device for enzyme-linked immunosorbent assay (ELISA) and its application to bisphenol a sensing, M Y U Scientific Publishing Division.

Bisphenol A (BPA) is a commonly used material made of polycarbonate, which is used in food containers. BPA is known to be an endocrine disruptor. To investigate the effect of BPA on health, animal experiments are necessary. To determine the intake of BPA in food or drink by animals, a BPA-sensing system that can detect a small amount of BPA in biological samples within a short reaction time is needed. We have developed a disc-shaped microfluidic device for enzyme linked immunosorbent assay (ELISA) with 32 microchannels and chambers. In order to establish a rapid and sensitive assay system for BPA in biological samples, in this study, anti-BPA

antibody was immobilized on microbeads and introduced into microchambers on the microchannels in the device. A competitive immunoassay was performed using horse radish peroxidase (HRP)-conjugated BPA with a small amount of sample solution within 20 min. After the immune reaction, the HRP activity in each microchamber was detected by chemiluminescence. BPA could be determined on the microfluidic disk at a concentration range between 3.9 and 250 ng/ml. BPA-spiked rat serum was also determined on the disk.

Kubowicz, S. and A. M. Booth (2017). "Biodegradability of Plastics: Challenges and Misconceptions." Environmental Science and Technology **51**(21): 12058-12060.

Plastics are one of the most widely used materials and, in most cases, they are designed to have long life times. Thus, plastics contain a complex blend of stabilizers that prevent them from degrading too quickly. Unfortunately, many of the most advantageous properties of plastics such as their chemical, physical and biological inertness and durability present challenges when plastic is released into the environment. Common plastics such as polyethylene (PE), polypropylene (PP), polystyrene (PS), and polyethylene terephthalate (PET) are extremely persistent in the environment, where they undergo very slow fragmentation (projected to take centuries) into small particles through photo-, physical, and biological degradation processes¹. The fragmentation of the material into increasingly smaller pieces is an unavoidable stage of the degradation process. Ultimately, plastic materials degrade to micron-sized particles (microplastics), which are persistent in the environment and present a potential source of harm for organisms. Copyright © 2017 American Chemical Society.

Kudo, K., et al. (2018). "ESTIMATION OF TEMPORAL VARIATIONS AND ANNUAL FLUX OF MICROPLASTICS IN RIVERS UNDER LOW- AND HIGH-FLOW CONDITIONS." Doboku Gakkai Ronbunshu. B1, Suikogaku = Journal of Japan Society of Civil Engineers. Ser. B1, Hydraulic Engineering **74**(4).

Numerical and mass concentrations of microplastics in sizes < 5mm were investigated based on in-situ surveys on the surface of two rivers (Edo River and Ohori River), and annual flux of floating microplastics of Edo River were estimated by using a statistically significant relationship of the concentrations with river discharge. Good correlation between MP flux and discharge (i.e., L-Q relation) was also found in Edo River. Annual flux of numerical (mass) MP concentrations on the Edo River was 1.5×1010 pieces (2.42 ton). The ratio of numerical (mass) MP flux under high flow conditions was 73.5% (84.1%) in the total flux. These results indicate that the high ratio of MP flux in flooding conditions was similar to that of macro debris flux in rivers.

Kuhn, K. R., et al. (2019). "Production of whey protein isolate - gellan microbeads for encapsulation and release of flaxseed bioactive compounds." Journal of Food Engineering **247**: 104-114.

Production of 1.5% (w/v) whey protein isolate (WPI) - 0.1, 0.3 or 0.5% (w/v) gellan gum microbeads from extrusion of the oil-in-water (O/W) emulsions into a 0.56% (w/v) calcium chloride (CaCl₂) solution was evaluated to encapsulate flaxseed oil (15% v/v) and protein hydrolysate (FPH) (0, 0.25 or 0.5% w/v). Microgels resistance and controlled release of oil and FPH were also investigated. Microscopic images showed few free oil droplets and a prevailing presence of gellan on the external surface of the microbeads, indicating that oil and FPH were encapsulated. Microbeads produced at higher gellan concentrations (0.3 or 0.5% w/v) showed a more regular and spherical morphology. However a significant decrease in microbeads size (from ~55 micro m to ~50 micro m) and an increase in the polydispersity were observed with the FPH addition, which can be a consequence of the formation of a more dense biopolymers network. FPH presence (0.25% w/v) decreased the viscosity and shear thinning behavior of microbeads suspensions (10-90% w/v), which could be partly attributed to the smaller size of particles. The microbeads suspensions were stable at different salt concentrations (0.56, 1.11 or 2.22% w/v) regarding their shape, not releasing the encapsulated oil. 1.5% (w/v) WPI - 0.3% (w/v) gellan microbeads were resistant to simulated gastric conditions, but did not resist to intestinal conditions. Our results show that these microgels are adequate to encapsulate bioactive compounds to be released in the small intestine, passing intact in the stomach, which makes the process attractive in order to maintain the bioavailability and functionality of such compounds.

Kuhn, S. and J. A. v. Franeker (2012). "Plastic ingestion by the northern fulmar (Fulmarus glacialis) in Iceland." Marine Pollution Bulletin **64**(6): 1252-1254.

In 2011, northern fulmars (Fulmarus glacialis) from Iceland were used to test the hypothesis that plastic debris decreases at northern latitudes in the Atlantic when moving away from major human centres of coastal and marine activities. Stomach analyses of Icelandic fulmars confirm that plastic pollution levels in the North Atlantic tend to decrease towards higher latitudes. Levels of pollution thus appear to link to regions of intense human coastal and marine activities, suggesting substantial current inputs in those areas.

Kühn, S., et al. (2018). "Plastic ingestion by juvenile polar cod (<i>Boreogadus saida</i>) in the Arctic Ocean." Polar Biology **41**(6): 1269-1278.

One of the recently recognised stressors in Arctic ecosystems concerns plastic litter. In this study, juvenile polar cod (Boreogadus saida) were investigated for the presence of plastics in their stomachs. Polar cod is considered a key species in the Arctic ecosystem. The fish were collected both directly from underneath the sea ice in the Eurasian Basin and in open waters around Svalbard. We analysed the stomachs of 72 individuals under a stereo microscope. Two stomachs contained non-fibrous microplastic particles. According to µFTIR analysis, the particles consisted of epoxy resin and a mix of Kaolin with polymethylmethacrylate (PMMA). Fibrous objects were excluded from this analysis to avoid bias due to contamination with airborne micro-fibres. A systematic investigation of the risk for secondary micro-fibre contamination during analytical procedures showed that precautionary measures in all procedural steps are critical. Based on the two non-fibrous objects found in polar cod stomachs, our results show that ingestion of microplastic particles by this ecologically important fish species is possible. With increasing human activity, plastic ingestion may act as an increasing stressor on polar cod in combination with ocean warming and sea-ice decline in peripheral regions of the Arctic Ocean. To fully assess the significance of this stressor and its spatial and temporal variability, future studies must apply a rigorous approach to avoid secondary pollution.

Kuhn, S., et al. (2018). "Plastic ingestion by juvenile polar cod (Boreogadus saida) in the Arctic Ocean." Polar Biology **41**(6): 1269-1278.

One of the recently recognised stressors in Arctic ecosystems concerns plastic litter. In this study, juvenile polar cod (Boreogadus saida) were investigated for the presence of plastics in their stomachs. Polar cod is considered a key species in the Arctic ecosystem. The fish were collected both directly from underneath the sea ice in the Eurasian Basin and in open waters around Svalbard. We analysed the stomachs of 72 individuals under a stereo microscope. Fibrous objects were excluded from this analysis to avoid bias due to contamination with airborne micro-fibres. A systematic investigation of the risk for secondary micro-fibre

contamination during analytical procedures showed that precautionary measures in all procedural steps are critical. Based on the two non-fibrous objects found in polar cod stomachs, our results show that ingestion of microplastic particles by this ecologically important fish species is possible. With increasing human activity, plastic ingestion may act as an increasing stressor on polar cod in combination with ocean warming and sea-ice decline in peripheral regions of the Arctic Ocean. To fully assess the significance of this stressor and its spatial and temporal variability, future studies must apply a rigorous approach to avoid secondary pollution.

Kuhn, S., et al. (2019). "Details of plastic ingestion and fibre contamination in North Sea fishes." Environmental Pollution: 113569.

This study combines published datasets with unpublished data on plastic ingestion in several North Sea fish species. The combined dataset of 4389 individuals from 15 species allows the analysis of spatial distribution and temporal variability of plastic uptake in fish. Airborne fibre contamination was observed to be the main contributor to fibres encountered in the samples. The number of fibres in samples was strongly related to the time needed to process a sample, not to the number of individual fishes in the sample. Accurate correction for secondary fibre contamination was not possible, but corrections required would be similar to fibre numbers observed in the samples. Consequently, all fibres were omitted from further analysis. The frequency of occurrence and the average number of plastics in fish is generally low (1.8% and 0.022 pieces per organism respectively), with only cod having a higher prevalence (12.3%). While latitude of catch locations influences plastic uptake in fish, no correlation with the distance to the coast was found. Slightly less plastics were ingested in winter, and a decrease in plastics ingested was observed between 2009 and 2018. These factors should be considered when fish species, catch location and time are discussed as indicators for plastic pollution in the European Marine Strategy Framework Directive. We recommend considering demersal cod and pelagic sprat as two species suitable for monitoring plastic ingestion in biota, both on the seafloor and in the water column.

Kuhn, S., et al. (2018). "Marine microplastic: Preparation of relevant test materials for laboratory assessment of ecosystem impacts." Chemosphere **213**: 103-113.

Studies investigating the effects of plastic litter on marine biota have almost exclusively utilised pristine plastic materials that are homogeneous in polymer type, size, shape and chemical composition. This is particularly the case for microplastics (<5mm), where collecting sufficient quantities from the marine environment for use in laboratory impacts studies is simply not feasible. Weathered plastics collected from the marine environment show considerable physical and chemical differences to pristine and post-production consumer plastics. For this study, macroplastic litter was collected on a Dutch beach and cryo-milled to create a microplastic mixture for environmental impact assessments. The sample composition followed proportions of marine plastic litter types observed in an earlier large beach clean-up. Polymer composition of the sample was assessed by infrared spectroscopy (ATR-FTIR) and differential scanning calorimetry analysis (DSC). The particle size distribution of the cryo-milled microplastics showed that particles 0.5-2.0mm represented 68% of mass, but smaller sizes (<2mm) strongly dominated numerically. Inductively coupled plasma spectroscopy (ICP-MS and ICP-OES) analysis of the microplastic mixture revealed a broad range of metals and other elements (e.g. Al, Cd, Cr, Fe, Mg, Pb, S and Zn), representing common inorganic additives used as colorants, fillers and stabilisers. GC-MS analysis identified a broad range of organic plasticisers, stabilisers, antioxidants and flame retardants. Comparison of different analytical approaches showed that creation of a homogeneous microplastic mixture is possible, representing a first step in closing the gap between laboratory studies with pristine materials and realistic scenarios with weathered microplastic.

Kuhn, S., et al. (2017). "The use of potassium hydroxide (KOH) solution as a suitable approach to isolate plastics ingested by marine organisms." Marine Pollution Bulletin **115**(1-2): 86-90.

In studies of plastic ingestion by marine wildlife, visual separation of plastic particles from gastrointestinal tracts or their dietary content can be challenging. Earlier studies have used solutions to dissolve organic materials leaving synthetic particles unaffected. However, insufficient tests have been conducted to ensure that different categories of consumer products partly degraded in the environment and/or in gastrointestinal tracts were not affected. In this study 63 synthetic materials and 11 other dietary items and non-plastic marine debris were tested. Irrespective of shape or preceding environmental history, most polymers resisted potassium hydroxide (KOH) solution, with the exceptions of cellulose acetate from cigarette filters, some biodegradable plastics and a single polyethylene sheet. Exposure of hard diet components and other marine debris showed variable results. In conclusion, the results confirm that usage of KOH solutions can be a useful approach in general quantitative studies of plastic ingestion by marine wildlife.

Kukulka, T. and K. Brunner (2015). "Passive buoyant tracers in the ocean surface boundary layer: 1. Influence of equilibrium wind-waves on vertical distributions." Journal of Geophysical Research: Oceans **120**(5): 3837-3858.

This paper is the first of a two part series that investigates passive buoyant tracers in the ocean surface boundary layer. The first part examines the influence of equilibrium wind-waves on vertical tracer distributions, based on large eddy simulations (LES) of the wave-averaged Navier-Stokes equation. The second part applies the model to investigate observations of buoyant microplastic marine debris, which has emerged as a major ocean pollutant. The LES model captures both Langmuir turbulence (LT) and enhanced turbulent kinetic energy input due to breaking waves (BW) by imposing equilibrium wind-wave statistics for a range of wind and wave conditions. Concentration profiles of LES agree well with analytic solutions obtained for an eddy diffusivity profile that is constant near the surface and transitions into the K-Profile Parameterization (KPP) profile shape at greater depth. For a range of wind and wave conditions, the eddy diffusivity normalized by the product of water-side friction velocity and mixed layer depth, h, mainly depends on a single nondimensional parameter, the peak wavelength (which is related to Stokes drift decay depth) normalized by h. For smaller wave ages, BW critically enhances near-surface mixing, while LT effects are relatively small. For greater wave ages, both BW and LT contribute to elevated near-surface mixing, and LT significantly increases turbulent transport at greater depth. We identify a range of realistic wind and wave conditions for which only Langmuir (and not BW or shear driven) turbulence is capable of deeply submerging buoyant tracers. Key Points: * Langmuir (and not breaking wave) turbulence deeply submerges buoyant tracers * For young seas, breaking waves critically enhance near-surface mixing * Stokes drift decay length is a key for parameterizing wave-driven turbulence

Kulkarni, R. V., et al. "Novel interpenetrated polymer network microbeads of natural polysaccharides for modified release of water soluble drug: In-vitro and in-vivo evaluation." Journal of Pharmacy and Pharmacology.

Objectives The objective of this work was to prepare novel interpenetrating polymer network (IPN) microbeads of tamarind seed polysaccharide and sodium alginate for controlled release of the water soluble drug, diltiazem hydrochloride. Methods The diltiazem-Indion 254

(a cation exchange resin) complex was prepared and the resulting complex was entrapped within IPN microbeads prepared by ionotropic gelation and covalent crosslinking. Microbeads were characterized by scanning electron microscopy, differential scanning calorimetry, thermogravimetric analysis, X-ray diffraction and Fourier transform infrared spectroscopy (FTIR) analyses, and evaluated for swelling, in-vitro release and preclinical pharmacokinetics. Key findings The unformulated drug showed complete dissolution within 60min, while drug release from diltiazem-ion-exchange resin complex was extended for 2.5h but IPN microbeads extended the release for longer period. The ionically crosslinked microbeads released the drug for 6h, while dual crosslinked microbeads extended the release for 9h. The microbeads containing a higher amount of glutaraldehyde released the drug very slowly. The results of in-vivo pharmacokinetics of pure drug and drug-loaded IPN microbeads showed that the microbeads demonstrated prolonged release supporting the findings of in-vitro studies. Conclusions Prepared IPN microbeads showed prolonged in-vitro and in-vivo release for diltiazem, indicating that this IPN would be a versatile delivery system for water soluble drugs. © 2011 The Authors. Kumachev, A., et al. (2011). "High-throughput generation of hydrogel microbeads with varying elasticity for cell encapsulation." Biomaterials **32**(6): 1477-1483.

Elasticity of cellular microenvironments strongly influences cell motility, phagocytosis, growth and differentiation. Currently, the relationship between the cell behaviour and matrix stiffness is being studied for cells seeded on planar substrates, however in three-dimensional (3D) microenvironments cells may experience mechanical signalling that is distinct from that on a two-dimensional matrix. We report a microfluidic approach for high-throughput generation of 3D microenvironments with different elasticity for studies of cell fate. The generation of agarose microgels with different elastic moduli was achieved by (i) introducing into a microfluidic droplet generator two streams of agarose solutions, one with a high concentration of agarose and the other one with a low concentration of agarose, at varying relative volumetric flow rate ratios of the two streams, and (ii) on-chip gelation of the precursor droplets. At 37 degreeC, the method enabled a ~35-fold variation of the shear elastic modulus of the agarose gels. The application of the method was demonstrated by encapsulating two mouse embryonic stem cell lines within the agarose microgels. This work establishes a foundation for the high-throughput generation of combinatorial microenvironments with different mechanical properties for cell studies. © 2010.

Kumagai, Y., et al. (2017). "Low-density neutrophils (LDN) in circulating blood of postoperative patients may participate in the development of distant recurrence through the production of neutrophil extracellular traps (NETs)." Cancer Immunology Research. Conference **6**(9 Supplement).

Background: Low density neutrophils (LDN) which are co-purified with mononuclear cells by Ficoll-Hypaque density gradient preparations, have been reported to be increased in circulating blood in patients with autoimmune diseases, sepsis and cancer. Recent studies have suggested the LDN contributes to lupus pathogenesis as well as the development of organ damage in sepsis. Method(s): In patients who underwent curative surgery for gastrointestinal malignancy, peripheral blood was obtained at the timing of laparotomy (preoperative) and just before wound closure (postoperative) and the ratios of LDN were evaluated with flowcytometry. The LDN and mononuclear cells (MNC) in postoperative samples were separated using CD66b microbeads and MACS column and the proliferation of T cells were evaluated by in vitro culture on anti-CD3 coated plate using CFSE dilution method. The LDN were cultured for 2 hours and neutrophil extracellular traps (NETs) were observed with the addition of SYTOX green, dye for extracellular double strand (ds)-DNA. In adhesion experiments, human colon cancer, DLD-1,

were stained by PKH-26 and added on the cultured LDN for 5 min. After gentle washing, the remaining cells were counted under fluorescein microscope. Result(s): 1. Ratios of CD66b(+) LDG in CD45(+) leukocytes were markedly increased in postoperative as compared with preoperative blood samples. 2. Division of CD3(+) T cells were significantly suppressed by the addition autologous CD66b(+) LDN. 3. Short term culture of the LDN produced massive thread-like structures stained with SYTOX green. Immunostaining with specific mAbs revealed that histone and myeloperoxidase (MPO) were colocalized on the fibrous structure, indicating NETs 3. DLD-1, selectively attached to the NETs, which was totally abrogated by the pretreatment with 100u/ml DNAse. Conclusion(s): During abdominal surgery, immunosuppressive LDN are markedly increased in circulating blood. The LDN extensively produces NETs which support the metastasis formation by trapping the circulating tumor cells in target organ. Functional blockade of the LDN might effectively reduce the recurrence rate after curative surgery.

Kumar, A. and M. Bharkatiya (2019). "Simultaneous estimation of drugs present in microbeads for colon-targeted drug delivery system." Asian Journal of Pharmaceutical and Clinical Research **12**(11): 122-125.

Objectives: The present study was aimed to develop Eudragit S100 coated colon-targeted sustained-release formulations of alginate-pectin and alginate-hydroxypropyl methylcellulose microbeads containing norfloxacin (NF) and tinidazole (TZ) for the treatment of amebiasis which was simultaneous estimated. Method(s): Taguchi L9 orthogonal array design has been used to optimize the composition and operating conditions for the preparation of formulations. Nine batches (P1-H5) were prepared by taking three independent variables (X<inf>1</inf> - drug:polymer ratio, X<inf>2</inf> - concentration of sodium alginate, and X<inf>3</inf> - curing time) at three levels (1, 2, and 3). Response variables studied for batches (P1-H5) were mean particle size (micro m) (Y<inf>1</inf>), drug entrapment efficiency (% w/w) (Y<inf>2</inf>), and drug loading (% w/w) (Y<inf>3</inf>). NF and TZ were simultaneous estimated by ultraviolet spectrophotometric method. Drug-polymer compatibility study was carried out by differential scanning calorimetry and Fourier-transform infrared spectroscopy and indicates no physicochemical interaction. Result(s): Microbeads were analyzed for morphological characteristics, mean particle size, drug entrapment efficiency, drug loading, and in vitro drug release. The average size of optimized alginate-pectin microbeads was found to be 881+/-0.05 micro m with an entrapment efficiency of 78.50+/-0.28% (NF) and 86.50+/-0.32% (TZ) which was simultaneous estimated. Conclusion(s): The studies concluded that formulated enteric-coated alginate-pectin microbeads after enteric coating can be used effectively for the delivery of NF and TZ to colon. Kumar, A. and R. K. Dutta (2015). "CdS quantum dots immobilized on calcium alginate microbeads for rapid and selective detection of Hg super(2+) ions." RSC advances **5**(93): 76275-76284.

Mercury is extremely toxic to the environment and is detrimental to human health. We describe here the development of an analytical method comprising mercaptoacetic acid capped CdS quantum dots (QDs) immobilized on calcium alginate microbeads (referred here as CA[at]CdS) for rapid, selective and quantitative detection of Hg super(2+) ions based on a fluorescence quenching phenomenon. The feasibility of detecting Hg super(2+) ions in this method is extended to real time analysis by spiking 0.5 mg L super(-1) and 1.0 mg L super(-1) Hg super(2+) ions in batches of municipal tap water. The mechanism of fluorescence quenching has been explained on the basis of adsorption of Hg super(2+) (adsorption capacity was determined to be 88.33 mu g g super(-1)). The selectivity of Hg super(2+) ions is attributable to its soft acid-soft

base interaction between Hg super(2+) and the sulphydryl group of the mercaptoacetic acid capped CdS QDs. The fluorescence quenching phenomenon satisfied the Stern-Volmer equation and was linearly correlated with Hg super(2+) ions concentrations in the range of 0.015 and 2.0 mg L super(-1). The limit of detection of Hg super(2+) ion was determined to be 0.008 mg L super(-1) at an optimized condition, i.e., pH 6 and contact time 30 min; and the detection was not affected by other experimentally relevant cations like Na super(+), Mg super(2+), K super(+), Ca super(2+), Mn super(2+), Fe super(2+), Cu super(2+), Pb super(2+), Cr super(3+), Zn super(2+), As super(3+), Cd super(2+); and anions like Cl super(-), CO sub(3) super(2-), HCO sub(3) super(-), HPO sub(4) super(-), SeO sub(4) super(-), SO sub(4) super(2-). The major advantage of this nano-fluoroprobe is that it can detect as well as remove Hg super(2+) ions from an aqueous medium. The fluoroprobe can be recovered and re-used for subsequent cycles of detection and removal of Hg super(2+) ions.

Kumar, A., et al. (2017). "Immune mediators as biomarker candidates in familial amyotrophic lateral sclerosis." Neurology. Conference: 69th American Academy of Neurology Annual Meeting, AAN **88**(16 Supplement 1).

Objective: To identify immune mediators as pathogenic disease biomarkers in cerebrospinal fluid (CSF) and serum in familial amyotrophic lateral sclerosis (FALS) patients. Background(s): ALS produces severe disability and high rates of mortality, with 80% of the patients dying within 5 years of onset. FALS cases, caused by C9ORF72 hexanucleotide repeat expansion appear to be more aggressive than sporadic cases. Nonetheless, the pathophysiology of these cases has not been fully elucidated and requires the exploration for distinctive biomarkers. Design/Methods: CSF and serum were obtained from the Natural History and Biomarkers of C9ORF72 ALS and FTD study at NIH and the Johns Hopkins Neuroimmunology Biorepository. Immune meditors which included chemokines and cytokines were quantified using multiplexed microbead array assays (Luminex, EMD Millipore Corp., MA) in cases of FALS and frontotemporal dementia (n=15), sporadic ALS (n=9) and neurological disease controls (n=14). Non-parametric statistics was used to analyze the 3 groups. Result(s): IL-1 pro-inflammatory pathway appeared to be significantly increased in the CSF of familial ALS cases vs. neurological disease controls. In serum, significant increase were identified among the same groups for interferon a2, platelet derived growth factor AA (PDGF-AA) and soluble CD40 ligand. Differences were also observed between familial and sporadic ALS cases in serum concentrations of Flt3 ligand (Flt3-L), granulocyte-macrophage colonystimulating factor (GM-CSF) and CXCL5 (RANTES). Conclusion(s): Cases of FALS appear to have a pro-inflammatory immune mediators profile in the CSF and serum. Selective increases of IL-1 pro-inflammatory pathway were observed in cases of FALS compared to neurological disease controls. Increases in levels of Flt3-L, GM-CSF were seen in FALS cases compared with sporadic ALS. Despite no correspondence between the immune profile of CSF and serum, evidence of increase of immune mediators was observed in cases of FALS in both serum and CSF, a finding that support the presence of possible immune disturbances in cases of FALS.

Kumar, A. and B. Starly (2016). Modeling human mesenchymal stem cell expansion in vertical wheel bioreactors using lactate production rate in regenerative medicine biomanufacturing. ASME 2016 11th International Manufacturing Science and Engineering Conference, MSEC 2016.

Stem cells are critical components of regenerative medicine therapy. However, the therapy will require millions to billions of therapeutic stem cells. To address the need, we have recently cultured stem cells in 3D microgels and used them as a vehicle for cell expansion within a low shear stress rotating wheel type bioreactor within a 500ml volumetric setting. This study specifically highlights the cell encapsulation in microbead process, harvesting and operation of microbeads within a dynamic bioreactor environment. We have specifically encapsulated stem cells (human adipose derived) into microbeads prepared from alginate hydrogels via an electrostatic jetting process. This study highlights the effect of fabrication process parameters on end-point biological quality measures such as stem cell count and viability. We were able to maintain a >80% viability during the 21 day static culture period. We have also measured the concentration of metabolites produced during the expansion, specifically lactate production measured during specific time points within culture inside the rotating wheel bioreactor Future work will need to address predicting yields in higher volume settings, efficiency of harvest and a more detailed description of the hydrodynamics affecting stem cell growth. Kumar, C., et al. (2004). "Synthesis and characterization of S-Au interaction in gold nanoparticle bound polymeric beads." Journal of Nanoparticle Research **6**(4): 369-376.

A detailed X-ray Absorption Spectroscopic examination of S-Au interaction in gold nanoparticle bound to Polystyrene-Divinyl Benzene (PS-DVB) micro beads was carried out. Gold nanoparticles were bound to the surface of the commercially available PS-DVB beads using a simple one step procedure. Influence of polystyrene backbone on the electronic structure of the gold nanoparticles was observed through X-ray Absorption Near Edge Structure (XANES) spectra of Au at L III edge. An additional structure in the white line of the S K-edge XANES spectrum confirmed the presence of S-Au bonding. Transmission Electron Microscopy (TEM) studies coupled with Selected Area Electron Diffraction Pattern and X-ray Diffraction studies revealed the morphology of the Au nanoparticles bound to the micro beads.[PUBLICATION ABSTRACT]

Kumar, G. S., et al. (2016). "Thermostable alpha-amylase immobilization: Enhanced stability and performance for starch biocatalysis." Biotechnology & Applied Biochemistry **63**(1): 57-66.

The uses of thermostable starch hydrolytic biocatalysts are steadily increasing for the industrial application because of their obvious need for biocatalytic performance at elevated temperatures. The starch liquefaction and saccharification can be carried out simultaneously by the use of thermostable starch hydrolytic biocatalysts, thus minimizing the unit operations, time, and efforts. The cost factor hampers the industrialization of expensive soluble (free) enzymes for biocatalytic applications and the immobilization of enzymes offers promising alternative to the hurdle. The present investigation was aimed for immobilization of thermostable alpha-amylase using calcium alginate, and statistical optimization studies were carried out for enhanced biocatalytic performance. Initially, one-parameter at a time optimization studies were carried out for identification of significant factors influencing the immobilization. Furthermore, a statistical approach, response surface methodology, was applied for immobilization of alpha-amylase. The immobilized alpha-amylase in alginate microbeads showed enhanced stability to temperature and reusable property for up to seven cycles (with the retention of 50% initial activity). Finally, the kinetic behavior of free and immobilized enzyme showed the Km value of 1.2% and 2.6% (w/v) and Vmax of 1,020 and 1,030 U, respectively. Fifty percent reduction in affinity of the immobilized enzyme toward substrate was compensated by its longer stability.

Kumar, J., et al. (2013). "ECONOMICAL SYNTHESIS OF MAGNETIC MICROBEADS FOR BIOREMEDIATION APPLICATIONS." OnLine Journal of Biological Sciences **13**(1): 35.

There are very few reports of utilizing the iron based wastes materials for applications like the removal of heavy metals like arsenic, lead and also, for the adsorption of the hazardous dyes. In the current study, the focus has been to utilize the metal tailings of irregular morphology to

obtain the spherical magnetic beads. The precursor substances were studied for their morphology transformation under different reaction conditions viz., atmospheric conditions, under pressure and on an aluminium hot plate along with the fatty acid mixtures. The particles were characterized for their morphology through the SEM analysis. The results of post functionalization reveals the particles do not undergo size reduction under atmospheric pressure but significant change in morphology was observed. On the contrary, under pressure at 25 psi (using single stage air cooled reciprocating compressor), it was observed to have not only changed the morphology but also the size reduction of about 30% for a slight increase of pressure above atmospheric pressure.

Kumar, K., et al. (2013). "Hmg-coa reductase inhibitors do not attenuate the inflammatory response associated with glutaraldehyde-fixed bioprosthetic heart valve conduits." Canadian Journal of Cardiology **1)**: S261.

BACKGROUND: Bioprosthetic valve failure due to calcification continues to remain the major determinant in utilizing this valve type for young adults. Evidence suggests that there is an immunological response of the recipient to xenograft bioprosthetic heart valves leading to inflammation and eventual premature calcification. Information on the impact of statins and their anti-inflammatory properties on bioprosthetic valve failure remains limited and difficult to study in the clinical setting. We sought to examine the efficacy of statin therapy in a rodent model of bioprosthetic valve implantation. METHOD(S): To mimic the human scenario, fresh or 48-hour glutaraldehyde-fixed aortic valve root conduits fromLewis rats or Hartley guinea pigs were microsurgically implanted intravascularly into the infra-renal aorta of Lewis rats.Animals were assigned to 1 of 4 groups (n = 10 / group). The syngeneic control group consisted of a fresh rat valve conduit implanted into a rat (Group 1). The xenogeneic control group consisted of glutaraldehydefixed guinea pig valve conduit implanted into a rat (Group 2), thusmimicking the clinical scenario. Groups 3 and 4 consisted of xenogeneic groups treated with either daily steroids (methylprednisolone [0.5mg/kg]) or rosuvastatin (20mg/kg). At the study end-point (28-days post implantation), valve conduits were excised for histological and immunological analyses. RESULT(S): Electron microscopy confirmed that following fixation, our rodent model prosthesis conduit undergoes similar changes that occur with bioprosthetic valves for humans. Steroid treatment attenuated the inflammatory response seen within the xenogeneic glutaraldehyde-fixed valve conduits. This finding was confirmed by H&E analysis (median inflammatory score 0 versus ++ as reviewed by two blinded pathologists), immunohistochemistry (median CD68 infiltration 32% versus 42%, Figure 1), and micro-bead cytokine analyses (IL-1 alpha, IL-beta, TNF-alpha, IFN). Treatment with rosuvastatin did not decrease this inflammatory response and was consistent among all tests performed. CONCLUSION(S): In vivo rodent models represent a new field of valve prosthesis study. Data from our in vivo rodent model of bioprosthetic valve implantation confirms that prosthesis failure is associated with a localized inflammatory response. Treatment with daily rosuvastatin was unable to attenuate this response. This data is in keeping with emerging clinical studies that have also failed to show benefit with statin therapy for valvular heart disease. Utilizing this rodent model, further analyses can be performed to identify possible therapeutic interventions for bioprosthetic calcification. (Figer Presented) .

Kumar, P. S. and G. Sankaranarayanan (2016). "Investigation on environmental factors of waste plastics into oil and its emulsion to control the emission in DI diesel engine." Ecotoxicology & Environmental Safety **134**: 440-444.

Rapid depletion of conventional fossil fuel resources, their rising prices and environmental issues are the major concern of alternative fuels. On the other hand waste plastics cause a very serious environmental dispute because of their disposal problems. Waste plastics are one of the promising factors for fuel production because of their high heat of combustion and their increasing availability in local communities. In this study, waste plastic oil (WPO) is tested in DI diesel engine to evaluate its performance and emission characteristics. Results showed that oxides of nitrogen (NO x) emission get increased with WPO when compared to diesel oil. Further, the three phase (O/W/O) plastic oil emulsion is prepared with an aid of ultrasonicater according to the %v (10, 20 & 30). Results expose that brake thermal efficiency (BTE) is found to be increased. NO x and smoke emissions were reduced up to 247 ppm and 41% respectively, when compared to diesel at full load condition with use of 30% emulsified WPO. [ABSTRACT FROM AUTHOR]

Kumar, S., et al. (2015). "Investigation of the tracers for plastic-enriched waste burning aerosols." Atmospheric Environment **108**: 49-58.

To better identify the tracers for open-waste burning (OWB) aerosols, we have conducted aerosol sampling at 2 landfill sites, i.e., Okhla and Bhalswa in New Delhi. The metals such as, As, Cd, Sb and Sn, which have been observed almost negligible in remote aerosols, are found abundantly in these OWB aerosol samples (n=26), i.e., 60+/-65, 41+/-53, 537+/-847 and 1325+/-1218ngm⁻³, respectively. Samples (n=20) collected at urban locations in New Delhi, i.e., at Employees' State Insurance (ESI) hospital and National Physical Laboratory (NPL) also show high abundances of these metals in the particles. Filter samples are also analyzed for water-soluble dicarboxylic acids (C<inf>2</inf>-C<inf>12</inf>) and related compounds (oxocarboxylic acids and alpha-dicarbonyls). Terephthalic acid (tPh) was found to account for more than 77% of total diacids determined in OWB aerosols. However, such a high abundance of tPh is not observed in aerosols collected at urban sites. Instead, phthalic acid (Ph) was found as the third/fourth most abundant diacid (~3%) following C<inf>2</inf> (>70%) and C<inf>4</inf> (>12%) in these waste burning influenced urban aerosols. A possible secondary formation pathway of Ph by photo-degradation of phthalate ester (di-2-ethylhexyl phthalate) in plastic-waste burning aerosol is suggested. Ionic composition of OWB aerosols showed that Cl⁻ is the most abundant ion (40+/-8% of total ions determined). The correlation studies of the potential metals with the organic tracers of garbage burning, i.e., phthalic, isophthalic and terephthalic acids show that especially Sn can be used as marker for tracing the plastic-enriched waste burning aerosols. Copyright © 2015.

Kumar, V. E., et al. (2018). "Occurrence of microplastics in fishes from two landing sites in Tuticorin, South east coast of India." Marine Pollution Bulletin **135**: 889-894.

Microplastics pollution of the marine environment has been reported worldwide. Here, we investigate the occurrence of microplastics in two species of fishes namely Rastrilleger kanagurta and Epinephalus merra bought from Thirespuram and Punnakayal fish landing sites at Tuticorin. Out of the total 40 fish, 12 fish showed the presence of microplastic particulates in the intestine. The particulates included microfibers (80%) in red, black and translucent colors and irregularly shaped microplastic fragments (20%). The microplastics were identified as

Polyethylene and Polypropylene by Fourier Transform Infrared Radiation analysis. Though microplastics were detected in the gut of the species, the risk of transfer due to consumption can be safely ruled out as the fish are degutted prior to consumption here. Presence of microplastics in the Tuticorin coast is a matter of concern due to its proximity to the Gulf of Mannar, a sensitive coral reef patch already threatened by marine pollution.

Kumari, B. and C. D. Naidu (2018). "Influence of plastic waste strips on engineering behaviour of soils." International Journal for Research in Applied Science and Engineering Technology **6**(3): 1685-1698.

Rapid improvements in the engineering world have influence a lifestyle of human beings in utmost extends but day to day activities of mankind are augmenting risk in the environment in the same proportion. Plastic wastes have become one of the major problems for the world. The harmful gas which is being produced by this agent leads to tremendous health related problems. So, effective engineering implementation of this has become one of the challenging jobs for engineers. Engineer are seeking for astute implementation of these wastes in ample amount and implementing these wastes in Soil stabilization helps to reduce the risk of natural destruction which is caused due to rainfall or other aspect and also it aid in reducing the waste in an ample amount. Plastic is considered as one of the major pollutant of environment as it would not decay or can't be destroyed so implementing this for some good purpose helps to reduce its effect also. This implies that stabilization using waste plastic strips is an economic method where use of waste materials as plastic and other cheaply available material of plastic can be used which is found accessibly. This paper reflects that plastic wastes can be used in stabilization of soil which is concluded from various tests conducted on fiber reinforced soil with varying fiber content and different aspect ratio and profound analysis of their results depicts that it can be used in the fields. Therefore, it is of utmost importance considering the design and construction methodology to maintain and improve the performance of such pavements. In this paper, different means of plastic waste as shopping bags and other plastic material which is locally available are used so as a reinforcement to perform the CBR studies while mixing with soil for improving engineering performance of sub grade soil. In this the Plastic strips which are collected for stabilization of soil were mixed randomly with the soil. With this a series of California Bearing Ratio (CBR) tests were carried out randomly reinforced soil in which the percentage of plastic strips with varying percentage of plastic strips with different lengths and proportions were carried on. And the results and conclusion were summed up which shows that use of plastic in soil in an appropriate amount really aids in improving the strength of soil and also helps in modification of soil properties which might be in term of strength of sub grade soil The amount of wastes has increased year by year and the disposal becomes a serious problem. Particularly, recycling ratio of the plastic wastes in life and industry is low and many of them have been reclaimed for the reason of unsuitable ones for incineration. It is necessary to utilize the wastes effectively with technical development in each field. This study presents a simple way of recycling plastic waste in the field of civil engineering as reinforcing material. Reinforced soil construction is an efficient and reliable technique for improving the strength and stability of soils. The technique is used in a variety of applications, ranging from retaining structures and embankments to subgrade stabilization beneath footings and pavements. This paper describes an experimental study on mixing plastic waste pieces with two types of soil (clayey soil and sandy soil) at different mixing ratios (0,2,4,6,8)% by weight respectively. For the two types of soils, the shear strength parameters (cohesion value and angle of internal friction) of reinforced and unreinforced samples were investigated by the direct shear test. In addition, a series of compaction tests were performed on clayey soil mixed with different percentages of waste pieces. It was found that, there is significant improvement in the strength of soils due to increase in internal friction. The percentage of increase in the angle of internal friction for sandy soil is slightly more than that in clayey soil, but there is no significant increase in cohesion for the two types of soils. Also, it was concluded that the plastic pieces decreases the maximum dr

Kumari, R., et al. (2014). "Calorific Value Measurements and Optimization of Waste Cooking Oil Bio-Diesel, Crude Plastic Oil and Their Blends for the Synthesis of Low Cost High Energy Fuels." National Journal on Chembiosis **5**(1).

Plastic is an artificial polymer which is having a wide application in manufacturing industries and consumer products as it is light weight, economical, strong, convenient and durable. Plastic is a non-biodegradable material because of which it is very harmful to the environment. Plastics have use in various spheres of economy - infrastructure, construction, agriculture, consumer goods, telecommunications, packaging, etc. Because of growing plastic industries the amount of plastic waste has also increased which is a major problem in front of environmental researchers. Currently worldwide accepted technology used for plastic disposal is incineration which releases extremely toxic compounds leading to environmental issues if not handled carefully. Hence an alternate solution to the exponentially growing plastic waste is being analyzed across the globe. Plastic waste can well be handled with pyrolysis, a thermochemical decomposition method. Pyrolysis, a Plastic to Fuel (PTF) technology, is done at a temperature of 420-440?C. Oil derived from PTF technology has a complex chemical composition but can be used as a fuel conveniently because of its higher energy density. The bio-diesel obtained from the waste cooking oil is blended in different proportions with crude plastic oil obtained from the pyrolysis process of the plastic waste using ultrasonic vibrator. The calorific values of diesel, Crude plastic oil, Standard bio-diesel and bio-diesel obtained from waste cooking oil are 45,457kJ/kg, 25,353 - 43,496 kJ/kg, 39,011kJ/kg and 37,120.16kJ/kg respectively. Bio-diesel from waste cooking oil synthesized by conventional route blended with crude plastic oil obtained after pyrolysis in different proportion was analyzed for its calorific value and was tested with constant speed 4- stroke diesel engine to study the fuel blend performance.

Kumi-Larbi, A. J., et al. (2018). "Recycling waste plastics in developing countries: Use of low-density polyethylene water sachets to form plastic bonded sand blocks." Waste Management **80**: 112-118.

In many developing countries low-density polyethylene (LDPE) sheets, bags and water sachets are a major waste problem because local collection and recycling systems do not exist. As a result, LDPE has no value and is dumped causing aesthetic, environmental and public health issues. A relatively simple technology has been developed in the Cameroon that produces LDPE-bonded sand blocks and pavers. The application of this technology is an example of a community-driven waste management initiative that has potential to impact on the global plastics waste crisis because it can transform waste LDPE and other readily available types of plastics into a valuable local resource. In this research, waste LDPE water sachets have been melted and mixed with sand to form LDPE-bonded sand blocks. The effect of sand particle size and sand to plastic ratio on density, the compressive strength and water adsorption are reported. Optimum samples have been further characterised for flexural strength and thermal conductivity. LDPE-bonded sand is a strong, tough material with compressive strengths up to ~27MPa when produced under optimum processing conditions. The density and compressive strength increase as the particle size of the sand decreases. The potential for using this simple technology and the materials it produces to transform LDPE plastic waste management in developing countries is discussed.

Kuny, T. and H. Leuenberger (2003). "Compression behaviour of the enzyme beta-galactosidase and its mixture with microcrystalline cellulose." International Journal of Pharmaceutics **260**(1): 137-147.

The behaviour of beta-galactosidase powder under compaction was investigated to get more information on powder properties and to further characterise tablet excipients. The enzyme beta-galactosidase, the model excipient microcrystalline cellulose and several mixtures of these two substances were compressed at different compaction forces. The relative density of the obtained tablets was calculated and the Heckel equation as well as the modified Heckel equation was used to characterise the bulk powders and their mixtures. Microcrystalline cellulose is known as a model substance for plastic powders, the used beta-galactosidase was found to be a brittle substance. In further experiments, the activity loss of the compacted enzyme powder was investigated and used to characterise the behaviour of the binary mixtures in various ratios. Data interpretation with percolation theory led to a critical beta-galactosidase concentration of 20%. Between 100 and 20%, the enzyme builds a lattice and dominates the binary system. For beta-galactosidase amounts below 20% in mixtures with plastic excipients, the activity loss increases strongly because of higher shearing forces during compaction due to the system dominance of the plastic particles.

Kuo, C. T. and C. H. Liu (2008). "A novel microfluidic driver via AC electrokinetics." Lab on a Chip **8**(5): 725-733.

A novel ac electrokinetic microfluidic driver based on alternating current electro-osmosis flow induced by asymmetrically capacitance/chemistry-modulated microelectrode arrays has been successfully developed and demonstrated. Asymmetric capacitance modulation (ACM) is made of comb electrode arrays and parts of individual electrode surfaces are modulated/deposited with a SiO(2) dielectric layer. This proposed design can be utilized to shift the optimal operation frequency of maximum velocity to a higher frequency to minimize electrolytic bubble generation and enhance micropumping performance. The pumping velocity, described in this paper, is measured via the tracing of microbeads and is a function of applied potential, signal frequency, buffer concentration, and dielectric layer thickness. A maximum pumping velocity up to 290 microm s(-1) in 5 mM buffer solution with the applied potential of 10 Vpp is observed in our prototype device, and the estimated maximum flow rate is up to 26.1 microl h(-1). This is the first successful demonstration regarding bubble-free ac electrokinetic micropumping via such asymmetrically capacitance-modulated electrode arrays.

Küpper, F. C. and N. A. Kamenos (2018). "The future of marine biodiversity and marine ecosystem functioning in UK coastal and territorial waters (including UK Overseas Territories) – with an emphasis on marine macrophyte communities." Botanica Marina **61**(6): 521-535.

Marine biodiversity and ecosystem functioning – including seaweed communities – in the territorial waters of the UK and its Overseas Territories are facing unprecedented pressures. Key stressors are changes in ecosystem functioning due to biodiversity loss caused by ocean warming (species replacement and migration, e.g. affecting kelp forests), sea level rise (e.g. loss of habitats including salt marshes), plastic pollution (e.g. entanglement and ingestion), alien species with increasing numbers of alien seaweeds (e.g. outcompeting native species and parasite transmission), overexploitation (e.g. loss of energy supply further up the food web), habitat destruction (e.g. loss of nursery areas for commercially important species) and ocean acidification (e.g. skeletal weakening of ecosystem engineers including coralline algal beds). These stressors are currently affecting biodiversity, and their impact can be projected for the future. All stressors may act alone or in synergy. Marine biodiversity provides crucial goods and services. Climate change and biodiversity loss pose new challenges for legislation. In particular, there are implications of climate change for the designation and management of Marine

Protected Areas and natural carbon storage by marine systems to help control the global climate system. The UK currently has legal obligations to protect biodiversity under international and European law.

Kuppers, B., et al. (2019). "Influence of surface roughness and surface moisture of plastics on sensor-based sorting in the near infrared range." Waste Management & Research **37**(8): 843-850.

In the project 'NEW-MINE' the use of sensor-based sorting machinery in the field of 'landfill mining' is investigated. Defilements pose a particular challenge in the treatment and sorting of plastics contained in landfills. For this reason, the effects of various pollutants caused by the interactions in the landfill body or the mechanical treatment steps in landfill mining are examined. In the following elaboration, the focus is on the influences of surface moisture and surface roughness of plastics on sensor-based sorting by means of near-infrared technology. Near-infrared radiation (NIR) in a wavelength range of 990 nm to 1500 nm has been used for the detection and classification of plastic particles. The experiments demonstrate that increased surface roughness reduces signal noise and thereby improves the classification of both spectrally similar and transparent plastics, but reduces the yield of low-softening plastics because their sliding speed on a sensor-based chute sorter varies as a result of the heating of the chute. Surface moisture causes the absorption of radiation from 1115 nm (high density polyethylene [HDPE], linear low density polyethylene [LLDPE], polyethylen terephthalate [PET] and polyvinylchloride [PVC]) or from 1230 nm (low density polyethylene [LDPE], polypropylene [PP] and thermoplastic polyurethane [TPU]) up to at least 1680 nm, which causes amplification or attenuation of various extremes in the derivative. However, the influence of surface moisture on the yield of plastics is usually very low and depends on the spectral differences between the different plastics.

Kuramitz, H., et al. (2006). "Application of an automated fluidic system using electrochemical bead-based immunoassay to detect the bacteriophage MS2 and ovalbumin." Analytica Chimica Acta **561**(1-2): 69-77.

A fully-automated fluidic system for a bead-based immunoassay with electrochemical detection was developed. Assays for the bacteriophage MS2 and ovalbumin (OVA) were demonstrated using this system. Streptavidin-coated paramagnetic microbeads were used as a mobile solid phase. The immunoassay sandwich was made by attaching a biotinylated antibody to the streptavidin-coated beads, capturing antigen, and then exposing the antigen to an antibody conjugated with beta-galactosidase. beta-Galactosidase converts p-aminophenyl galactopyranoside (PAPG) to p-aminophenol (PAP), which is electrochemically oxidized to p-quinone imine (PQI). The behavior of paramagnetic microbeads in the fluidic system was investigated using beads with immobilized beta-galactosidase at different concentrations of beads and flow rates for each procedure in the assay. Furthermore, the fully-automated MS2 and OVA assays were demonstrated using the fluidic system. The limits of detection for MS2 and OVA were 990 (1.6 x 10¹¹ particles mL⁻¹) and 470 ng mL⁻¹, respectively. © 2006 Elsevier B.V. All rights reserved.

Kurbonov, U., et al. (2013). "Intracoronary infusion of autologous CD133+ cells in myocardial infarction and tracing by Tc99m MIBI scintigraphy of the heart areas involved in cell homing." Stem Cells International.

CD133 mesenchymal cells were enriched using magnetic microbead anti-CD133 antibody from bone marrow mononuclear cells (BMMNCs). Flow cytometry and immunocytochemistry analysis using specific antibodies revealed that these cells were essentially 89 ± 4% CD133+ and 8 ± 5%

CD34 +. CD133+/CD34+ BMMNCs secrete important bioactive proteins such as cardiotrophin-1, angiogenic and neurogenic factors, morphogenetic proteins, and proinflammatory and remodeling factors in vitro. Single intracoronary infusions of autologous CD133+/CD34+ BMMNCs are effective and reduce infarct size in patients as analyzed by Tc99m MIBI myocardial scintigraphy. The majority of patients were treated via left coronary artery. Nine months after cell therapy, 5 out of 8 patients showed a net positive response to therapy in different regions of the heart. Uptake of Tc99 isotope and revitalization of the heart area in inferoseptal region are more pronounced (P = 0.016) as compared to apex and anterosptal regions after intracoronary injection of the stem cells. The cells chosen here have the properties essential for their potential use in cell therapy and their homing can be followed without major difficulty by the scintigraphy. The cell therapy proposed here is safe and should be practiced, as we found, in conjunction with scintigraphic observation of areas of heart which respond optimally to the infusion of autologous CD133+/CD34+ BMMNCs. © 2013 Ubaidullo Kurbonov et al.

Kurien, B. T., et al. (2013). "Prolidase deficiency breaks tolerance to lupus-associated antigens." International Journal of Rheumatic Diseases **16**(6): 674-680.

AIM: Prolidase deficiency is a rare autosomal recessive disease in which one of the last steps of collagen metabolism, cleavage of proline-containing dipeptides, is impaired. Only about 93 patients have been reported with about 10% also having systemic lupus erythematosus (SLE).

METHODS: We studied a large extended Amish pedigree with four prolidase deficiency patients and three heterozygous individuals for lupus-associated autoimmunity. Eight unaffected Amish children served as normal controls. Prolidase genetics and enzyme activity were confirmed. Antinuclear antibodies (ANA) were determined using indirect immunofluorescence and antibodies against extractable nuclear antigens were determined by various methods, including double immunodiffusion, immunoprecipitation and multiplex bead assay. Serum C1q levels were determined by enzyme-linked immunosorbent assay.

RESULTS: Two of the four homozygous prolidase deficiency subjects had a positive ANA. One had anti-double-stranded DNA, while another had precipitating anti-Ro. By the simultaneous microbead assay, three of the four had anti-Sm and anti-chromatin. One of the three heterozygous subjects had a positive ANA and immunoprecipitation of a 75 000 molecular weight protein. The unaffected controls had normal prolidase activity and were negative for autoantibodies.

CONCLUSIONS: Prolidase deficiency may be associated with the loss of immune tolerance to lupus-associated autoantigens even without clinical SLE.

Kurihara, K., et al. (2019). "Significance of IL-17A-producing CD8⁺CD103⁺ skin resident memory T cells in psoriasis lesion and their possible relationship to clinical course." Journal of Dermatological Science **95**(1): 21-27.

BACKGROUND: A number of studies have shown the relationship between the pathogenesis of psoriasis and skin resident memory T (T_{RM}) cells.

OBJECTIVE: To investigate the cytokine profile of T_{RM} cells from skin lesions of psoriasis and the relationship of skin T_{RM} cells to the future clinical course of psoriasis.

METHODS: We used stocked samples of T cells that were ex vivo expanded from skin biopsies of 10 patients with psoriasis vulgaris. A half of 4-mm punch biopsy specimens was subjected to expansion of skin-infiltrating T cells using IL-2 and anti-CD3/CD28 antibody-coated microbeads. More than 10⁶ T cells per specimen were stocked at -80degreeC. Defrosted cells were subjected to flow cytometric analysis. Another half of skin biopsies were subjected to immmunofluorescence staining for CD103 and other markers.

RESULTS: The biopsied skin revealed CD8⁺CD103⁺ T_{RM} cells were present in the epidermis of psoriasis and associated with acanthosis. Sorted CD103⁺ T cells were mostly CD8⁺ memory T cells expressing CD69 with a skin-homing potential. A part of CD8⁺CD103⁺ T cells produced interferon-gamma, IL-17A or IL-22. Notably, CD8⁺CD103⁺ T_{RM} cells more frequently produced IL-17A than did CD8⁺CD103⁻ T cells. We retrospectively divided the 10 cases into the non-advanced therapy group, and the advanced therapy group in which systemic biologics or others were initiated within one year. The frequency of CD8⁺CD103⁺IL-17A⁺ T_{RM} cells tended to be higher in the advanced therapy group.
CONCLUSION: These results suggest that IL-17A-producing CD8⁺CD103⁺ T_{RM} cells are associated with a progressive clinical course of psoriasis.

Kuriyama, N., et al. (2009). "Predictive markers of blood cytokine and chemokine in recurrent brain infarction." Journal of Interferon & Cytokine Research **29**(11): 729-734.

The mechanism of the inflammatory response in the vascular wall in atherothrombosis and during the progression of atherosclerosis has attracted attention. We focused on the potential usefulness of inflammatory markers in chronic recurrent brain infarction, and analyzed the role of inflammatory markers in atherosclerosis of the intracranial artery. The subjects were 2 groups of patients treated between 2004 and 2006: a group of outpatients with recurrent infarction (group RI), who developed atherothrombotic brain infarction twice; another group of outpatients with brain infarction without recurrence (group BI), who developed brain infarction once and remained free of recurrence for >1 year; and a group of control subjects with normal brain magnetic resonance imaging (MRI) and magnetic resonance angiography (MRA) (group C). Plasma samples were collected from each group of patients for the simultaneous measurement of 17 kinds of candidate inflammatory markers, using a fluorescent microbead array system, and the results were compared with head MRA findings. The levels of high-sensitivity C-reactive protein (hsCRP) and monocyte chemoattractant protein-1 (MCP-1) were significantly higher in group RI patients than in groups C and BI. Subjects with a hsCRP level > or =0.3 and a MCP-1 level > or =200 in the serum have, respectively, a 1.92 and 2.98 relative risk to have a potential recurrent infarction. Regarding the relation of inflammatory marker levels with MRA findings, group RI showed significantly higher levels of hsCRP at M1 lesions and MCP-1 at A1 and M1 lesions than group BI (P < 0.05). In conclusion, the MCP-1 level as well as hsCRP in the blood can be a potential predictive marker of recurrent thrombotic brain infarction, and may reflect inflammation that promotes intracranial large-artery atherosclerosis.

Kurowska-Stolarska, M., et al. (2009). "MiR-155 and MiR-34a regulate TNF-alpha production by human monocytes." Arthritis and Rheumatism **10)**: 1242.

Purpose: Dysregulated pro-inflammatory activation of synovial monocyte and macrophage is of fundamental importance in pathogenesis of rheumatoid arthritis (RA). Recently microRNA (miRNA) have been identified as critical post-transcriptional regulators of many components of immune responses. The aim of our study was to investigate the role of candidate miRNAs, miR-155 and mir-34a in the activation of RA synovial fluid (SF) and blood monocyte/macrophages. Method(s): CD14+ cells from SF or peripheral blood (PB) of RA patients (n=7) and CD14+ cells from PB of healthy controls (n=6) were isolated using CD14 MACS MicroBeads. PB CD14+ cells were stimulated with LPS (100 ng/ml), Pam3CSK4 (300 ng/ml), PolyI:C (50 mug/ml), CPG (3 mug/ml), control CPG (3 mug/ml) or protease activated receptor-2

(PAR2) agonist (SLIGKV-NH2; 50muM) for 24h. PB CD14+ cells were transfected with miR-155, miR-34a or scramble mimics (all 3.5 mg/3x106 cells) by electroporation (Amaxa). Expression of AXL (receptor tyrosine kinase) and TNF production were tested 36 h later. Total RNA was isolated by miRNeasy kit. TaqMan miRNA and mRNA assays were used for semiquantitative determination of the expression of miR-155, miR-34a and AXL, respectively. The expression of U6B small nuclear RNA and beta-actin were used as endogenous controls. To identify the cellular targets of candidate miRs, multiple target prediction programs and mRNA transcriptomic signatures of SF CD14+ cells were employed. Result(s): Synovial fluid CD14+ cells expressed higher levels of miR-155 (64 fold, p<0.05) and miR-34a (4.5 fold, p<0.05) than PB matched CD14+ cells. Expression of miR-155 was up-regulated by TLR2, TLR3, TLR4 and TLR9 ligands (p<0.05) but not by PAR2 agonist in PB CD14+ cells. In contrast, miR-34a expression was either not affected (Pam3CSK4, SLIGKV-NH2) or down-regulated (LPS, PolyI:C, CPG; p<0.05) under the same conditions. Overexpression of miR-155 and miR-34a mimics in PB monocytes induced TNF production (10170 +/- 385 pg/ml) and (991 +/- 33), respectively. Using computational target ranking system combined with mRNA transcriptomic data we identified a negative regulator of TLR/IL-1R signalling, AXL, to be targeted by miR-34a. Overexpression of miR-34a and miR-155 mimics decreased the expression of AXL in PB monocytes by (48 +/- 3%) and (38 +/- 16%), respectively. Conclusion(s): These data suggest that overexpression of miR-155 and miR-34a in CD14+ cells can result in downregulation of AXL expression which in turn can lead to the overproduction of TNF. We provide a novel mechanism for deregulated TNF production in RA synovial macrophages amenable to therapeutic intervention in due course.

Kurowska-Stolarska, M. S., et al. (2010). "The role of miR-155 in the activation of RA and PsA synovial fluid monocytes." Arthritis and Rheumatism **10)**: 1422.

Purpose: MicroRNA (miR) network has emerged recently as an important post transcriptional regulator of immune response. Each individual miRNA species is capable of targeting a large number of distinct mRNA transcripts often belonging to one pathway. In our previous study we identified miR-155 to be strongly up-regulated in RA and PsA synovial fluid (SF) CD14+ cells compared to matched peripheral blood (PB) CD14+ cells suggesting that this miR may be involved in regulation of inflammatory pathways in arthritic joints. The aim of our study was to investigate the impact of miR 155 on the cytokine production and transcriptomic signature of RA and PsA SF monocyte and macrophage. Method(s): CD14+ cells from SF or PB of RA patients (n=14), PsA patients (n=13) and CD14+ cells from PB of healthy controls (n=6) were purified using CD14 MACS MicroBeads. PB CD14+ cells were transfected with miR-155 or scramble mimics (20 nM). Total RNA was isolated by miRNeasy kit. TaqMan miRNA and mRNA assays were used for semi-quantitative determination of the expression of miR-155 and its targets. The expressions of U6B small nuclear RNA or beta-actin were used as endogenous controls. Target prediction program and mRNA transcriptomic signature of RA and PsA SF CD14+ cells were employed to identify the cellular targets of miR-155 in SF CD14+ cells. Result(s): Overexpression of miR-155 in PB CD14+ monocytes and PB CD14+ derived macrophages triggered TNF production suggesting that miR-155 may indeed be involved in post-transcriptional control of inflammatory pathways in SF monocyte. A computational target ranking system (TargetScan human 5.1, aggregate Pct above 4.0) predicted 127 mRNA targets for miR-155. To identify mRNAs that are specifically targeted in SF monocytes we cross-referenced TargetScan predictions with a list of 2312 mRNAs that were differentially expressed in SF CD14+ cells compared to PB CD14+ cells of RA (n=8) and PsA (n=7) patients (GeneChip Affymetrix U133 plus 2). This approach produced a list of 26 miR-155 targets that were relevant to SF CD14+ activation. Among them, 24 genes were up-regulated and 2 genes were down-regulated in SF

CD14+ cells compared to PB CD14+ cells. Since miRs exert their function by mRNA degradation, we focused on genes that were down-regulated in SF CD14+ cells, namely SHIP1 (Src homology-2 domain-containing inositol 5-phosphatase 1) and ZNF652 (zinc finger DNA-binding protein). Expression of SHIP1 was down-regulated by 9 and 3.9 fold in SF CD14+ cells from RA (n=8) and PsA (n=7) patients, respectively. ZNF652 was decreased by 4.43 and 2.97 fold in SF CD14+ cells from RA and PsA patients, respectively. The decrease of SHIP1 and ZNF652 expression in SF monocyte was confirmed by QPCR on additional patient samples. Experimental validation revealed that the expression of SHIP1 and ZNF652 was inhibited in PB CD14+ cells transfected with miR-155 mimic compared to control mimic transfected cells (48 +/- 10% and 43+/- 7%, respectively). Conclusion(s): This study identified functional miRNA-mRNA networks that may be responsible for pro-inflammatory activation of synovial fluid monocyte and macrophage in RA and PsA patients.

Kurtela, A. and N. Antolović (2019). "The problem of plastic waste and microplastics in the seas and oceans: Impact on marine organisms." Ribarstvo, Croatian Journal of Fisheries **77**(1): 51-56.

A global problem of today is the large amount of waste in the seas and oceans, primarily plastic waste. It is estimated that every year 1.25 to 2.41 million tons of plastic material is being carried by rivers into the seas and oceans. Waste is a major problem for marine organisms, causing entanglement, choking, strangulation, malnutrition and death. In 1972 the problems caused by microplastics, particles smaller than 5 mm, were first observed. Such particles bind pathogenic microorganisms on to their surface. Increasing quantities of microplastics have been found in the stomachs of fish, and also in shellfish that feed by filtering sea water. Ingested by marine organisms, such plastics may eventually pass through the food web and can end up ingested by humans. In addition, plastic releases chemical compounds whose effect on marine organisms and humans has still not been studied. Many international and state organizations offer solutions through recycling plastic waste, as well as reducing the production of plastic materials and informing the public about the problem. © The Author(s) 2019.

Kushima, S., et al. (2019). "Targeting nicotinamide adenine dinucleotide (NAD) glycohydrase activity of CD38 exerts anti-myeloma effect accompanying intracellular NAD elevation." Blood. Conference: 61st Annual Meeting of the American Society of Hematology, ASH **134**(Supplement 1).

Introduction. The development of novel agents has improved the outcomes of multiple myeloma (MM) patients. Especially, daratumumab, an anti-CD38 monoclonal antibody which exerts therapeutic effect against MM cells through direct cell damage, antibody dependent cellular cytotoxicity (ADCC) and complement-dependent cytotoxicity (CDC), has shown its high efficacy in clinical practice. CD38 is a transmembrane glycoprotein highly expressed in plasma cells. CD38 is also a major nicotinamide adenine dinucleotide (NAD) glycohydrase in mammalian tissues, which regulate cellular levels of NAD. However, the role of CD38 as a NAD glycohydrase (NADase) in survival of MM cells is not well understood. In the present study, we conducted CD38 enzyme activity inhibition on MM cells using a small molecule compound 78c, a specific inhibitor for NADase enzymatic activity of CD38, in order to study the role of CD38 NADase activity in MM cell survival and to examine whether CD38 enzyme inhibition could be a new therapeutic strategy of MM. Materials and methods. MM cell lines (NCI-H929, KMS-12BM, KMS-12PE, U266) were treated with CD38 NADase inhibitor, 78c, in vitro. Viability of MM cell lines and patient-derived MM cells were analyzed by flow cytometry after 7AAD staining. MM cell lines possessing CD38 positive and negative fraction were sorted according to the CD38 expression using CD38 Micro-Beads. CD38 low MM cell lines were treated with All-trans retinoic acid(ATRA)to increase surface CD38 expression. Intracellular NAD and NADH concentrations in

MM cells were analyzed using NAD / NADH assay kit. Detection of apoptosis in MM cell lines were examined by Annexin V and PI staining followed by flow cytometry analysis. Caspase inhibitor, Z-VAD-FMK, was used in combination with 78c to study the mechanism of 78c induced MM cell death. Results. 78c induced cell death in MM cell lines at low concentrations (IC<inf>50</inf> 10-20 muM). Addition of 78c to patient derived bone marrow cells showed cytotoxicity to MM cells, while toxicity to non-MM cells were limited. CD38 positive fraction of MM cell lines had better sensitivity to 78c compared to CD38 negative fraction. CD38 induction by ATRA in CD38 low MM cell lines showed increased sensitivity to 78c. These results proved that 78c efficacy correlates with surface CD38 expression. Comparison of intracellular NAD and NADH concentrations between CD38 positive and negative fractions of MM cell lines demonstrated a significant increase of NAD in the CD38 negative fraction compared to their positive counterparts, indicating that CD38 is indeed controlling the intracellular NAD concentration. Marked increase of NAD / NADH ratio was observed in 78c treated MM cell lines compared to control, proving that CD38 NADase inhibition affects intracellular NAD concentration in MM cells (Fig. 1). 78c treatment of MM cell lines significantly reduced the number of viable cells in the Annexin- / PI- region, however, addition of Z-VAD-FMK did not lead to recovery of viable cell numbers, indicating non-apototic cell death induction by CD38 NADase inhibition. Conclusions. CD38 is the major NADase in mammalian tissues, and involved in catabolism of NAD. CD38 NADase inhibitor, 78c, inhibited the growth of MM cells at low concentrations. 78c induced cell death was found to be highly specific to MM cells and its cytotoxic effect was associated with surface CD38 expression of MM cells. Increased amount of NAD in MM cells by 78c treatment suggests that NAD elevation is associated with MM cell death induced by CD38 NADase inhibition. Since, daratumumab has limited effect against CD38 NADase activity, modulation of intracellular NAD levels by CD38 NADase inhibition could provide a novel therapeutic strategy for MM (Fig. 2). (Figure Presented).

Kusmartsev, S., et al. (2014). "Human macrophages facilitate kidney stone clearances." Journal of Urology **1)**: e271.

INTRODUCTION AND OBJECTIVES: Kidney stones affect one of eleven Americans, costing 10 billion dollars yearly to treat. Renal macrophages play a critical role to maintain healthy, functional kidneys. In this report, we investigate macrophage phagocytic and inflammatory responses to natural stones as well as to inorganic crystals- calcium oxalate (CaOx) and calcium phosphate (CaP) crystals. METHOD(S): Human buffy coats were purchased from Life South Community Blood Center. The peripheral blood mononuclear cells were collected by histopaque-1077 and monocytes were purified using CD14 Miltenyi Biotec magnetic microbeads. Monocytes were differentiated into macrophages with macrophage colony-stimulating factor over a 7-day period. Macrophages were treated with crushed natural stones from human donors and synthetically produced CaOx and CaP crystals. Untreated macrophages were used as controls. Macrophage phagocytosis and morphological changes were observed in x200 and x400 field with a light microscope. Thirty-one Chemokine and thirty-six Cytokine protein levels in the cell supernatant were measured with R&D Proteome Profiler Human Array kits at 24 hours. RESULT(S): Within 24 hours, natural stones and both crystal types were surrounded by macrophages (A, B). Between 24 and 48 hours, small stones/crystals were visibly being phagocytized by the macrophages leading to their gradual destruction (C, arrows) while larger stones/crystals were more resistant to the macrophagemediated destruction. Macrophages that phagocytized stones/crystals displayed dark spots, indicative of mineral uptake (D). CCL2, CCL22, and MIP-1a/b were upregulated in macrophages exposed to all three stone types. Natural stone and CaOx crystals increased

C5/C5a, IL-1ra, and IL-8 within supernatant, but these signaling proteins were decreased in response to CaP crystals compared to controls. CONCLUSION(S): Human macrophages are capable of phagocytizing and eroding naturally-produced kidney stones. Composition of the stone appears to play a role in chemokine and cytokine production. The present study suggests that macrophages play an important role in clearing stones and initiating an immune response.(Figure Presented).

Kusunoki, T. and T. Kobayashi (2010). "Molecular imprinting micropolymerbeads having cooperative effect of both surfactant and inosine template." Journal of Applied Polymer Science **117**(1): 565-571.

Molecular imprinted polymer (MIP) microbeads were prepared by emulsion copolymerization of divinylbenzene (DVB) and methacrylic acid (MAA) in the presence of inosine (INO) template and laurylbenzenesulfonic acid (LBSA) as surfactant. The polymerization was carried out at 55 degree C under ultrasound exposure. The resulting copolymer microbeads, having 0.1-0.4 mu m diameter, were observed to have a binding behavior of INO and surfactant to the polymer which was strongly dependent of the bulk pH; for example, at pH 3, 6, and 10 values of binding for INO to the imprinted copolymer were 3.7 mu mol/g, 2.1 mu mol/g, and 0 mu mol/g, respectively. It was found that LBSA surfactant bound to the MIP microbeads similarly depending on pHs. At pH 3, 6, and 10, the LBSA values of binding were 23 mu mol/g, 1.3 mu mol/g, and 4.8 mu mol/g. It was also noted that the surfactant binding was enhanced in the presence of the INO template. This demonstrated that a cooperative binding with the surfactant was cooperatively occurred in the presence of INO. [copy 2010 Wiley Periodicals, Inc. J Appl Polym Sci, 2010

Kvaratskhelia, E., et al. (2017). "Alteration in the Cytokine Secretion Pattern in T Cells of Patients with Cystic Fibrosis Caused by DNA Methyltransferase Inhibitor 5-Azacitidine." Georgian Medical News(272): 153-157.

Cystic fibrosis (CF) is the autosomal-recessive disorder caused by mutation in the cystic fibrosis transmembrane conductance regulator gene (CFTR). The Airway inflammation plays a central role in the progression of CF disease. Cystic fibrosis characterized by the overproduction of the pro-inflammatory cytokines and reduced expression of anti-inflammatory cytokines. Although the mechanisms of abnormal cytokine expression is still poorly understood, altered epigenetic regulations in T cells might contribute. In the present study we examined the expression of IFN-gamma and IL-10 by CF T cells prior to and following 5-azaC treatment. In addition we investigated DNMTs levels in nuclear extracts of CD4+ T cells derived from CF and non-CF individuals. Seven CF patients (age: 5-12 years) were included in the study and compared to six age-matched healthy subjects (age: 6- 13 years). CD4+ T cells were isolated from PBMC using CD4 MicroBead kit (Miltenyi Biotec GmbH) and were cultured in RPMI 1640 medium at 37degreeC with 5% CO2, in presence or absence of 5-azacytidine. Concentrations of IL-10 and gamma-INF in CD4+ T Cells were measured by ELISA (eBoiscience, san Diego, CA, USA). In our study we showed that 5 Azacytidine alters nuclear levels of DNMT 3a as well as modulates cytokine levels in CD4+ T cells derived from CF patients. After 5-azaC treatment secretion of IFN-gamma was significantly decreased in CF T cells, while amount of IL-10 was elevated by ~2.5 times compared to untreated controls (P<0.05). In summary, data presented in this report demonstrates that epigenetic mechanisms such as DNA methylation may be considered as a one of the potential therapeutic target in a treatment of Cystic Fibrosis.

Kwak, N. S., et al. (2012). "The synthesis of poly(vinylphosphonic acid-co-methacrylic acid) microbeads by suspension polymerization and the characterization of their indium adsorption properties." Journal of Hazardous Materials **203-204**: 213-220.

Poly(vinylphosphonic acid-co-methacrylic acid) microbeads were synthesized by suspension polymerization, and their indium adsorption properties were investigated. The obtained microbeads were characterized by Fourier transform infrared (FT-IR) spectroscopy and scanning electron microscopy (SEM). The microbeads were wrinkled spheres, irrespective of the components, and their sizes ranged from 100 to 200 mum. The microbeads were thermally stable up to 260degreeC. As the vinylphosphonic acid (VPA) content was increased, the synthetic yields and ion-exchange capacities decreased and the water uptakes increased. The optimum synthetic yield, ion-exchange capacity and water uptake were obtained at a 0.5 mol ratio of VPA. In addition, the maximum adsorption predicted by the Langmuir adsorption isotherm model was greatest at a 0.5 mol ratio of VPA.

Kwan, C. S., et al. (2014). "Historical occurrences of polybrominated diphenyl ethers and polychlorinated biphenyls in Manila Bay, Philippines, and in the upper Gulf of Thailand." Science of the Total Environment **470-471**: 427-437.

Historical trends of the accumulation of polybrominated diphenyl ethers (PBDEs) and polychlorinated biphenyls (PCBs) in a typical tropical Asian environment were investigated using radio-dated sediment cores from Manila Bay, the Philippines and from the upper Gulf of Thailand. Vertical profiles indicated earlier usage of PCBs than of PBDEs which coincided with their industrial production. The increasing concentrations of total PBDEs and PCBs toward the surface suggested an increased consumption of PBDEs; and possible leakage of PCBs from old machineries into the aquatic environment in recent years. Current input of PCBs to the catchment of Manila Bay was supported by the analyses of air samples and plastic resin pellets. The vertical profiles of total PBDEs in the cores (i.e., rapidly increasing concentrations corresponding to the mid-1980s until mid-1990s, followed by a decrease until the early 2000s, and increasing again toward the surface) likely corresponded to the rapid economic growth in Asia in the 1990s, the Asian financial crisis in 1997, and the economic recovery since early 2000s. BDE-209 was predominant especially on the surface layers. BDEs 47 and 99 generally decreased toward the surface, reflecting the phase-out of the technical penta-PBDE products and the regulation by the Stockholm Convention in recent years. Increasing ratios of BDE-202/209, 206/209, 207/209 and decreasing % of BDE-209 down the core layers may provide evidence for the anaerobic debromination of BDE-209 in the sediment cores. Inventories in ng/cm(2) of total PCBs were higher than total PBDEs (92 vs. 34 and 47 vs. 11 in the Philippines; 47 vs. 33 in Thailand). However, the doubling times indicated faster accumulation of total PBDEs (6-7 years) and BDE-209 (6-7.5 years) than of PCBs (8-11 years). Furthermore, the temporal increase in BDE-209 was comparable to or faster than those reported in other water bodies around the world.

Kwon, B., et al. (2017). "Monitoring of styrene oligomers as indicators of polystyrene plastic pollution in the North-West Pacific Ocean." Chemosphere **180**: 500-505.

Styrene oligomers (SOs) as global contaminants are an environmental concern. However, little is known on the distribution of SOs in the ocean. Here, we show the distribution of anthropogenic SOs generated from discarded polystyrene (PS) plastic monitored from the coastal ocean surface waters (horizontal distribution) and deep seawaters (vertical distribution) in the North-West Pacific Ocean. SOs concentrations in surface seawater and deep seawater ranged from 0.17 to 4.26 micro g L⁻¹ (total mean: 1.48+or-1.23 micro g L⁻¹) and from 0.31 to 4.31 micro g L⁻¹ (total mean: 1.32+or-0.87 micro g L⁻¹), respectively. Since there is no significant difference in the mean concentrations, SOs seems to be spread across marine environment selected in this study. Nevertheless, regional SOs appears

to persist to varying degrees with their broad horizontal and vertical distribution in the ocean. Each horizontal and vertical distribution of SOs differs by approximately 1.95-2.57 times, probably depending on the events of weather and global ocean circulation. These results provide the distribution pattern of SOs for assessing environmental pollution arising from PS plastic.

Kwon, B. and K. Moon (2019). "Physicochemical properties of styrene oligomers in the environment." Science of the Total Environment **683**: 216-220.

Currently, styrene oligomers (SOs) are persistent contaminants that are present in the environment globally. SOs are artificial substances originating from styrene-based polymer materials, mainly including PS plastic, resin, and rubber. However, the behavior of SOs in the environment is not well-understood yet due to the scarcity of experimental data. The objective of this study was to use in-silico tool to estimate key physicochemical properties of these SOs. The US EPA EPI suite program was used to predict SOs' physicochemical properties including solubility, vapor pressure, LogKow, Henry's constant, LogKoc, and fugacity-based multimedia mass balance. Although styrene monomer (SM) and SOs have structural similarity, the physicochemical properties of SOs are significantly different from those of SM, a precursor of SOs. In particular, it is estimated that as much as the heavy molecular weight, most SOs persist for comparable periods of time in a sandy environment. Although there is uncertainty, this preliminary in-silico study provides a sufficient reason to assure an experimental study to better determine properties of SOs.

Kwon, B. G., et al. (2018). "Qualitative assessment to determine internal and external factors influencing the origin of styrene oligomers pollution by polystyrene plastic in coastal marine environments." Environmental Pollution **234**: 167-173.

The objective of this study is to investigate the qualitative contribution of internal and external factors of the area contaminated by polystyrene (PS) in coastal marine environments. This study is based on the extensive results of monitoring the styrene oligomers (SOs) present in sand and seawater samples along various coastlines of the Pacific Ocean. Here, anthropogenic SOs is derived from PS during manufacture and use, and can provide clues about the origin of SOs by PS pollution. The monitoring results showed that, if the concentration of SOs in water is higher than those concentrations in beach sand, this area could be affected by PS plastic caused by an external factor. On the other hand, if the concentration of SOs is higher in the beach sand, the region can be mainly influenced by PS plastic derived from its own area. Unlike the case of an external factor, in this case (internal influence), it is possible to take policy measures of the area itself for the PS plastic problem. Thus, this study is motivated by the need of policy measures to establish a specific alternative to the problems of PS plastic pollution in ocean environments.

Kwon, B. G., et al. (2015). "Global styrene oligomers monitoring as new chemical contamination from polystyrene plastic marine pollution." Journal of Hazardous Materials **300**: 359-367.

Polystyrene (PS) plastic marine pollution is an environmental concern. However, a reliable and objective assessment of the scope of this problem, which can lead to persistent organic contaminants, has yet to be performed. Here, we show that anthropogenic styrene oligomers (SOs), a possible indicator of PS pollution in the ocean, are found globally at concentrations that are higher than those expected based on the stability of PS. SOs appear to persist to varying degrees in the seawater and sand samples collected from beaches around the world. The most persistent forms are styrene monomer, styrene dimer, and styrene trimer. Sand samples from beaches, which are commonly recreation sites, are particularly polluted with these high SOs concentrations. This finding is of interest from both scientific and public perspectives because SOs may pose potential long-term risks to the environment in combination with other endocrine disrupting chemicals. From SOs monitoring results, this study proposes a flow diagram for SOs leaching from PS cycle. Using this flow diagram, we conclude that SOs are global contaminants in sandy beaches around the world due to their broad spatial distribution.

Kwon, H., et al. (2017). "DNA as an environmental sensor: detection and identification of pesticide contaminants in water with fluorescent nucleobases." Organic & Biomolecular Chemistry **15**(8): 1801-1809.

Environmental contaminants pose a substantial health risk in many areas of the world. One of these risks is contamination of water with toxic organic species, such as herbicides and insecticides. Here we describe the discovery and properties of a set of fluorescent chemosensors that respond to micromolar concentrations of a broad range of common organic pesticides. The chemosensors are short DNA-like oligomers with fluorophores replacing DNA bases that are assembled via a DNA synthesizer. We screened a library of 1296 tetrameric compounds on polystyrene microbeads, and identified a set of chemosensor sequences that respond strongly to a set of structurally varied pesticide analytes. We show that ten chemosensors on beads can be used to detect and identify 14 different common pesticides at 100 muM, using the pattern of fluorescence intensity and wavelength changes. Limits of detection for two analytes were as low as 2 muM. The chemosensors are shown to function successfully in a practical setting, correctly identifying unknown pesticide contaminants in water from Felt Lake, California. The results establish a simple, low cost strategy for sensing environmental spills of toxic organics.

Kwon, H., et al. (2015). "Pattern-based detection of anion pollutants in water with DNA polyfluorophores." Chemical Science **6**(4): 2575-2583.

Many existing irrigation, industrial and chemical storage sites are currently introducing hazardous anions into groundwater, making the monitoring of such sites a high priority. Detecting and quantifying anions in water samples typically requires complex instrumentation, adding cost and delaying analysis. Here we address these challenges by development of an optical molecular method to detect and discriminate a broad range of anionic contaminants with DNA-based fluorescent sensors. A library of 1296 tetrameric-length oligodeoxyfluorosides (ODFs) composed of metal ligand and fluorescence modulating monomers was constructed with a DNA synthesizer on PEG-polystyrene microbeads. These oligomers on beads were incubated with Y super(III) or Zn super(II) ions to provide affinity and responsiveness to anions. Seventeen anions were screened with the library under an epifluorescence microscope, ultimately yielding eight chemosensors that could discriminate 250 mu M solutions of all 17 anions in buffered water using their patterns of response. This sensor set was able to identify two unknown anion samples from ten closely-responding anions and could also function quantitatively, determining unknown concentrations of anions such as cyanide (as low as 1 mM) and selenate (as low as 50 mu M). Further studies with calibration curves established detection limits of selected anions including thiocyanate (detection limit similar to 300 mu M) and arsenate (similar to 800 mu M). The results demonstrate DNA-like fluorescent chemosensors as versatile tools for optically analyzing environmentally hazardous anions in aqueous environments.

Kwon, J.-H., et al. (2017). "Microplastics as a vector of hydrophobic contaminants: Importance of hydrophobic additives." Integrated Environmental Assessment & Management **13**(3): 494-499.

ABSTRACT Despite a recent boom in research on the environmental fate, distribution, and

harmful effects of chemical substances associated with marine plastic debris, no consensus has been reached on whether chemicals originating from microplastics cause serious environmental harm. For the risk assessment of chemical contaminants associated with microplastics, it would be useful to group organic chemicals into 2 categories: additives and nonadditives. Whereas plastic particles are not likely to be diffuse sources of chemicals that are not intentionally added to plastic products, continuous leaching of additives would result in higher concentrations, at least at a local scale. Unlike plasticizers and flame retardants, which have been relatively well investigated, antioxidants and photostabilizers have been rarely studied, even though many of them are highly hydrophobic and are not readily biodegradable. More research on the fate and effects of chemicals via microplastics should focus on those additives. Integr Environ Assess Manag 2017;13:494-499. © 2017 SETAC [ABSTRACT FROM AUTHOR]

Kyrikou, I. and D. Briassoulis (2007). "Biodegradation of Agricultural Plastic Films: A Critical Review." Journal of Polymers & the Environment **15**(2): 125-150.

The growing use of plastics in agriculture has enabled farmers to increase their crop production. One major drawback of most polymers used in agriculture is the problem with their disposal, following their useful life-time. Non-degradable polymers, being resistive to degradation (depending on the polymer, additives, conditions etc) tend to accumulate as plastic waste, creating a serious problem of plastic waste management. In cases such plastic waste ends-up in landfills or it is buried in soil, questions are raised about their possible effects on the environment, whether they biodegrade at all, and if they do, what is the rate of (bio?)degradation and what effect the products of (bio?)degradation have on the environment, including the effects of the additives used. Possible degradation of agricultural plastic waste should not result in contamination of the soil and pollution of the environment (including aesthetic pollution or problems with the agricultural products safety). Ideally, a degradable polymer should be fully biodegradable leaving no harmful substances in the environment. Most experts and acceptable standards define a fully biodegradable polymer as a polymer that is completely converted by microorganisms to carbon dioxide, water, mineral and biomass, with no negative environmental impact or ecotoxicity. However, part of the ongoing debate concerns the question of what is an acceptable period of time for the biodegradation to occur and how this is measured. Many polymers that are claimed to be ‘biodegradable’ are in fact ‘bioerodable’, ‘hydrobiodegradable’, ‘photodegradable’, controlled degradable or just partially biodegradable. This review paper attempts to delineate the definition of degradability of polymers used in agriculture. Emphasis is placed on the controversial issues regarding biodegradability of some of these polymers. [ABSTRACT FROM AUTHOR]

Kyun-Woo, L., et al. (2013). "Size-Dependent Effects of Micro Polystyrene Particles in the Marine Copepod Tigriopus japonicus." Environmental Science & Technology **47**(19): 11278-11283.

We investigated the effects of three sizes of polystyrene (PS) microbeads (0.05, 0.5, and 6-µm diameter) on the survival, development, and fecundity of the copepod Tigriopus japonicus using acute and chronic toxicity tests. T. japonicus ingested and egested all three sizes of PS beads used and exhibited no selective feeding when phytoplankton were added. The copepods (nauplius and adult females) survived all sizes of PS beads and the various concentrations tested in the acute toxicity test for 96 h. In the two-generation chronic toxicity test, 0.05-µm PS beads at a concentration greater than 12.5 µg/mL caused the mortality of nauplii and copepodites in the F0 generation and even triggered mortality at a concentration of 1.25 µg/mL in the next generation. In the 0.5-µm PS bead treatment, despite there being no significant effect on the F0 generation, the highest concentration (25 µg/mL) induced a significant decrease in survival compared with the control population in the F1 generation. The 6-µm PS beads did not affect the survival of T. japonicus over two generations. The 0.5- and 6-µm PS beads caused a significant decrease in fecundity at all concentrations. These results suggest that microplastics such as micro- or nanosized PS beads may have negative impacts on marine copepods. [ABSTRACT FROM AUTHOR]

La Monica, G., et al. (2014). "TCR stimulation up-regulates the expression of klotho mRNA in T cells." Transplantation **1)**: 316.

Background:There has been an increasing awareness of the role of Fibroblast growth factor 23(FGF23) in mineral metabolism and in chronic kidney disease(CKD). FGF23 mediates its functions through FGF receptors and the co-receptor Klotho. Klotho is known to participate in aging-related phenomena, but data on possible participation of Klotho in the immune cell functions are fragmentary. To investigate the role of FGF23 signaling in human lymphocytes, we analyzed FGF23 receptor and Klotho expression following T and B cell stimulation. Method(s):PBMC were isolated from healthy volunteers and CD4+CD25- T cells and CD19+ B cells were selected using magnetic microbeads. CD4+CD25- T cells were cultured with alphaCD3/CD28 microbeads while CD19+B cells were cultured with anti-IgM, anti-CD40, IL-21 (BCR/CD40-stimulation) for 24, 48 and 72h. A variety of parameters of T and B cells activity including proliferation and activation, were monitored by flow cytometry. RNA expression of Klotho, FGF23 and FGF23R1 were analyzed by RT-PCR. Result(s):At mRNA level, FGF23 was not expressed in resting T or B cells, FGF23R1 was expressed in both. Klotho was up-regulated in T cells only, even as early as 24h after TCR activation and the level of expression increased over time up to 72h, but it was completely absent in B cells subsets. The expression of Klotho closely correlated with the proliferation of T cells and activation markers CD25, CD69, CD44 on stimulated T cells. Adding recombinant FGF23 at different doses (0.01, 0.1, 1, 10, 100 and 1000ng/ml) in the T and B cell cultures, showed that the proliferation of T cells at 24, 48, 72h decreased at high doses of FGF23 (10 to 1000ng/ml) with no evidence of increased T cell death. Conclusion(s):These data indicate that Klotho is up-regulated in T cells upon stimulation but it is completely absent in B cells. FGF23 at high doses decreased T cell proliferation, suggesting a potential inhibitory role for Klotho in human T cells. (Figure Presented).

La Seta Catamancio, S., et al. (2015). "Automated manufacturing process for the production of genetically modified lymphocytes using the CliniMACS Prodigyc platform." Human Gene Therapy **26 (10)**: A36.

MM-TK is a medicinal product constituted of T lymphocytes engineered ex vivo with the retroviral vector (RVV) SFCMM-3 Mut2 #48 to express a mutated form of the Herpes Simplex Virus Thymidine kinase (HSV-TK Mut2) and a truncated form of the human Low affinity Nerve Growth Factor Receptor (DLNGFR) genes. It was developed as adjunctive therapy in leukaemia patients undergoing stem cell transplantation, to promote immune reconstitution and to control viral infections and disease relapses. In order to optimize the cellular manufacturing process, MolMed have strengthened an alliance with Miltenyi Biotec for tailoring of CliniMACS Prodigy platform. A closed and automated process was developed with a specific software designed to manufacture a robust, safe and consistent product. The manufacturing process consists in PBMC stimulation, RVV transduction in RetroNectin-coated bags and immunoselection of transduced cells by CD271-LS Microbeads reagent. Selected cells are then further expanded before final formulation in freezing medium. Four development full-scale runs demonstrated that cell processing can be performed in the closed-automated-system. Good results were achieved for all inprocess parameters evaluated (cell recovery and viability, total process yield), for quality attributes (product and process related impurities), and potency (DLNGFR expression, ganciclovir sensitivity, Vector Copy Number; immunophenotype for identity, activation and sub-populations markers) of the final product. A formal process GMP validation is ongoing. These results will support discussion with Regulatory Authorities for the introduction of this new process in the late phase of the ongoing clinical study and for the market.

La Seta Catamancio, S., et al. (2015). "Automated manufacturing process for the production of genetically modified lymphocytes." Molecular Therapy **1)**: S183-S184.

The MM-TK is a medicinal product constituted of T lymphocytes ex vivo genetically modified with the gamma retroviral vector SFCMM-3 Mut2 #48 to express a mutated form of the Herpes Simplex Virus Thymidine kinase (HSV-TK Mut2) and a truncated form of the human Low affinity Nerve Growth Factor Receptor (DELTALNGFR) genes. It has development as adjunctive therapy in leukaemia patients or undergone bone marrow transplantation. The current manufacturing process is performed following semi-automated procedure using instrument and tubing set not marketing compliant. In order to optimize this and to standardize cellular therapeutic production for clinical trial and for the market, MolMed have strengthened an alliance with Miltenyi Biotec for tailoring of CliniMACS Prodigy platform for MM-TK DS manufacturing. A closed and automated cell process was developed using the new device with a specific software designed in order to manufacture a robust, safe and consistent product. The manufacturing process essentially consists in the stimulation of a large number of PBMCs (about 3x109 cells) isolated from an haploidentical donor, with anti-CD3 monoclonal antibody and IL-2, transduction of the stimulated cells with the SFCMM-3 Mut2 #48 retroviral vector in RetroNectin coated bags and immunoselection of positively transduced cells using the CD271-LS Microbeads reagent (Miltenyi Biotec). Selected TK cells are then further expanded for 7 days before final formulation in freezing medium. The whole manufacturing process lasts 13 days. The following steps have been automated: cell concentration and cell washing at different manipulation steps and immunomagnetic selection of the transduced cells. Four development full-scale runs demonstrate that automated cell processing for the genetic manipulation of T lymphocytes can be performed in the closed- and automated-system designed by MolMed, reaching good results for all in-process parameters evaluated: cell recovery of 80-90%; cell viability more than 80% at each step; total process yield of 72%. The DS/DP product has been evaluated for the quality attributes as product and process related impurities (CD14% + CD16% + CD19% and residual retronectin, residual anti-CD3, residual CD271 microbeads) and potency of the product (DELTALNGFR expression; sensitivity to Ganciclovir; Vector Copy Number; immunophenotype as CD3%, CD4%, CD8%, CD45%, CD25, CD69, , HLA-DR, CD95; CD45RA and CD62L). The results will support the discussion with Regulatory Autorities and permit the introduction of the new optimized closed manufacturing process in the late phase of the clinical trial and for the market.

Laban, S., et al. (2018). "Cancer-specific antibodies to self-antigens and HPV-16 E6 in recurrent and non-recurrent head and neck squamous cell carcinoma patients." Oncology Research and Treatment **41 (Supplement 1)**: 96.

Purpose: We have previously shown that the expression of cancer-testis antigens is associated with shorter survival in head and neck squamous cell carcinoma (HNSCC) patients. Here we present serologic immune- monitoring data for cancer-specific antibodies in patients with or without recurrence during follow-up. Method(s): Serum or plasma samples from the biobank of the Head & Neck Cancer Center Ulm (117 patients) were analyzed to determine the sero-prevalence of antigen reactivity in non-recurrent (NR) patients (pt) and in recurrent disease (RD). Samples were analyzed by multiplex serology for antibodies to 20 tumor-specific self-antigens, 9 oncogenes, to HPV-16 E6 and to polyomavirus BKV and JCV VP1 capsid protein as positive control antigens. Median fluorescence intensity (MFI) of microbead- bound human immunoglobulins was determined using a Luminex platform. Result(s): Antibody reactivity to >=1 antigen was detected in 70/95 NR pt and in 21/22 RD pt. Sero-positivity against MAGE-A3, -A4, NY-ESO-1, SpanXa1, cmyc and HPV16 E6 was found in >=10% of NR pt. In RD pt, antibodies against MAGE-A1, -A3, -A4, Recoverin, N-Rhodopsin, SpanXa1, cmyc, Histone H2B and p53 were found in >=10% of pt. In most patients with recurrence-free follow-up, antibody reactivities stayed stable or decreased over time. In contrast, in many recurrent patients, increased reactivity was found at the time of recurrence. Conclusion(s): Overall sero-positivity to self-antigens and HPV-16 E6, as well as patterns of antigen sero-positivity differed between NR and RD pt. Multiplex serology may be useful for individual risk assessment and the monitoring for disease recurrence during follow-up. Data analysis and the analysis of a validation cohort is ongoing.

Lacerda, A., et al. (2019). "Plastics in sea surface waters around the Antarctic Peninsula." Scientific Reports **9**(1): 3977.

Although marine plastic pollution has been the focus of several studies, there are still many gaps in our understanding of the concentrations, characteristics and impacts of plastics in the oceans. This study aimed to quantify and characterize plastic debris in oceanic surface waters of the Antarctic Peninsula. Sampling was done through surface trawls, and mean debris concentration was estimated at 1,794 items.km⁻² with an average weight of 27.8 g.km⁻². No statistical difference was found between the amount of mesoplastics (46%) and microplastics (54%). We found hard and flexible fragments, spheres and lines, in nine colors, composed mostly of polyurethane, polyamide, and polyethylene. An oceanographic dispersal model showed that, for at least seven years, sampled plastics likely did not originate from latitudes lower than 58degreeS. Analysis of epiplastic community diversity revealed bacteria, microalgae, and invertebrate groups adhered to debris. Paint fragments were present at all sampling stations and were approximately 30 times more abundant than plastics. Although paint particles were not included in plastic concentration estimates, we highlight that they could

have similar impacts as marine plastics. We call for urgent action to avoid and mitigate plastic and paint fragment inputs to the Southern Ocean.

Lachenmeier, D. W., et al. (2015). "Microplastic identification in German beer - an artefact of laboratory contamination?" Deutsche Lebensmittel Rundschau **111**(10): 437-440.

Recent studies have detected microplastic fibres and particles in some food groups including honey and beer. The aim of this work was to replicate a method for microplastic analysis in beer. Several methodological pitfalls were detected in the literature method, including the staining agent rose bengal used in microscopic analysis, which false-negatively excludes some synthetic agents including the beer filtration aid polyvinylpolypyrrolidone (PVPP). False positive results may occur for non-plastic compounds such as starch or kieselgur. Other pitfalls in the analysis include the considerable background contamination, which did not allow differentiation between beer samples from blank samples in our laboratory. Specialized cleanrooms are required, but even then contamination may occur, because cleanroom classifications focus on small particles and may exclude the relevant sizes of microplastic particles. We judge the previous nonvalidated literature methods that reported positive findings in foods as unsuitable for the purpose of microplastic identification and believe that the results were artefacts due to contamination. Especially because beer production includes a microfiltration step to remove yeast cells, microplastic contamination due to raw materials is highly unlikely. So far, a validated methodology for microplastic detection in foods or beverages is unavailable.

Ladewig, S. M., et al. (2015). "Natural Fibers: A Missing Link to Chemical Pollution Dispersion in Aquatic Environments." Environmental Science & Technology **49**(21): 12609-12610.

Lagarda-Leyva, E. A., et al. (2019). "Managing plastic waste from agriculture through reverse logistics and dynamic modeling." Clean Technologies & Environmental Policy **21**(7): 1415-1432.

Agrofood companies in the region of southern Sonora, Mexico, including those in Valle del Yaqui, employ agrochemical products (insecticides, herbicides, fertilizers, adhesives, fungicides) in the production of foods and face the problem of plastic waste management, specifically from the empty containers and packages from the different products used. This paper proposes a reverse logistics model in the tomato supply chain to economically and environmentally assess the collection process and final disposal of the empty agrochemical packages using dynamic hypotheses and scenario assessment. The challenge in the proposal was to create a dynamic model to observe the current behavior with special attention to environmental pollution and its effects on the health of the communities with the greatest exposure. The results show that this proposal is viable following these stages: (1) analysis of the product supply chain; (2) characterization of the production process; (3) preparation of the causal diagram and dynamic hypotheses; (4) construction of the Forrester diagram and equations; (5) simulation and sensitivity analysis; and (6) design of the user interface. The application of the proposed model supports decision making in the organization regarding the use of containers of discarded agrochemicals, with the aim of reducing their environmental impact. [ABSTRACT FROM AUTHOR]

Lagarde, F., et al. (2016). "Microplastic interactions with freshwater microalgae: Hetero-aggregation and changes in plastic density appear strongly dependent on polymer type." Environmental Pollution **215**: 331-339.

In this study, the interactions between microplastics, chosen among the most widely used in industry such as polypropylene (PP) and high-density polyethylene (HDPE), and a model freshwater microalgae, Chlamydomas reinhardtii , were investigated. It was shown that the presence of high concentrations of microplastics with size >400 µm did not directly impact the growth of microalgae in the first days of contact and that the expression of three genes involved in the stress response was not modified after 78 days. In parallel, a similar colonization was observed for the two polymers. However, after 20 days of contact, in the case of PP only, hetero-aggregates constituted of microalgae, microplastics and exopolysaccharides were formed. An estimation of the hetero-aggregates composition was approximately 50% of PP fragments and 50% of microalgae, which led to a final density close to 1.2. Such hetero-aggregates appear as an important pathway for the vertical transport of PP microplastics from the water surface to sediment. Moreover, after more than 70 days of contact with microplastics, the microalgae genes involved in the sugar biosynthesis pathways were strongly over-expressed compared to control conditions. The levels of over-expression were higher in the case of HDPE than in PP condition. This work presents the first evidence that depending on their chemical nature, microplastics will follow different fates in the environment. [ABSTRACT FROM AUTHOR]

Laglbauer, B. J. L., et al. (2014). "Macrodebris and microplastics from beaches in Slovenia." Marine Pollution Bulletin **89**(1/2): 356-366.

The amount of marine debris in the environment is increasing worldwide, which results in an array of negative effects to biota. This study provides the first account of macrodebris on the beach and microplastics in the sediment (shoreline and infralittoral) in relation to tourism activities in Slovenia. The study assessed the quality and quantity of macrodebris and the quality, size and quantity of microplastics at six beaches, contrasting those under the influences of tourism and those that were not. Beach cleanliness was estimated using the Clean Coast Index. Tourism did not seem to have an effect on macrodebris or microplastic quantity at beaches. Over 64% of macrodebris was plastic, and microplastics were ubiquitous, which calls for classification of plastics as hazardous materials. Standard measures for marine debris assessment are needed, especially in the form of an all-encompassing debris index. Recommendations for future assessments are provided for the Adriatic region.

Lahens, L., et al. (2018). "Macroplastic and microplastic contamination assessment of a tropical river (Saigon River, Vietnam) transversed by a developing megacity." Environmental Pollution **236**: 661-671.

Both macroplastic and microplastic contamination levels were assessed for the first time in a tropical river estuary system, i.e. the Saigon River, that traverses a developing South East Asian megacity, i.e. Ho Chi Minh City, Vietnam. The analysis of floating debris collected daily on the Nhieu Loc - Thi Nghe canal by the municipal waste management service shows that the plastic

mass percentage represents 11-43%, and the land-based plastic debris entering the river was estimated from 0.96 to 19.91g inhabitant⁻¹ d⁻¹, namely 350 to 7270g inhabitant⁻¹ yr⁻¹. Microplastics were assessed in the Saigon River and in four urban canals by sampling bulk water for anthropogenic fiber analysis and 300mum mesh size plankton net exposition for fragment analysis. Fibers and fragments are highly concentrated in this system, respectively 172,000 to 519,000 items m⁻³ and 10 to 223 items m⁻³. They were found in various colors and shapes with smallest size and surface classes being predominant. The macroplastics and fragments were mainly made of polyethylene and polypropylene while the anthropogenic fibers were mainly made of polyester. The relation between macroplastic and microplastic concentrations, waste management, population density and water treatment are further discussed.

Lahive, E., et al. (2019). "Microplastic particles reduce reproduction in the terrestrial worm Enchytraeus crypticus in a soil exposure." Environmental Pollution **255**(Part 2).

Terrestrial environments are subject to extensive pollution by plastics and, based on the slow degradation of plastics, are likely to act as long term sinks for microplastic debris. Currently the hazards of microplastics in soil and the potential impacts on soil organisms is poorly understood. Particularly the role of particle characteristics, such a size or polymer type, in dose-response relationships for microplastics is not known. The aim of this study was to assess the ingestion and toxicity of nylon (polyamide) particles, in three different size ranges, to Enchytraeus crypticus in a soil exposure. Effects were also compared with those of polyvinyl chloride (PVC) particles, in a single size range. Nylon particle ingestion was confirmed using fluorescence microscopy, with greatest ingestion for particles in the smallest size range (13-18 micro m). To investigate how particle size affected survival and reproduction, E. crypticus were exposed to nylon particles in two well-defined size ranges (13-18 and 90-150 micro m) and concentrations of 20, 50, 90 and 120 g/kg (2-12% w/w). An intermediate nylon size range (63-90 micro m) and a larger sized PVC particle (106-150 micro m), both at 90 g/kg, were also tested. Survival was not affected by either of the polymer types or sizes. Reproduction was significantly reduced, in a dose-dependent manner, by the nylon particles at high exposure concentrations (>90 g/kg). Smaller size ranges (13-18 micro m) had a greater effect compared to larger size ranges (>63 micro m), with a calculated EC₅₀ for the 13-18 micro m size range of 108+or-8.5 g/kg. This greater hazard could be qualitatively linked with the ingestion of a greater number of smaller particles. This study highlights the potential for toxic effects of plastics in small size ranges to soil organisms at high exposure concentrations, providing understanding of the hazards microplastics may pose in the terrestrial environment.

Lai, Y. H., et al. (2019). "Nutritional optimization of Arthrospira platensis for starch and Total carbohydrates production." Biotechnology Progress **35**(3): e2798.

Present study aims to optimize the production of starch and total carbohydrates from Arthrospira platensis. Growing concerns toward unprecedented environmental issues associated with plastic pollution has created a tremendous impetus to develop new biomaterials for the production of bioplastic. Starch-based biopolymers from algae serve as sustainable feedstock for thermoplastic starch production due to their abundant availability and low cost. A. platensis was cultivated in Zarrouk's medium at 32 +/- 1degreeC and exposed to red light with a photoperiod of 12:12 hr light/dark. Growth kinetics studies showed that the maximum specific growth rate (mu_{max}) obtained was 0.059 day⁻¹ with the doubling time (t_d) of 11.748 days. Subsequently, Zarrouk's medium with different concentrations of sulfur, phosphorus and nitrogen was prepared to establish the nutrient-limiting conditions to

enhance the accumulation of starch and total carbohydrates. In this study, the highest starch accumulated was 6.406 +/- 0.622 mg L⁻¹ under optimized phosphorus limitation (0.025 g L⁻¹) conditions. Nitrogen limitation (0.250 g L⁻¹) results demonstrated significant influenced (p < 0.05) on total carbohydrates (67.573 +/- 2.893 mg L⁻¹) accumulation in A. platensis. The starch accumulation in A. platensis was significantly affected (p < 0.05) by phosphorus limitation (0.0025 g L⁻¹). Subsequently, the optimized phosphorus concentration was coupled with mixotrophic cultivation to further enhance the starch accumulation. The results obtained indicated that, the starch (11.426 +/- 0.314 mg L⁻¹) and carbohydrates (43.053 +/- 2.986 mg L⁻¹) concentration obtained was significantly high (p < 0.05) under mixotrophic cultivation. Therefore, it shown that nutrient limitation and mixotrophic cultivation are viable strategies to enhance the accumulation of starch and total carbohydrates in A. platensis.

Laina, E. (2018). "Expert Group Identifies Barriers and Response Options on Marine Litter and Microplastics." Environmental Policy & Law **48**(3/4): 168-171.

The article offers information on the first meeting of the Ad Hoc Open-ended Expert Group on Marine Litter and Microplastics held from May 29–31, 2018 in Nairobi, Kenya, under the United Nations Environment Programme (UNEP). Topics discussed include environmental, social and economic costs of marine litter and microplastics; plastic-to-energy strategies, uncoordinated clean-up efforts and consequences of unplanned transitions to green development; and need to address consumer use of plastics.

Laitala, K., et al. (2018). "Does Use Matter? Comparison of Environmental Impacts of Clothing Based on Fiber Type." Sustainability **10**(7): 2524.

Several tools have been developed to compare the environmental impact of textiles. The most widely used are Higg Materials Sustainability Index (MSI) and MADE-BY Fiber Benchmark. They use data from production to evaluate the environmental impacts of textiles differentiated by fiber type. The use phase is excluded from both tools. This article discusses whether there is evidence that the use of textiles differs systematically between different fiber types and examines the consequences of comparing the environmental impacts of clothing based on differences in production of fibers alone without including differences in their use. The empirical material in this paper is based on analysis of rating tools and a literature review on clothing use. It shows that fiber content contributes to the way consumers take care of and use their clothing. When use is omitted, major environmental problems associated with this stage, such as spread of microplastics, are also excluded. This one-sided focus on material production impacts also excludes the importance of product lifespans, quality, and functionality. The consequence is that short-lived disposable products are equated with durable products. Comparing dissimilar garments will not help consumers to make choices that will reduce the environmental burden of clothing. We need an informed discussion on how to use all materials in the most environmentally sustainable way possible.

Lakew, M., et al. (1997). "Combined immunomagnetic cell sorting and ELISPOT assay for the phenotypic characterization of specific antibody-forming cells." Journal of Immunological Methods **203**(2): 193-198.

A combination of immunomagnetic cell sorting and ELISPOT (enzyme-linked immunospot) techniques were evaluated to permit enrichment and characterization of antibody-secreting cells (ASC). Cell suspensions containing putative ASC were first incubated with magnetic microbeads coated with antibodies specific for a given cell surface marker. After separation of bead-cell clusters and free cells, the resulting cell populations were examined for the presence of ASC by an ELISPOT assay. As a model system, the expression of selected cell differentiation markers by human circulating ASC was evaluated after parenteral tetanus vaccination and during the course of a Leishmania infection. Prior treatment of blood MNC with beads coated with antibodies to CD38, HLA-DR or CD19 permitted the isolation of virtually all blood ASC. Further, prior immunomagnetic removal of T (CD2⁺) cells from blood MNC, followed by isolation of CD38⁺ cells facilitated the detection of Leishmania major-specific ASC in all 6 patients examined, whereas parasite-specific ASC among unfractionated blood mononuclear cells could only be detected in 3 of these 6 patients. This simple and rapid approach provides accurate estimates of the frequency of ASC within a given B cell population or subpopulation, and can efficiently enrich functional ASC from complex cell suspensions. It should be particularly useful in situations where ASC are present at low frequencies.

Lalegul, O., et al. (2012). "Encapsulation of human adipose mesenchymal stem cells in fibrin microbeads from platelet rich plasma and their in vitro evaluation." Journal of Tissue Engineering and Regenerative Medicine **1)**: 160.

Platelet-rich plasma (PRP) is identified as autologous blood with a concentration of platelets in high levels. Platelets contain a variety of growth factors and cytokines that are principal in soft tissue healing and bone mineralization. In this study, fibrin microbeads were developed using a novel technique for encapsulating mammalian cells (patent application TR-PT 2012/01068). PRP was obtained from anticoagulated human whole blood samples. Human adipose derived mesenchymal stem cells (hAdMSCs) were isolated from lipoaspirates collected under ethical approval; then cultured and characterized by FACS. Encapsulation protocol was optimised. hAdMSCs-containing PRP-alginate solution was prepared and fibrin microbeads were dropwise formed in CaCl2 solution. Later, alginate was extracted by the calcium chelator sodium citrate. hAdMSC-encapsulated fibrin microbeads were cultured at 5% CO2-95% air and 37 degreeC. Microbeads obtained from PRP and platelet poor plasma were used as controls. SEM analyses were performed to characterize fibrin microbeads. In vitro release of TGF-b1 from fibrin microbeads was examined in cell culture medium by using ELISA kit. Viability of encapsulated hAdMSCs was evaluated by MTT assay. In vitro differentiation properties of encapsulated hAd-MSCs were investigated histologically. In vitro experiments demonstrated that encapsulated hAdMSCs retained viability, proliferated for >6 weeks and retained tri-lineage differentiation property inside fibrin microbeads.

Lalitha, K. (2015). "Work place evaluation of safe biomedical waste management practices in designated microscopy centres(DMC) and tuberculosis unit(TU) under revised national tuberculosis control programme." Indian Journal of Public Health Research and Development **6**(1): 99-102.

Safe biomedical waste management (BMWM) at RNTCP centres is critical for worker and patient safety. Though there are guidelines, wide gap between precept and practice of BMWM exists. Hence this cross sectional study was undertaken in randomly selected 8 DMCs/ TUs of two districts of Bihar state in 2007 to evaluate the infrastructure, resource availability and to identify the constraints and difficulties in effective implementation of guidelines for safe BMWM practices at DMC/TUs.16 Lab technicians and 60 patients on DOTS were interviewed. Main observations were that sharp-pits available in 50%DMCs/TUs; sputum sample not disposed as per guidelines in 50%DMCs/TUs and in 6 DMCs, foot-operated bins and running water supply not available. Plastic waste incinerated at 3 DMC/TUs. All lab-technicians trained in last 6 months but hand washing practices glaringly lacking. Only 25% patients were aware of safe disposal of sputum. Need for emphasis on worker safety among lab technicians and Proper

Patient counseling regarding safe sputum disposal. Copyright © 2015, Indian Journal of Public Health Research and Development. All rights reserved.

Lam, C. S., et al. (2018). "A Comprehensive Analysis of Plastics and Microplastic Legislation Worldwide." Water, Air, and Soil Pollution **229 (11) (no pagination)**(345).

Aquatic or land-based plastic pollution has raised serious concerns for ecosystems, and especially human and animal health worldwide. A variety of legislative instruments were developed to control, reduce, and manage the usage of plastics in day-to-day life to minimize the adverse outcomes brought by sending these plastic to landfill. Existing legislation heavily embraces levies, bans, and voluntary efforts through "reduce and reuse campaigns." Thus, the present review highlights the pros and cons of the existing legislation and its implementation. It also assesses the need for the improvement of plastic legislation to better consider environmental and human health impacts. The paper proposes new efficient management strategies to aid in the development of plastic legislation which prevents increase of plastic pollution worldwide, the potential challenges that would arise from its implementation, and the mechanisms for overcoming these challenges. The paper proposes a conventional management strategy based on the current plastic management and legislation. It aims to improve the feasibility and effectiveness of the implementation of future plastic policies. Copyright © 2018, Springer Nature Switzerland AG.

Lam, L. T. and L. Roberts-Rapp (2014). "Multiplex analysis of anti-apoptotic BCL2 family and caspase 3 activation by microbead arrays." Assay & Drug Development Technologies **12**(3): 190-196.

We have developed a multiplex assay to measure the expression of anti-apoptotic proteins and caspase 3 activation using the Luminex platform. In this report, we show three applications for this assay. First, we used this assay to identify biomarkers for BCL2 inhibitors to obtain a quantitative measure of expression of anti-apoptotic proteins (BCL2, BCLxL, and MCL1) in a panel of cell lines and correlated their response to BCL2/BCLxL inhibitor, ABT-263 (navitoclax). Second, we used this assay to monitor the change of MCL1 protein expression and induction of active caspase 3 after treatment with cyclin-dependent kinase inhibitor flavopiridol. Finally, we used this assay to screen for small molecules that decrease MCL1 protein and identified new combinations with ABT-263. This method provides a quick and convenient way to measure basal expression of the anti-apoptotic proteins and monitor expression change upon drug treatment. It is also applicable for high-throughput screening for compounds that decrease the expression of these anti-apoptotic proteins.

Lam, S. S., et al. (2019). "Microwave vacuum pyrolysis of waste plastic and used cooking oil for simultaneous waste reduction and sustainable energy conversion: Recovery of cleaner liquid fuel and techno-economic analysis." Renewable & Sustainable Energy Reviews **115**: N.PAG-N.PAG.

Microwave vacuum pyrolysis was examined and compared to conventional pyrolysis for its technical and economic feasibility in co-processing of waste plastic and used cooking oil simultaneously to generate fuel product. The pyrolysis demonstrated beneficial process features with respect to high heating rate (29 °C/min) to provide fast heating, high process temperature for extensive cracking (581 °C), short process time (20 min), and low electrical energy consumption (0.38 kWh). The combined use of microwave vacuum pyrolysis and activated carbon reaction bed produced up to 84 wt% yield of liquid oil, containing light hydrocarbons and higher heating value (49 MJ/kg) than diesel and gasoline, hence showing great promise for application as fuel. The use of activated carbon reaction bed showed beneficial effect in creating a reduction environment that prevented the oxidation or formation of oxygenated by-products.

A positive synergistic effect between waste plastic and used cooking oil was also observed. The liquid oil obtained from this pyrolysis approach presented a low oxygen and nitrogen content, and free of sulphur, showing 'cleaner' properties with respect to reduced char residues, sludge formation, corrosiveness, degradation of oil quality, and emission of undesired SOx and NOx during its utilization in combustion process. The techno-economic analysis indicated that this pyrolysis approach showed low production cost (USD 0.25/L compared to USD 0.523/L of diesel price in Malaysia). Our results demonstrate that microwave vacuum pyrolysis is potentially economically feasible and show promise as a sustainable approach for energy conversion in providing improved process features and production of cleaner liquid fuel. Image 1 • Microwave vacuum pyrolysis treats waste plastic and used cooking oil simultaneouly. • It combines microwave heating, activated carbon reaction bed and vacuum condition. • It shows high heating rate, temperature, low process time and electric consumption. • 84 wt% yield of liquid oil with diesel-range hydrocarbons and high energy content. • Cleaner liquid composition (sulphur free, low oxygen and nitrogen) is observed. [ABSTRACT FROM AUTHOR]

Lamb, C. L., et al. (2019). "Enrichment of Antigen-Specific Class-Switched B Cells from Individuals Naturally Immunized by Infection with Group A Streptococcus." Msphere **4**(6): 06.

The low frequency of circulating antigen-specific memory B cells is a considerable obstacle in the discovery and development of human monoclonal antibodies for therapeutic application. Here, we evaluate two solid-phase isolation methods to enrich the number of antigen-specific B cells from individuals naturally immunized against streptolysin O (SLO), a key virulence factor and known immunogen of group A streptococcus (GAS). Class-switched B cells obtained from individuals with a history of GAS infection were separated from peripheral blood mononuclear cells (PBMCs) by immunomagnetic methods. SLO-specific B cells were further enriched directly by binding to SLO monomers and captured by streptavidin-coated magnetic microbeads or indirectly by binding a fluorescently labeled SLO-streptavidin tetramer and captured by anti-fluorophore immunomagnetic microbeads. SLO-bound B cells were quantitated by flow cytometry and/or expanded in batch culture to determine IgG specificity. From individuals who have suffered a GAS infection >=2 years prior, only the direct method enriched SLO-specific B cells, as determined by flow cytometry. Likewise, in batch culture, B cells isolated by the direct method resulted in an average of 375-fold enrichment in anti-SLO IgG, while no enrichment was observed for B cells isolated by the indirect method. The direct method established here provides a simple approach to increase low-frequency antigen-specific B cell populations supporting many downstream applications, such as immortalization of B cells, cloning of immunoglobulin genes, or purification of antibodies from supernatant for future study. Overall, this process is efficient, is inexpensive, and can be applied to many naturally immunogenic antigens. IMPORTANCE Bacteria called group A streptococci can cause a variety of skin and soft tissue infections ranging from mild pharyngitis ("strep throat") to deadly necrotizing fasciitis (sometimes called "flesh-eating" disease). In each case, the development of disease and the degree of tissue damage are mediated by toxins released from the bacteria during infection. Consequently, novel therapies aimed at clearing bacterial toxins are greatly needed. One promising new treatment is the utilization of monoclonal antibodies delivered as an

immunotherapeutic for toxin neutralization. However, current methods of antibody development are laborious and costly. Here, we report a method to enrich and increase the detection of highly desirable antigen-specific memory B cells from individuals previously exposed to GAS using a cost-effective and less-time-intensive strategy. We envision that this method will be incorporated into many applications supporting the development of immunotherapeutics.

Lamb, J. B., et al. (2018). "Plastic waste associated with disease on coral reefs." Science **359**(6374): 460-462.

Plastic waste can promote microbial colonization by pathogens implicated in outbreaks of disease in the ocean. We assessed the influence of plastic waste on disease risk in 124,000 reef-building corals from 159 reefs in the Asia-Pacific region. The likelihood of disease increases from 4% to 89% when corals are in contact with plastic. Structurally complex corals are eight times more likely to be affected by plastic, suggesting that microhabitats for reef-associated organisms and valuable fisheries will be disproportionately affected. Plastic levels on coral reefs correspond to estimates of terrestrial mismanaged plastic waste entering the ocean. We estimate that 11.1 billion plastic items are entangled on coral reefs across the Asia-Pacific and project this number to increase 40% by 2025. Plastic waste management is critical for reducing diseases that threaten ecosystem health and human livelihoods.

Lambert, S., et al. (2014). "Occurrence, degradation, and effect of polymer-based materials in the environment." Reviews of Environmental Contamination & Toxicology **227**: 1-53.

There is now a plethora of polymer-based materials (PBMs) on the market, because of the increasing demand for cheaper consumable goods, and light-weight industrial materials. Each PBM constitutes a mixture of their representative polymer/sand their various chemical additives. The major polymer types are polyethylene, polypropylene,and polyvinyl chloride, with natural rubber and biodegradable polymers becoming increasingly more important. The most important additives are those that are biologically active, because to be effective such chemicals often have properties that make them resistant to photo-degradation and biodegradation. During their lifecycle,PBMs can be released into the environment form a variety of sources. The principal introduction routes being general littering, dumping of unwanted waste materials,migration from landfills and emission during refuse collection. Once in the environment,PBMs are primarily broken down by photo-degradation processes, but due to the complex chemical makeup of PBMs, receiving environments are potentially exposed to a mixture of macro-, meso-, and micro-size polymer fragments, leached additives, and subsequent degradation products. In environments where sunlight is absent (i.e., soils and the deep sea) degradation for most PBMs is minimal .The majority of literature to date that has addressed the environmental contamination or disposition of PBMs has focused on the marine environment. This is because the oceans are identified as the major sink for macro PBMs, where they are known to present a hazard to wildlife via entanglement and ingestion. The published literature has established the occurrence of microplastics in marine environment and beach sediments, but is inadequate as regards contamination of soils and freshwater sediments. The uptake of microplastics for a limited range of aquatic organisms has also been established, but there is a lack of information regarding soil organisms, and the long-term effects of microplastic uptake are also less well understood.There is currently a need to establish appropriate degradation test strategies consistent with realistic environmental conditions, because the complexity of environmental systems is lost when only one process (e.g., hydrolysis) is assessed in isolation. Enhanced methodologies are also needed to evaluate the impact of PBMs to soil and freshwater

environments.

Lambert, S. and M. Wagner (2016). "Characterisation of nanoplastics during the degradation of polystyrene." Chemosphere **145**: 265-268.

The release of plastics into the environment has been identified as an important issue for some time. Recent publications have suggested that the degradation of plastic materials will result in the release of nano-sized plastic particles to the environment. Nanoparticle tracking analysis was applied to characterise the formation of nanoplastics during the degradation of a polystyrene (PS) disposable coffee cup lid. The results clearly show an increase in the formation of nanoplastics over time. After 56 days' exposure the concentration of nanoplastics in the PS sample was 1.26 x 10(8) particles/ml (average particles size 224 nm) compared to 0.41 x 10(8) particles/ml in the control.

Lambert, S. and M. Wagner (2016). "Formation of microscopic particles during the degradation of different polymers." Chemosphere **161**: 510-517.

This study investigated the formation and size distribution of microscopic plastic particles during the degradation of different plastic materials. Particle number concentrations in the size range 30 nm–60 µm were measured by nanoparticle tracking analysis (NTA) and Coulter Counter techniques. Each of the plastics used exhibited a measureable increase in the release of particles into the surrounding solution, with polystyrene (PS) and polylactic acid (PLA) generating the highest particle concentrations. After 112 d, particle concentrations ranged from 2147 particles ml −1 in the control (C) to 92,465 particles ml −1 for PS in the 2–60 µm size class; 1.2 × 10 5 particles ml −1 (C) to 11.6 × 10 6 for PLA in the 0.6–18 µm size class; and 0.2 × 10 8 particles ml −1 (C) to 6.4 × 10 8 particles ml −1 for PS in the 30–2000 nm size class (84 d). A classification of samples based on principal component analysis showed a separation between the different plastic types, with PLA clustering individually in each of the three size classes. In addition, particle size distribution models were used to examine more closely the size distribution data generated by NTA. Overall, the results indicate that at the beginning of plastic weathering processes chain scission at the polymer surface causes many very small particles to be released into the surrounding solution and those concentrations may vary between plastic types. [ABSTRACT FROM AUTHOR]

Lambert, W. S., et al. (2017). "Oral Delivery of a Synthetic Sterol Reduces Axonopathy and Inflammation in a Rodent Model of Glaucoma." Frontiers in Neuroscience **11**: 45.

Glaucoma is a group of optic neuropathies associated with aging and sensitivity to intraocular pressure (IOP). The disease is the leading cause of irreversible blindness worldwide. Early progression in glaucoma involves dysfunction of retinal ganglion cell (RGC) axons, which comprise the optic nerve. Deficits in anterograde transport along RGC axons to central visual structures precede outright degeneration, and preventing these deficits is efficacious at abating subsequent progression. HE3286 is a synthetic sterol derivative that has shown therapeutic promise in models of inflammatory disease and neurodegenerative disease. We examined the efficacy of HE3286 oral delivery in preventing loss of anterograde transport in an inducible

model of glaucoma (microbead occlusion). Adult rats received HE3286 (20 or 100 mg/kg) or vehicle daily via oral gavage for 4 weeks. Microbead occlusion elevated IOP ~30% in all treatment groups, and elevation was not affected by HE3286 treatment. In the vehicle group, elevated IOP reduced anterograde axonal transport to the superior colliculus, the most distal site in the optic projection, by 43% (p = 0.003); HE3286 (100 mg/kg) prevented this reduction (p = 0.025). HE3286 increased brain-derived neurotrophic factor (BDNF) in the optic nerve head and retina, while decreasing inflammatory and pathogenic proteins associated with elevated IOP compared to vehicle treatment. Treatment with HE3286 also increased nuclear localization of the transcription factor NFkappaB in collicular and retinal neurons, but decreased NFkappaB in glial nuclei in the optic nerve head. Thus, HE3286 may have a neuroprotective influence in glaucoma, as well as other chronic neurodegenerations.

Lambert, W. S., et al. (2019). "Towards A Microbead Occlusion Model of Glaucoma for a Non-Human Primate." Scientific Reports **9**(1): 11572.

Glaucoma is a group of optic neuropathies associated with aging and sensitivity to intraocular pressure (IOP). The disease causes vision loss through the degeneration of retinal ganglion cell neurons and their axons in the optic nerve. Using an inducible model of glaucoma, we elevated IOP in the squirrel monkey (Saimiri boliviensis) using intracameral injection of 35 mum polystyrene microbeads and measured common pathogenic outcomes in the optic projection. A 42% elevation in IOP over 28 weeks reduced anterograde transport of fluorescently-labeled cholera toxin beta from retina to the lateral geniculate nucleus (60% decrease), and to the superior colliculus (49% decrease). Pressure also reduced survival of ganglion cellaxons in the optic nerve by 22%. The same elevation caused upregulation of proteins associated with glaucomatous neurodegeneration in the retina and optic nerve, including complement 1q, interleukin 6, and brain-derived neurotrophic factor. That axon degeneration in the nerve lagged deficits in anterograde transport is consistent with progression in rodent models, while the observed protein changes also occur in tissue from human glaucoma patients. Thus, microbead occlusion in a non-human primate with a visual system similar to our own represents an attractive model to investigate neurodegenerative mechanisms and therapeutic interventions for glaucoma.

Lambert, W. S., et al. (2015). "Nanosponge-Mediated Drug Delivery Lowers Intraocular Pressure." Translational Vision Science & Technology **4**(1): 1.

PURPOSE: We examined the efficacy of an extended-release drug delivery system, nanosponge (NS) encapsulated compounds, administered intravitreally to lower intraocular pressure (IOP) in mice.

METHODS: Bilateral ocular hypertension was induced in mice by injecting microbeads into the anterior chamber. Hypertensive mice received NS loaded with ocular hypotensive drugs via intravitreal injection and IOP was monitored. Retinal deposition and retinal ganglion cell (RGC) uptake of Neuro-DiO were examined following intravitreal injection of Neuro-DiO-NS using confocal microscopy.

RESULTS: Brimonidine-loaded NS lowered IOP 12% to 30% for up to 6 days (P < 0.02), whereas travoprost-NS lowered IOP 19% to 29% for up to 4 days (P < 0.02) compared to saline injection. Three bimatoprost NS were tested: a 400-nm NS and two 700-nm NS with amorphous (A-NS) or amorphous/crystalline (AC-NS) crosslinkers. A single injection of 400 nm NS lowered IOP 24% to 33% for up to 17 days compared to saline, while A-NS and AC-NS lowered IOP 22% to 32% and 18% to 26%, respectively, for up to 32 days (P < 0.046). Over time retinal deposition of Neuro-DiO increased from 19% to 71%; Neuro-DiO released from NS was internalized by RGCs.

CONCLUSIONS: A single injection of NS can effectively deliver ocular hypotensive drugs in a linear and continuous manner for up to 32 days. Also, NS may be effective at targeting RGCs, the neurons that degenerate in glaucoma.

TRANSLATIONAL RELEVANCE: Patient compliance is a major issue in glaucoma. The use of NS to deliver a controlled, sustained release of therapeutics could drastically reduce the number of patients that progress to vision loss in this disease.

Lambertini, E., et al. (2012). "Role of slug transcription factor and different cell culture conditions on osteogenic potential of human mesenchymal stem cells." Osteoporosis International **2)**: S413.

Objective(s): In order to develop alternative strategies to induce efficient osteogenic differentiation of human mesenchymal stem cells (hMSCs) for their clinical use in bone tissue repair we aimed to identify i. new transcription factors with crucial role in determining MSC fate, and ii. new static or dynamic 3D culture systems for affecting MSC behaviour. Material(s) and Method(s): We used hMSCs from periodontal ligament (PDL) and umbilical cord Wharton's jelly (WJ) after standard immunophenotyping. We assessed cell viabilty with propidium iodide and Calcein-AM, morphological changes by different microscopic techniques (optical microscopy, SEM, TEM), gene expression by qRT-PCR, immunocytochemistry, and Western blot. Slug gene knockdown was obtained by transfection with siRNA sequence targeting Slug gene transcript. 3D dynamic culture experiments were performed in RCCS bioreactor (Synthecon) with High Aspect Ratio Vessel (HARV) using the cells incapsulated in Ba-alginate microbeads. ALP activity measuring and Alizarin Red S staining were used to monitor osteogenic differentiation after culturing the cells in osteogenic medium. Result(s): We demonstrated that Slug transcription factor expression is essential for osteogenesis. Slug knockdown negatively affects deposition of mineralized matrix, but seems to reprogram the hMSC towards chondrocyte differentiation, by modulating the expression of specific differentiation markers (Runx2, Sox5, Sox6, Sox9, Stat1, Col1 and >Col2) and miRNA-221. Comparing 2D vs 3D culture >conditions we demonstrated that hMSCs osteogenic potential, cell adhesion and interaction, osteoblastic markers expression and deposition of mineralized matrix were improved when alginate-entrapped hMSCs were cultured in the bioreactor. In addition, when Polymeric Micelles (self-assembling colloidal systems) were chosen to deliver in culture medium osteogenic inducers (instead of traditional solubilization with DMSO which is known to be cytotoxic), an increase of osteogenic potential was observed. Conclusion(s): The goal of using new modality for in vitro hMSCs culture and discovering new regulatory signaling pathways for a possible cell phenotype manipulation is to bridge the gap between traditional 2D cell culture and the in vivo setting, with an approach that places cultured hMSCs in an environment that more closely represents the complex 3D structure of native tissue. Therefore, our data add new informations to develop innovative therapeutic strategies for metabolic bone disease and bone regenerative medicine.

Lamblin, A., et al. (2001). "Blood mediated reaction following intraportal islet allograft in pigs. [French]." Annales de Chirurgie **126**(8): 743-750.

Study aim: Intraportal islet allograft appears to be one of the promising treatments for type I diabetes. However, many limiting factors persist. An activation of the coagulation cascade upon contact with islets, has been reported recently in vitro and could play a crucial role in a non specific inflammatory reaction and favour the specific immune reaction. The aim of this experimental study was to confirm in vivo this activation of the coagulation cascade. Material(s) and Method(s): An allogenic islets preparation or a material control (inert microbeads) was injected intraportally, in Large White pigs (n=26), associated with or without an anticoagulant

treatment (heparin). Systemic markers of haemostasis were measured in pigs for 72 hours following injection of the studied material. Result(s): The thrombin-antithrombin complex increased and platelet count decreased in groups receiving preparation of islets, both indicators of an activation of the coagulation cascade. This activation was proportional to the injected volume and was partially attenuated by heparin. No activation was observed in pigs receiving the material control. Conclusion(s): The activation of the coagulation cascade and the non specific inflammatory reaction could be one of the obstacles to the success of the islet allografts. The use of anticoagulant and anti-inflammatory molecules could potentially allow an improvement of the present results of islet allograft. © 2001 Editions scientifiques et medicales Elsevier SAS.

Lambrechts, D., et al. (2013). "Fluorescent oxygen sensitive microbead incorporation for measuring oxygen tension in cell aggregates." Biomaterials **34**(4): 922-929.

Molecular oxygen is a main regulator of various cell functions. Imaging methods designed as screening tools for fast, in situ, 3D and non-interfering measurement of oxygen tension in the cellular microenvironment would serve great purpose in identifying and monitoring this vital and pivotal signalling molecule. We describe the use of dual luminophore oxygen sensitive microbeads to measure absolute oxygen concentrations in cellular aggregates. Stable microbead integration, a prerequisite for their practical application, was ensured by a site-specific delivery method that is based on the interactions between streptavidin and biotin. The spatial stability introduced by this method allowed for long term measurements of oxygen tension without interfering with the cell aggregation process. By making multiple calibration experiments we further demonstrated the potential of these sensors to measure local oxygen tension in optically dense cellular environments.

Lammel, D. R., et al. (2019). "Testing Contrast Agents to Improve Micro Computerized Tomography (µCT) for Spatial Location of Organic Matter and Biological Material in Soil." Frontiers in Environmental Science.

Soil carbon is essential for soil and ecosystem functioning. Its turnover and storage in soil are multifaceted processes that involve microbial activity in complex physical matrices. Biological litter, which include plants, animals and microorganisms, is decomposed in soil stimulating soil biota (archaea, bacteria, fungi, protists and animals) activity and yielding soil organic matter (SOM). Such decomposition processes are influenced by local physico-chemical characteristics including the spatial distribution of aggregates and pores. More refined analytical tools are needed to better understand these processes, especially considering the spatial 3D structure of soil matrices. Using synchrotron radiation (X-ray) micro computerized tomography (SR-µCT), we tested different contrast agents (staining methods) based on silver (Ag), eosin (Br based) and liquid and gaseous iodine (I) in order to spatially image biological material and SOM in soil samples. We also performed K-edge SR-µCT for the Ag and I2 treatments and conventional µCT for additional soil samples applying the I2 treatment. Our results indicated that I2 was the most efficient contrast method for SR-µCT imaging of soil samples. I2 qualitatively improved the images, but mainly, by using the K-edge SR-µCT, this method provided a powerful tool to determine the spatial location of SOM. We acknowledge that the use of SR-µCT is an expensive technique to study soil samples, which comes with bottlenecks in terms of access to facilities and measurement time. Nevertheless, we show that the I2 treatment improved soil images also using standard µCT. In conventional µCT the I2 treatment improved the visualization of biological material and consequently improved the qualitative analysis of fine plants roots and micro-fauna (Collembola). This improvement may have a positive implication in soil biology, by improving a non-destructive method to detect fungi (SR-μCT), soil fauna (conventional μCT) and roots in undisturbed soil samples. An unexpected finding was that the I2 treatment also stained the plastic sample containers (nylon and polyimide), indicating the potential for the I2 staining procedure to be applied for the detection of plastic pollution in soil samples.

Lan, M. l. (2008). "Biomaterials for trellising and mulching in tomato cultivation: efficacy and time saving." PHM Revue Horticole **506**: 14-19.

An on-going trial begun in 2007 at the South Brittany Horticultural Experiment Station on the testing of biodegradable materials (biomaterials) in tomato production is described. Tomato plants of cv. Brazil were planted in April in soil with plastic film mulching in a cold tunnel, with harvesting from June to November. The efficacy of 17 micro m biodegradable Bi-OPL film for mulching, and 2 mm Plantobio string made from paper and Plantobio 20 mm clips for plant training was compared to that of their plastic homologues. The advantages of the biodegradable products included reducing work load at the end of the cropping season, requiring 4 times less work time than traditional plastic products, and there were none of the problems associated with the disposal of plastic waste. Despite the higher prices of the biodegradable products, an economic balance analysis involving costs of supplies and labour showed that plastic and biodegradable products were equally favourable.

Lan, W. J., et al. (2010). "Duplexed on-microbead binding assay for competitive inhibitor of epidermal growth factor receptor by quantitative flow cytometry." Basic & Clinical Pharmacology & Toxicology **107**(1): 560-564.

Upon binding agonist, the epidermal growth factor receptor (EGFR) is dimerized and auto-phosphorylated to activate downstream pathway that induces diverse physiology and pathology processes. Conventional methods for evaluation of EGFR inhibitors are limited. This study describes a duplexed on-microbead binding assay allowing competitive EGFR inhibitors to be quantificationally evaluated in vitro. Polystyrene microbeads barcoded by fluoresceine isothiocyanate fluorescence as high brightness and low brightness microspheres were coated with receptor tyrosine kinase (RTK) ligand-epidermal growth factor (EGF)/stem cell factor (SCF) and ATP/GTP, respectively. High and low brightness microbeads were mixed and incubated with EGFR and its competitive inhibitor in binding assay buffer. Phycoerythrin (PE) fluorescence-labelled antibody was employed to report the level of EGFR binding to EGF/SCF and ATP/GTP. Values were numbered via PE molecules assessed by quantitative flow cytometry.

Lanctôt, C. M., et al. (2018). "Application of nuclear techniques to environmental plastics research." Journal of Environmental Radioactivity **192**: 368-375.

Plastic pollution is ubiquitous in aquatic environments and its potential impacts to wildlife and humans present a growing global concern. Despite recent efforts in understanding environmental impacts associated with plastic pollution, considerable uncertainties still exist regarding the true risks of nano- and micro-sized plastics (<5 mm). The challenges faced in this field largely relate to the methodological and analytical limitations associated with studying plastic debris at low (environmentally relevant) concentrations. The present paper highlights how radiotracing techniques that are commonly applied to trace the fate and behaviour of chemicals and particles in various systems, can contribute towards addressing several important and outstanding questions in environmental plastic pollution research. Specifically, we discuss the use of radiolabeled microplastics and/or chemicals for 1) determining sorption/desorption kinetics of a range of contaminants to different types of plastics under varying conditions, 2) understanding the influence of microplastics on contaminant and nutrient bioaccumulation in

aquatic organisms, and 3) assessing biokinetics, biodistribution, trophic transfer and potential biological impacts of microplastic at realistic concentrations. Radiotracer techniques are uniquely suited for this research because of their sensitivity, accuracy and capacity to measure relevant parameters over time. Obtaining precise and timely information on the fate of plastic particles and co-contaminants in wildlife has widespread applications towards effective monitoring programmes and environmental management strategies.

Lang, P., et al. (2004). "Transplantation of a combination of CD133+ and CD34+ selected progenitor cells from alternative donors." British Journal of Haematology **124**(1): 72-79.

Positive selected haematopoietic stem cells are increasingly used for allogeneic transplantation with the CD34 antigen employed in most separation techniques. However, the recently described pentaspan molecule CD133 appears to be a marker of more primitive haematopoietic progenitors. Here we report our experience with a new CD133-based selection method in 10 paediatric patients with matched unrelated (n = 2) or mismatched-related donors (n = 8). These patients received a combination of stem cells (median = 29.3 x 10(6)/kg), selected with either anti-CD34 or anti-CD133 coated microbeads. The proportion of CD133+ selected cells was gradually increased from patient to patient from 10% to 100%. Comparison of CD133+ and CD34+ separation procedures revealed similar purity and recovery of target populations but a lower depletion of T cells by CD133+ selection (3.7 log vs. 4.1 log, P < 0.001). Both separation procedures produced >90% CD34+/CD133+ double positive target cells. Engraftment occurred in all patients (sustained primary, n = 8; after reconditioning, n = 2). No primary acute graft versus host disease (GvHD) >/= grade II or chronic GvHD was observed. The patients showed a rapid platelet recovery (median time to independence from substitution = 13.5 d), whereas T cell regeneration was variable. Five patients are alive with a median follow-up of 10 months. Our data demonstrates the feasibility of CD133+ selection for transplantation from alternative donors and encourages further trials with total CD133+ separated grafts.

Lang, P., et al. (2016). "Final results of a multicenter phase I/II study using CD3/ CD19 depleted stem cells for haploidentical transplantation in children." Bone Marrow Transplantation **1)**: S463-S464.

Introduction: A total of 163 pediatric patients with ALL, AML/ MDS, CML/JMML (n = 67) relapsed/refractory solid tumors (neuroblastoma, soft tissue sarcomas, n = 68) and nonmalignant diseases (immune deficiencies, hemoglobinopathies) (n = 28) received T and B cell depleted peripheral stem cells from full haplotype mismatched family donors within this phase I/II trial. 34/163 patients received a 2nd or 3rd HSCT. Material (or patients) and methods: AntiCD3/antiCD19 coated magnetic microbeads and the CliniMACSs device were used for graft manipulation. A short course single agent prophylaxis with MMF was given. Patients received either myeloablative TBI or Busulfan based conditioning regimens (n = 26) or a toxicity reduced regimen (Melphalan (140 mg/m²) fludarabine (160 mg/m²) thiotepa (10 mg/kg), n = 131) and serotherapy with ATG-F or OKT3. Result(s): A median number of 15.2x10E6/kg CD34+ progenitors, 77x10E6/kg NK cells and 48x10E3/kg residual T cells were infused. Primary engraftment occurred in 90.8% of patients. In a multivariate analysis, the influence of diagnosis, conditioning regimen, number of infused progenitors/T cells/NK cells and type of serotherapy was investigated. Only diagnosis remained significant. Median time to reach >500 neutrophiles/mul was 10 days. GvHD grade 0-1 occurred in 78%. 16% and 6% had GvHD grade II and III-IV, respectively. Chronic limited and extensive GvHD was observed in 13% and 12%. In an univariate analysis, only use of ATG-F significantly reduced the incidence of aGvHD, whereas the above factors did not. Transplant related mortality was low with 8% at one year. Regeneration of NK cells was very fast (mean number CD56 +/mul at day +90/180: 234/233), whereas T cells recovered slower (mean number CD3+/mul at day +90/180:205/426). Event free survival at 3 years was 41% for patients with acute leukemias CR 1-3 (1st HSCT) and 14% for patients with active disease. Patients with nonmalignant diseases had a favorable EFS at 3 years of 60% whereas patients with solid tumors did worse (25%). Conclusion(s): Transplantation of CD3/CD19 depleted haploidentical stem cells resulted in a robust myeloic engraftment and in a fast recovery of donor NK cells. The method helped to prevent GvHD very effectively and to reduce TRM, despite intensive pretreatment of the patients. Patients with acute leukemias in any CR had a favorable EFS whereas potential anti tumor effects were not sufficient in patients with active disease. Since only short course MMF was used, the method offers a basis for further post-transplant immune therapies.

Lang, P., et al. (2016). "Transplantation of haploidentical CD3/CD19 depleted stem cells in children: Final results of a multicenter phase I/II study." <u>Biology of Blood and Marrow Transplantation</u> **1)**: S62.

A total of 163 pediatric patients with ALL, AML/MDS, CML/JMML (n=67) relapsed/refractory solid tumors (neuroblastoma, soft tissue sarcomas, n=68) and nonmalignant diseases (immune deficiencies, hemoglobinopathies) (n=28) received T and B cell depleted peripheral stem cells from full haplotype mismatched family donors. Thirty-four patients received a 2nd or 3rd HSCT. AntiCD3/antiCD19 coated magnetic microbeads and the CliniMACS device were used for graft manipulation. A short course single agent prophylaxis with MMF was given. Patients received either myeloablative TBI or Busulfan based conditioning regimens (n=26) or a toxicity reduced regimen (Melphalan (140 mg/m²) fludar-abine (160 mg/m²) thiotepa (10mg/kg), n=131) and serotherapy with ATG-F or OKT3. A median number of 15.2x 10E6/kg CD34+ progenitors, 77x 10E6/kg NK cells and 48x 10E3/kg residual T cells were infused. Primary engraft-ment occurred in 90.8% of patients. In a multivariate analysis, the influence of diagnosis, conditioning regimen, number of infused progenitors/T cells/NK cells and type of serotherapy was investigated. Only diagnosis remained significant. Median time to reach >=500 neutrophiles/mul was 10 days. GvHD grade 0-1 occurred in 78%. 16% and 6% had GvHD grade II and III-IV, respectively. Chronic limited and extensive GvHD was observed in 13% and 12%. In an univariate analysis, only use of ATG-F significantly reduced the incidence of aGvHD, whereas the above factors did not. Transplant related mortality was low with 8% at one year. Regeneration of NK cells was very fast (mean number CD56+/mul at day +90/180: 234/233), whereas Tcells recovered slower (mean number CD3+/mul at day +90/180: 205/426). Event free survival (EFS) at 3 years was 41% for patients with acute leukemias CR 1-3 (1stHSCT) and 14% for patients with active disease. Patients with nonmalignant diseases had a favorable EFS at 3 years of 60% whereas patients with solid tumors did worse (25%). Conclusion(s): Transplantation of CD3/CD19 depleted hap-loidentical stem cells resulted in a robust myeloid engraftment and in a fast recovery of donor NK cells. The method helped to prevent GvHD very effectively and to reduce TRM, despite intensive pretreatment of the patients. Patients with acute leukemias in any CR had a favorable EFS whereas potential anti-tumor effects were not sufficient in patients with active disease. Since only short course MMF was used, the method offers a basis for further post-transplant immune therapies.

Lang, P., et al. (2014). "Effects of a new dosing scheme of ATG-F of donor NK cells and immune recovery in haploidentical T and B cell depleted stem cell transplantation." <u>Bone Marrow Transplantation</u> **1)**: S214-S215.

Introduction: T and B cell depletion of haploidentical peripheral stem cells with CD3/CD19 coated magnetic microbeads effectively prevents from GvHD and allows to coinfuse large numbers of donor NK cells and other accessory cells Additional in vivo depletion of the graft with serotherapy is not mandatory. Thus, a dosing scheme of ATG is needed, which provides a rejection prophylaxis by depleting lymphocyte subsets of the patients but which does not harm the stem cell graft. We present data with reduced ATG doses given at the beginning of the conditioning regimen in order not to impair cotransfused NK cells and immune recovery. Materials (or patients) and Methods: A total of 33 pediatric patients received 3x10 mg/kg ATG-F (Fresenius) starting at day -12, followed by fludarabine (160 mg/m², d -8 to -5), thiotepa (10 mg/m² d -4) and melphalan (140 mg/m² d -3 to -2). Most patients received MMF untill day 30-60. ATG serum levels were measured in 19 patients by flow cytometry (amount of ATG binding to the Jurkat cell line, defined as T cell specific rabbit IgG). Apoptosis/ necrosis of donor NK cells was assessed with Annexin V/PI staining and flow cytometry. Result(s): Median time to ANC>500 and to independence from platelet transfusion was 9.5 and 13.5 days. Graft rejection occurred in 7/33 patients (21%). All rejectors could be rescued with reconditioning and 2nd stem cell donation or with infusion of autologous back ups. Acute GvHD grade I and II-IV was observed in 12/26 (46%) and 2/26 (8%) patients without rejection, respectively. Limited (extensive) chronic GvHD occurred in 5/24 (1/24) evaluable patients. Median peak levels of 22.1 mug/ml specific rabbit IgG were reached between day -8 and -6 and dropped to 2.9 mug/ml at day 0. In vitro incubation of NK cells from healthy donors with a comparable dosage of ATG-F (1 mug/ml) resulted in 26 % apoptosis and 0.2 % necrosis (70% vital cells) after 24 hours. Moreover, NK cells were incubated with patient's serum, taken after ATG treatment and adjusted to a concentration of 1 or 2 mug/ml. Cell death occurred in 20% of NK cells each. Functional activity was measured against K562 targets. Specific lysis of decreased from 83% to 71% (corresponding to a loss of 15% activity) after incubation with 2mug/ml and to 11% (87% loss of activity) with 1000mug/ml. Immune recovery was monitored and compared with a historical group receiving OKT3 and the same chemotherapy (n=34). Recovery of CD56+ NK cells was fast with a mean number of 414 vs. 232 cells/mul (ATG group vs. OKT3 group, P<0.01) at day +14, 252 vs. 342 cells/mul at day +30 (P=0.1) and 189 vs. 217 cells/mul at day +90 (P=0.3). CD3+ T cells reached 36 vs. 12/mul at day +30 and 189 vs. 225/mul at day +90 (no significant differences for all data pairs). Discussion(s): Conclusion(s): ATG-F was started at an early time point, resulting in low serum levels of specific ATG at day 0 and in a fast NK cell recovery. In vitro results suggested, that the majority of NK cells will not be damaged herewith. Immune recovery of T and NK cells was comparable to that of a historical control group who received OKT3. However. The rejection rate was higher than expected and an increase of the ATG dose has to be considered. This approach will be also of interest for other transplantation strategies in which various components of the grafts and additionally given T cells have to be preserved.

Lang, P., et al. (2013). "Transplantation of TcRalphabeta/CD19 depleted stem cells from haploidentical donors in children: Current results." Blood. Conference: 55th Annual Meeting of the American Society of Hematology, ASH **122**(21).

Graphic T-cell depletion of the graft is an effective method to prevent or completely avoid Graft-versus-Host Disease (GvHD) in haploidentical stem cell transplantation. In order to increase the T-cell depletion efficacy while maintaining the anti-tumor and anti-infectious properties of the graft, we have investigated a new T-cell depletion method which removes alphabeta+ T-lymphocytes via a biotinylated anti-TcRalphabeta antibody followed by an anti-biotin antibody conjugated to magnetic microbeads while retaining gammadelta+ T-lymphocytes, Natural killer (NK) cells and other cells in the graft. In addition, CD19+ B-lymphocytes were concomitantly depleted for the prevention of posttransplant EBV-associated lymphoproliferative disease. The CliniMACS system was used for manipulation of peripheral stem cell grafts from full haplotype mismatched family donors in 35 patients. Results The overall depletion of alphabeta+ T-cells was highly effective with 4.6 log (range 3.8-5.0). Patients received a median number of only 14 x 103/kg residual alphabeta+ T-cells. Recovery of CD34+ stem cells was 72%, and the median number of infused CD34+ stem cells was 12 x 106/kg (range 5-38 x 106/kg). Additionally, the patients received 2 types of potential antileukemic effector cells: 107 x 106/kg (range 35 -192 x 106/kg) CD56+ NK-cells and 11 x 106/kg (range 5-30 x 106/kg) gammadelta+ T-lymphocytes. Diagnoses were ALL (n=20), AML/MDS/JMML (n=9), nonmalignant diseases (n=4), solid tumors (n=2); disease status: CR2-CR6 (n=17), active disease (n=18). 23 patients received a second or third SCT (65%). A toxicity reduced conditioning regimen (fludarabin 40mg/m² or clofarabin 50mg/m² (day -8 to d -5), thiotepa 10mg/kg (d -4), melphalan 70mg/m² (d -3 and d -2) was used. The anti CD3 specific OKT3 antibody was used as rejection prophylaxis from day -8 to day -1 without affecting cotransfused effector cells because of its short half-life period in the first 7 patients. However, due to its restricted availability, the substance was substituted since 2011 by a reduced ATG-F dose (15mg/kg) given at start of the conditioning regimen in order not to impair NK and gammadelta+ T-cells of the grafts (1 mg/kg d -12, 4 mg/kg d -11, 5 mg/kg d -10 and -9; n=28 patients). Short course MMF (until day +30) was given in 25 patients. Graft rejection occurred in 14% of the patients. However, after reconditioning and second stem cell donation, final engraftment was achieved in all patients. The median time to reach neutrophil and platelet recovery in patients with primary engraftment was 10 and 11 days respectively. All patients showed a rapid immune reconstitution with 250 (OKT3 conditioning) and 273 (ATG conditioning) CD3+ T-cells/mul, 30 (OKT3) and 47 (ATG) CD3+4+/mul and 300 (OKT3) and 382 (ATG) CD56+ NK-cells/mul at day +30 posttransplant. gammadelta+ T-cells started to expand faster than alphabeta+ T-cells in the early post-transplant period (156 vs. 82 cells/mul at day +30) whereas at day +90, alphabeta+ T-cells were predominant (170 vs. 134 cells/mul). Acute GvHD grade 0-I occurred in 25 patients (71%); 6 patients had GvHD II (17%), 3 patients had GvHD III (9%) and one patients experienced GvHD grade IV (3%). 3 patients experienced chronic GvHD (8%). Incidence of acute GvHD was not influenced by the number of residual T cells or by the type of serotherapy. 1 year EFS for patients with acute leukemias was 66% (any CR) and 14% (active disease).TRM at 1 year was 20%. Conclusions These data indicate that transplantation of TcR alphabeta+/CD19 depleted cells from a haploidentical donor results in sustained engraftment, remarkably fast immune reconstitution and low incidence of both acute and chronic GvHD. OKT3 could be substituted by ATG without negative effects. The anti-leukemic efficacy of this approach in comparison to other methods of T-cell depletion needs to be evaluated with a longer patient follow-up.

Lang, P., et al. (2014). "Current results with transplantation of tcrab/CD19 depleted stem cells from haploidentical donors in children." Bone Marrow Transplantation **1)**: S377.

Introduction: T-cell depletion is an effective method to prevent Graft-versus-Host Disease (GvHD) in haploidentical stem cell transplantation. Materials (or patients) and Methods: In order to increase T-cell depletion efficacy while maintaining anti-tumor and anti-infectious activity of the graft, we have evaluated a new method which removes alphabeta+ T-cells via a biotinylated anti-TcRalphabeta antibody followed by an anti-biotin antibody conjugated to magnetic microbeads while retaining gammadelta+ T-cells, Natural killer (NK) cells and others. CD19+ B-cells were concomitantly depleted to prevent EBV-LPD. The CliniMACS system was used for manipulation of PBSCs from full haplotype mismatched family donors. Result(s): The overall depletion of alphabeta+ T-cells was highly effective with 4.6 log. Patients received a median number of only 14 x 10³/ kg residual alphabeta+ T-cells. Recovery of CD34+ stem cells was 72%, and the median number of infused CD34+ stem cells was 12x106/kg. Additionally, the patients received potential antileukemic effector cells: 107x106/kg CD56+ NK cells and 11x106/kg gammadelta+ T-cells. Diagnoses: ALL (n=20), AML/MDS/JMML (n=9), nonmalignant diseases (n=4), solid tumors (n=2); disease status: CR2-CR6 (n=17), active disease (n=11, 45%). 23 patients received a 2nd/3rd SCT (65%). The conditioning regimen comprised fludarabin 40mg/m² or clofarabin 50mg/m² (day -8 to d -5), thiotepa 10mg/kg (d -4), melphalan 70mg/m² (d -3 and d -2). OKT3 was used as rejection prophylaxis from day -8 to day -1 in the first 7 patients and was substituted since 2011 by a reduced ATG-F dose (15mg/kg) given at start of the regimen in order not to impair NK and gammadelta+ T-cells of the grafts (1 mg/kg d -12, 4 mg/kg d -11, 5 mg/kg d -10 and -9; n=28 patients). Short course MMF (until day +30) was given in 25 patients. Graft rejection occurred in 14% of the patients. However, after reconditioning and second stem cell donation, final engraftment was achieved in all patients. Median time to reach neutrophil and platelet recovery in patients with primary engraftment was 10 and 11 days respectively. All patients showed a rapid immune reconstitution with 250 (OKT3 conditioning) and 273 (ATG conditioning) CD3+ T-cells/mul 30 (OKT3) and 47 (ATG) CD3+4+/mul and 300 (OKT3) and 382 (ATG) CD56+ NK-cells/mul at day +30 posttransplant. gammadelta+ T-cells started to expand faster than alphabeta+ T-cells in the early post-transplant period (156 vs 82 cells/mul at day +30) whereas at day +90, alphabeta+ T-cells were predominant (170 vs 134 cells/mul). Acute GvHD grade 0-I occurred in 25 patients (71%); 6 patients had GvHD II (17%), 3 patients had GvHD III (9%) and one patients experienced GvHD grade IV (3%). 3 patients experienced chronic GvHD (8%). Incidence of acute GvHD was not influenced by the number of residual T cells or by type of serotherapy. 2 year EFS was: 80% (nonmalignant diseases); 37% and 9% (acute leukemias, any CR and active disease). Patients with any CR and 1st SCT showed better results than patients with subsequent SCT (100% vs 30%). Discussion(s): These data indicate that transplantation of TcR alphabeta+/ CD19 depleted cells from a haploidentical donor results in fast immune reconstitution and low incidence of both acute and chronic GvHD. OKT3 could be substituted by ATG without negative effects. The anti-leukemic efficacy of this approach in comparison to other methods of T-cell depletion needs to be evaluated with a longer patient follow-up.

Lang, P., et al. (2015). "Improved immune recovery after transplantation of TCRalphabeta/CD19-depleted allografts from haploidentical donors in pediatric patients." Bone Marrow Transplantation **50 Suppl 2**: S6-10.

Immune recovery was retrospectively analyzed in a cohort of 41 patients with acute leukemia, myelodysplastic syndrome and nonmalignant diseases, who received alphabeta T- and B-cell-depleted allografts from haploidentical family donors. Conditioning regimens consisted of fludarabine or clofarabine, thiotepa, melphalan and serotherapy with OKT3 or ATG-Fresenius. Graft manipulation was carried out with anti-TCRalphabeta and anti-CD19 Abs and immunomagnetic microbeads. The gammadelta T cells and natural killer cells remained in the grafts. Primary engraftment occurred in 88%, acute GvHD (aGvHD) grades II and III-IV occurred in 10% and 15%, respectively. Immune recovery data were available in 26 patients and comparable after OKT3 (n=7) or ATG-F (n=19). Median time to reach >100 CD3+ cells/muL, >200 CD19+ cells/muL and >200 CD56+ cells/muL for the whole group was 13, 127 and 12.5 days, respectively. Compared with a historical control group of patients with CD34+ selected grafts, significantly higher cell numbers were found for CD3+ at days +30 and +90 (267 vs 27 and 397 vs 163 cells/muL), for CD3+4+ at day +30 (58 vs 11 cells/muL) and for CD56+ at day +14 (622 vs 27 cells/muL). The clinical impact of this accelerated immune recovery will be evaluated in an ongoing prospective multicenter trial.

Lang, P., et al. (2014). "Improved immune recovery after transplantation of TCRalphabeta/CD19 depleted allografts from haploidentical donors in pediatric patients." Blood. Conference: 56th Annual Meeting of the American Society of Hematology, ASH **124**(21).

Transplantation of haploidentical stem cells has become an accepted option for pediatric patients and adults with high risk malignancies who lack a matched related or unrelated donor. In recent years, the majority of pediatric transplant centers chose the CD34 positive selection of peripheral stem cells, which allowed minimizing GvHD by effective reduction of T cells in the graft. However, infectious complications caused by delayed immune recovery were a major reason for transplant related mortality (TRM). In order to improve the immune recovery, we have established a new T-cell depletion method which removes alphabeta+ T-lymphocytes via a biotinylated anti-TcRalphabeta antibody followed by an anti-biotin antibody conjugated to magnetic microbeads while retaining gammadelta+ T-lymphocytes, natural killer (NK) cells and other cells in the graft. In addition, CD19+ B-lymphocytes were concomitantly depleted for the prevention of post-transplant EBV-associated lymphoproliferative disease. Immune recovery was retrospectively analyzed in a cohort of 41 patients with acute leukemia, MDS and non-malignant diseases, who received alphabeta T and B cell depleted allografts from haploidentical family donors. Conditioning regimens consisted of fludarabine or clofarabine, thiotepa, melphalan and serotherapy with OKT3 or ATG-Fresenius. Graft manipulation was carried out with anti TCRalphabeta and anti CD19 antibodies and immunomagnetic microbeads. gammadelta T cells and NK cells remained in the grafts. Primary engraftment occurred in 88%, acute graft versus host disease (aGvHD) grade II and III-IV occurred in 10% and 15%. Immune recovery data were available in 26 patients and comparable after OKT3 (n=7) or ATG-F (n=19). Median time to reach > 100 CD3+/mul, > 200 CD19+ cells/mul and > 200 CD56+ cells/mul for the whole group was 13, 127 and 12.5 days. Compared to a historical control group of patients with CD34 positive selected grafts, significantly higher cell numbers were found for CD3+ at days +30 and +90 (267 vs. 27 and 397 vs. 163 cells/mul), for CD3+4+ at day +30 (58 vs. 11 cells/mul) and for CD56+ at day +14 (622 vs. 27 cells/mul). The clinical impact of this accelerated immune recovery will be evaluated in an ongoing prospective multi-center trial.

Lang, P., et al. (2012). "A new dosing scheme of ATG-f prevents rejection and maintains immune recovery in haploidentical t and b cell depleted stem cell transplantation." Blood. Conference: 54th Annual Meeting of the American Society of Hematology, ASH **120**(21).

T and B cell depletion of haploidentical peripheral stem cells with CD3/CD19 coated magnetic microbeads prevents GvHD and allows to coinfuse large numbers of donor NK cells and other accessory cells. The anti CD3 specific OKT3 antibody was routinely used as rejection prophylaxis without affecting CD3 negative cells. However, due to its restricted availability, the substance had to be substituted by polyclonal ATG preparations with a longer half life period and comprising a broader variety of antigen, with the CD56 antigen in particular. We present data with reduced ATG doses given at the beginning of the conditioning regimen in order not to impair cotransfused NK cells and immune recovery. A total of 27 pediatric patients (ALL/AML n=9, relapsed solid tumors n=13, nonmalignant diseases n=5) received either 3x5 mg/kg (n=7) or 3x10 mg/kg (n=20) ATG-F (Fresenius) starting at day -12, followed by fludarabine (160 mg/m², d -8 to -5) thiotepa (10 mg/m² d -4) and melphalan (140 mg/m² d -3 to -2). A median number of 14.4x106 CD34/kg and 62x106 NK cells/kg with 37x103 T cells/kg were infused. Median time to ANC>500 was 9 days in both groups. Graft rejection occurred in 3/7 patients with 15 mg ATG (42%) and in 2/20 patients with 30 mg ATG (10%). After reconditioning with a TLI based regimen, final engraftment was achieved in all patients. Acute GvHD grade II-IV was observed in 1/4 (15 mg) and 1/18 (6%, 30 mg) patients without rejection. Extensive chronic GvHD occurred in 1/4 (15 mg group) and 1/18 (30 mg group) patients. Immune recovery was monitored in the 30 mg group and compared with a historical group receiving OKT3 and the same chemotherapy (n=34). Recovery of CD56+ NK cells was fast with a mean number of 473 vs. 230 cells/mul at day +14, 299 vs. 281 cells/mul at day +30 and 245 vs. 236 cells/mul at day +90. CD3+ T cells reached 12 vs. 16/mul at day +30 and 138 vs. 217/mul at day +90 (30 mg group vs. OKT3 group; no significant differences for all data pairs). ATG serum levels were measured in 9 patients by flow cytometry (amount of ATG binding to the Jurkat cell line, defined as T cell specific rabbit IgG). Median peak levels of 10.5 mug/ml (15 mg group) and 15.0 mug/ml (30 mg group) specific rabbit IgG were reached between day -8 and -6 and dropped to 1.2 and 2.6 mug/ml at day 0. In vitro incubation of NK cells from healthy donors with a comparable dosage of ATG-F (1 or 10 mug/ml) resulted in 26 (41)% apoptosis and 0.2 (0.2)% necrosis (70 (52)% vital cells) after 24 hours. Conclusion(s): Our aim was to substitute OKT3 by ATG in patients who receive CD3/19 depleted haploidentical peripheral stem cells without hampering donor NK cells infused on day 0 and subsequent immune recovery. Administration of 15 or 30 mg/kg ATG-F was started at an early time point (day -12) of the regimen. Both doses resulted in low serum levels of specific ATG at day 0 and in a fast NK cell recovery. In vitro results suggested, that the majority of NK cells will not be damaged herewith. However, 15 mg/kg seemed to be not effective in preventing graft rejection and use of 30 mg/kg ATG-F has to be recommended. Immune recovery of T and NK cells was comparable to that of a historical control group who received OKT3. This approach will be also of interest for other transplantation strategies in which various components of the grafts and additionally given Tregs or specific T cells have to be preserved.

Lang, P., et al. (2004). "Long-term outcome after haploidentical stem cell transplantation in children." Blood Cells Molecules & Diseases **33**(3): 281-287.

We present an update of our results with transplantation of highly purified stem cells from one to three loci mismatched parental donors. Sixty-three pediatric patients with acute lymphoblastic leukemias (n = 32), acute myeloid, chronic myeloid and myelomonocytic leukemias (n = 13), myelodysplastic syndromes (n = 4), lymphomas (n = 4), and various nonmalignant diseases (n = 10) underwent transplantation. Mobilized peripheral-blood stem cells were selected with either anti-CD34- or anti-CD133-coated microbeads. Patients received a median of 19.5 x 10(6) purified cells and <25,000 CD3+ T lymphocytes per kilogram, with no regular posttransplant pharmacological immunosuppression. Engraftment occurred in 98% of patients (primary sustained engraftment, 83%; engraftment after reconditioning/stem cell boosts, 15%). Moreover, all survivors but one had a stable three-lineage engraftment with a median follow up of 4.1 years (range 0.6-8 years). Primary acute graft-versus-host disease (GvHD) grade II was seen in only 7% of patients. No severe primary acute GvHD grades III-IV occurred. Thirteen percent of the patients developed transient chronic GvHD. Probability of disease-free survival (DFS) at 3 years was 60% for patients with nonmalignant diseases and 48% for patients with acute lymphatic leukemia (ALL)/non-Hodgkin lymphoma (NHL) in complete remission (CR)1-3. None of the ALL/NHL patients with active disease survived. Children with acute and chronic myeloid leukemias had a poorer outcome (3-year DFS = 18%), whereas two of four patients with myelodysplastic syndrome (MDS) are alive. Relapse probability of the whole group was not significantly increased when compared to a historical control group. The incidence of lethal viral infections was 18% between 1995 and 2002 and has since been reduced to 8% by the introduction of new therapeutic strategies. In summary, the use of stem cells from haploidentical parental donors should be strongly considered in all children who need transplantation but lack an identical donor.

Lang, P., et al. (2010). "Long-term survival and relapse rate after transplantation of highly T and B cell-depleted stem cells from alternative donors in paediatric patients with acute lymphatic leukaemia." Bone Marrow Transplantation **2)**: S72.

We present long term results in 68 children with ALL who received highly T and B cell depleted stem cells from matched unrelated (n = 17) or full haplotype mismatched related donors (n = 51) at our institution. Our aim was to minimize GvHD and to avoid EBV LPD in both matched and mismatched transplantations. Remission status was: CR1, n = 18; CR2, n = 23; >=CR3, n = 12; non remission or second transplant, n = 15. Graft manipulation was carried out with microbeads and the CliniMACS^{TM} device (indirect depletion of T and B cells with CD34 + positive selection (n = 50); or direct depletion with anti-CD3/anti-CD19 coated microbeads (n = 18)). T and B cell counts were reduced for 4-5 log with median numbers of residual T cells of 15 000/kg bw (CD34 + selection) and 49 000/kg bw (CD3/19 depletion). No pharmacological immune suppression was given after positive selection, whereas patients with CD3/19 depletion received MMF. The conditioning regimens were either TBI or Bu based (n = 50) or a toxicity reduced protocol (Flud, TT, Mel) was used (n = 18). Rejection prophylaxis was carried out with ATG or OKT3. Primary engraftment occurred in 85%. After reconditioning, final engraftment was achieved in 98%. GvHD grade 0-1 occurred in 86%. 12% had grade II, 4% had grade III. Chronic GvHD occurred in 4 patients. No GvHD related mortality was observed. Median follow up was 5.9 years. EFS at 1 year was 56% (CR1), 51% (CR2) and 50% (>=CR3); EFS at 5 years was 49% (CR1), 46% (CR2) and 27% (>=CR3). Median survival of patients with active disease was 0.2 years. Relapse rates at 1 year were 0.32 (CR1), 0.47 (CR2) and 0.46 (>=CR3); relapse rates at 5 years were 0.32 (CR1), 0.47 (CR2) and 0.64 (>=CR3). TRM at 1 year was 14%, causes of death remained viral and fungal infections, no EBV LPD occurred. Conclusion(s): positive selection of progenitor cells or depletion of T and B cells can minimize acute and chronic GVHD in both matched unrelated and mismatched related transplantations and may prevent GvHD related mortality. Lethal infections occurred in 14% of the patients probably due to the delayed recovery of T cells. Despite profound depletion of donor T cells, relapse rates were acceptable and remained on a stable level after the first year in patients with complete remission. Thus, absence of GvHD may not necessarily be associated with high relapse rates in childhood ALL. Apart from T cells, other effector cells like NK cells are likely to exert GvL effects and may contribute to the favorable EFS of our patients.

Lang, P., et al. (2011). "Role of IL15 stimulation of CD3/19 depleted transplants from haplo-identical donors in paediatric malignancies." Bone Marrow Transplantation **1)**: S136.

T and B cell depleted haploidentical grafts and a melphalan based intensity reduced regimen result in low toxicity and stable survival in patients with leukemias in CR. However, patients with active disease or second transplantation show unacceptable relapse rates. In an ongoing study, 36 pediatric patients with acute leukemias and advanced MDS received melphalan, fludarabine or clofarabine, thiotepa and OKT3. T and B cells were depleted by antiCD3/antiCD19 coated magnetic microbeads, whereas NK cells remained into the grafts. Remission status was: CR1-3=18, NR=18, 18/36 already had received previous allogeneic transplantations. Relapse rates at 2 years were 20% (CR patients) and 73% (active disease or 2nd trp). Thus, we investigated options to reduce the risk of relapse by increasing antileukemic activity of donor NK cells in the grafts. Over night incubation with Interleukin 15 increased NK activity most effectively (specific lysis at E:T=20:1 against K562: 28% prior to and 71% after stimulation, n=10). After additional IL2 stimulation a 22 fold increase in thymidine uptake indicated proliferation of

NK cells (n=5). No T cell proliferation was detectable. Based on these results, we started a pilot study with ex vivo IL15 stimulated grafts in 4 patients at very high risk (ALL, 2nd or 3rd relapse, active disease or CR (n=2); AML 1st relapse, active disease (n=2)). All patients received a backbone of unstimulated cells at day 0 to ensure engraftment. Additionally, parts of the grafts were incubated over night and infused at day +1 (medians: CD56=9.4x10⁶/kg (range 3.7-24.4); CD34=1.5x10⁶/kg; CD14=34x10⁶/kg, CD3=0.01x10⁶/kg). No side effects occurred. All patients engrafted within 12 days. 3 patients had acute GvDH grade 0-I, 1 patient had GvHD grade III. Recovery of NK cells was remarkably fast (526 CD56+/mul at day +14 versus 256 CD56+/mul in patients without IL15 stimulation). After additional administration of IL2 in vivo high NK activity (specific lysis>90% against K 562, E:T=20:1) was detectable in peripheral blood. Two patients are disease free (day +244 and 764), 2 patients died from relapse (day 56 and 64). Conclusion(s): ex vivo stimulation with IL15 strongly increases cytotoxic activity of NK cells in T and B cell depleted grafts and can counterbalance G-CSF mediated inhibitory effects. Those grafts were infused without any side effects and resulted in a fast recovery of functional donor NK cells. Further studies have to evaluate this approach.

Lang, P., et al. (2010). "Use of IL15 stimulated, CD3/19 depleted transplants from haploidentical donors in pediatric malignancies." Blood. Conference: 52nd Annual Meeting of the American Society of Hematology, ASH **116**(21).

T and B cell depleted haploidentical grafts and a melphalan based intensity reduced regimen result in low toxicity and stable event free survival in patients with leukemias in CR1-3. However, patients with active disease or with second or subsequent transplantation show unacceptable relapse rates. In an ongoing study, 36 pediatric patients with acute leukemias and advanced MDS (median age: 11 years) received melphalan (2x70mg/m²), fludarabine (4x40mg/m²) or clofarabine (4x50mg/m²), thiotepa (10mg/kg) and OKT3 (0.1mg/kg). T and B cells were depleted by antiCD3/antiCD19 coated magnetic microbeads, whereas NK cells remained into the grafts (median number= 120x106/kg). Remission status was: CR1-3=18, NR=18, 18/36 already received previous allogeneic transplantations. Relapse rates at 2 years were 20% (CR patients) and 73% (active disease patients or 2nd trp). Thus, we investigated options to reduce the risk of relapse by increasing antileukemic activity of donor NK cells in the grafts in vitro. Over night incubation with Interleukin 15 increased NK activity most effectively (specific lysis at E:T=20:1 against K562: 28% prior to and 71% after stimulation, n=10). After additional IL2 stimulation a 22 fold increase in thymidine uptake indicated proliferation of NK cells (n=5). Due to the profound depletion, no T cell proliferation was detectable. Based on these results, we started a pilot study with ex vivo IL15 stimulated grafts in 4 patients at very high risk (ALL, 3rd relapse, active disease (n=1); ALL 2nd relapse, remission (n=1); AML 1st relapse, active disease (n=2)). All patients received a backbone of unstimulated cells at day 0 to ensure engraftment. Additionally, parts of the grafts were incubated over night, washed four times and afterwards infused at day +1 (median numbers: CD56+CD3- =9.4x106/kg (range 3.7-24.4); CD34=1.5x106/kg; CD14=34x106/kg, CD3=0.01x106/kg). No acute side effects occurred. All patients engrafted within 12 days. 3 patients had acute GvDH grade 0-I, 1 patient had GvHD grade III. Recovery of NK cells was remarkably fast (526 CD56+/mul at day 14 posttransplant versus 256 CD56+/mul in patients without IL15 stimulation (means)). After additional administration of IL2 in vivo (1x106 Units/m²/day s.c.) high NK activity (specific lysis>90% against K 562, E:T=20:1) was detectable in peripheral blood. Two patients are disease free (day 154 and 674 posttransplant), 2 patients died from relapse (day 56 and 64). Conclusion(s): ex vivo stimulation with IL15 strongly increases cytotoxic activity of NK cells in T and B cell depleted grafts from haploidentical donors and can counterbalance G-CSF mediated inhibitory effects. Those grafts were infused without any acute side effects and resulted in a fast recovery of functional donor NK cells. Potential interactions with stem cells and stem cell derived NK reconstitution have to be investigated. Further studies have to evaluate if this approach might contribute to reduce relapse rates in high risk patients.

Lang, P., et al. (2011). "NK cell activity influences long term outcome of pediatric leucemias after T cell depleted stem cell transplantation." Blood. Conference: 53rd Annual Meeting of the American Society of Hematology, ASH **118**(21).

T cell depletion with magnetic microbeads can effectively reduce GvHD rates after stem cell transplantation from both mismatched related donors as well as from matched or partially matched unrelated donors. However, T cell recovery is markedly delayed after this procedure and T cell mediated antileukemic effects may be reduced. Thus, we focused on the rapidly regenerating donor derived NK cell system and addressed the question, whether its functional activity would influence the probability of relapse in a long term analysis. Temporal development of NK cell activity was monitored in 47 pediatric patients with leukemias (ALL, AML, CML, JMML) and myelodysplastic syndromes after transplantation of T cell depleted stem cells from matched unrelated (n=18) and mismatched related (haploidentical, n=29) donors with a median follow up of 7.4 years (2.1-12). 38 patients had CR1-3, 9 patients had active disease at time of transplantation. EFS and relapse rate at 5 years for the entire group were 36% and 40%, respectively (EFS and relapse rate for ALL patients in CR1-3: 50% and 36%; EFS and relapse rate for AML/MDS patients: 22% and 30%). CD34+ selection with magnetic microbeads resulted in 8x10³/kg residual T cells. No posttransplant immune suppression was given. 89% of the patients had no GvHD, 9% had GvHD grade I and only 2 patients had GvHD grade II or III. NK cells recovered rapidly after transplantation (300 CD56+/muL at day 30, median), whereas T cell recovery was delayed (median: 12 CD3+/muL at day 90). NK activity was measured as specific lysis of K562 targets several times after transplantation (mean: 3 assays per patient). Four temporal patterns of lytic activity could be differentiated: consistently low, consistently high, decreasing and increasing activity. Patients with consistently high or increasing activity had significantly lower relapse probability than patients with consistently low or decreasing levels (0.18 vs 0.73 at 5 years, p<0.05). The subgroup of patients with ALL showed similar results (0.75 vs 0.14 at 5 years, p<0.05). Speed of T cell recovery had no influence. These data suggest that both achieving and maintaining a high level of NK activity may contribute to prevent relapse. Thus, this model comprises direct functional data in the form of NK cell activation levels which are likely to be influenced by the presence of different cytokines in each patient. Our observations may have some clinical implications: immunomagnetic depletion of T cells prevents GvHD and can be performed in pediatric leukemias in remission without excessive increase in relapse rates. High levels of NK activity seem to be of importance. Since NK activity could be markedly increased by in vitro stimulation with Interleukin 2 (IL-2), in vivo administration should be considered.

Lang, P., et al. (2011). "First clinical results with alpha-beta+ T-cell depleted haplo-identical stem cells in children." Bone Marrow Transplantation **1)**: S135-S136.

We have investigated the depletion of alpha-beta+ T-lymphocytes via a biotinylated anti-alpha-beta antibody followed by an anti-biotin antibody conjugated to magnetic microbeads in order to increase anti-tumor effects of haploidentical stem cell grafts. 5 pediatric patients with advanced and refractory leukemias (ALL, active disease n=3, graft failure n=1;

AML, active dis, n=1) received a haploidentical transplantation with such alpha-beta+ T cell depleted grafts using the CliniMACSmu system. Depletion of alpha-beta+ T-cells was 4.5 log (range 3.8 - 5.0). The recovery of CD34+ stem cells, CD56+ NK cells and gamma-delta+ T-cells was 72%, 76% and 80%, respectively. The median number of infused CD34+ stem cells, CD56+ NK cells and gamma-delta+ T-lymphocytes was 11.9 x10⁶/kg (range 7.5 -30 x 10⁶/kg), 107 x 10⁶/kg (range 35 -186 x10⁶/kg) and 11.9 x10⁶/kg (range 7.5 - 30.2 x 10⁶/kg), respectively. The conditioning regimen comprised melphalan, thiotepa, fludarabin and OKT-3 from day -7 to day -1 in 4 patients and treosulphan, thiotepa, fludarabin and OKT-3 in 1 patient. No further posttransplant prophylaxis for GvHD was given. All patients showed a rapid engraftment with a median of 9 days to reach an ANC > 500 and 12 days (range 6 -21) to reach >20000 platelets. All patients had a complete donor engraftment and showed a rapid immune reconstitution with circulating donor-derived gamma- delta T-cells first observed at day +3 followed by circulating donor-derived alpha-beta+ T-cells first observed at around day +20. Median time to reach 100 CD3/mul was only 30 days. Despite the high number of infused gamma-delta+ T-lymphocytes, only 1 patient experienced a grade 3 GvHD of the skin. 2 patients relapsed after transplantation, 3 patients are in remission for 0.46 (ALL, active dis.), 0.42 (AML, active dis.) and 0.26 (ALL, second trp) years up to now. In conclusion, the first preliminary experience of haploidentical transplantation with - T-cell depleted grafts showed a rapid and sustained engraftment, a rapid immune reconstitution and a low incidence of GvHD. A clinical trial in children and adults is underway to corroborate these promising preliminary findings.

Lang, P., et al. (2014). "Transplantation of CD3/CD19 depleted allografts from haploidentical family donors in paediatric leukaemia." British Journal of Haematology **165**(5): 688-698.

Transplantation of T- and B-cell depleted allografts from haploidentical family donors was evaluated within a prospective phase II trial in children with acute lymphoblastic leukaemia, acute myeloid leukaemia and advanced myelodysplastic syndrome (n = 46). 20 patients had active disease; 19 patients received a second or third stem cell transplantation (SCT). Toxicity-reduced conditioning regimens consisted of fludarabine or clofarabine (in active disease only), thiotepa, melphalan and serotherapy. Graft manipulation was carried out with immunomagnetic microbeads. Primary engraftment occurred in 88%, with a median time to reach >1.0 x 109/l leucocytes, >20 x 109/l platelets and >0.1 x 109/l T-cells of 10, 11 and 50 days, respectively. After retransplantation, engraftment occurred in 100%. Acute graft-versus-host disease (GvHD) grade II and III-IV occurred in 20% and 7%, chronic GvHD occurred in 21%. Both conditioning regimens had comparable toxicity. Transplant-related mortality (TRM) was 8% at one year and 20% at 5 years. Event-free survival at 3 years was: 25% (whole group), 46% (first, second or third complete remission [CR], first SCT) vs. 8% (active disease, first SCT) and 20% (second or third SCT, any disease status). This approach allows first or subsequent haploidentical SCTs to be performed with low TRM. Patients in CR may benefit from SCT, whereas the results in patients with active disease were poor.

Lang, P., et al. (2011). "Transplantation of haploidentical CD3/CD19 depleted stem cells in pediatric patients: Current results of the Tubingen trial and additional immunotherapeutic approaches." European Surgery - Acta Chirurgica Austriaca **242)**: 20-21.

Background. We investigated the safety and efficacy of T and B cell depleted peripheral stem cells from full haplotype mismatched parental donors in pediatric patients. Methods. Use of the Clinimacs system and CD3/CD19 coated magnetic microbeads resulted in a 4 log depletion of T cells and allowed to cotransfuse high numbers of donor NK cells (median:

107+/-10⁶/kg). TBI or busulfan based myeloablative regimens or a melphalan based intensity reduced regimen were used. All patients underwent intensive pretreatment according to current study protocols; 41/106 already received previous allogeneic transplantations. The diagnoses were: acute leukemias and MDS (n=60), solid tumors (n=32) and nonmalignant diseases (n=14). Results. Primary engraftment occurred in 89% of patients. After TLI based reconditioning and second haploidentical stem cell donation, final engraftment was achieved in 100%. Median time to reach >500 neutrophiles/mul and independence from platelet substitution was 10 (8-15) and 9 (5-59) days respectively. 35% of patients had no GvHD, 36% had grade I, 23% had grade II and 4% had grade III. Chronic limited and extensive GvHD was observed in 8 and 11%. Transplant related mortality was 0% at day 100 and 8% at one year. Event free survival at 3 years was 66% for patients with leukemias in any CR and 80% for patients with nonmalignant diseases. Over all survival at 2 years was 20% for patients with solid tumors. Relapse or progression were themajor causes of death. Thus, pilot studies with IL-15 stimulated grafts and posttransplant donor-NK cell infusions were initiated and are currently ongoing. Conclusions. Transplantation of CD3/CD19 depleted haploidentical stem cells resulted in a fast recovery of neutrophiles and platelets. Engraftment rates similar to that of patients with myeloablative standard conditioning and positive selected stem cells could be achieved, possibly due to a graft facilitating effect of cotransfused NK cells. The regimen helped to minimize TRM, despite intensive pretreatment (including previous transplantation). However, relapse remains a major problem and further immunotherapeutic elements have to be evaluated.

Lang, P., et al. (2010). "Haploidentical stem cell transplantation with reduced-intensity conditioning in refractory diseases: Current results." Bone Marrow Transplantation **2)**: S295.

Transplantation of haploidentical, positive selected stem cells in combination with TBI or Bu based conditioning regimens can result in significant toxicity. New graft manipulation methods and a melphalan based intensity reduced regimen may help to reduce these complications. We present our results with a direct depletion procedure for T and B cells using antiCD3/ antiCD19 coated magnetic microbeads. Melphalan (2 x 70 mg/ m²), fludarabine (4 x 40 mg/m²) or clofarabine (4 x 50 mg/m²), thiotepa (10 mg/kg) and OKT3 (0.1 mg/kg) was used as preparative regimen. 36 pediatric patients (median age: 11 years) were included. All patients underwent intensive pretreatment according to current study protocols; 18/36 already received previous allogeneic transplantations. The diagnoses were: ALL (n = 19), AML (n = 14), advanced MDS (n = 3); remission status was: CR1 = 2, CR2 = 7, CR3 = 9, NR = 18. All donors were full haplotype mismatched parents. Primary engraftment occurred in 89% of patients. After TLI based reconditioning and second haploidentical stem cell donation, final engraftment was achieved in 100%. Median time to reach > 500 neutrophiles/mul and independence from platelet substitution was 10 (8-15) and 9 (5-59) days respectively. GvHD grade 0 occurred in 36%. 54% and 8% had GvHD grade I-II and III, respectively. Chronic limited and extensive GvHD was observed in 8 and 11%. Transplant related mortality was 0% at day 100 and 8% at one year. Event free survival at 2 years was 66% for patients with any CR (1st SCT) (n = 8) and 10% for patients with active disease (1st SCT) (n = 12). 1 year EFS in patients after 2nd SCT was 30% (n = 18). Causes of death were myocardiopathy (n = 2), infection (n = 1), GvHD (n = 1) and relapse (n = 22). Relapse rates at 2 years were 20% (CR patients) and 73% (active disease patients or 2nd trp). Conclusion(s): Transplantation of CD3/CD19 depleted haploidentical stem cells with a reduced intensity regimen resulted in a fast recovery of neutrophiles and platelets. Engraftment rates similar to that of patients with myeloablative standard conditioning and positive selected stem cells could be achieved, possibly due to a graft facilitating effect of cotransfused NK cells. The regimen helped to minimize TRM, despite intensive pretreatment, and is suited for 2nd or 3rd transplantation. Patients in any CR had a favorable outcome, whereas patients with active disease showed high relapse rates. Especially in these patients, further therapeutic elements have to be evaluated.

Lang, P. J., et al. (2010). "Long term survival and relapse rate after transplantation of highly T and B cell depleted stem cells from alternative donors in pediatric patients with acute lymphatic leukemia." Biology of Blood and Marrow Transplantation **16 (2 SUPPL 2)**: S301-S302.

We present long term results in 68 children with ALL who received highly T and B cell depleted stem cells from matched unrelated (n = 17) or full haplotype mismatched related donors (n = 51) at our institution. Our aim was to minimize GvHD and to avoid EBV LPD in both matched and mismatched transplantations. Remission status was: CR1, n = 18; CR2, n = 23; >=CR3, n = 12; non remission or second transplant, n = 15. Graft manipulation was carried out with microbeads and the CliniMACSTM device (indirect depletion of T and B cells with CD34+ positive selection (n 5 50); or direct depletion with anti-CD3/anti-CD19 coated microbeads (n = 18)). Tand B cell counts were reduced for4-5 log with mediannumbers of residual T cells of 15 000/kg bw (CD34+ selection) and 49 000/kg bw (CD3/19 depletion). No pharmacological immune suppression was given after positive selection, whereas patients with CD3/19 depletion received MMF. The conditioning regimens were either TBI or Bu based (n 5 50) or a toxicity reduced protocol (Flud, TT, Mel) was used (n 5 18). Rejection prophylaxis was carried out with ATG or OKT3. Primary engraftment occurred in 85%. After reconditioning, final engraftment was achieved in 98%. GvHD grade 0-1 occurred in 86%. 12% had grade II, 4% had grade III. Chronic GvHD occurred in 4 patients. No GvHD related mortality was observed. Median follow up was 5.9 years. EFS at 1 year was 56%(CR1), 51%(CR2) and 50%(>=CR3); EFS at 5 years was 49%(CR1), 46%(CR2) and 27%(>=CR3). Median survival of patients with active disease was 0.2 years. Relapse rates at 1 year were 0.32(CR1), 0.47(CR2) and 0.46(>=CR3); relapse rates at 5 years were 0.32(CR1), 0.47(CR2) and 0.64(>=CR3). TRM at 1 year was 14%, causes of death remained viral and fungal infections, no EBV LPD occurred. Conclusion(s): positive selection of progenitor cells or depletion of T and B cells can minimize acute and chronic GVHD in both matched unrelated and mismatched related transplantations and may prevent GvHD related mortality. Lethal infections occurred in 14% of the patients probablydue to the delayed recovery of Tcells. Despite profound depletion of donor T cells, relapse rates were acceptable and remained on a stable level after the first year in patients with complete remission. Thus, absence of GvHD may not necessarily be associated with high relapse rates in childhood ALL. Apart from T cells, other effector cells like NK cells are likelyto exert GvL effects and may contribute to the favorable EFS of our patients.

Lang, P. J., et al. (2017). "Effects of various ATG doses on rejection rate and immune recovery in haploidentical T and B cell depleted stem cell transplantation." Blood. Conference: 59th Annual Meeting of the American Society of Hematology, ASH **130**(Supplement 1).

T and B cell depletion of haploidentical stem cells with CD3/CD19 coated magnetic microbeads prevents from GvHD and allows to coinfuse donor NK cells and other accessory cells. Additional in vivo depletion of the graft by serotherapy is not necessary. Thus, a dosing scheme of ATG is needed, which provides a rejection prophylaxis by depleting lymphocyte subsets of the patients but which does not harm the graft, in particular cotransfused NK cells. We retrospectively analyzed the impact of various Grafalon (anti-human T-lymphocyte immunoglobulin = ATLG; formerly ATG-Fresenius) doses given at day -12 on engraftment rate and on posttransplant immune recovery. A total of 50 pediatric patients received either 3x5 (n=7), 3x10 (n=34) or

3x20mg/kg (n=9) ATLG starting at day -12 to day -9, followed by fludarabine (160 mg/m², d -8 to -5), thiotepa (10 mg/m²d -4) and melphalan (140 mg/m²d -3 to -2). Diagnoses were: ALL/AML n=10, relapsed solid tumors n=33, nonmalignant diseases n=7. Most patients received MMF until day 30-60. ATLG serum levels were measured in 24 patients by flow cytometry (T cell specific rabbit IgG). Apoptosis/necrosis of donor NK cells was assessed with Annexin V/PI staining. A median number of 16x10 CD34/kg and 65x10 NK cells/kg with 29x10 T cells/kg were infused. Median time to ANC>500/mul was 9.5 days. Graft rejection occurred in 3/7 patients with 15mg (42%), in 7/34 patients with 30mg (20%) and in 1/9 patients with 60mg ATLG (11%). All rejectors could be rescued by reconditioning and 2 stem cell donation or by infusion of autologous back ups. Acute GvHD grade 0-I occurred in 47 patients (94%), GvHD grade II and III-IV was observed in 1 and 2 patients (2%, 4%), respectively. Chronic GvHD occurred in 9 patients (18%). TRM at 1 year was 10% for the entire group. Immune recovery of CD3+ T cells was influenced by the various amounts of ATLG given in the 3 subgroups (15 vs 30 vs 60mg/kg) with a median number of 98 vs 10 vs 2 cells/mul at day +30, 95 vs 100 vs 2 cells/mul at day +90 and 75 vs 218 vs 239 cells/mul at day +180 (figure 1a). Recovery of CD56+ NK cells was fast and reliable and reached peaks of 459 vs 342 vs 155 cells/mul at day +30. Later on NK cells dropped to normal levels of 152 vs 167 vs 104 cells/mul at day +90 and 118 vs 172 vs 99 cells /mul at day +180. ATLG serum levels reached mean peak values of 9.6 mug/ml +/-4.7 vs 22.1+/-13.8 mug/ml vs 53.7 +/-13.9 mug/ml at day -8 and dropped to 1.4 +/-1mug/ml vs and 3.0 +/-1.98 mug/ml and 11.5 +/-5.8 mug/ml at day 0 (15 vs 30 vs 60mg/kg, figure 1b). In vitro incubation of isolated NK cells from healthy donors with comparable ATLG doses (1 or 10 mug/ml) resulted in 26 (41)% apoptosis and 0.2 (0.2)% necrosis after 24 hours. Thus, vitality of 73 (59)% of NK cells were preserved. Conclusion(s): Our aim was to reduce the rejection rate and to improve immune recovery in patients receiving CD3/19 depleted haploidentical peripheral stem cells, in particular without hampering donor NK cells in the grafts. Administration of 15, 30 or 60 mg/kg ATLG was started at an early time point (day -12) of the regimen. Higher ATLG doses correlated with higher serum levels. Peak levels at day -8 provided a rejection prophylaxis. At day 0, various lower levels were achieved and minimized further in vivo depletion. Increased ATLG doses were associated with a lower rejection rate. On the other hand, recovery of T cells was slower after 60mg/kg ATLG in the early posttransplant phase with lower CD3 counts at day 30 and 90. Since all rejectors were successfully regrafted, it may be reasonable to balance between rejection risk and impaired immune recovery and to use an average dose (30mg). Further studies should investigate if serotherapy might be given even earlier than in this analysis.

Lanouar, S., et al. (2018). "Effect of cross-linking on the physicochemical and in vitro properties of pullulan/dextran microbeads." Journal of Materials Science: Materials in Medicine **29 (6) (no pagination)**(77).

Hydrogels are very promising for tissue engineering as they provide scaffolds and a suitable microenvironment to control cell behavior and tissue regeneration. We used a patented method to obtain beads of pullulan/dextran cross-linked with sodium trimetaphosphate (STMP), that were already described for in vivo bone repair. The aim of this study was to provide a comparative analysis of microbeads made of polysaccharides prepared using three different STMP feeding ratio of 1.5, 2.25 or 3 % w/w. The morphology, swelling and biodegradability of these structures were assessed. Mesenchymal stem cells were also seeded to evaluate the cell organization onto the beads. We found that the amount of phosphorus resulting from the cross-linking was proportional to the introduced STMP concentration. An increase of cross-linking decreased the in vitro enzymatic degradability, and also decreased the swelling in

PBS or water. The microstructures observed by SEM and confocal microscopy indicated that homogeneous spherical microbeads were obtained, except for the lower cross-linking ratio where the shapes were altered. Beads hydrated in PBS exhibited a mean diameter ranging from 400 to 550 micro m with the decrease of STMP ratio. Cells adhered to the surface of microbeads even in the absence of protein coating. Cell viability studies revealed an increase in cell numbers over two weeks for the highest cross-linked beads, whereas the two lowest STMP concentrations induced a decrease of cell viability. Overall, this study demonstrated that pullulan/dextran hydrogels can be designed as microbeads with adjustable physicochemical and biological properties to fulfill requirements for tissue engineering approaches. Lares, M., et al. (2019). "Intercomparison study on commonly used methods to determine microplastics in wastewater and sludge samples." Environmental Science & Pollution Research **26**(12): 12109-12122.

The harmonized procedures in terms of the sampling, sample treatment and identification of microplastics in different environmental samples are missing, which poses challenges to researchers to compare the results or to adopt 'the most effective' monitoring approach. Furthermore, in the related literature, the used procedures are rarely tested with spiked microplastics to predetermine their recovery rates. Without this knowledge, results should only be discussed as rough estimations of the real environmental concentrations of microplastics. In this study, six different methods previously used in microplastic studies of different media were tested with municipal wastewater and digested sludge samples, spiked with seven different types of plastic particles and fibres. Recovery rates, time consumption, advantages and disadvantages were assessed and most suitable treatment procedures (i.e. high recovery rates in short amount of time) were chosen for both wastewater and sludge. Suitability of staining with Rose Bengal was examined together with most efficient methods, but it did not improve the recovery of microplastics. In addition, the possible impacts of the treatments for identification with micro-Raman and FTIR microscope were assessed. Filtration with size fractioning was found to be the best method for both wastewater and sludge samples, with recovery rates of spiked microplastics around 91.4% and 92.9%, respectively.

Larin, K. V., et al. (2012). Optical sensing of macromolecules and microparticles distribution in tissues. 11th IEEE SENSORS 2012 Conference, October 28, 2012 - October 31, 2012, Taipei, Taiwan, Institute of Electrical and Electronics Engineers Inc.

This paper describe a highly systematic set of experiments demonstrating capability of Optical Coherence Tomography (OCT) technique for depth-resolved, real-time and truly noninvasive analysis of complex diffusion processes of macromolecules in epithelial and vascular tissues as well to image and detect magnetic microparticles (stationary and moving) under the skin with single-particle sensitivity. For example, we demonstrate that the permeation of VLDL, LDL, HDL, and glucose in normal and diseased human carotid endarterectomy tissues could be quantified that supported previous suggestions of an enhanced transport mechanism specific to LDL. Additionally, we investigated sensitivity of OCT to assess magnetic microbead (d=2.8 um) count under the skin, which could the basis for development of continuous glucose sensing platform. 2012 IEEE.

Lasee, S., et al. (2017). "Microplastics in a freshwater environment receiving treated wastewater effluent." Integrated Environmental Assessment & Management **13**(3): 528-532.

Small plastic fragments (microplastics or solid particles <5 mm in size or "microbeads" used in personal care products and cosmetics) may ultimately find their way into aquatic environments.

We studied the presence of microplastics (particle sizes 53-105 mum and 106-179 mum) spatially and temporally in 3 connected urban lakes being fed by treated wastewater effluent in Lubbock, Texas. These lakes also serve as drainage during storm events. Water samples from drainage playa wetlands within the city were also collected. Our interest was in determining the presence or absence of microplastics in a freshwater environment as well as the source apportionment between personal care products (via wastewater) and discarded plastics (via runoff).

Lauper, M., et al. (2013). "Rumination of different-sized particles in muskoxen (Ovibos moschatus) and moose (Alces alces) on grass and browse diets, and implications for rumination in different ruminant feeding types." Mammalian Biology **78**(2): 142-152.

The obligatory, periodic regurgitation of forestomach material and its subsequent re-mastication is the hallmark of the most diverse extant large herbivore group, the ruminants. Although the process of rumination is well understood in domestic species, differences between free-ranging wild ruminant species, for example of different body size or different feeding type, remain speculative to date. Here we investigate the proportion of plastic particles of varying size (1, 10 and 20 mm) and density (1.03, 1.20 and 1.44 mg/ml) that are recovered intact or ruminated-upon after insertion into the reticulorumen (RR) of domestic cattle (Bos primigenius f. taurus) on grass silage, and of muskoxen (Ovibos moschatus; n=4) and moose (Alces alces; n=2) both fed browse and grass diets. In the three species, the proportion of particles leaving the RR intact depended on particle size, with density showing no effect in this study. The major proportion of 1 mm particles was excreted intact, whereas intact 10-20 mm particles were only excreted sporadically, and not in all animals. Intact particles were mostly found in the initial samples after marker application, and mean retention times of intact particles were always shorter than those of ruminated particles. There were no differences between moose and muskoxen, but diet had a significant effect, with a higher proportion of 1 mm particles ruminated upon on the grass diet in both species, indicating a higher 'filter-bed effect' with entrapment of small particles in a fibre mat in the RR on a grass diet. Given that less particles were ruminated on the grass diet, one could either assume that free-ranging browsers ruminate less than grazers on similar food intakes (or that they have higher food intakes at similar levels of rumination). The existing data on time-budgets of free-ranging ruminants, however, does not suffice to test these hypotheses. The fact that indication of a 'filter-bed effect' was also detectable in moose raises the question whether adaptations described in 'cattle-type' ruminants really serve to re-inforce the processes of RR contents stratification and the 'filter-bed', or whether they are not rather directed at other aims, such as maximizing microbial yield from the RR.

Laurent, V. M., et al. (2002). "Assessment of mechanical properties of adherent living cells by bead micromanipulation: comparison of magnetic twisting cytometry vs optical tweezers." Journal of Biomechanical Engineering **124**(4): 408-421.

We compare the measurements of viscoelastic properties of adherent alveolar epithelial cells by two micromanipulation techniques: (i) magnetic twisting cytometry and (ii) optical tweezers, using microbeads of same size and similarly attached to F-actin. The values of equivalent Young modulus E, derived from linear viscoelasticity theory, become consistent when the degree of bead immersion in the cell is taken into account. E-values are smaller in (i) than in (ii): approximately 34-58 Pa vs approximately 29-258 Pa, probably because higher stress in (i) reinforces nonlinearity and cellular plasticity. Otherwise, similar relaxation time constants, around 2 s, suggest similar dissipative mechanisms.

Lavelli, V. and P. S. C. Sri Harsha (2019). "Microencapsulation of grape skin phenolics for pH controlled release of antiglycation agents." Food Research International **119**: 822-828.

Grape skin (GS) phenolics can prevent structural damage of proteins due to reducing sugars or dicarbonyl compounds, which is the leading cause of hyperglycaemia damage and is involved in inflammatory diseases. In this study, alginate hydrogel was used to encapsulate GS phenolics as a pH dependent releasing system. Microbeads were obtained by a vibrating nozzle method using calcium chloride as hardening agent. Encapsulation efficiency for total phenolics was 68%. At pH 1.4, the alginate microbeads remained intact and only 13% of total phenolic compounds of the microbeads was released. The percent release depended on the compound: procyanidin B1 release was 74%, catechin and epicatechin release was ~ 50%, while anthocyanin and flavonol release was less than 11%. At pH 7.4, the microbeads were dissolved and formed a viscous solution that showed ability to protect bovine serum albumin from glycation induced by both fructose and methylglyoxal. The antiglycation activity was 246 mmol catechin equivalents (CE)/kg of dry microbeads in the fructose model system and 78 mmol CE/kg of dry microbeads in the methylglyoxal model system. These values corresponded to 68% and 62% of the expected activity, probably due to interaction between phenolics and the alginate carrier. Despite the recovery of antiglycation activity was incomplete, results of this study confirmed the efficiency of alginate to act as a pH controlled released system for GS phenolics. This functionalized polymer could be applied in the prevention of advanced-glycation-endproducts related diseases.

Lavers, J. L. and A. L. Bond (2016). "Ingested plastic as a route for trace metals in Laysan Albatross (Phoebastria immutabilis) and Bonin Petrel (Pterodroma hypoleuca) from Midway Atoll." Marine Pollution Bulletin **110**(1): 493-500.

Seabirds are declining faster than any other group of birds, with plastic ingestion and associated contaminants linked to negative impacts on marine wildlife, including >170 seabird species. To provide quantitative data on the effects of plastic pollution, we sampled feathers and stomach contents from Laysan Albatross (Phoebastria immutabilis) and Bonin Petrel (Pterodroma hypoleuca) on Midway Atoll, North Pacific Ocean, and assessed our ability to detect change over time by synthesizing previous studies. Between 25 and 100% of fledglings exceed international targets for plastic ingestion by seabirds. High levels of ingested plastic were correlated with increased concentrations of chlorine, iron, lead, manganese, and rubidium in feathers. The frequency of plastic ingestion by Laysan Albatross and concentration of some elements in both species is increasing, suggesting deterioration in the health of the marine environment. Variability in the frequency of plastic ingestion by Laysan Albatross may limit their utility as an indicator species.

Lavers, J. L., et al. (2014). "Plastic ingestion by Flesh-footed Shearwaters (Puffinus carneipes): implications for fledgling body condition and the accumulation of plastic-derived chemicals." Environmental Pollution **187**: 124-129.

To provide much needed quantitative data on the lethal and sublethal effects of plastic pollution on marine wildlife, we sampled breast feathers and stomach contents from Flesh-footed Shearwater (Puffinus carneipes) fledglings in eastern Australia. Birds with high levels of ingested plastic exhibited reduced body condition and increased contaminant load ($p<0.05$). More than 60% of fledglings exceed international targets for plastic ingestion by seabirds, with 16% of fledglings failing these targets after a single feeding (range: 0.13-3.21 g of plastic/feeding). As top predators, seabirds are considered sentinels of the marine environment. The amount of plastic ingested and corresponding damage to Flesh-footed Shearwater fledglings is the highest reported for any marine vertebrate, suggesting the condition of the Australian marine environment is poor. These findings help explain the ongoing decline of this species and are worrying in light of increasing levels of plastic pollution in our oceans.

Lavers, J. L., et al. (2019). "Clinical Pathology of Plastic Ingestion in Marine Birds and Relationships with Blood Chemistry." Environmental Science & Technology **53**(15): 9224.

Pollution of the environment with plastic debris is a significant and rapidly expanding threat to biodiversity due to its abundance, durability, and persistence. Current knowledge of the negative effects of debris on wildlife is largely based on consequences that are readily observed, such as entanglement or starvation. Many interactions with debris, however, result in less visible and poorly documented sublethal effects, and as a consequence, the true impact of plastic is underestimated. We investigated the sublethal effects of ingested plastic in Flesh-footed Shearwaters (Ardenna carneipes) using blood chemistry parameters as a measure of bird health. The presence of plastic had a significant negative effect on bird morphometrics and blood calcium levels and a positive relationship with the concentration of uric acid, cholesterol, and amylase. That we found blood chemistry parameters being related to plastic pollution is one of the few examples to date of the sublethal effects of marine debris and highlights that superficially healthy individuals may still experience the negative consequences of ingesting plastic debris. Moving beyond crude measures, such as reduced body mass, to physiological parameters will provide much needed insight into the nuanced and less visible effects of plastic.

Law, K. L., et al. (2014). "Distribution of surface plastic debris in the eastern Pacific Ocean from an 11-year data set." Environmental Science & Technology **48**(9): 4732-4738.

We present an extensive survey of floating plastic debris in the eastern North and South Pacific Oceans from more than 2500 plankton net tows conducted between 2001 and 2012. From these data we defined an accumulation zone (25 to 41 degreeN, 130 to 180 degreeW) in the North Pacific subtropical gyre that closely corresponds to centers of accumulation resulting from the convergence of ocean surface currents predicted by several oceanographic numerical models. Maximum plastic concentrations from individual surface net tows exceeded 10(6) pieces km(-2), with concentrations decreasing with increasing distance from the predicted center of accumulation. Outside the North Pacific subtropical gyre the median plastic concentration was 0 pieces km(-2). We were unable to detect a robust temporal trend in the data set, perhaps because of confounded spatial and temporal variability. Large spatiotemporal variability in plastic concentration causes order of magnitude differences in summary statistics calculated over short time periods or in limited geographic areas. Utilizing all available plankton net data collected in the eastern Pacific Ocean (17.4 degreeS to 61.0 degreeN; 85.0 to 180.0 degreeW) since 1999, we estimated a minimum of 21,290 t of floating microplastic.

Lawren, B. (1990). "Plastic Rapt." National Wildlife **28**(6): 10.

The most effective way to address the plastic waste problem in the US is to make less of it. Known as source reduction, this approach focuses on banning frivolous uses of plastic whenever possible. Grass roots consumer involvement in this problem is forcing plastic manufacturers to search out new solutions, such as biodegradable and photodegradable plastics. The pros and cons of the degradable plastics debate are presented and assessed. The most environmentally benign solution is recycling so that eventually very little new plastic would have to be produced. Recycling will involve the concerted efforts of industry, science, and the consuming public.

Lawton, G. (2019). "Plastic measures." New Scientist **244**(3259): 38-38.

Microplastics now contaminate the food we eat and the air we breathe. The race is on to see if our health is at risk, reports Graham Lawton

Lazarevic, D., et al. (2010). "Plastic waste management in the context of a European recycling society: Comparing results and uncertainties in a life cycle perspective." Resources, Conservation and Recycling **55**(2): 246-259.

A number of life cycle assessment (LCA) studies have been undertaken within the last 15 years comparing end-of-life treatment options for post-consumer plastic waste, including techniques such as: mechanical recycling, feedstock recycling, incineration with energy recovery and landfilling. These have attempted to support decisions in the formulation of waste management strategies and policies. In light of the introduction of life cycle thinking into European waste policies, specifically in relation to the waste hierarchy, a literature review of publically available LCA studies evaluating alternative end-of-life treatment options for plastic waste has been conducted. This has been done in order to: establish if a consensus exists as to the environmentally preferable treatment option for plastic waste; identify the methodological considerations and assumptions that have led to these conclusions; and determine the legitimacy of applying the waste hierarchy to the plastic waste stream. The majority of the LCA studies concluded that, when single polymer plastic waste fractions with little organic contamination are recycled and replace virgin plastic at a ratio of close to 1:1, recycling is generally the environmentally preferred treatment option when compared to municipal solid waste incineration. It has been found that assumptions relating to the virgin material substitution ratio and level of organic contamination can have a significant influence upon the results of these studies. Although a limited number of studies addressed feedstock recycling, feedstock recycling and the use of plastic waste as a solid recovered fuel in cement kilns were preferred to municipal solid waste incineration. Landfilling of plastic waste compared to municipal solid waste incineration proved to be the least preferred option for all impact categories except for global warming potential. Due to the uncertainty surrounding some assumptions in the studies, it cannot be said with confidence that the waste hierarchy should be applied to plastic waste management as a general rule. © 2010 Elsevier B.V. Le, D. Q., et al. (2016). "Temporal and spatial changes in persistent organic pollutants in Vietnamese coastal waters detected from plastic resin pellets." Marine Pollution Bulletin **109**(1): 320-324.

Plastic resin pellets collected at Minh Chau island and Ba Lat estuary between 2007 and 2014 in Vietnam were analyzed for dichloro-diphenyl-trichloroethanes (DDTs), polychlorinated biphenyls (PCBs) and hexachlorocyclohexanes (HCHs). The study was carried out as part of the International Pellet Watch program for monitoring the global distribution of persistent organic pollutants (POPs). Higher levels of DDTs compared to PCBs indicated agricultural inputs rather than industrial discharges in the region. Most POP concentrations on both beaches decreased over the period, with the exception of HCH isomers. Though the concentration of DDTs showed a drastic decline on both beaches between 2007/2008 and 2014, DDTs accounted for 60-80% of total DDTs, suggesting that there is still a fresh input of these chemicals in the region. This study strongly recommends further investigations to track temporal and spatial patterns of POP levels in the marine environment using plastic resin pellets.

Le Guen, C., et al. (2020). "Microplastic study reveals the presence of natural and synthetic fibres in the diet of King Penguins (Aptenodytes patagonicus) foraging from South Georgia." Environment International **134**: 105303.

Marine ecosystems are experiencing substantial disturbances due to climate change and overfishing, and plastic pollution is an additional growing threat. Microfibres are among the most pervasive pollutants in the marine environment, including in the Southern Ocean. However, evidence for microfibre contamination in the diet of top predators in the Southern Ocean is rare. King Penguins (Aptenodytes patagonicus) feed on mesopelagic fish, which undergo diel vertical migrations towards the surface at night. Microfibres are concentrated in surface waters and sediments but can also be concentrated in fish, therefore acting as contamination vectors for diving predators feeding at depth. In this study, we investigate microfibre contamination of King Penguin faecal samples collected in February and March 2017 at South Georgia across three groups: incubating, chick-rearing and non-breeding birds. After a KOH digestion to dissolve the organic matter and a density separation step using a NaCl solution, the samples were filtered to collect microfibres. A total of 77% of the penguin faecal samples (36 of 47) contained microfibres. Fibres were measured and characterized using Fourier-Transform Infrared spectroscopy to determine their polymeric identity. Most fibres (88%) were made of natural cellulosic materials (e.g. cotton, linen), with only 12% synthetic (e.g. polyester, nylon) or semi-synthetic (e.g. rayon). An average of 21.9+/-5.8 microfibres g⁻¹ of faeces (lab dried mass) was found, with concentrations more than twice as high in incubating penguins than in penguins rearing chicks. Incubating birds forage further north at the Antarctic Polar Front and travel longer distances from South Georgia than chick-rearing birds. This suggests that long-distance travelling penguins are probably more exposed to the risk of ingesting microfibres when feeding north of the Antarctic Polar Front, which might act as a semi-permeable barrier for microfibres. Microfibres could therefore provide a signature for foraging location in King Penguins.

Le Guernic, A., et al. (2019). "Comparison of viability and phagocytic responses of hemocytes withdrawn from the bivalves Mytilus edulis and Dreissena polymorpha, and exposed to human parasitic protozoa." International Journal for Parasitology **16**: 16.

Bivalve molluscs are now considered indicator species of aquatic contamination by human parasitic protozoa. Nonetheless, the possible effects of these protozoa on the immune system of their paratenic hosts are poorly documented. The aim of this study was to evaluate the effects of two protozoa on hemocyte viability and phagocytosis from two mussels, the zebra mussel (freshwater habitat) and the blue mussel (seawater habitat). For these purposes, viability and phagocytic markers have been analysed on hemocytes from mussels without biological stress (control hemocytes), and on hemocytes exposed to a biological stress (Toxoplasma gondii and Cryptosporidium parvum oocysts). We report, for the first known time, the interactions between protozoa and hemocytes of mussels from different aquatic environments. Zebra mussel hemocytes showed a decrease in phagocytosis of fluorescent microbeads after exposure to both protozoa, while blue mussel hemocytes reacted only to T. gondii oocysts. These decreases in the ingestion of microbeads can be caused by competition between beads and oocysts and can be influenced by the size of the oocysts. New characterisations of their immune capacities, including aggregation, remain to be developed to understand the specificities of both mussels.

Le Hingrat, Q., et al. (2018). "Efficiency of HIV-2 cultures from clinical isolates is enhanced after purification by anti-CD44 microbeads." Journal of Virological Methods **257**: 12-15.

In-depth study of HIV often requires large stock of patients-derived viruses obtained through viral cultures. HIV cultures are currently limited by low recovery rates, especially when viral load is below 100,000 copies per mL. This is problematic for HIV-2 as most patients have

spontaneously low to undetectable viremia. New approaches have been developed to enhance viral recovery rates but they are complex or costly to implement. We tested the impact of muMACS^{TM} VitalVirus Isolation Kit (Miltenyi), a HIV virions capture method using paramagnetic microbeads directed against CD44, a human glycoprotein present in HIV envelope. This method separates viruses from interfering proteins in 45 min, using a reduced sample volume (200 muL versus 1000 muL for classic culture assays). The impact of this purification method on virus recovery rate was assessed with 23 HIV-1 and 29 HIV-2 plasma samples with a wide range of viral loads, in comparison to a classic culture assay used routinely in our laboratory. For both HIV-1 and HIV-2, the culture identification delay was decreased using viral purification (<=7days in most cases). The recovery rate of cultures was improved for HIV-2 isolates (17/29 versus 8/29; p = 0.03) but not for HIV-1 (7/23 versus 5/23; p = 0.74). Notably, HIV-2 isolates with viral loads over 10,000 copies per mL were frequently recovered in culture (68% versus 32% without purification; p = 0.03). This marked improvement on HIV-2, but not on HIV-1, cultures is puzzling. CD44-microbeads may enable a close and prolonged contact between cells and viruses, and may thus overcome HIV-2 difficulties to infect target cells. Copyright © 2018 Elsevier B.V.

Le Ly Thuy, T., et al. (2012). "Isolation and detection of Campylobacter jejuni from chicken fecal samples by immunomagnetic separation-PCR." Food Control **24**(1/2): 23-28.

Campylobacter jejuni (C. jejuni) is one of the leading causes of bacterial food-borne disease worldwide. The presence of Campylobacter in chicken feces poses a high risk for contamination of chicken meat and for Campylobacter infections in human. Detection of this bacterium in chicken fecal specimens before slaughter is therefore vital to prevent disease transmission. By combining two techniques - immunomagnetic separation (IMS) and polymerase chain reaction (PCR), this study developed a reliable and specific method for rapid detection of C. jejuni in chicken fecal samples. The specificity of the assay was assured by two selection steps: (1) DynabeadsReg.M-270 Amine microbeads (2.8 micro m in diameter) coated with C. jejuni monoclonal antibodies were used as the primary selection to isolate bacteria from fecal samples. (2) A PCR assay amplifying the Hippuricase gene was performed as the specific selection to accurately confirm the presence of C. jejuni. Without pre-enrichment, this method was able to detect approximately 10 CFU of C. jejuni in 1 micro l of spiked feces within 3 h.

Le, S., et al. (2017). "Fabrication of paper devices via laser-heating-wax-printing for high-tech enzyme-linked immunosorbent assays with low-tech pen-type pH meter readout." Analyst **142**(3): 511-516.

In this work, a new method named laser-heating-wax-printing (LHWP) is described to fabricate paper devices for developing sensitive, affordable, user-friendly paper-based enzyme-linked immunosorbent assays (P-ELISAs) that initially use common pen-type pH meters for portable, quantitative readout. The LHWP enables a rapid patterning of wax in paper via one step of heating the wax layer coated on the paper surface using a mini-type CO₂ laser machine. Wax-patterned paper microzones created in this way are utilized to conduct the pen-type pH meter-based P-ELISAs with enzyme-loaded SiO₂ microbeads for highly efficient signal amplification of each antibody-antigen binding event. The results show that this new P-ELISA system is quantitatively sensitive to the concentrations of a model protein analyte in buffer samples ranging from 12.5 to 200 pg mL⁻¹, with a limit of detection of ca. 7.5 pg mL⁻¹ (3sigma). Moreover, the satisfactory recovery results of assaying several human serum samples validate its feasibility for practical applications.

Leads, R. R., et al. (2019). "The Effect of Microplastic Ingestion on Survival of the Grass Shrimp Palaemonetes pugio (Holthuis, 1949) Challenged with Vibrio campbellii." Environmental Toxicology & Chemistry **38**(10): 2233-2242.

Recent research indicates that microplastic (<5 mm) ingestion may impact the immune function of marine and aquatic organisms at the tissue and cellular levels; however, their susceptibility to disease following exposure has not been directly investigated. The objective of the present study was to directly evaluate the impact of microplastic ingestion on the susceptibility of the grass shrimp Palaemonetes pugio to bacterial infection with Vibrio campbellii. Grass shrimp were exposed to one of several particle treatments (natural sediment, polyethylene spheres, polypropylene fragments, tire fragments, and polyester fibers) or particle-free water for 96 h at a nominal concentration of 50 000 particles/L prior to a bacterial challenge with V. campbellii. No significant mortality was observed among any of the particle types during the 96-h particle exposure. The survival of grass shrimp following V. campbellii challenge did not vary significantly among shrimp exposed to particle-free water, sediment, polyethylene spheres, polypropylene fragments, tire fragments, and polyester fibers. Grass shrimp cleared the majority of ingested particles and all the ventilated particles within 48 h. The present study shows that microplastic ingestion did not alter the susceptibility of grass shrimp to bacterial infection, and also provides depuration rates for a variety of microplastic shapes and polymer types that were previously lacking. This information increases our understanding of the size- and shape-dependent effects of microplastic ingestion. Environ Toxicol Chem 2019;38:2233-2242. © 2019 SETAC.

Leads, R. R. and J. E. Weinstein (2019). "Occurrence of tire wear particles and other microplastics within the tributaries of the Charleston Harbor Estuary, South Carolina, USA." Marine Pollution Bulletin **145**: 569-582.

Microplastics (<5 mm) are ubiquitous in the marine environment, occurring in both sediments and surface waters worldwide. However, few studies have documented the presence of microplastics and tire wear particles in coastal rivers. A survey of microplastics and low-density tire wear particles (>=63 mum) in the sediment and surface water of the three major tributaries within the Charleston Harbor estuary was conducted. Intertidal sediment, subtidal sediment, and sea surface microlayer concentrations ranged from 0 to 652 microplastics/m², 3-4,375 microplastics/kg wet weight, and 3-36 microplastics/L, respectively. Blue fibers and tire wear particles were the two most abundant microplastic types observed, constituting 26.2% and 17.1%, respectively, of total microplastics. Tire wear particles were primarily identified by morphology, and ATR-FTIR analysis was conducted for a small subset (n = 5) of larger particles (>=500 mum). The present study provides the first microplastic field assessment of low-density tire wear particles in estuarine tributaries. Copyright © 2019 Elsevier Ltd

Leary, T. F., et al. (2015). "Mass transfer in the biomolecular binding of a target against probe molecules on the surface of microbeads sequestered in wells in a microfluidic cell." Lab on a Chip **15**(2): 459-477.

Diagnostic tools which screen the binding interactions of a protein target against a display of biomolecular probes to identify molecules which bind the target are central to cell proteomic studies, and to diagnostic assays. Here, we study a microfluidic design for screening interactions in which the probe molecules are hosted on microbeads sequestered in wells arranged at the bottom of a microfluidic flow channel. Assays are undertaken by streaming an analyte solution with a fluorescently labelled target through the cell, and identifying the fluorescing beads. Numerical simulations are first constructed for the analyte flow over the microbeads in the well array, and the increase in the target concentration on the microbead surface. The binding profile is expressed as a function of the ratio of the convective to the diffusive transport rates

(Peclet number or Pe), and the ratio of the kinetic to the diffusive rates (Damkohler number, Da). For any Pe, as Da becomes small enough, the transport is determined by the intrinsic kinetic binding rate. As Pe increases, a thin concentration boundary layer develops over the top surface of the microbead because of the convective flow, and target binds more rapidly. However, the relatively stagnant layers of liquid in the well provide a diffusion barrier which slows the target transport, and for any Da and Pe the transport is slower than equivalent patches of probes arranged on the channel wall. Experiments are also undertaken at high Pe, using the binding of fluorescently labelled NeutrAvidin as a target to probes of its binding partner, biotin, on the microbead surface. The binding profile is compared to the simulations to measure the kinetic rate constant, and this comparison shows that the transport in the cell is not kinetically limited because of the diffusion barriers created by the stagnant liquid layer in the well. Simulations and experiments on microbeads which are only partially recessed in the well demonstrate an increase in the mass transfer rate as more of the microbead surface intersects the flow and the diffusion limitation due to the stagnant layer of liquid surrounding the bottom part of the microbead is minimized.

Leautaud, V., et al. (2014). Evaluation of a qualitative human immunodeficiency virus-1 diagnostic assay based on nucleic acid sequence based amplification and lateral flow readout. 2014 IEEE Healthcare Innovation Conference, HIC 2014.

In this study, a qualitative human immunodeficiency virus-1 (HIV-1) diagnostic assay was developed and evaluated as part of an effort to create a point-of-care diagnostic test for pediatric HIV-1. The assay is based on extraction of viral ribonucleic acid (RNA) with magnetic microbeads, isothermal amplification using nucleic acid sequence based amplification (NASBA), and detection of amplified RNA on lateral flow strips. Using mock samples consisting of plasma spiked with in vitro transcribed RNA or HIV-1C particles, more than 80% of samples with a concentration of 1,000 copies/mL or higher tested positive with the assay. Using clinical samples from pediatric patients at the Queen Elizabeth Central Hospital in Blantyre, Malawi, more than 80% of samples with a concentration of 10,000 copies/mL or higher tested positive. These results indicate that this assay is capable of detecting HIV-1 at concentrations found in pediatric samples and shows promise for use in low resource settings but requires further improvements to increase the specificity and sensitivity at low viral loads. © 2014 IEEE.

Lebreton, L., et al. (2019). "A global mass budget for positively buoyant macroplastic debris in the ocean." Scientific Reports **9**(1): 12922.

Predicted global figures for plastic debris accumulation in the ocean surface layer range on the order of hundreds of thousands of metric tons, representing only a few percent of estimated annual emissions into the marine environment. The current accepted explanation for this difference is that positively buoyant macroplastic objects do not persist on the ocean surface. Subject to degradation into microplastics, the major part of the mass is predicted to have settled below the surface. However, we argue that such a simple emission-degradation model cannot explain the occurrence of decades-old objects collected by oceanic expeditions. We show that debris circulation dynamics in coastal environments may be a better explanation for this difference. The results presented here suggest that there is a significant time interval, on the order of several years to decades, between terrestrial emissions and representative accumulation in offshore waters. Importantly, our results also indicate that the current generation of secondary microplastics in the global ocean is mostly a result of the degradation of objects produced in the 1990s and earlier. Finally, we propose a series of future emission scenarios until 2050, discussing the necessity to rapidly reduce emissions and actively remove waste accumulated in the environment to mitigate further microplastic contamination in the global ocean.

Lebreton, L., et al. (2018). "Evidence that the Great Pacific Garbage Patch is rapidly accumulating plastic." Scientific Reports **8**(1): 4666.

Ocean plastic can persist in sea surface waters, eventually accumulating in remote areas of the world's oceans. Here we characterise and quantify a major ocean plastic accumulation zone formed in subtropical waters between California and Hawaii: The Great Pacific Garbage Patch (GPGP). Our model, calibrated with data from multi-vessel and aircraft surveys, predicted at least 79 (45-129) thousand tonnes of ocean plastic are floating inside an area of 1.6 million km²; a figure four to sixteen times higher than previously reported. We explain this difference through the use of more robust methods to quantify larger debris. Over three-quarters of the GPGP mass was carried by debris larger than 5 cm and at least 46% was comprised of fishing nets. Microplastics accounted for 8% of the total mass but 94% of the estimated 1.8 (1.1-3.6) trillion pieces floating in the area. Plastic collected during our study has specific characteristics such as small surface-to-volume ratio, indicating that only certain types of debris have the capacity to persist and accumulate at the surface of the GPGP. Finally, our results suggest that ocean plastic pollution within the GPGP is increasing exponentially and at a faster rate than in surrounding waters.

Lebreton, L. C. M. and J. C. Borrero (2013). "Modeling the transport and accumulation floating debris generated by the 11 March 2011 Tohoku tsunami." Marine Pollution Bulletin **66**(1-2): 53-58.

A global ocean circulation model is coupled to a particle-tracking model to simulate the transport of floating debris washed into the North Pacific Ocean by the Tohoku tsunami. A release scenario for the tsunami debris is based on coastal population and measured tsunami runup. Archived 2011/2012 hindcast current data is used to model the transport of debris since the tsunami, while data from 2008 to 2012 is used to investigate the distribution of debris on timescales up to 4. years. The vast amount of debris pushed into ocean likely represents thousands of years worth of 'normal' litter flux from Japan's urbanized coastline. This is important since a significant fraction of the debris will be comprised of plastics, some of which will degrade into tiny particles and be consumed by marine organisms, thereby allowing adsorbed organic pollutants to enter our food supply in quantities much higher than present. © 2012 Elsevier Ltd.

Lebreton, L. C. M., et al. "Numerical modelling of floating debris in the world's oceans." Marine Pollution Bulletin.

A global ocean circulation model is coupled to a Lagrangian particle tracking model to simulate 30 years of input, transport and accumulation of floating debris in the world ocean. Using both terrestrial and maritime inputs, the modelling results clearly show the formation of five accumulation zones in the subtropical latitudes of the major ocean basins. The relative size and concentration of each clearly illustrate the dominance of the accumulation zones in the northern hemisphere, while smaller seas surrounded by densely populated areas are also shown to have a high concentration of floating debris. We also determine the relative contribution of different source regions to the total amount of material in a particular accumulation zone. This study provides a framework for describing the transport, distribution and accumulation of floating marine debris and can be continuously updated and adapted to assess scenarios reflecting changes in the production and disposal of plastic worldwide. © 2012.

Lebreton, L. C. M., et al. (2017). "River plastic emissions to the world's oceans." Nature communications **8**: 15611.

Plastics in the marine environment have become a major concern because of their persistence at sea, and adverse consequences to marine life and potentially human health. Implementing mitigation strategies requires an understanding and quantification of marine plastic sources, taking spatial and temporal variability into account. Here we present a global model of plastic inputs from rivers into oceans based on waste management, population density and hydrological information. Our model is calibrated against measurements available in the literature. We estimate that between 1.15 and 2.41 million tonnes of plastic waste currently enters the ocean every year from rivers, with over 74% of emissions occurring between May and October. The top 20 polluting rivers, mostly located in Asia, account for 67% of the global total. The findings of this study provide baseline data for ocean plastic mass balance exercises, and assist in prioritizing future plastic debris monitoring and mitigation strategies.

Lechner, A. and D. Ramler (2015). "The discharge of certain amounts of industrial microplastic from a production plant into the River Danube is permitted by the Austrian legislation." Environmental Pollution **200**: 159-160.

Numerous studies have quantified the amount of plastic litter in aquatic ecosystems and tried to assess its impacts and threats. This reflects a rising awareness of plastic as an environmental problem. As a next logical step, identifying and regulating the sources must be in the focus of scientific efforts. We report on a spillage of industrial microplastic (IMP) from a production plant situated at an Austrian Danube tributary. This is the first identified point source of IMP litter in freshwater systems. However, due to generous thresholds established by the Austrian government substantial amounts of IMP are legally introduced into running waters. Copyright © 2015 Elsevier Ltd All rights reserved.

Leddy, H. A., et al. (2014). "Follistatin in chondrocytes: the link between TRPV4 channelopathies and skeletal malformations." FASEB Journal **28**(6): 2525-2537.

Point mutations in the calcium-permeable TRPV4 ion channel have been identified as the cause of autosomal-dominant human motor neuropathies, arthropathies, and skeletal malformations of varying severity. The objective of this study was to determine the mechanism by which TRPV4 channelopathy mutations cause skeletal dysplasia. The human TRPV4(V620I) channelopathy mutation was transfected into primary porcine chondrocytes and caused significant (2.6-fold) up-regulation of follistatin (FST) expression levels. Pore altering mutations that prevent calcium influx through the channel prevented significant FST up-regulation (1.1-fold). We generated a mouse model of the TRPV4(V620I) mutation, and found significant skeletal deformities (e.g., shortening of tibiae and digits, similar to the human disease brachyolmia) and increases in Fst/TRPV4 mRNA levels (2.8-fold). FST was significantly up-regulated in primary chondrocytes transfected with 3 different dysplasia-causing TRPV4 mutations (2- to 2.3-fold), but was not affected by an arthropathy mutation (1.1-fold). Furthermore, FST-loaded microbeads decreased bone ossification in developing chick femora (6%) and tibiae (11%). FST gene and protein levels were also increased 4-fold in human chondrocytes from an individual natively expressing the TRPV4(T89I) mutation. Taken together, these data strongly support that up-regulation of FST in chondrocytes by skeletal dysplasia-inducing TRPV4 mutations contributes to disease pathogenesis.

Lee, B. S., et al. (2009). Microbead-based suspension immuoassay in a lab-on-a-disc. 13th International Conference on Miniaturized Systems for Chemistry and Life Sciences, MicroTAS 2009, November 1, 2009

- November 5, 2009, Jeju, Korea, Republic of, Chemical and Biological Microsystems Society.

A portable, disc-based, and fully automated enzyme-linked immuno-sorbent assay (ELISA) system is developed to test infectious diseases from whole blood. The innovative laser irradiated ferrowax microvalves and centrifugal microfluidics were utilized for the full integration of the microbead-based suspension ELISA assays on a disc starting from whole blood. The concentrations of the antigen and the antibody of Hepatitis B virus (HBV), HBsAg and Anti-HBs respectively, were measured using the lab-on-a-disc (LOD). All the necessary reagents are preloaded on the disc and the total process of the plasma separation, incubation with target specific antigen or antibody coated microbeads, multiple steps of washing, enzyme reaction with substrates, and the absorbance detection could be finished within 30 minutes. Compared to the conventional ELISA, the operation time was dramatically reduced from over 2 hours to less than 30 minutes while the limit of detection was kept similar; e.g. the limit of detection of Anti-HBs tests were 8.6 mIU mL-1 and 10 mIU mL-1 for the disc-based and the conventional ELISA respectively. 2009 CBMS.

Lee, B. S., et al. (2009). "A fully automated immunoassay from whole blood on a disc." Lab on a Chip **9**(11): 1548-1555.

Lee, C. A., et al. (2018). "Cryopreserved neonatal hepatocytes may be a source for transplantation: Evaluation of functionality toward clinical use." Liver Transplantation **24**(3): 394-406.

Neonatal livers are a potential source of good-quality hepatocytes for clinical transplantation. We compared viability and function of neonatal hepatocytes (NHs) and adult hepatocytes (AHs) and report their clinical use both intraportally and in alginate microbeads. Following isolation from donor livers, hepatocyte function was assessed using albumin, alpha-1-antitrypsin, and factor VII. Metabolic function was investigated by measuring resorufin conjugation, ammonia metabolism, uridine diphosphate glucuronosyltransferase enzyme activity, and cytochrome P450 (CYP) function following induction. Activation of the instant blood-mediated inflammatory reaction by NHs and AHs was investigated using an in vitro blood perfusion model, and tissue factor expression was analyzed using real-time polymerase chain reaction (RT-PCR). Clinical hepatocyte transplantation (HT) was undertaken using standard protocols. Hepatocytes were isolated from 14 neonatal livers, with an average viability of 89.4% +/- 1.8% (mean +/- standard error of the mean) and average yield of 9.3 x 10⁶ +/- 2.0 x 10⁶ cells/g. Hepatocytes were isolated from 14 adult livers with an average viability of 78.6% +/- 2.4% and yield 2.2 x 10⁶ +/- 0.5 x 10⁵ cells/g. NHs had significantly higher viability after cryopreservation than AHs, with better attachment efficiency and less plasma

membrane leakage. There were no differences in albumin, alpha-1-antitrypsin, and factor VII synthesis between NHs and AHs (P > 0.05). Neonatal cells had inducible phase 1 enzymes as assessed by CYP function and functional phase 2 enzymes, in which activity was comparable to AHs. In an in vitro blood perfusion model, AHs elicited increased thrombus formation with a greater consumption of platelets and white cells compared with NHs (28.3 x 10⁹ versus 118.7 x 10⁹ and 3.3 x 10⁹ versus 6.6 x 10⁹ ; P < 0.01). Intraportal transplantation and intraperitoneal transplantation of alginate encapsulated hepatocytes was safe, and preliminary data suggest the cells may activate the immune response to a lesser degree than adult cells. In conclusion, we have shown NHs have excellent cell viability, function, and drug metabolism making them a suitable alternative source for clinical HT. Liver Transplantation 24 394-406 2018 AASLD.

Lee, C. S., et al. (2013). "Tailoring adipose stem cell trophic factor production with differentiation medium components to regenerate chondral defects." Tissue engineering. Part A. **19**(11-12): 1451-1464.

Recent endeavors to use stem cells as trophic factor production sources have the potential to translate into viable therapies for damaged or diseased musculoskeletal tissues. Adipose stem cells (ASCs) can be differentiated into chondrocytes using the chondrogenic medium (CM), but it is unknown if this approach can optimize ASC growth factor secretion for cartilage regeneration by increasing the chondrogenic factor production, while decreasing angiogenic and hypertrophic factor production. The objective of this study was to determine the effects the CM and its components have on growth factor production from ASCs to promote cartilage regeneration. ASCs isolated from male Sprague-Dawley rats and cultured in monolayer or alginate microbeads were treated with either the growth medium (GM) or the CM for 5 days. In subsequent studies, ASC monolayers were treated with either the GM supplemented with different combinations of 50 mug/mL ascorbic acid-2-phosphate (AA2P), 100 nM dexamethasone (Dex), 10 ng/mL transforming growth factor (TGF)-beta1, and 100 ng/mL bone morphogenetic protein (BMP)-6 or with the CM excluding different combinations of AA2P, Dex, TGF-beta1, and BMP-6. mRNA levels and growth factor production were quantified at 8 and 24 h after the last media change, respectively. The CM increased chondrogenic factor secretion (TGF-beta2, TGF-beta3, and insulin-like growth factor [IGF]-I) and decreased angiogenic factor production (the vascular endothelial growth factor [VEGF]-A, the fibroblast growth factor [FGF]-2). Microencapsulation in the GM increased production of the chondrogenic (IGF-I, TGF-beta2) and angiogenic (VEGF-A) factors. AA2P increased secretion of chondrogenic factors (IGF-I, TGF-beta2), and decreased angiogenic factor (VEGF-A) secretion, in addition to decreasing mRNA levels for factors associated with chondrocyte hypertrophy (FGF-18). Dex increased mRNA levels for hypertrophic factors (BMP-2, FGF-18) and decreased angiogenic factor secretion (VEGF-A). TGF-beta1 increased angiogenic factor production (FGF-2, VEGF-A) and decreased chondrogenic factor mRNA levels (IGF-I, PTHrP). BMP-6 increased hypertrophic mRNA levels (FGF-18) and chondrogenic factor production (TGF-beta2). When ASC microbeads preconditioned with the CM were implanted in a focal cartilage defect and immobilized within an RGD-conjugated hydrogel, tissue infiltration from the edges of the defect and perichondrium was observed. These results show that differentiation media components have distinct effects on ASC's production of angiogenic, chondrogenic, and hypertrophic factors and that AA2P may be the most beneficial CM component for preconditioning ASCs to stimulate cartilage regeneration.

Lee, D. H. and J. S. Rhee (2018). "Microplastic dynamics in a marine mysid and potential effect on mysid growth." Toxicology and Environmental Health Sciences **10 (4)**: S43.

Mysids are relatively small-sized crustaceans that are commonly found in most aquatic environments, such as brackish, estuarine, coastal, and oceanic environments. Mysids are one of the most important food items for numerous aquariums, fisheries, and even for human. For more than 20 years, they have served as an ecotoxicology model taxonomic group because of its ease of culturing and handling in the laboratory, wide geographical distribution, short life-span, and physiological sensitivity to various environmental factors. In this study, juvenile and adult marine mysids (Neomysis awatschensis; Crustacea; Mysidae) were exposed to different sizes of microplastics, and the bioconcentration dynamics and responses of ecotoxicological and physiological responses were measured during the exposure and additional depuration periods. Microplastics bioconcentrated by age-and sizespecifically and the levels reduced gradually during the depuration phase. We measured morphological growth parameters and quantified the hormone ecdysterone (20-hydroxyecdysone: 20E), which controls molting in mysids. The lengths of the whole body, antennal scale, exopod, endopod, and telson were significantly smaller microplastics-exposed juvenile mysids than control group. Although no significant modulation in the levels of 20E was observed by initial microplatics exposure in juvenile, levels of 20E were significantly lower at constant exposures. After exposure to different sizes of microplastics, a series of parameters of antioxidant defenses system were significantly modulated during exposure and early depuration periods in juvenile mysids, while adult mysids showed no significant change. Our results suggest that microplastics could affect mysid growth and the significances are strongly associated with microplastics' sizes and exposure period in N. awathchesis.

Lee, H., et al. (2013). "Systemic immune modulation induced by alcoholic beverage intake in obese-diabetes (db/db) mice." Food and Chemical Toxicology **53**: 286-293.

Alcohol over-consumption is generally immunosuppressive. In this study, the effects of single or repetitive alcohol administration on the systemic immunity of db/db mice were observed to clarify the possible mechanisms for the increased susceptibility of obese individuals to alcohol-related immunological health problems. Alcohol (as a form of commercially available 20% distilled-alcoholic beverage) was orally administered one-time or seven times over 2 weeks to db/db mice and normal C57BL/6J mice. Immunologic alterations were analyzed by observation of body weight and animal activity, along with proportional changes of splenocytes for natural killer cells, macrophages, and T and B lymphocytes. Modulation of plasma cytokine level and immune-related genes were also ascertained by micro-bead assay and a microarray method, respectively. The immune micro-environment of db/db mice was an inflammatory state and adaptive cellular immunity was significantly suppressed. Low-dose alcohol administration reversed the immune response, decreasing inflammatory responses and the increment of adaptive immunity mainly related to CD4⁺ T cells, but not CD8⁺ T cells, to normal background levels. Systemic immune modulation due to alcohol administration in the obese-diabetic mouse model may be useful in the understanding of the induction mechanism, which will aid the development of therapeutics for related secondary diseases.

Lee, H. and Y. Kim (2018). "Treatment characteristics of microplastics at biological sewage treatment facilities in Korea." Marine Pollution Bulletin **137**: 1-8.

Microplastics that are contained in household dust, personal care products, and other factors, are discharged into sewage treatment facilities (STF). While these microplastics are treated at the STF with a high treatment efficiency through settling, precipitation, filtering, and other treatments, considering the large amount of effluent, large quantities of microplastics are still discharged into marine environments. In this study, biological STF using the anaerobic-anoxic-aerobic (A2O), sequence batch reactor (SBR), and the Media processes were

investigated to confirm the efficiency of these treatments and the associated amounts of microplastics released for each process. The three investigated processes were found to have treatment efficiencies of about 98% or more. However, due to the large amount of effluent, more than four billion pieces of microplastic were released each year in each facility. Thus, even though biological STF show high treatment efficiencies, substantially large amounts of microplastics are still released into the marine environment.

Lee, H., et al. (2019). "Microplastic contamination of table salts from Taiwan, including a global review." Scientific Reports **9**(1): 10145.

Plastic pollution is a rapidly worsening environmental problem, especially in oceanic habitats. Environmental pollution with microplastic particles is also causing food consumed by humans to be increasingly polluted, including table salts. Therefore, we present the first study which focuses only on table salt products purchased in Taiwan which we examined for the presence of microplastics. We used Fourier transform infrared spectroscopy to identify the polymer type of each particle. Within 4.4 kg of salt, we detected 43 microplastic particles which averages to 9.77 microplastic particles/kg. The identified polymer types were, in descending abundance, polypropylene, polyethylene, polystyrene, polyester, polyetherimide, polyethylene terephthalate, and polyoxymethylene. We combined our novel results with those of previous studies to provide the first global review of microplastic contamination of table salts. We found that 94% of salt products tested worldwide contained microplastics, with 3 out of 27 polymer types (polyethylene terephthalate, polypropylene, polyethylene) accounting for the majority of all particles. Averaging over seven separate studies, table salts contain a mean of 140.2 microplastic particles/kg. With a mean annual salt consumption of ~3.75 kg/year, humans therefore annually ingest several hundred microplastic particles from salt alone.

Lee, H., et al. (2019). "Estimating microplastic-bound intake of hydrophobic organic chemicals by fish using measured desorption rates to artificial gut fluid." Science of the Total Environment **651**(Part 1): 162-170.

One of the most important concerns about marine microplastics is their role in delivery of chemical contaminants to biota. The contribution of microplastic ingestion to the overall uptake of five hydrophobic organic chemicals (HOCs) [alpha -, beta -, and gamma -hexachlorocyclohexanes (HCHs), pentachlorobenzene (PeCB), and hexachlorobenzene (HeCB)] by fish is evaluated in this study. Partition coefficients of all five HOCs between surfactant micelles and simulated intestinal fluid (SIF), as well as between protein and SIF, were experimentally determined. Desorption of model HOCs from a polyethylene film into an artificial gut solution was measured to estimate the fraction of HOCs that can be absorbed from microplastics during their gut retention time. Monte-Carlo simulation (n=100,000) showed that the uptake via microplastic ingestion will be negligible for HCHs as compared to uptake via other exposure routes, water ventilation and food ingestion. On the other hand, microplastic ingestion might increase the total uptake rate of PeCB and HeCB due to their accelerated desorption from microplastics into the artificial gut solution under the model scenario, assuming an extremely high intake of microplastics. However, the steady-state bioaccumulation factor was predicted to decrease with increasing ingestion of microplastics, showing a dilution effect by microplastic ingestion. Results indicate that HOCs that are close to be at phase equilibrium between microplastics and environmental media are not likely to be further accumulated via ingestion of microplastics; this is true even for cases, where ingestion of microplastics contributes significantly to the total uptake of HOCs. Therefore, future studies need to focus on hydrophobic plastic additives that may exist in microplastics at a concentration higher than their equilibrium

concentration with water.

Lee, H., et al. (2014). "Sorption capacity of plastic debris for hydrophobic organic chemicals. (Special Section: The persistent and toxic substances in Korea.)." Science of the Total Environment **470**(471): 1545-1552.

The occurrence of microplastics (MPs) in the ocean is an emerging world-wide concern. Due to high sorption capacity of plastics for hydrophobic organic chemicals (HOCs), sorption may play an important role in the transport processes of HOCs. However, sorption capacity of various plastic materials is rarely documented except in the case of those used for environmental sampling purposes. In this study, we measured partition coefficients between MPs and seawater (K_{MPsw}) for 8 polycyclic aromatic hydrocarbons (PAHs), 4 hexachlorocyclohexanes (HCHs) and 2 chlorinated benzenes (CBs). Three surrogate polymers - polyethylene, polypropylene, and polystyrene - were used as model plastic debris because they are the major components of microplastic debris found. Due to the limited solubility of HOCs in seawater and their long equilibration time, a third-phase partitioning method was used for the determination of K_{MPsw}. First, partition coefficients between polydimethylsiloxane (PDMS) and seawater (K_{PDMSsw}) were measured. For the determination of K_{MPsw}, the distribution of HOCs between PDMS or plastics and solvent mixture (methanol:water=8:2 (v/v)) was determined after apparent equilibrium up to 12 weeks. Plastic debris was prepared in a laboratory by physical crushing; the median longest dimension was 320-440 micro m. Partition coefficients between polyethylene and seawater obtained using the third-phase equilibrium method agreed well with experimental partition coefficients between low-density polyethylene and water in the literature. The values of K_{MPsw} were generally in the order of polystyrene, polyethylene, and polypropylene for most of the chemicals tested. The ranges of log K_{MPsw} were 2.04-7.87, 2.18-7.00, and 2.63-7.52 for polyethylene, polypropylene, and polystyrene, respectively. The partition coefficients of plastic debris can be as high as other frequently used partition coefficients, such as 1-octanol-water partition coefficients (K_{ow}) and log K_{MPsw} showed good linear correlations with log K_{ow}. High sorption capacity of microplastics implies the importance of MP-associated transport of HOCs in the marine environment.

Lee, H. J., et al. (2008). "Rapid and separation-free sandwich immunosensing based on accumulation of microbeads by negative-dielectrophoresis." Biosensors and Bioelectronics **24**(4): 1000-1005.

We report here a rapid and separation-free immunoassay using a dielectrophoresis (DEP) device consisting of an interdigitated microarray (IDA) electrode and a polydimethylsiloxane (PDMS) substrate. On applying an AC voltage to the IDA in a negative-DEP (n-DEP) frequency region, goat anti-mouse immunoglobulin (anti-mouse IgG)-immobilized microbeads moved to the surface of the PDMS substrate placed above the IDA. The microbeads accumulated at designated areas of the PDMS surface that had been precoated with anti-mouse IgG. When the fluorescence microbeads bearing anti-mouse IgG were suspended in an analyte (mouse IgG) solution, the microbeads trapped the analyte to form immunocomplexes on microbeads. The microbeads reacted with mouse IgG accumulated and were captured at the designated areas of the PDMS surface via an antibody-antigen-antibody (sandwich) reaction. The captured microbeads were detected selectively by fluorescence measurements at the focused designated areas, regardless of the presence of uncaptured microbeads suspended in solution. Thus, the separation and washing-out steps usually required for conventional immunoassay are eliminated in the presented procedure. Since the formation of the sandwich structures was accelerated significantly by n-DEP, a period as short as 30 s was sufficient to detect the

immunoreaction at the surface. The fluorescence intensity of the captured microbeads at the designated areas increased with analyte concentration in the range 0.01-10 ng/mL. The present procedure therefore yields a rapid, sensitive, and separation-free immunoassay in a simple device. © 2008 Elsevier B.V. All rights reserved.

Lee, I. S., et al. (2006). "Ni/NiO core/shell nanoparticles for selective binding and magnetic separation of histidine-tagged proteins." Journal of the American Chemical Society **128**(33): 10658-10659.
Ni/NiO core/shell nanoparticles having high affinity with polyhistidine were synthesized by decomposition of a Ni surfactant complex followed by air oxidation. Ni/NiO nanoparticles showed selective and efficient binding to histidine-tagged proteins and easy separation by using a magnet. These provided a more convenient way to efficient purification of histidine-tagged proteins compared with the conventional Ni-NTA complex-bound resins and microbeads.

Lee, J., et al. (2010). "Diffractometric detection of proteins using microbead-based rolling circle amplification." Analytical Chemistry **82**(1): 197-202.
We present a robust, sensitive, fluorescent- or radiolabel-free self-assembled optical diffraction biosensor that utilizes rolling circle amplification (RCA) and magnetic microbeads as a signal enhancement method. An aptamer-based sandwich assay was performed on microcontact-printed streptavidin arranged in 15 microm wide alternating lines and could specifically capture and detect platelet-derived growth factor B-chain (PDGF-BB). An aptamer served as a template for the ligation of a padlock probe, and the circularized probe could in turn be used as a template for RCA. The concatameric RCA product hybridized to biotinylated oligonuclotides which then captured streptavidin-labeled magnetic beads. In consequence, the signal from the captured PDGF-BB was amplified via the concatameric RCA product, and the diffraction gratings on the printed areas produced varying intensities of diffraction modes. The detected diffraction intensity and the density of the microbeads on the surface varied as a function of PDGF-BB concentration. Our results demonstrate a robust biosensing platform that is easy to construct and use and devoid of fluorescence microscopy. The self-assembled bead patterns allow both a visual analysis of the molecular binding events under an ordinary bright-field microscope and serve as a diffraction grating biosensor.

Lee, J., et al. (2012). "Estrogen upregulates IL-21 production of CD4+ T lymphocytes in patients with systemic lupus erythematosus." International Journal of Rheumatic Diseases **1)**: 17.
Introduction: Systemic lupus erythematosus (SLE) is an autoimmune disease in which various organs and tissues are damaged through abnormal immune responses mediated by tissue-binding autoantibodies and immune complex deposition. As the majority of SLE patients are women of child-bearing age, estrogen has been suggested to play an important role in the pathogenesis of SLE. One of the proposed roles of estrogen is to induce B cell activation culminating in increased autoantibody production. IL-21, a common-c chain cytokine, has been shown to be crucial in differentiation of activated B cells into plasma cells. Based on these concepts, we hypothesized that estrogen contributes to pathogenesis of SLE via IL-21 dependent way and investigated the effect of estrogen on the production of IL-21 by T cells and subsequent B cell activation in SLE patients. Method(s): Peripheral blood mononuclear cells (PBMCs) were obtained from peripheral blood of 23 SLE patients and 16 healthy controls. CD4+ T cells, non CD4+ T cells, B cells were isolated using microbeads. Isolated cells were treated with 17-b estradiol at various concentrations for 48 hours (up to 72 hours in some experiments). The expression of IL-21 and its receptors was assessed by measuring protein and mRNA level using ELISA and RT-PCR, respectively. The level of immunoglobulin G secreted by activated B cells

were measured with specific ELISA. Result(s): The expression of IL-21 and its receptors in serum, PBMCs, and CD4+ T cells was higher in patients with SLE than healthy controls. Exposure of CD4+ T cells from SLE patients to 17-b estradiol leads to a dose-and time-dependent increase in IL-21 expression. The increase was abolished in the presence of MAP kinase (MEK, p38, JNK) inhibitors. B cells of healthy controls showed an increased antibody production when they were co-cultured with estrogen treated CD4+ T cells of patients with SLE. Treatment with anti-IL-21 antibody abrogated the increased antibody production of the co-culture systems, suggesting the increase was mediated by IL-21 dependent manner. Conclusion(s): This study revealed another role of estrogen in the pathogenesis of SLE. Estrogen upregulates IL-21 expression of CD4+ T cells via MAPK dependent pathways in SLE patients, which in turn in turn induces increased antibody production by B cells.

Lee, J., et al. (2014). "Estrogen upregulates interleukin-21 production of clusters of differentiation 4 positive T lymphocytes in patients with systemic lupus erythematosus." Annals of the Rheumatic Diseases. Conference: Annual European Congress of Rheumatology of the European League Against Rheumatism, EULAR **73**(SUPPL. 2).

Background Systemic lupus erythematosus (SLE) is an autoimmune disease in which various organs and tissues are damaged through abnormal immune responses mediated by tissue-binding autoantibodies and immune complex deposition. As the majority of SLE patients are women of child-bearing age, estrogen has been suggested to play an important role in the pathogenesis of SLE. One of the proposed roles of estrogen is to increase autoantibody production. IL-21, a common-gamma chain cytokine, has been shown to be crucial in the differentiation of activated B cells into plasma cells. Objectives Based on these concepts, we investigated the effect of estrogen on the production of IL-21 by T cells and subsequent B cell activation in SLE patients. Methods Peripheral blood mononuclear cells (PBMCs) were obtained from peripheral blood of 23 SLE patients and 16 healthy controls. CD4+ T cells, non CD4+ T cells and B cells were isolated using microbeads. Isolated cells were treated with 17-beta estradiol at various concentrations for 48hrs. The expression of IL-21 and its receptor was assessed by measuring the level of protein and mRNA using ELISA and RT-PCR, respectively. The level of immunoglobulin G was measured with specific ELISA. Results The expression of IL-21 and its receptor in serum, PBMCs, and CD4+ T cells were higher in the patients with SLE compared to healthy controls. Exposure of CD4+ T cells from SLE patients to 17-beta estradiol leads to a dose-and time-dependent increase in the IL-21 expression. The increase was abolished in the presence of MAP kinase (MEK, p38, JNK) inhibitors. B cells of healthy controls showed an increased antibody production when they were co-cultured with estrogen treated CD4+ T cells of patients with SLE. Treatment with anti-IL-21 antibody abrogated the increased antibody production of the co-culture systems, suggesting the increase was mediated by IL-21 dependent manner. Conclusions Estrogen upregulates IL-21 expression of CD4+ T cells via MAPK dependent pathways in SLE patients, which in turn induces increased antibody production by B cells.

Lee, J., et al. (2015). "Distribution and Size Relationships of Plastic Marine Debris on Beaches in South Korea." Archives of Environmental Contamination & Toxicology **69**(3): 288-298.

The characteristics of the distribution of plastic marine debris were determined on 12 beaches in South Korea in 2013 and 2014. The abundances of large micro- (1-5 mm), meso- (5-25 mm), and macroplastics (>25 mm) were 880.4, 37.7, and 1.0 particles/m(2), respectively. Styrofoam was the most abundant debris type for large microplastics and mesoplastics (99.1 and 90.9 %, respectively). Fiber (including fabric) was the most abundant of the macroplastics (54.7 %). There were no statistical differences in the mean numbers and weights of plastic debris among

three beach groups from west, south, and east coasts. No significant differences were detected between the abundances of beached plastics in high strandline and backshore for all three size groups. Spearman's rank correlation was used to determine the relationships between the three debris size classes. The abundance of large microplastics was strongly correlated with that of mesoplastics for most material types, which suggests that the contamination level of large microplastics can be estimated from that of mesoplastics. As surveying of smaller particles is more labor intensive, the surveying of mesoplastics with a 5-mm sieve is an efficient and useful way to determine "hot-spots" on beaches contaminated with large microplastics.

Lee, J., et al. (2013). "Mechanical, Thermal and Water Absorption Properties of Kenaf-Fiber-Based Polypropylene and Poly(Butylene Succinate) Composites." Journal of Polymers & the Environment **21**(1): 293-302.

The use of composites made from non-biodegradable conventional plastic materials (e.g., polypropylene, PP) is creating global environmental concern. Biodegradable plastics such as poly(butylene succinate) (PBS) are sought after to reduce plastic waste accumulation. Unfortunately, these types of plastics are very costly; therefore, natural lignocellulosic fibers are incorporated to reduce the cost. Kenaf fibers are also incorporated into PP and PBS for reinforcing purposes and they have low densities, high specific properties and renewable sourcing. However without good compatibilization, the interfacial adhesion between the matrix and the fibers is poor due to differences in polarity between the two materials. Maleic anhydride-grafted compatibilizers may be introduced into the system to improve the matrix-fiber interactions. The overall mechanical, thermal and water absorption properties of PP and PBS composites prepared with 30 vol.% short kenaf fibers (KFs) using a twin-screw extruder were being investigated in this study. The flexural properties for both types of composites were enhanced by the addition of compatibilizer, with improvements of 56 and 16 % in flexural strength for the PP/KF and PBS/KF composites, respectively. Good matrix-fiber adhesion was also observed by scanning electron microscopy. However, the thermal stability of the PBS/KF composites was lower than that of the PP/KF composites. This result was confirmed by both DSC and TGA thermal analysis tests. The water absorption at equilibrium of a PBS composite filled with KFs is inherently lower than of a PP/KF composite because the water molecules more readily penetrate the PP composites through existing voids between the fibers and the matrix. Based on this research, it can be concluded that PBS/KF composites are good candidates for replacing PP/KF composites in applications whereby biodegradability is essential and no extreme thermal and moisture exposures are required. [ABSTRACT FROM AUTHOR]

Lee, J., et al. (2014). "The influence of resource strategies on childhood phthalate exposure-The role of REACH in a zero waste society." Environment International **73**: 312-322.

The present study aims to investigate how resource strategies, which intend to reduce waste and increase recycling, influence on human exposure to hazardous chemicals from material recycling. In order to examine the flows of hazardous chemicals in recycled material, a mass flow analysis of plastics and paper at European level, including the flow of phthalates, i.e. di(2-ethylhexyl) phthalate (DEHP), di-n-butyl phthalate (DBP), and benzyl-butyl phthalate (BBP), has been performed. The result for the year 2012 shows that 26% of plastic wastes and 60% of paper consumed in Europe were recycled. This corresponds to the finding that approximately 4% of DEHP and BBP and 18% of DBP annual demands in Europe as raw material re-enter the product cycle with recycled plastics and paper. To examine the potential contribution of the phthalate exposure through recycled plastics and paper, a case study assessing the childhood exposures to phthalates from foods packed in recycled paper and plastics has been performed for 2-year-old children in Denmark. The result verifies that an increase in recycled paperboard and PET bottles in food packaging material causes a significant increase in childhood exposure to DBP corresponding to an additional exposure of 0.116-0.355. μg/kg. bw/day; up to 18% of the total DBP exposure in Danish 2-year-olds. While most of the DEHP exposure can be explained, more than 50% of DBP and 70% of BBP exposure sources still remain to be identified. Finally, a conceptual framework for a circular economy based on sustainable and clean resource flows is proposed in order to increase material recycling without increasing adverse health effects. •The regulation under REACH to control the quality of recycled materials is reviewed. © 2014 Elsevier Ltd.

Lee, J. H., et al. (2009). "Facile preparation of highly-scattering metal nanoparticle-coated polymer microbeads and their surface plasmon resonance." Journal of the American Chemical Society **131**(14): 5048-5049.

We report on the facile preparation of highly scattering metal-coated polystyrene (PS) latex beads by using solvent-controlled heterocoagulation. Starting with an aqueous dispersion of PS beads and poly(vinyl pyrrolidone)-capped metal nanoparticles (NPs), homogeneous and dense metal coatings were obtained by the controlled addition and removal of tetrahydrofuran (THF). Different sizes (30, 60, and 80 nm), chemistries (gold and silver), and shapes (sphere and cube) of NPs were successfully incorporated on commercially available PS beads. The resulting metal coated-PS microspheres exhibited highly enhanced scattering and tunable optical characteristics useful for biomedical imaging, sensors, and opto-electronic devices. The fabricated composite beads were stable, with no loss of metal coating, during long-term water storage. The morphology and coverage of the metal coating, and the bead's optical properties, were controllable over a wide range by the concentration of THF and metal NP, and NP size, shape, and chemistry.

Lee, K., et al. (2017). "Dual ionic cross-linked interpenetrating network of alginate-cellulose beads with enhanced mechanical properties for biocompatible encapsulation." Tissue Engineering - Part A **23 (Supplement 1)**: S135-S136.

Spherical hydrogels ('micro beads') made from alginate has been explored and used for biomedical application, delivery of biomolecule and cell transplantation, although restricted mechanical strength and short-term structural cohesion. In this study, controlling mechanical properties and maintaining the long-term structural integrity of spherical hydrogels could be achieved by creating interpenetrating networks (IPN) of alginate and aqueous-soluble cellulose with divalent and trivalent ions. By using various the aqueous-soluble cellulose, with varying concentration of cellulose or types of ions, the moduli of the resulting hydrogels could be controlled in a wide range with a simple yet highly efficient method of engineering alginate beads. We found that processing a dual sequential ionic crosslinking scheme to create IPN of alginate and cellulose with divalent and trivalent ions has synergistic effect to increase moduli and structural stability of hydrogels. Also the aqueous-soluble cellulose is found to undergo crosslinking reaction with trivalent ions more favorably than divalent ions. Especially, the aqueous-soluble anionic cellulose, containing either carboxylate or sulfonate, is easier to control

mechanical properties than other types of celluloses. As a result, the IPN alginate-cellulose beads demonstrate enhanced resistance to harsh chemical environment as compared to alginate beads and suitability for biomedical applications by encapsulating microbial species and therapeutic agents for controlled release.

Lee, K. H., et al. (2016). "Mixotrophic ability of the phototrophic dinoflagellates Alexandrium andersonii, A. affine, and A. fraterculus." Harmful Algae **59**: 67-81.

The dinoflagellate Alexandrium spp. have received much attention due to their harmful effects on diverse marine organisms, including commercially important species. For minimizing loss due to red tides or blooms of Alexandrium spp., it is very important to understand the eco-physiology of each Alexandrium species and to predict its population dynamics. Its trophic mode (i.e., exclusively autotrophic or mixotrophic) is one of the most critical parameters in establishing prediction models. However, among the 35 Alexandrium species so far described, only six Alexandrium species have been revealed to be mixotrophic. Thus, mixotrophic ability of the other Alexandrium species should be explored. In the present study, whether each of three Alexandrium species (A. andersonii, A. affine, and A. fraterculus) isolated from Korean waters has or lacks mixotrophic ability, was investigated. When diets of diverse algal prey, cyanobacteria, and bacteria sized micro-beads were provided, A. andersonii was able to feed on the prasinophyte Pyramimonas sp., the cryptophyte Teleaulax sp., and the dinoflagellate Heterocapsa rotundata, whereas neither A. affine nor A. fraterculus fed on any prey item. Moreover, mixotrophy elevated the growth rate of A. andersonii. The maximum mixotrophic growth rates of A. andersonii on Pyramimonas sp. under a 14:10h light/dark cycle of 20muEm⁻²s⁻¹ was 0.432d⁻¹, while the autotrophic growth rate was 0.243d⁻¹. With increasing mean prey concentration, the ingestion rate of A. andersonii increased rapidly at prey concentrations <650ngCml⁻¹ (ca. 16,240 cellsml⁻¹), but became saturated at the higher prey concentrations. The maximum ingestion rate by A. andersonii of Pyramimonas sp. was 1.03ngC predator⁻¹d⁻¹ (25.6 cells predator⁻¹d⁻¹). This evidence suggests that the mixotrophic ability of A. andersonii should be taken into consideration in predicting the outbreak, persistence, and decline of its harmful algal blooms.

Lee, N., et al. (2017). "Association of HLA Types with Non-Specific Binding of Negative Control Beads in Luminex Panel Reactive Antibody (PRA) Screening Assay." Clinical Laboratory **63**(1): 169-174.

BACKGROUND: Luminex panel reactive antibody (PRA) screening assays using microbeads are widely used for organ transplantation. Anti-HLA serum reactivity is calculated by correcting for non-specific binding to the negative control (NC) beads. High mean fluorescence intensity (MFI) value of NC beads are observed in some patients and can result in false negative results in the PRA screening assay. We analyzed the clinical characteristics and HLA types of those patients with high MFI values of NC beads.

METHODS: Sixty-six patients with high MFI values of NC beads (> 300) in the PRA LABScreen Mixed assay (One Lambda) tested were included as the high NC group. Age and gender matched controls with low MFI values of NC beads (< 100) (n = 132), tested with PRA, were selected as the low NC group and 207 healthy Koreans were used as normal controls. Association of clinical characteristics and HLA types with the high NC group were analyzed using Chi-square test or Fischer's exact test, as appropriate.

RESULTS: The proportion of patients with underlying liver disease was higher in the high NC group compared to the low NC group (18.1% vs. 1.5%, p < 0.001, OR = 14.2). The seropositivity of anti-nuclear antibody and rheumatoid factor, the frequency of use of intravenous immunoglobulin G, anti-thymocyte globulin, and rituximab showed no difference between two groups. The phenotype frequency (PF) of HLA-B46 was higher in the high NC group than in the low NC group (8.0% vs. 3.2%, p = 0.036, OR = 2.8). The PF of HLA-B7 was lower in the high NC group than in the healthy controls (0.0% vs. 6.5%, p = 0.008, OR = 0.1). The PF of HLA-DR1 was lower in the high NC group than in the low NC group (0.8% vs. 6.6%, p = 0.015, OR = 0.1) or healthy controls (0.8% vs. 7.4%, p = 0.003, Pc = 0.042, OR = 0.1).

CONCLUSIONS: Increased non-specific binding to NC beads was associated with underlying liver disease and HLAB46. HLA-B7 and HLA-DR1 were related to a lower chance of non-specific binding to NC beads. The mechanism of those associations, such as differences in non-specific antibody response according to HLA phenotype or underlying disease, needs to be elucidated in further studies.

Lee, R. J. and S. C. Mears (2012). "Reducing and Recycling in Joint Arthroplasty." Journal of Arthroplasty **27**(10): 1757-1760.

Reducing the need for costly contaminated waste processing after total hip arthroplasties (THAs) and total knee arthroplasties (TKAs) could decrease hospital overhead and the environmental impact. From March through April 2011, we prospectively identified 20 consecutive patients undergoing primary THA or TKA by 1 surgeon in 1 operating room at our institution. For each case, waste (excluding liquids) was collected and sorted as it was produced. The 10 THAs and 10 TKAs produced an average of 30.0 lb (range, 27.1-32.5) and 33.2 lb (range, 30.9-35.2) of waste per procedure, respectively, of which 6.8 lb (range, 6.0-7.8; 22.8%) and 7.3 lb (range, 5.4-8.7; 22.0%), respectively, were potentially recyclable paper or plastic. Waste management programs should focus on recycling clean operating room waste. © 2012 Elsevier Inc.

Lee, S., et al. (2019). "Aptamer Affinity-Bead Mediated Capture and Displacement of Gram-Negative Bacteria Using Acoustophoresis." Micromachines **10**(11): 11.

Here, we report a simple and effective method for capturing and displacement of gram-negative bacteria using aptamer-modified microbeads and acoustophoresis. As acoustophoresis allows for simultaneous washing and size-dependent separation in continuous flow mode, we efficiently obtained gram-negative bacteria that showed high affinity without any additional washing steps. The proposed device has a simple and efficient channel design, utilizing a long, square-shaped microchannel that shows excellent separation performance in terms of the purity, recovery, and concentration factor. Microbeads (10 micro m) coated with the GN6 aptamer can specifically bind gram-negative bacteria. After incubation of bacteria culture sample with aptamer affinity bead, gram-negative bacteria-bound microbeads, and other unbound/contaminants can be separated by size with high purity and recovery. The device demonstrated excellent separation performance, with high recovery (up to 98%), high purity (up to 99%), and a high-volume rate (500 micro L/min). The acoustophoretic separation performances were conducted using 5 Gram-negative bacteria and 5 Gram-positive bacteria. Thanks to GN6 aptamer's binding affinity, aptamer affinity bead also showed binding affinity to multiple strains of gram-negative bacteria, but not to gram-positive bacteria. GN6 coated bead can capture Gram-negative bacteria but not Gram-positive bacteria. This study may present a different perspective in the field of early diagnosis in bacterial infectious diseases. In addition to detecting living bacteria or bacteria-derived biomarkers, this protocol can be extended to monitoring the contamination of water resources and may aid quick responses to bioterrorism and pathogenic bacterial infections.

Lee, S. F., et al. (1996). "Separation of copper from plastic waste material by air classification and water flotation." Journal of Environmental Science and Health - Part A Environmental Science and Engineering and Toxic and Hazardous Substance Control **31**(5): 1197-1214.

The purpose of this research is to study air classification and water flotation as techniques to recover a large percentage of the copper currently being sent to landfills by metal recycling industries. These are appropriate techniques because they utilize internal plant streams which are the plant storm water and air from air conveyors used in material transport. The waste stream studied was a copper plastic waste stream that contains 3-13% copper with particle sizes between 0.5 and 5 mm. It is a crude chopped mixture that cannot be easily characterized. Air classification of the crude material could achieve an average of 60% copper recovery with 40% purity. Water flotation of the crude material could achieve an average of 60% copper recovery with 90% purity. A separation scheme is proposed that uses air classification columns that are followed by water flotation separators. The air classification operation removes the lighter fluff material. The water flotation operation purifies the recovered material. Based on the measurements made in this study, a minimum of 50% recovery of the input copper with a 90% purity can be obtained. For a 1000 tons/month feed of crude copper/plastic waste, this will result in approximately $2,000,000/year revenues (1994$) in copper and additional savings in landfill costs.

Lee, S. H., et al. (2014). "Generation of polyacrylamide microbeads by droplet based microfluidic platform and application." Toxicology and Environmental Health Sciences **6 (1 Supplement)**: S46.

Aptamers are single strand nucleic acids that binds specifically to their target molecules. Systematic Evolution of Ligands by Exponential Enrichment (SELEX) is a combinatorial chemistry technique in molecular biology for producing oligonucleotides of single strand nucleic acids. One of the most critical steps in the DNA SELEX is the conversion of double strand DNA (dsDNA) to ssDNA by asymmetric PCR or Biotin-sfreptavidin separations. We have studied that the generation of Copolymer Based Polyacrylamide microBeads (CBPmB) could be covalently cross-linked with acrydite modified oligomer by placing on droplet based microfluidic platform system. Acrydite oligomers are exposed on the surface of microbeads, they are used to amplification of ssDNA used aptamer-sensor and aptafilter, diagnostic tools, formatting some modified oligomer and DNA SELEX. Moreover, CBPmB formation was a simple method for uniformly shaped polyacrylamide gel microbeads that can be heatresistant during PCR amplification and circumvent the asymmetric PCR limitations mentioned above.

Lee, S. J., et al. (2014). "Aptamer/ISET-MS: a new affinity-based MALDI technique for improved detection of biomarkers." Analytical Chemistry **86**(15): 7627-7634.

With the rapid progress in the development of new clinical biomarkers there is an unmet need of fast and sensitive multiplex analysis methods for disease specific protein monitoring. Immunoaffinity extraction integrated with matrix-assisted laser desorption/ionization mass spectrometry (MALDI-MS) analysis offers a route to rapid and sensitive protein analysis and potentially multiplex biomarker analysis. In this study, the previously reported integrated selective enrichment target (ISET)-MALDI-MS analysis was implemented with ssDNA aptamer functionalized microbeads to address the specific capturing of thrombin in complex samples. The main objective for using an aptamer as the capturing ligand was to avoid the inherently high background components, which are produced during the digestion step following the target extraction when antibodies are used. By applying a thrombin specific aptamer linked to ISET-MALDI-MS detection, a proof of concept of antibody fragment background reduction in the ISET-MALDI-MS readout is presented. Detection sensitivity was significantly increased compared to the corresponding system based on antibody-specific binding as the aptamer ligand does not induce any interfering background residues from the antibodies. The limit of detection for thrombin was 10 fmol in buffer using the aptamer/ISET-MALDI-MS configuration as confirmed by MS/MS fragmentation. The aptamer/ISET-MALDI-MS platform also displayed a limit of detection of 10 fmol for thrombin in five different human serum samples (1/10 diluted), demonstrating the applicability of the aptamer/ISET-MALDI-MS analysis in clinical samples.

Lee, S. J., et al. (2015). "Pressure-Induced Alterations in PEDF and PEDF-R Expression: Implications for Neuroprotective Signaling in Glaucoma." Journal of Clinical & Experimental Ophthalmology **6**(5).

INTRODUCTION: Alterations in neuron-glia signaling are implicated in glaucoma, a neurodegenerative disease characterized by retinal ganglion cell (RGC) death. Pigment epithelium derived factor (PEDF) is a secreted protein with potential neuroprotective qualities in retinal disease, including chronic ocular hypertension. Here we sought to determine whether moderate, short-term elevations in IOP alter PEDF signaling and whether pressure-induced PEDF signaling directly impacts RGC apoptosis.

METHODS: In retina from naive mice and mice with unilateral, microbead-induced glaucoma, we examined expression and cell type-specific localization of PEDF and its receptor (PEDF-R), using quantitative PCR and immunohistochemistry. Using primary cultures of purified RGCs and Muller cells, we examined cell type-specific expression of PEDF in response to 48 hours of elevated hydrostatic pressure, using multiplex ELISA and immunocytochemistry. We also measured pressure-induced apoptosis of RGCs in the presence or absence of atglistatin, a potent and selective inhibitor of PEDF-R, and recombinant PEDF, using TUNEL assays.

RESULTS: PEDF and PEDF-R are constitutively expressed in naive retina, primarily in the ganglion cell and nerve fiber layers. Elevated IOP increases PEDF and PEDF-R expression, particularly associated with RGCs and Muller cells. Elevated pressure in vitro increased PEDF secretion by 6-fold in RGCs and trended towards an increase in expression by Muller cells, as compared to ambient pressure. This was accompanied by changes in the subcellular localization of PEDF-R in both cell types. Inhibition of PEDF signaling with atglistatin increased pressure-induced apoptosis in RGCs and treatment with recombinant PEDF inhibited pressure-induced apoptosis, both in a dose-dependent manner.

CONCLUSION: Our findings suggest that moderate, short-term elevations in IOP promote PEDF signaling via up-regulation of both PEDF and PEDF-R. Based on in vivo and in vitro studies, this PEDF signaling likely arises from both Muller cells and RGCs, and has the potential to directly inhibit RGC apoptosis.

Lee, S. J., et al. (2005). "Selective immobilization of fusion proteins on poly(hydroxyalkanoate) microbeads." Analytical Chemistry **77**(17): 5755-5759.

A novel fusion protein system employing the substrate-binding domain (SBD) of poly(hydroxyalkanoate) (PHA) depolymerase was developed for the specific immobilization of proteins on PHA microbeads, and was consequently used for immunoassays. The enhanced green fluorescent protein, red fluorescent protein, and severe acute respiratory syndrome coronavirus envelope protein were used as model proteins, and were selectively and functionally immobilized to the PHA microbeads by fusing them to the SBD. Using this PHA microbead system combined with SBD fusion technology, immunoassays could be successfully carried out.

Lee, S. K., et al. (2014). "High throughput synthesis of uniform biocompatible polymer beads with high quantum dot loading using microfluidic jet-mode breakup." Langmuir **30**(8): 2216-2222.

Uniform polymer microbeads with highly loaded quantum dots (QDs) are produced using high-throughput coherent jet breakup of a biocompatible poly(ethylene glycol) diacrylate (PEGDA) prepolymer resin, followed by in-line photopolymerization. A spiraling and gradually widening channel enables maximum absorption of radiated UV light for the in-line photopolymerization without coalescence and clogging issues. Although the dripping mode in general provides superior uniformity to the jet mode, our nozzle design with tapered geometry brings controlled jet breakup leading to 3% of uniform particle size distribution, comparable to dripping-mode performance. We achieve a maximum production rate of 2.32 kHz, 38 times faster than the dripping mode, at a same polymer flow rate. In addition, the jet-mode scheme provides better versatility with 3 times wider range of size control as well as the compatibility with viscous fluids that could cause pressure buildup in the microsystem. As a demonstration, a QD-doped prepolymer resin is introduced to create uniform biocompatible polymer beads with 10 wt % CdSe/ZnSe QD loading. In spite of this high loading, the resulting polymer beads exhibits narrow bandwidth of 28 nm to be used for the ultrasensitive bioimaging, optical coding, and sensing sufficiently with single bead.

Lee, S. Y., et al. (2013). "Development of microbiochip for detection of metalloproteinase 7 using fluorescence resonance energy transfer." Biochip Journal **7**(2): 164-172.

A protease is any enzyme that catalyzes the hydrolysis of proteins into smaller peptide fragments and amino acids, a process known as proteolysis. They are involved in a multitude of normal biological processes as well as in diseases, including cancer, stroke and infections. Here we present a microfluidicbased assay system to detect proteolytic activity using fluorescence resonance energy transfer (FRET) by quantum dot (QD)-peptide conjugates immobilized on microbeads. As an energy donor, QD was immobilized on the microbead surface by the avidin-biotin interaction. As an energy acceptor, the fluorophorelabeled peptide was then associated with QD, thus quenching the photoluminescence (PL) of the QD. The functionalized microbeads were introduced into the microbiochip and captured by a micropillar in the reaction chamber. In the presence of matrix metalloprotease-7 (MMP-7) as a model protease, the PL of QD quenched by fluorophore was recovered due to the proteolytic activity of MMP-7 in the fabricated microbiochip. Moreover, the FRET efficiency induced by MMP-7 was linearly dependent on the logarithmic concentration of MMP-7. This technology is not limited to sensing MMP-7, but could be used to monitor other protease activities (Schematic diagram). © 2013 The Korean BioChip Society and Springer-Verlag Berlin Heidelberg.

Lee, W. S., et al. (2019). "Bioaccumulation of polystyrene nanoplastics and their effect on the toxicity of Au ions in zebrafish embryos." Nanoscale **11**(7): 3173-3185.

As nano- and micro-sized plastics accumulate in the environment and the food chain of animals, including humans, it is imperative to assess the effects of nanoplastics in living organisms in a systematic manner, especially because of their ability to adsorb potential toxicants such as pollutants, heavy metals, and organic macromolecules that coexist in the environment. Using the zebrafish embryo as an animal model, we investigated the bioaccumulation and in vivo toxicity of polystyrene (PS) nanoplastics individually or in combination with the Au ion. We showed that smaller PS nanoplastics readily penetrated the chorion and developing embryos and accumulated throughout the whole body, mostly in lipid-rich regions such as in yolk lipids. We also showed that PS nanoplastics induced only marginal effects on the survival, hatching rate, developmental abnormalities, and cell death of zebrafish embryos but that these effects were synergistically exacerbated by the Au ion in a dose- and size-dependent manner. Such exacerbation of toxicity was well correlated with the production of reactive oxygen species and the pro-inflammatory responses synergized by the presence of PS, supporting the combined toxicity of PS and Au ions. The synergistic effect of PS on toxicity appeared to relate to mitochondrial damage as determined by ultrastructural analysis. Taken together, the effects of PS nanoplastics were marginal but could be a trigger for exacerbating the toxicity induced by other toxicants such as metal ions.

Lee, Y. H., et al. (2019). "Application of alginate microbeads as a carrier of bone morphogenetic protein-2 for bone regeneration." Journal of Biomedical Materials Research **107**(2): 286.

Bone morphogenetic protein-2 (BMP-2) is commonly used to enhance bone regeneration. The potential of BMP-2 for bone regeneration varies according to the concentration and release kinetics on the implanted site. Therefore, it is important to determine appropriate carriers of BMP-2. However, no optimal delivery vehicles have been identified. In the present study, we used alginate microbeads as a delivery vehicle for BMP-2. Alginate microbeads can be implanted onto the disease site through surgery or injection. The objective of this study was to evaluate that the osteoinductive properties of BMP-2 are effective in alginate microbeads as a carrier. In this study, the release kinetics of BMP-2 in alginate microbeads was evaluated using an enzyme-linked immunosorbent assay. BMP-2 released from alginate microbeads induced high alkaline phosphatase activity in canine adipose tissue-derived mesenchymal stem cells. Injection of alginate microbeads with BMP-2 into mouse subcutaneous tissue, as well as surgical implantation into the 5-mm circular calvarial defects in rats, was conducted and the results showed extensive new bone formation. In conclusion, alginate microbeads can be utilized as an effective BMP-2 delivery vehicle for use in orthopedic surgery and as an injectable vehicle for a minimally invasive therapy. © 2018 Wiley Periodicals, Inc. J Biomed Mater Res Part B: Appl Biomater, 107B: 286–294, 2019.

Lee, Y. H., et al. (2019). "Application of alginate microbeads as a carrier of bone morphogenetic protein-2 for bone regeneration." Journal of Biomedical Materials Research. Part B, Applied Biomaterials **107**(2): 286-294.

Bone morphogenetic protein-2 (BMP-2) is commonly used to enhance bone regeneration. The potential of BMP-2 for bone regeneration varies according to the concentration and release kinetics on the implanted site. Therefore, it is important to determine appropriate carriers of BMP-2. However, no optimal delivery vehicles have been identified. In the present study, we used alginate microbeads as a delivery vehicle for BMP-2. Alginate microbeads can be implanted onto the disease site through surgery or injection. The objective of this study was to evaluate that the osteoinductive properties of BMP-2 are effective in alginate microbeads as a carrier. In this study, the release kinetics of BMP-2 in alginate microbeads was evaluated using an enzyme-linked immunosorbent assay. BMP-2 released from alginate microbeads induced high alkaline phosphatase activity in canine adipose tissue-derived mesenchymal stem cells. Injection of alginate microbeads with BMP-2 into mouse subcutaneous tissue, as well as surgical implantation into the 5-mm circular calvarial defects in rats, was conducted and the results showed extensive new bone formation. In conclusion, alginate microbeads can be utilized as an effective BMP-2 delivery vehicle for use in orthopedic surgery and as an injectable vehicle for a minimally invasive therapy. © 2018 Wiley Periodicals, Inc. J Biomed Mater Res Part B: Appl Biomater, 107B: 286-294, 2019.

Lee, Y. M., et al. (2009). "Cascade enzyme-linked immunosorbent assay (CELISA)." Biosensors & Bioelectronics **25**(2): 332-337.

Immunoassays are representative biochemical detection methods. Among them, sandwich-type immunoassays, typified by sandwich ELISA, have used in disease diagnosis or biochemical detection with high target selectivity. Horseradish peroxidase and alkaline phosphatase have been typically used for signal amplification in ELISA. Recently developed sandwich-type immunoassays such as biobarcode immunoassays, immuno-PCR, and immuno-RCA have improved sensitivity by changing mainly the signal amplification method. To develop a novel amplification method in ELISA, an enzyme-cascading system was incorporated into an ELISA, and the new assay is termed a cascading enzyme-linked immunosorbent assay (CELISA). This CELISA includes a trypsinogen-enterokinase combination as the cascading enzyme system, and was used to detect alpha-fetoprotein (AFP), which is a liver cancer marker, and prostate-specific antigen (PSA). Using a colorimetric reagent for signal generation, CELISA had 0.1-10pM limits-of-detection for AFP and PSA in whole human serum and assay buffers, depending on the platform, well plate, or microbead type used. This study represents the first example that incorporated an enzyme cascading step in an ELISA system, resulting in successful signal amplification with sensitive detection of pathogenic antigens in serum.

Lefebvre, C., et al. (2019). "Microplastics FTIR characterisation and distribution in the water column and digestive tracts of small pelagic fish in the Gulf of Lions." Marine Pollution Bulletin **142**: 510-519.

This study aims at quantifying and characterising microplastics (MP) distribution in the water column of the NW Mediterranean Sea as well as MP ingestion by the 2 main planktivorous fish of the area, sardine and anchovy. Debris of similar sizes were found in all water column samples and in all but 2 fish guts (out of 169). MP were found in 93% of water column samples with an average concentration of 0.23+or-0.20 MP.m⁻³, but in only 12% of sardines (0.20+or-0.69 MP.ind⁻¹) and 11% of anchovies (0.11+or-0.31 MP.ind⁻¹). Fibres were the only shape of MP encountered and polyethylene terephthalate was the main polymer identified in water columns (61%), sardines (71%) and anchovies (89%). This study confirms the ubiquity of MP in the Mediterranean Sea and imparts low occurrence in fish digestive tracts.

Lehmann, C., et al. (2012). "Magnetic colocalization of viral vectors and target cells improves transduction efficiency in human hematopoietic cells." Molecular Therapy **1)**: S223.

A major factor limiting viral transduction of target cells in cell culture is the diffusion of virus particles to the cell surface. Polycationic reagents, recombinant fibronectin, spinoculation or the use of polycationic magnetic particles and a magnetic field can be used to increase vector concentration at the cell surface. In a further refinement of this latter method, we have labeled the target cells with standard magnetic cell separation reagents (MACSMicroBeads) in addition to magnetic labeling of the viral vector particles before placing these on a magnetic cell separation column. Magnetic labeling of both virus particles and the target cells ensures an efficient colocalization within the high-gradient magnetic field of a MACS Separator leading to reduced viral reagent requirements and specific transduction of only the magnetically-labeled target cells (Blood: 117: e171-181). In this study, both polycationic magnetic particles and antibody-conjugated superparamagnetic nanoparticles (MicroBeads) were assessed for their ability to bind to viral vector particles and transduce human cell lines and primary hematopoietic cells. Polycationic magnetic particles complexed GFP-encoding adenoviral (AdV) and lentiviral (LV) vector particles effectively. After AdV transduction (pMOI, physical particles per cell=200-500) of human cells of low permissivity (K562, M-07e, HuT78), up to 15- fold more cells were transduced after magnetic colocalization with increases in target gene expression of over 40-fold. Similarly, CD34+ cells isolated from peripheral blood with CD34 MicroBeads could be transduced efficiently (pMOI=2000, 15% GFP+ cells (3 fold over control) and 8-fold higher

MFI). Transduction of human T cells and CD34+ cells with LV vectors was also supported using this protocol. Both numbers of transduced cells and the expression intensity of the transgene were increased (T cells, MOI=0.5, 30% GFP+; CD34+ cells, MOI=50, 75% GFP+). During LV budding from the cell membrane, host membrane proteins are also incorporated into the viral membrane. MicroBeads that bind these molecules can be used to isolate wildtype HIV from patient samples, but can also be used to magnetically label recombinant LV vectors (efficiency >90%) and direct them to a target cell. Using this approach, vector particles could be directed to target cells expressing the same surface molecule. An enhanced transduction was observed (3-fold) when both magnetically labeled vector and cells were combined in MACS columns as described above. (T cells, MOI=0.5, 30% GFP+; CD34+ cells, MOI=25, 69% GFP+). These novel transduction reagents and protocols enable a fast, flexible and reproducible transduction of target cells to be performed that is independent of vector titer. As current cell therapy and gene therapy approaches require many manual handling steps between collecting the patient or donor cell sample and returning the modified cell product to the patient, these protocols are currently being assessed for their suitability for incorporation into a functionally closed and fully automated cell processing device for the manufacture of gene therapeutic cellular products.

Lehner, R., et al. (2019). "Emergence of Nanoplastic in the Environment and Possible Impact on Human Health." Environmental Science & Technology **53**(4): 1748-1765.

On account of environmental concerns, the fate and adverse effects of plastics have attracted considerable interest in the past few years. Recent studies have indicated the potential for fragmentation of plastic materials into nanoparticles, i.e., "nanoplastics," and their possible accumulation in the environment. Nanoparticles can show markedly different chemical and physical properties than their bulk material form. Therefore possible risks and hazards to the environment need to be considered and addressed. However, the fate and effect of nanoplastics in the (aquatic) environment has so far been little explored. In this review, we aim to provide an overview of the literature on this emerging topic, with an emphasis on the reported impacts of nanoplastics on human health, including the challenges involved in detecting plastics in a biological environment. We first discuss the possible sources of nanoplastics and their fates and effects in the environment and then describe the possible entry routes of these particles into the human body, as well as their uptake mechanisms at the cellular level. Since the potential risks of environmental nanoplastics to humans have not yet been extensively studied, we focus on studies demonstrating cell responses induced by polystyrene nanoparticles. In particular, the influence of particle size and surface chemistry are discussed, in order to understand the possible risks of nanoplastics for humans and provide recommendations for future studies.

Lei, K., et al. (2017). "Microplastics releasing from personal care and cosmetic products in China." Marine Pollution Bulletin **123**(1-2): 122-126.

Microplastics (MPs) have become a major global issue; their release from various products affects the aquatic environment, especially marine ecosystems. As a primary source of MPs, personal care and cosmetics products (PCCPs) containing MPs contribute to this environmental risk. We visited several supermarket chains in Beijing, China to identify PCCPs containing MPs. Overall, 7.1% of facial cleansers contained MPs, with an average weight of 25.04+/-10.69mgMP/g and average size of 313+/-130mum; whereas, 2.2% of shower gel products contained an average weight of 17.80+/-7.50mgMPs/g with an average size of 422+/-185mum. The majority of MPs were made of polyethylene, based on Raman and Fourier transform-infrared spectra analyses, while only a few were made of walnut shells and carbon particles. Finally, estimated 39tons MPs were released into the environment based on PCCPs

use in China based on available data.

Lei, L., et al. (2018). "Polystyrene (nano)microplastics cause size-dependent neurotoxicity, oxidative damage and other adverse effects in Caenorhabditis elegans." Environmental Science: Nano **5**(8): 2009-2020.

(Nano)microplastics (N/MPs) are emerging contaminants of increasing concern. However, little is known about the potential toxicity difference between nanoplastics and microplastics on organisms. In this study, we investigated the effects of polystyrene N/MPs with diameter sizes of 100 and 500 nm at the nanoscale and 1.0, 2.0 and 5.0 micro m at the microscale on the survival, lifespan, motor behavior, movement-related neurons and oxidative stress in Caenorhabditis elegans. After 3 days of exposure to 1.0 mg L⁻¹ polystyrene particles of the five sizes, the 1.0 micro m group had the lowest survival rate, the largest decrease in body length and the shortest average lifespan in nematodes. We demonstrated that exposure to N/MPs accelerated the frequency of body bending and head thrashing, and increased crawling speed, which indicate that N/MPs can induce size-dependent excitatory toxicity on locomotor behavior. Of the five sizes of N/MPs, 1.0 micro m particles significantly downregulated the expression of unc-17 and unc-47, and resulted in obvious damage to cholinergic and GABAergic neurons. We also found that polystyrene N/MPs significantly elevated the expression of gst-4, which encodes glutathione S-transferase-4, a key enzyme in oxidative stress. Additionally, N/MPs-induced oxidative damage was effectively attenuated by natural antioxidants, curcumin and oligometric proanthocyanidins. Taken together, these findings suggest that (nano)microplastics can exert size-dependent toxicity and have extensive impacts on organisms.

Lei, L., et al. (2018). "Microplastic particles cause intestinal damage and other adverse effects in zebrafish Danio rerio and nematode Caenorhabditis elegans." Science of the Total Environment **619**(620): 1-8.

Microplastics have been frequently detected in aquatic environments, and there are increasing concerns about potential effects on biota. In this study, zebrafish Danio rerio and nematode Caenorhabditis elegans were used as model organisms for microplastic exposure in freshwater pelagic (i. e. water column) and benthic (i. e. sediment) environments. We investigated the toxic effects of five common types of microplastics: polyamides (PA), polyethylene (PE), polypropylene (PP), polyvinyl chloride (PVC) and polystyrene (PS) particles. Results showed no or low lethality in D. rerio after exposure for 10 d at 0.001-10.0 mg L⁻¹ microplastics. The PA, PE, PP and/or PVC microplastics with ~70 micro m size caused intestinal damage including cracking of villi and splitting of enterocytes. Exposure to 5.0 mg m⁻² microplastics for 2 d significantly inhibited survival rates, body length and reproduction of C. elegans. Moreover, exposure to microplastics reduced calcium levels but increased expression of the glutathione S-transferase 4 enzyme in the intestine, which indicates intestinal damage and oxidative stress are major effects of microplastic exposure. Among 0.1, 1.0 and 5.0 micro m sizes of fluorescently labeled PS, 1.0 micro m particles caused the highest lethality, the maximum accumulation, the lowest Ca²⁺ level in the intestine and the highest expression of glutathione S-transferase 4 in nematodes. Taken together, these findings suggest that intestinal damage is a key effect of microplastics; and that the toxicity of microplastics is closely dependent on their size, rather than their composition.

Leibacher, J., et al. (2017). "Human mesenchymal stromal cells undergo apoptosis and fragmentation after intravenous application in immune-competent mice." Cytotherapy **19**(1): 61-74.

BACKGROUND AIMS: The biodistribution of human MSCs after systemic delivery is incompletely understood. We investigated the changes in cell size and cell surface markers of human MSCs after intravenous (IV) injection in immune competent mice.

METHODS: Male human MSCs were labeled with fluorescent vital dye PKH67 and tracked after IV administration in C57/BL6 mice. MSCs were tracked in blood and different murine tissues by human SRY gene quantitative polymerase chain reaction (qPCR) analysis, flow cytometry and fluorescence microscopy. Calibrated microbeads were used to track the size of transplanted MSCs.

RESULTS: The majority of injected MSCs were detected by qPCR in the lungs 5 min after transplantation, whereas <0.1% were detected in other tissues over 24 h. Flow cytometric and fluorescence microscopic analysis indicated that MSCs continuously decreased in size after transplantation and underwent fragmentation. The majority of PKH⁺ MSCs and their fragments were found in lungs and liver. PKH⁺ MSCs rapidly became positive for annexin V, propidium iodide and calreticulin, indicating loss of cell integrity. In addition, PKH⁺ fragments co-stained with antibodies against C3b, F4/80 and/or GR-1 indicating opsonization. Preincubation of MSCs in hyperosmolaric hydroxyethyl starch (HyperHAES) decreased MSCs size before transplantation, delayed the loss of viability markers and increased the frequency of traceable MSCs up to 24 h after transplantation.

CONCLUSIONS: PKH67 labeled MSCs are fragmented after IV injection in mice, acquire apoptotic and phagocytic cell markers and accumulate in the lungs and liver.

Leifeld, F. (1996). "COTTON WASTE RECLAMATION." Recycling Textile & Plastic Waste: 107-119.

The article concentrates on the reclamation of cotton waste. It focuses on the recovery of cotton fibers that are used as wadding which is added to blends of raw materials to be spun in their pure state for special fabric qualities suitable cotton spinning. It is implied that efficient cleaning is related to the separated quantities of waste. It is stated that the quality of cleaning can only be judged by figures and is essential to maintain the quantity of separated wastes and their composition.

Leissner, S. and Y. Ryan-Fogarty (2019). "Challenges and opportunities for reduction of single use plastics in healthcare: A case study of single use infant formula bottles in two Irish maternity hospitals." Resources, Conservation & Recycling **151**: N.PAG-N.PAG.

• Quality assessment showed high material variability and problems in material labelling. • Quantity assessment explored recycling potentials and need for proper waste management. • Waste management practices can cause secondary environmental impacts. • Recycling potential may be greatest for smallest mass materials. • Mitigation calls for demand reduction, product adjustment and waste management. • Collaborative efforts are required to reduce quantity of single-use plastics. The issue of plastic pollution is now recognised as a catastrophic global crisis. Single-use plastics have attracted much attention in terms of elimination and mitigation measures. The concept of circular economy aims to attain a state where waste no longer exists. Pathways to eliminate or adapt stages of the life cycle, long before the end-of-life phase, are necessary to address single-use plastics. This paper examines single-use food packaging plastic waste in Irish maternity hospital settings through a case study of ready-to-use infant formula bottles. A quantitative and qualitative assessment of single-use plastics arising from infant feeding bottles is presented. Quantitative examination reveals a high variability in materials used for bottles, teats and associated packaging, thus creating difficulties in standardising labelling and identifying appropriate waste treatment options. Quantitative calculations reveal the extent of plastic waste generated by this single use product. Possible mitigation options include: demand reduction for single-use bottles in the first place, alternative solutions to

eliminate single-use bottles, opportunities for manufacturers to address product design, impetus for policy makers to act on coherent labelling systems for materials and improved overall waste management. Considering the level of confusion at hospital and household levels as to best practice in recycling, this research highlights the need for targeted collaborative research utilising sectoral best practice, waste hierarchy and circular economy principles. Leitner, G., et al. (2013). "Immunotherapy of mastitis." Veterinary Immunology and Immunopathology **153**(3/4): 209-216.
The aim of this study was to examine an alternative, immunologically based treatment for mastitis. A microbead carrying specific anti-mastitis bacteria antibodies and an enhancer of phagocytosis, termed Y-complex, was tested in two experiments. In experiment 1, 21 cows were challenged with Streptococcus dysgalactiae and treated with Y-complex, Cobactan LCReg. or saline. Y-complex cleared the bacteria by day 4 and by day 10 only one cow was positive and remained positive up to day 28. No bacteria were isolated from any of the seven cows treated with Cobactan LC after day 4; however, in two out of the seven cows, the bacteria were re-isolated on day 24. On day 28, cows treated with placebo had still not cleared the bacteria. Experiment 2 was a field study in which cows, naturally infected with Escherichia coli, S. dysgalactiae or coagulase-negative staphylococci (CNS), were treated with Y-complex (32 cows), sulfadiazine+trimethoprim or procaine penicillin+streptomycin (BA) (8 cows), or a non-steroidal anti-inflammatory drug (NSAID) (19 cows). Y-complex was as effective as antibiotics, and superior to NSAID, in eliminating bacteria. Milk quantity and quality following infection and treatment were similar for all treatments, but significantly less milk was discarded from cows treated with Y-complex as compared to antibiotics. Y-complex was proven to be safe and effective, and may serve as a new approach for the treatment of mastitis.

Leitner, W. W. and U. Krzych (1997). "Plasmodium falciparum malaria blood stage parasites preferentially inhibit macrophages with high phagocytic activity." Parasite Immunology **19**(3): 103-110.
Exposure to malaria blood stage antigens results in several defects of macrophages/monocytes one of which is an irreversible reduction of phagocytic activity. In the present study we analysed phagocytic activity of subpopulations of human monocyte-derived-macrophages (MDM) based on the capacity of individual cells to ingest FITC-labelled microbeads. The results demonstrate that malaria infection affected predominantly MDM subpopulations with high level of phagocytosis. This population decreased during parasitaemia, however, during recovery from the infection the highly phagocytic cells replaced the damaged cells. The exposure of MDM cultures to blood stage antigens showed that the highly active macrophages from persons with active malaria infection decreased further, while the population increased during recovery. Furthermore, we observed that while ingestion of a few parasitized RBC (3 schizonts) stimulated phagocytosis, larger amounts or longer exposure periods eventually paralysed the entire phagocytic system. Accordingly, by selectively blocking actively phagocytizing macrophages, the malaria parasite prevents both specific and non-specific immune responses, which are initiated by macrophages as phagocytes and professional antigen presenting cells.

Leitz, K. H., et al. (2011). "Ultrafast microsphere near-field nanostructuring." Proceedings of SPIE - The International Society for Optical Engineering **7925**.

Due to the steadily advancing miniaturization in all fields of technology nanostructuring becomes increasingly important. Whereas the classical lithographic nanostructuring suffers from both high costs and low flexibility, for many applications in biomedicine and technology laser based nanostructuring approaches, where near-field effects allow a sub-diffraction limited laser focusing, are on the rise. In combination with ultrashort pulsed laser sources, that allow the utilization of non-linear multi-photon absorption effects, a flexible, low-cost laser based nanostructuring with sub-wavelength resolution becomes possible. Among various near-field nanostructuring approaches the microsphere based techniques, which use small microbead particles of the size of the wavelength for a sub-diffraction limited focusing of pulsed laser radiation, are the most promising. Compared to the tip or aperture based techniques this approach is very robust and can be applied both for a large-scale production of periodic arrays of nanostructures and in combination with optical trapping also for a direct-write. Size and shape of the features produced by microsphere near-field nanostructuring strongly depend on the respective processing parameters. In this contribution a basic study of the influence of processing parameters on the microsphere near-field nanostructuring with nano-, pico- and femtosecond laser pulses will be presented. The experimental and numerical results with dielectric and metal nanoparticles on semiconductor and dielectric substrates show the influence of particle size and material, substrate material, pulse duration, laser fluence, number of contributing laser pulses and polarization on the structuring process.

Lembo, S., et al. (2012). "Visible blue light effects on denditric cells." Journal of Investigative Dermatology **2)**: S120.

Visible blue light has a wavelength spectrum from 400 nm to 475 nm with a peak at 420 nm. Theoretically, blue light could induce biological effects comparable to UVA radiation, since wavelengths of blue light are closely related to the UVA spectrum, hence effects on the skin have been reported. In the present study, the effects of blue light on dendritic cells (DCs) maturation and pro-inflammatory cytokines production are investigated. Monocyte derived dendritic cells were isolated from peripheral blood mononuclear cells, using anti-CD14 conjugate magnetic microbeads. To assess whether blue light was able to modify DCs differentiation and maturation process, CD 14+ cells were irradiated with 2.5; 5; 10 and 15 J/cmdegree of blue light. Thereafter immature DCs (iDCs) were generated through incubation with granulocytes monocytes-colony stimulating factor (GM-CSF) and interleukin (IL)-4. Finally mature DCs were obtained after incubation of iDCs with LPS and were identified through flow cytometry using anti CD83 and CD86 antibodies. The production of proinflammatory cytokines, such as IL-6 and TNF-alpha, was also assessed by intracitoplasmatic immunofluorescence in irradiated and unirradiated cells. The exposure to blue light did not alter the ability to terminal differentiate in mature DCs. Blue light treatment reduced, in a dose dependent manner, the production of IL-6 and TNF-alpha promoted by LPS in the mature DCs. This report indicates that blue light has anti-inflammatory effects on DCs, without altering their differentiation process.

Lemechko, P., et al. (2019). "Production of poly(3-hydroxybutyrate-co-3-hydroxyvalerate) using agro-industrial effluents with tunable proportion of 3-hydroxyvalerate monomer units." International Journal of Biological Macromolecules **128**: 429-434.

With increasing concerns about future oil depletion and plastic pollution, bioplastics saw an increasing interest from scientists and industrials. Among bioplastics, the polyhydroxyalkanoates

(PHA) are a promising family of polyester which are both biosourced and biodegradable. Biosynthesized by microorganisms, especially bacteria, control of their monomeric composition, and thus their thermal and mechanical properties, is still a challenge to really make tailor-made syntheses. Moreover, one way to decrease the high cost of production is to use waste as substrates for the microorganisms. In this study, a marine bacteria, Halomonas sp. SF2003 was grown on agro-industrial effluents as the sole carbon sources and was able to produce poly(3-hydroxybutyrate) (PHB) with a productivity of 1.3 g.L⁻¹ in 40 h of culture and a number-average molar weight of 342,000 g.mol⁻¹. With the addition of valeric acid in the substrates, poly(3-hydroxybutyrate-co-3-hydroxyvalerate) (PHBHV) with controlled proportion of hydroxyvalerate (HV) monomers were obtained. Their thermal and mechanical characteristics were investigated as a function of HV amount and showed a decrease of the glass transition and melting temperatures and in Young modulus with the HV content increase.

Lemoine, C. M. R., et al. (2018). "Transcriptional effects of polyethylene microplastics ingestion in developing zebrafish (Danio rerio)." Environmental Pollution **243**(Part A): 591-600.

Over the last few decades, plastic waste has become an increasing environmental concern as it accumulates in every environment on our planet. Though traditionally seen as a macroscopic problem (i.e., large plastic debris), plastic pollution is also evident at smaller scales. Indeed, the intentional industrial production of small plastic particles and the physical degradation of larger plastic debris have overtime resulted in an increased environmental prevalence of smaller plastic particles, including microplastics. While the effects of these small polymers on marine biota have been an important research focus, recent global surveys indicate that our freshwater lakes and rivers are also plagued by microplastics. However, despite these discoveries we currently have a limited understanding of the impact these particles may have on freshwater animals, particularly on vertebrate species. Thus, the aim of the present study was to assess the impact of high concentrations of microplastics (5 and 20 mg.L⁻¹) on the early life stages in zebrafish, a model freshwater vertebrate model. To do this, we exposed embryonic and larval zebrafish to fluorescently labelled polyethylene microspheres for up to 14 days and assessed their microplastic content, growth, hatching and oxygen consumption rates. We then explored the molecular underpinnings of the microplastic response by RNA sequencing. Over the course of the exposure, we observed a consistent accumulation of microplastics in the gastrointestinal tract of the fish in a concentration dependent manner, but could not detect any detrimental effects of these particles on larval development, growth or metabolism. However, whole animal transcriptomics revealed that microplastics induced a transient and extensive change in larval gene expression within 48 h exposure, which largely disappeared by 14 days. However, as these transcriptional changes occurred during a critical period of larval development, we suggest that an evaluation of the potential long-term impact of these particles is warranted.

Lenaker, P. L., et al. (2019). "Vertical Distribution of Microplastics in the Water Column and Surficial Sediment from the Milwaukee River Basin to Lake Michigan." Environmental Science & Technology **53**(21): 12227-12237.

Microplastic contamination was studied along a freshwater continuum from inland streams to the Milwaukee River estuary to Lake Michigan and vertically from the water surface, water subsurface, and sediment. Microplastics were detected in all 96 water samples and 9 sediment samples collected.

Lenormand, G., et al. (2007). "Out-of-equilibrium dynamics in the cytoskeleton of the living cell." Physical Review E. Statistical, Nonlinear, & Soft Matter Physics **76**(4 Pt 1): 041901.

We report here measurements of rheological properties of the human airway smooth muscle cell using forced nanoscale motions of Arg-Gly-Asp RGD-coated microbeads tightly bound to the cytoskeleton. With changes of forcing amplitude, the storage modulus showed small but systematic nonlinearities, especially after treatment with a contractile agonist. In a dose-dependent manner, a large oscillatory shear applied from a few seconds up to 400 s caused the cytoskeleton matrix to soften, a behavior comparable to physical rejuvenation observed in certain inert soft materials; the stiffness remained constant for as long as the large oscillatory shear was maintained, but suddenly fell with shear cessation. Stiffness then followed a slow scale-free recovery, a phenomenon comparable to physical aging. However, acetylated low-density lipoprotein acLDL-coated microbeads, which connect mainly to scavenger receptors, did not show similar out-of-equilibrium behaviors. Taken together, these data demonstrate in the cytoskeleton of the living cell behaviors with all the same signatures as that of soft inert condensed systems. This unexpected intersection of condensed matter physics and cytoskeletal biology suggests that trapping, intermittency, and approach to kinetic arrest represent central mesoscale features linking underlying molecular events to integrative cellular functions.

Lenz, R., et al. (2016). "Microplastic exposure studies should be environmentally realistic." Proceedings of the National Academy of Sciences of the United States of America **113**(29): E4121-4122.

Lenz, R., et al. (2015). "A critical assessment of visual identification of marine microplastic using Raman spectroscopy for analysis improvement." Marine Pollution Bulletin **100**(1): 82-91.

Identification and characterisation of microplastic (MP) is a necessary step to evaluate their concentrations, chemical composition and interactions with biota. MP >=10mum diameter filtered from below the sea surface in the European and subtropical North Atlantic were simultaneously identified by visual microscopy and Raman micro-spectroscopy. Visually identified particles below 100mum had a significantly lower percentage confirmed by Raman than larger ones indicating that visual identification alone is inappropriate for studies on small microplastics. Sixty-eight percent of visually counted MP (n=1279) were spectroscopically confirmed being plastic. The percentage varied with type, colour and size of the MP. Fibres had a higher success rate (75%) than particles (64%). We tested Raman micro-spectroscopy applicability for MP identification with respect to varying chemical composition (additives), degradation state and organic matter coating. Partially UV-degraded post-consumer plastics provided identifiable Raman spectra for polymers most common among marine MP, i.e. polyethylene and polypropylene.

Lenz, R. and M. Labrenz (2018). "Small microplastic sampling in water: development of an encapsulated filtration device." Water **10**(8).

A variety of microplastic sampling instrumentation is currently used for water pollution studies. Plankton net-based approaches have been the most adopted techniques for water column and surface sampling. When applied to microplastics (MP) in the lower micro m size range these methods, however, introduce non-negligible risks of sample contamination and loss due to instrument and procedure design. Based on the first principles of systems engineering design we have developed a mobile sampling platform for field application that fulfils the needs of producing usable MP samples with a lower size limit of 10 micro m using an encapsulated flow-through filtration concept. Here, we explain the requirements, development, and construction of the device for others to replicate and improve.

Lenzi, J., et al. (2016). "Plastic ingestion by a generalist seabird on the coast of Uruguay." Marine Pollution Bulletin **107**(1): 71-76.

We analyzed plastic ingestion by Kelp Gull (Larus dominicanus) from 806 pellets collected between 2011 and 2013. Employing a Raman spectroscopy, we characterized those polymers used to produce the plastics ingested. Debris was recorded in 143 pellets (%FO=17.7%, n=202, 92.58 g). Plastic was found in 119 pellets (%FO=83%) and non-plastic occurred in 56 pellets (%FO=39%). The most important debris category was plastic film with 55.3% (n=79). Plastic bags were observed in 19 pellets (%FO=2.4%, weight=25.02 g). Glass was the second most important component (%FO=18.9%) followed by plastic fragments (%FO=17.8%). Plastic debris represented the 65.3% of the debris fragments (n=132, weight=58.84 g), and was composed by polyethylene (52%), polypropylene (26%), polyamide (12%), polystyrene (6%), polyvinyl chloride (2%), and polyethylene terephthalate (2%). How plastics were obtained by gulls and the effects on individuals are discussed, as well as environmental considerations about plastic pollution on coastal environments.

Leo, C., et al. (2013). "Cell-cell contact is essential for IgE-regulating activity of human CD8-positive cytotoxic T lymphocytes in vitro." Experimental Dermatology **22 (3)**: e4-e5.

IgE-production in vitro in patients with extrinic atopic dermatitis (AD) / atopy syndrome is controlled in part by CD8pos T cells. Mechanisms remain unclear. Whereas in mice cell-cell contact is essential for this regulatory activity this was not investigated in humans, yet. Ficoll-isolated peripheral blood mononuclear cells (PBMC) of seven patients with exacerbated extrinsic atopic dermatitis/atopy syndrome were depleted of CD8pos lymphocytes using two purification cycles (MS-columns, anti-CD8 microbeads, Miltenyi Biotec, Bergisch Gladbach) according to the manufacturer's instruction. 5 9 105 cells/well were seeded in 24 well flat bottom plates (Corning, 6.5 mm transwell inserts, 0.4 m pore size, RPMI supplemented with fetal calf serum) and incubated for 10 days at 37degreeC. Conditions: (i) all PBMC, (ii) PBMC w/o CD8pos cells, (iii) PBMC CD8-depleted and subsequently reconstituted with CD8pos cells, (iv) CD8-depleted PBMC (lower transwell chamber) and CD8pos cells (upper chamber). Cell free supernatants were collected and stored at -80degreeC until determination of IgE levels using the ImmunoCap100 system (low rage level, Phadia, Freiburg). Under these experimental conditions, CD8-depletion resulted in elevated IgE-levels as compared to all PBMC in 50% of patients. CD8-reconstitution with cell-cell contact abandoned this elevation confirming earlier findings. In contrast, CD8-reconstitution in the transwell system, i.e. without cellcell contact, did not influence IgE-production significantly. Thus, the majority of IgE controlling mechanisms in vitro by CD8pos T cells seems to be dependent of T-B cell contact.

León, V. M., et al. (2018). "Potential transfer of organic pollutants from littoral plastics debris to the marine environment." Environmental Pollution **236**: 442-453.

Plastic polymers act as passive samplers in air system and concentrate hydrophobic organic contaminants by sorption or specific interactions, which can be transported to other systems such as the marine environment. In this study plastic debris was sampled in the surrounding area of a Mediterranean lagoon in order to determine the concentration of persistent and emerging organic contaminants. More specifically, desorption of 91 regulated and emerging organic contaminants (polycyclic aromatic hydrocarbons, polychlorinated biphenyls, organochlorinated pesticides, current-use pesticides, personal care products, other pesticides and plastic additives) was characterized for the first 24 h from different polymers to seawater and the remaining content of these contaminants was also extracted by ultrasonic extraction

with methanol. All samples were analyzed by Stir Bar Sorptive Extraction coupled to GC/MS. A significant fraction of sorbed contaminants in polymers was desorbed in the first 24 h, particularly for triazines and organophosphorus pesticides due to their lower hydrophobicity than other considered analytes. The remaining contaminants contained in plastics can be also transferred to seawater, sediments or biota. Considering 24 h desorbed fraction plus the remaining methanol extracted fraction, the highest transfer levels corresponded to personal care products, plastic additives, current-use pesticides and PAHs. This is the first study to show the relevance of the transport of organic contaminants on plastic debris from littoral areas to the marine environment. [ABSTRACT FROM AUTHOR]

Leonard, A., et al. (2017). "Bone marrow characterization in sickle cell disease: Inflammation and stress erythropoiesis lead to suboptimal cd34 recovery compared to normal volunteer bone marrow." Blood. Conference: 59th Annual Meeting of the American Society of Hematology, ASH **130**(Supplement 1).

Introduction Gene therapy for sickle cell disease (SCD) requires modification of a high number of long term engrafting hematopoietic stem cells (LT-HSCs) sufficient to sustain production of the gene of interest at levels capable of overcoming the pathogenic HbSS phenotype. Unlike beta-Thalassemia, the inflammatory bone marrow (BM) environment and stress erythropoiesis associated with SCD may have significant impacts on HSC quality and yield necessary for disease amelioration. Important work to optimize gene therapy through improvement in gene transfer efficiency, editing strategies, or transplant conditioning can only improve gene therapy in SCD if enough autologous HSCs are LT-HSCs, thus characterization of SCD BM and CD34+ HSCs is required. Collection type, storage, and delays in processing may further impact CD34+ recovery and should be investigated as a strategy to maximize LT-HSC recovery. Method(s): Twenty milliliters of BM from subjects with SCD (HbSS genotype) and normal volunteers was collected in different anticoagulants (Heparin, ACD-A) and processed immediately(day 0) or stored at 4C and processed the following day(day 1). After isolation via Ficoll density gradient centrifugation, the mononuclear (MN) layer was stained with antibodies against inflammatory markers (CD36, CD35, CD11b, CD62L, CD62P), non-MN cells (GPA, CD66b, CD41/61), or processed for CD34+ selection using a magnetic microbead CD34+ selection kit and stained for CD34, CD45, and GPA expression. Data were analyzed by conventional and imaging flow cytometry, the latter confirming post-CD34+ selection flow data and demonstrating antibody intensity as a characterization of HSC heterogeneity and progenitor lineage. Complete blood count and hemoglobin (HB) electrophoresis were obtained at the time of BM collection. Statistical analyses were performed using unpaired t-tests. Result(s): BM was collected from 18 subjects (16 with SCD; 11M; age 21-41 years). Median Hb (8.6 vs. 13.5 gm/dL, $p<0.01$) and white blood cell count (8.8 vs. 4.2 K/mcL, $p<0.05$) differed significantly between SCD and non-SCD subjects. Median percent sickle Hb in SCD subjects was 62%. Inflammatory markers and contamination with red cell and platelet markers in the post-Ficoll MN layer were higher in SCD vs. non-SCD BM regardless of anticoagulant (CD35 24% vs. 13%, $p<0.05$; CD36 22% vs. 11%, $p<0.05$; CD62P 16% vs. 3%, $p<0.05$; GPA 16% vs. 4%, $p<0.05$; CD41/61 19% vs. 3%, $p<0.05$), and trended higher on day 1 in SCD BM in both anticoagulants, significantly in Heparin (GPA 23% vs. 33% on day 1, $p<0.05$). Total CD45 expression was lower in SCD vs. non-SCD BM in both anticoagulants (p<0.05) and on day 0 (p<0.05) and 1 (p<0.01), with Amnis data confirming a higher CD34+CD45-population in SCD BM (4 +/- 2% vs. 0.5 +/- 0.3%, p<0.05). While there was no significant difference in total CD34+ cell count between SCD and non-SCD BM after selection post-Ficoll, there was a trend for lower CD34+ count in SCD in both anticoagulants (2.6x105 vs. 4.7x105, p=0.1). SCD CD34+ cells were characterized by higher GPA expression (28 +/- 5% vs. 13 +/- 3% in non-SCD BM, p<0.01) that worsened in Heparin on day 1 (22 +/- 6.3% vs. 35 +/- 12.4%, p<0.05). Image cytometry confirmed a majority of GPA expression in SCD BM is from single cell CD34+CD45+GPA+ and CD34+CD45-GPA+ HSCs in addition to red cell aggregates, with an increase in CD34+CD45-GPA+ HSCs on day 1 (10 +/- 5% vs. 0.6 +/- 0.2 % on day 0, p<0.05). Furthermore, the percentage of CD34hi HSCs was lower in SCD vs. non-SCD BM, with >50% SCD HSCs characterized as CD34dim (56% vs. 4% in non-SCD BM, p<0.001). Lastly, the purity of CD34+ selection worsened from day 0 to day 1 in SCD BM in heparin (94% vs. 68 +/- 8%, p<0.05) and ACD-A (88% vs. 68 +/- 0.7%, p<0.05). Conclusion(s): SCD BM is characterized by increased inflammation and cell contamination in the MN layer regardless of anticoagulant that worsens over time in Heparin more significantly than in ACD-A. Compared to non-SCD BM, CD34+ HSC yield post-Ficoll is lower in SCD subjects, and is characterized by a larger proportion of CD34+CD45+GPA+ and CD34+CD45-GPA+ HSCs that rise with delays in processing. This indication of early differentiation along the erythroid lineage, with more than 50% of HSCs losing CD34+ intensity suggesting they are not LT-HSCs, suggests suppression of inflammation and stress erythropoiesis, combined with early cell processing may be critical for maximal HSC recovery necessary for successful gene therapy in SCD.

Leonardo Pantoja, M., et al. (2018). "Characterisation of “flushable” and “non-flushable” commercial wet wipes using microRaman, FTIR spectroscopy and fluorescence microscopy: to flush or not to flush." Environmental science and pollution research international **25**(20): 20268-20279.

The introduction to the market of wet wipes, advertised and labelled as “flushable”, has been the subject of controversy due to their perceived potential to block sewer systems as observed with other non-woven cloths such as traditional non-flushable wipes. Non-woven cloths that enter wastewater systems can find their way into the aquatic environment via wastewater effluents and it has been suggested that the breakdown of these fabrics can release materials such as microplastics into the environment. Worldwide research has revealed the alarming number of aquatic organisms affected by the presence of plastic debris in the aquatic environment harbouring a potential risk to humans through the introduction of microplastics into the food chains. However, the actual material composition of flushable wipes, their fate and impacts in the aquatic environment have not yet been scientifically studied. This paper investigates the fibre composition of flushable and non-flushable wipes, specifically with regard to synthetic polymer material, using Fourier transform infrared (FTIR) and microRaman spectroscopy along with fluorescence microscopy. The study demonstrated the presence of polyester (polyethylene terephthalate, (PET)), high-density polyethylene (HDPE) and polyethylene/vinyl acetate (PEVA/EVA) in some flushable wipes and PET in all non-flushable. Other polymers such us polypropylene (PP), low-density polyethylene (LDPE), expanded polystyrene (EPS) and polyurethane (PU) were also identified as potential components in the flushable material. Hence, commercially available wet wipes labelled as flushable could also be considered as a possible source of microplastic fibres in the wastewater streams and, if not retained, in the environment.

Leon-Zayas, R., et al. (2019). "Draft genome sequences of five environmental bacterial isolates that degrade polyethylene terephthalate plastic." Microbiology Resource Announcements **8 (25) (no**

pagination)(e00237-19).

Here, we report the annotated draft genome sequences of three Pseudomonas spp. and two Bacillus spp. that, as consortia, degrade polyethylene terephthalate plastic. Improved microbial degradation of plastic waste could help reduce the billions of metric tons of these materials that currently exist in our environment. Copyright © 2019 Leon-Zayas et al.

Lesher-Perez, S. C., et al. (2017). "Dispersible oxygen microsensors map oxygen gradients in three-dimensional cell cultures." Biomaterials Science **5**(10): 2106-2113.

Phase fluorimetry, unlike the more commonly used intensity-based measurement, is not affected by differences in light paths from culture vessels or by optical attenuation through dense 3D cell cultures and hydrogels thereby minimizing dependence on signal intensity for accurate measurements. This work describes the use of phase fluorimetry on oxygen-sensor microbeads to perform oxygen measurements in different microtissue culture environments. In one example, cell spheroids were observed to deplete oxygen from the cell-culture medium filling the bottom of conventional microwells within minutes, whereas oxygen concentrations remained close to ambient levels for several days in hanging-drop cultures. By dispersing multiple oxygen microsensors in cell-laden hydrogels, we also mapped cell-generated oxygen gradients. The spatial oxygen mapping was sufficiently precise to enable the use of computational models of oxygen diffusion and uptake to give estimates of the cellular oxygen uptake rate and the half-saturation constant. The results show the importance of integrated design and analysis of 3D cell cultures from both biomaterial and oxygen supply aspects. While this paper specifically tests spheroids and cell-laden gel cultures, the described methods should be useful for measuring pericellular oxygen concentrations in a variety of biomaterials and culture formats. Leskow, A., et al. (2019). "Can contamination of the environment by dioxins cause craniofacial defects?" Human & Experimental Toxicology **38**(9): 1014-1023.

Cleft lip and cleft palate also known as orofacial cleft is a congenital malformation involving the partial or total lack of anatomical continuity of craniofacial tissue. The most common environmental factors that may cause orofacial clefts include pharmaceuticals, alcohol, addictive drugs, and tobacco smoke. Living in the area of industrial factories, garbage, ironworks, crematoria, wastewater treatment plants, and plastic waste landfills also has a significant impact on the development of the craniofacial defects. Some of the main factors causing the formation of congenital craniofacial defects are dioxins, of which emission to the environment is an important environmental and health problem. Dioxins are a diverse group of organic chemical compounds, derivatives of oxanthrene and fumarates, which are organoleptically imperceptible. Acting mainly through induction of inflammation, they influence a number of metabolic processes, including the process of bone mineralization and embryonic development. In this work, we highlight the problem of orofacial cleft including the impact of dioxin on development of this defect and the recommended prevention.

Leslie, H. A., et al. (2017). "Microplastics en route: Field measurements in the Dutch river delta and Amsterdam canals, wastewater treatment plants, North Sea sediments and biota." Environment International **101**: 133-142.

Environmental contamination by plastic particles, also known as 'microplastics', brings synthetic materials that are non-degradable and biologically incompatible into contact with ecosystems. In this paper we present concentration data for this emerging contaminant in wastewater treatment plants (WWTPs) and freshwater and marine systems, reflecting the routes via which these particles can travel and the ecosystems they potentially impact along their path. Raw sewage influents, effluents and sewage sludge from seven municipal WWTPs in the Netherlands contained mean particle concentrations of 68-910L⁻¹, 51-81L⁻¹ and 510-760kg⁻¹ wet weight (ww), respectively (particle sizes between 10 and 5000mum). Even after treatment, wastewater constitutes a source of microplastic pollution of surface waters, and via biosolids applications in farming and forestry, plastic retained in sewage sludge can be transferred to terrestrial environments. The WWTPs investigated here had a mean microplastics retention efficiency of 72% (s.d. 61%) in the sewage sludge. In the receiving waters of treated and untreated wastewaters, we detected high microplastic levels in riverine suspended particulate matter (1400-4900kg⁻¹ dry weight (dw)) from the Rhine and Meuse rivers. Amsterdam canal water sampled at different urban locations contained microplastic concentrations (48-187L⁻¹), similar to those observed in wastewater that is emitted from sewage treatment facilities in the area. At least partial settling of the particles occurs in freshwater as well, as indicated by microplastics in urban canal sediments (<68 to 10,500particleskg⁻¹dw). Microplastics in suspension in the water column have the potential to be discharged into the sea with other riverine suspended particulates. We report microplastic concentrations from 100 up to 3600particleskg⁻¹ dry sediment collected at 15 locations along the Dutch North Sea coast. The high microplastic enrichment in marine sediments compared to most literature data for seawater at the surface supports the hypothesis of a seabed sink for these materials. Marine species are heavily exposed to plastic particles. Body residues between 10 and 100particlesg⁻¹dw were measured in benthic macroinvertebrate species inhabiting the Dutch North Sea coast: filter-feeding mussels and oysters (species for human consumption) as well as other consumers in the marine food chain.

Leslie, H. A., et al. (2016). "Propelling plastics into the circular economy - weeding out the toxics first." Environment International **94**: 230-234.

The Stockholm Convention bans toxic chemicals on its persistent organic pollutants (POPs) list in order to promote cleaner production and prevent POPs accumulation in the global environment. The original 'dirty dozen' set of POPs has been expanded to include some of the brominated diphenyl ether flame retardants (POP-BDEs). In addition to cleaner production, there is an urgent need for increased resource efficiency to address the finite amount of raw materials on Earth. Recycling plastic enhances resource efficiency and is part of the circular economy approach, but how clean are the materials we are recycling? With the help of a new screening method and detailed analyses, we set out to investigate where these largely obsolete BDEs were showing up in Dutch automotive and electronics waste streams, calculate mass flows and determine to what extent they are entering the new product chains. Our study revealed that banned BDEs and other toxic flame retardants are found at high concentrations in certain plastic materials destined for recycling markets. They were also found in a variety of new consumer products, including children's toys. A mass flow analysis showed that 22% of all the POP-BDE in waste electrical and electronic equipment (WEEE) is expected to end up in recycled plastics because these toxic, bioaccumulative and persistent substances are currently not effectively separated out of plastic waste streams. In the automotive sector, this is 14%, while an additional 19% is expected to end up in second-hand parts (reuse). These results raise the issue of delicate trade-offs between consumer safety/cleaner production and resource efficiency. As petroleum intensive materials, plastic products ought to be repaired, reused, remanufactured and recycled, making good use of the 'inner circles' of the circular economy. Keeping hazardous substances - whether they are well known POPs or emerging contaminants - out of products and plastic waste streams could make these cycles work better for businesses, people and nature.

Leslie, S. K., et al. (2016). "Development of a cell delivery system using alginate microbeads for tissue regeneration." Journal of materials chemistry. B, Materials for biology and medicine. **4**(20): 3515-3525.
Alginate microbeads incorporating adipose-derived stem cells (ASCs) have potential for delivering viable cells capable of facilitating tissue regeneration. These microbeads are formed in calcium crosslinking solutions containing organic osmolytes to ensure physiological osmolality, but the comparative effects of these osmolytes on the microencapsulated cells are not known. In addition, delivery parameters needed to use microencapsulated cells for tissue regeneration remain unknown. We investigated the following parameters: (1) osmolyte effects on microbead diameter, cell viability and growth factor production; (2) the effect of the number of cells per microbead and the number of microbeads per unit volume on cell viability, growth factor production, and microbead degradation; (3) the ability of both degradable and non-degradable alginate microbeads to localize cells at the delivery site in vivo; and (4) whether alginate microbeads containing alginate-lyase elicit an inflammatory response after repeated exposure. Smallest microbead diameters were achieved using glucose as the osmolyte but cell viability and growth factor production did not depend on osmolyte type. As cell number per microbead or microbead number per well increased, growth factor production per cell decreased although percent cell viability was unchanged. The rate of cell release varied with the number of beads per well and with the number of cells per microbead. At the highest microbead density and at the lowest density of cells per microbead, cell release was delayed. Therefore fewer microbeads may be sufficient for clinical applications. Both degradable (0.22 U g-1) and non-degradable (0 U g-1) alginate microbeads localized cells at the delivery site. Degradable alginate microbeads delivered subcutaneously elicited a mild chronic inflammatory response on second exposure, but how this might impact repeated use of the technology remains to be determined.

Lessa, M. A., et al. (2013). "Cutaneous microcirculation as a marker of endothelial dysfunction in patients undergoing on-pump coronary artery bypass graft." European Journal of Anaesthesiology **51)**: 71.
Background: Coronary artery bypass graf t (CABG) surgery with cardiopulmonary bypass (CPB) is associated with systemic inflammatory response and endothelial dysfunction. In the present study we used Laser Doppler perfusion monitoring associated with pharmacological and physiological stimulation to evaluate the subacute effects of the CPB in the skin microcirculation in patients undergoing CABG surgery. Material(s) and Method(s): Twenty-three patients were evaluated on the day of surgery and 7 days after the CABG surgery with CPB. Plasma nitrite/ nitrate (NOx) concentrations, cytokine detection by multiplex microbead Immunoassay and high-sensitivity C-reactive Protein (hs-CRP) were determined. The skin microcirculation was evaluated by microiontophoresis of acetykcoline (Ach) and sodium nitroprusside (SNP), post occlusive reactive hyperemia (POHR), and thermal hyperemia. Cytokines and inflammatory markers such as C-reactive protein (CPR), nitrite/nitrate and IL-6 were also analyzed. Results and Discussion: Seven days after the surgery patients presented high levels of IL-6 and CPR e low bioavailability of nitric oxide. CABG surgery with CPB induced a significant reduction in the skin microvascular flux after cumulative doses of Ach (endothelium-dependent) and after thermal hyperemia. There was a significant delay in time to maximum flux after POHR. CABG surgery with CPB did not induce any significant change in the microvascular flux after cumulative doses ot SNP (endothelium-independent). We observed a significant impairment of endothelial function and a well-preserved endothelium- independent vasodilatation in the skin

microcirculation in patients 7 days after the CABG surgery with CPB. Conclusion(s): Our results suggest that Laser Doppler perfusion monitoring in the skin microcirculation may be a useful tool for the assessment of the subacute CPB-induced endothelial dysfunction in patients.

Lestari, P. and Y. Trihadiningrum (2019). "The impact of improper solid waste management to plastic pollution in Indonesian coast and marine environment." Marine Pollution Bulletin **149**: 1.

Plastic pollution has become a major concern in Indonesian coast and marine environment today. It occurs because 14% of the solid waste (SW) components in this country is plastic, and the SW management (SWM) infrastructure and services are still limited. The objectives of this article are to discuss the improper SWM and its impact to plastic pollution in Indonesia. Ten plastic pollution studies concerning macroplastics (MaP) and microplastics (MP) were described. These studies covered 5 regions, namely Java, East Nusa Tenggara, East Kalimantan, South Sulawesi, North and Southwest Sumatera. The highest MP abundance of 37,440–38,790 particles/kg dry weight (DW) sediment was found in Jakarta Bay, followed by Wonorejo Coast in Surabaya City (414–590 MP particles/kg DW sediment). The MP has entered the food chain through bivalves and fish. Therefore, the plastic pollution which is related to population density, and inadequacy of SWM, needs urgent solution.

Le-Tien, C., et al. (2004). "Modified alginate matrices for the immobilization of bioactive agents." Biotechnology & Applied Biochemistry **39**(Pt 2): 189-198.

Bioactive agents (catalase - an enzyme, and nisin - a bacteriocin) were covalently immobilized on alginate activated with sodium periodate (oxidatively converting 2,3-dihydroxy groups into dialdehyde residues), followed or preceded by ionotropic gelation. For the same protein coupling yield, the retained enzyme activity of the immobilized enzyme (ImE) can be markedly increased by diminishing the bead diameter, a phenomenon that illustrates the role of substrate/product diffusion through the bead gel layer. When the amount of enzyme introduced for coupling was about 15 mg/100 mg of support and the bead diameter was about 100 microm, a high retained specific activity (95-98%) was obtained. Diffusion phenomena can be markedly decreased by enzyme immobilization on the surface of microbeads (obtained by gelation of activated alginate prior to immobilization). In this case, the retained activity was approx. 75% of that of the free enzyme. A slightly higher K (m) value of ImE suggested that the enzyme-substrate affinity was almost maintained. The profiles of ImE activities at various pH values, at various temperatures and when undergoing proteolysis showed a overall higher stability for the immbolized than that for the free enzyme. Nisin immobilized on the microbead surface, when submitted to proteolysis, conserved its bacteriocin activity, strongly inhibiting the growth of Lactobacillus sake when subjected to an agar spot test, whereas free nisin totally lost its activity.

Letzkus, M., et al. (2014). "Gene expression profiling of immunomagnetically separated cells directly from stabilized whole blood for multicenter clinical trials." Clinical and Translational Medicine **3**: 36.

BACKGROUND: Clinically useful biomarkers for patient stratification and monitoring of disease progression and drug response are in big demand in drug development and for addressing potential safety concerns. Many diseases influence the frequency and phenotype of cells found in the peripheral blood and the transcriptome of blood cells. Changes in cell type composition influence whole blood gene expression analysis results and thus the discovery of true transcript level changes remains a challenge. We propose a robust and reproducible procedure, which includes whole transcriptome gene expression profiling of major subsets of immune cell cells directly sorted from whole blood.

METHODS: Target cells were enriched using magnetic microbeads and an autoMACS Pro Separator (Miltenyi Biotec). Flow cytometric analysis for purity was performed before and after magnetic cell sorting. Total RNA was hybridized on HGU133 Plus 2.0 expression microarrays (Affymetrix, USA). CEL files signal intensity values were condensed using RMA and a custom CDF file (EntrezGene-based).

RESULTS: Positive selection by use of MACS Technology coupled to transcriptomics was assessed for eight different peripheral blood cell types, CD14+ monocytes, CD3+, CD4+, or CD8+ T cells, CD15+ granulocytes, CD19+ B cells, CD56+ NK cells, and CD45+ pan leukocytes. RNA quality from enriched cells was above a RIN of eight. GeneChip analysis confirmed cell type specific transcriptome profiles. Storing whole blood collected in an EDTA Vacutainer tube at 4degreeC followed by MACS does not activate sorted cells. Gene expression analysis supports cell enrichment measurements by MACS.

CONCLUSIONS: The proposed workflow generates reproducible cell-type specific transcriptome data which can be translated to clinical settings and used to identify clinically relevant gene expression biomarkers from whole blood samples. This procedure enables the integration of transcriptomics of relevant immune cell subsets sorted directly from whole blood in clinical trial protocols.

Leung, J. and K. Chan (2018). "Microplastics reduced posterior segment regeneration rate of the polychaete Perinereis aibuhitensis." Marine Pollution Bulletin **129**(2): 782-786.

Microplastics are found in abundance in and on coastal sediments, and yet, whether exposure to this emerging pollutant negatively impact whole organism function is unknown. Focusing on a commercially important polychaete, Perinereis aibuhitensis, we demonstrated that presence of microplastics increased mortality and reduced the rate of posterior segment regeneration. The impact of the micro-polystyrene beads was size-dependent with smaller beads (8-12 micro m in diameter) being more detrimental than those bigger in size (32-38 micro m). This observed difference suggests microplastic impact could be affected by physical properties, e.g., sinking speed, surface area available for sorption of chemicals and bacteria, and selective feeding behaviors of the target organism.

Leusden, P. v., et al. (2017). "Permeation of probe molecules into alginate microbeads: effect of salt and processing." Food Hydrocolloids **73**: 255-261.

The ability to exclude harmful factors from a hydrogel microbead is important for the degree of protection the beads offers to what is encapsulated within. The permeability of alginate microbeads, prepared by water-in-oil emulsification, was investigated by their ability to exclude FITC-labelled protein probes. The influence of alginate concentration, calcium concentration and method of addition, and salt content of the environment was investigated. The permeability was also compared to the permeability of beads made by the traditional method of dripping an alginate solution into a CaCl₂ solution. Beads produced with low amounts of CaCl₂ show a significant degree of swelling and are therefore very permeable (C/C₀ (BSA)=0.62, where C is the final concentration of BSA-FITC in the bead, and C₀ the concentration of BSA-FITC in the continuous phase). With additional calcium, either by adding more calcium crystals after the emulsification step or by washing with a CaCl₂ solution, beads swell less and are less permeable (C/C₀ (BSA)=0.13 and 0.12). Beads made by dripping are very permeable (C/C₀ (BSA) ~ 0.60). Because in this process the droplets of alginate are not constrained by a water-oil boundary, the beads can swell during gelation. The salt concentration in the continuous phase influences the strength of the electrostatic repulsion between the probes and the alginate

network and hence affects the permeation of the probes into the beads. In the absence of salt, even FITC (389Da) is mostly excluded from the interior of the beads (C/C₀ (FITC) ~ 0.09).

Leusden, P. v., et al. (2018). "Lipase diffusion in oil-filled, alginate micro- and macrobeads." Food Hydrocolloids **85**: 242-247.

Triglycerides, which are broken down in the lower part of the intestinal tract, give a stronger ileal brake feedback, resulting in a feeling of satiety and causing people to eat less. The digestion of triglycerides into fatty acids by lipase in the intestine can be delayed by encapsulating oil droplets. In this study the release of fatty acids and oil droplet breakdown in a simulated intestinal system was investigated, for oil droplets encapsulated in alginate micro- (10.7 micro m) and macrobeads (1.77 mm). It was found that fatty acid release rate was greatly decreased by encapsulating the oil droplets into an alginate matrix compared to loose droplets. Microscopic imaging of the breakdown of the oil droplets showed a sharp front moving from the bead interface to the centre of the bead, and the change in position of the front scaled linear with time. The motion of the front is well described by combining the mass balance for lipase with a Maxwell-Cattaneo type equation, for the mass flux vector. The front in microbeads seemed to move slightly slower (0.15 (+or-0.04) micro m per minute) than for the macrobeads (0.20 (+or-0.02) micro m per minute). The release of free fatty acids in microbeads was faster than in macrobeads, despite the slower front movement, because of the larger amount of surface area available.

Leveque, J. G. and R. C. Burns (2018). "Drinking water in West Virginia (USA): tap water or bottled water - what is the right choice for college students?" Journal of Water & Health **16**(5): 827-838.

West Virginia has had a history of water quality issues. In parallel, the world is facing a plastic pollution crisis. In order to better understand behavioral responses to perceived water quality, a survey was conducted at a major research university to ask participants about water quality perceptions and drinking water behaviors. A total of 4,188 students completed the survey during the Spring 2017 semester. Logistic regression analyses were used to predict behaviors.

Levett, P., et al. (2009). "Application of multiplex PCR and fluid microbead-based assay to investigation of institutional outbreaks of viral respiratory disease." International Journal of Antimicrobial Agents **2)**: S6.

Objective(s): The aim of this study was to investigate the use of molecular diagnostic assays for the detection of viral pathogens in institutional outbreaks. During the winter months from January to April 2008, specimens from 22 outbreaks of respiratory disease, investigated by public health departments in Saskatchewan, were tested at the Saskatchewan Disease Control Laboratory for viral pathogens. Method(s): 124 specimens were tested (mean 5.6 specimens per outbreak, range 2-12) using conventional virological methods (DFA and tissue culture) in addition to a multiplex PCR-fluid microbead-based assay (using the Abbott RVP kit on the Luminex 200) and real-time PCR assays. Result(s): Pathogens were detected by multiplex PCR-fluid microbeadbased assay in 79/124 specimens (63.7%). Of these, 60 specimens were positive for pathogens that were detectable by conventional virologic techniques. Viruses were detected in 22 specimens by DFA and in 18 by tissue culture. Multiple viruses were detected in 9 outbreaks. Real-time PCR assays were performed on all specimens from outbreaks in which pathogens were detected by multiplex PCRfluid microbead-based assay, with the exception of coronaviruses and rhinoviruses/enteroviruses, for which assays were not available. Realtime PCR assays were positive in 56/60 (93%) specimens. Conclusion(s): Using conventional

techniques (DFA and tissue culture), pathogens were detected from patients in 11 outbreaks. However, a commercial multiplex PCR-fluid microbead-based assay demonstrated pathogens in all 22 outbreaks, of which seven involved only coronaviruses and rhinoviruses/enteroviruses, which were not detectable by conventional methods and for which real-time PCR assays were not available. A combination of conventional methods (DFA) and the multiplex PCR-fluid microbead-based assay would give the most rapid and complete detection of viruses in the outbreaks studied.

Levin, A., et al. (2012). "Anti-TNF-induced regulatory macrophages mechanisms of immunosuppression." Journal of Crohn's and Colitis **1)**: S35.

Background: Anti TNF-a antibodies are effective at inducing and maintaining remission in Crohn's disease, although the exact mechanism by which they exert this function is not fully understood. We have previously shown that anti-TNF-a antibodies induce a distinct population of macrophages with immune-regulatory and wound healing properties. How these macrophages exert these functions has remained unclear. The aim of this study was to elucidate which pathways are involved in the wound healing and regulatory functions of anti-TNF induced regulatory macrophages. Method(s): PBMC were isolated from peripheral blood of healthy donors. Mixed lymphocyte reactions were established by coculturing PBMC of two individual donors in a 1:1 ratio. Cultures were treated with infliximab and macrophages were isolated using CD14-microbeads. Inflammatory M1 type macrophages were generated by culturing of monocytes in the presence of IFN-gamma. Gene expression was determined by microarray followed by pathway analysis. Result(s): As expected, infliximab-induced macrophages displayed upregulation of a number of genes associated with regulatory or wound healing macrophages including CD206 and CD163. Expression of known anti-inflammatory cytokines such as IL-10 and TGF-beta was not altered, indicating alterative mechanisms of immune-suppression. Interestingly, various lipid processing and signalling pathways were upregulated in infliximab induced regulatory macrophages, including cholesterol signalling through the lipid X and retinoic X receptors. Conclusion(s): Infliximab-induced macrophages express a number of genes associated with M2 macrophages, but do not show a clear upregulation of anti-inflammatory cytokines. Instead, various lipid signalling pathways are activated, suggesting a role for these pathways in the immunosuppression exerted by anti-TNF induced regulatory macrophages.

Levin, A., et al. (2013). "Vitamin D potentiates the immunosuppressive effect of anti-TNF induced regulatory macrophages." United European Gastroenterology Journal **1)**: A351.

INTRODUCTION: We have previously shown that anti-TNF-alpha antibodies induce a distinct population of macrophages with immune regulatory and wound healing properties. An environmental factor that has been shown to induce tolerogenicity in dendritic cells is Vitamin D. Interestingly, epidemiological studies have shown that Crohn's disease patients have a high prevalence of vitamin D deficiency. These results incited us to investigate the role of Vitamin D in anti-TNF induced macrophages. AIMS&METHODS: The aim of this study was to see if the Vitamin D receptor pathway is involved in the induction of anti-TNF induced macrophages and if Vitamin D can potentiate immunosuppressive effect of these macrophages. PBMC's were isolated from peripheral blood of healthy donors. Mixed lymphocyte reactions were established by co-culturing PBMC's of two healthy individual donors in a 1:1 ratio. Cultures were treated with anti-TNF to induce anti-TNF induced macrophages. Inflammatory M1 type macrophages were generated by culturing of monocytes in the presence of IFN-gamma. Gene expression of anti- TNF compared to M1 macrophages was determined by microarray followed by pathway analysis. To determine the effect of Vitamin D on the immunosuppressive effect of anti-TNF

induced regulatory macrophages, cell culture experiments were performed in the presence or absence of 1,25-dihydroxyvitamin D. Macrophages were isolated with CD14 microbeads and co-cultured with activated T-cells from a third donor. Proliferation was measured by ³H thymidine incorporation. RESULT(S): Anti-TNF induced macrophages displayed an increased expression of a number of components of the vitamin D receptor pathway, including the vitamin D receptor (VDR) and osteopontin (OPN). Addition of 1,25-dihydroxyvitamin D to the cultures did not result in enhanced numbers of regulatory macrophages. However, macrophages generated in the presence of 1,25-dihydroxyvitamin D did show an increased inhibition of T-cell proliferation, indicating increased immunosuppressive function. CONCLUSION(S): Anti-TNF induced macrophages show an increased activation of the vitamin D receptor pathway. Furthermore the immunosuppressive properties of wound healing macrophages induced by anti-TNF-alpha can be potentiated by 1,25-dihydroxyvitamin D.

Levina, V. V., et al. (2011). "Ovarian cancer stem cell cytokine microenvironment." Cancer Research. Conference: 102nd Annual Meeting of the American Association for Cancer Research, AACR **71**(8 SUPPL. 1).

Objectives: Epithelial ovarian cancer (EOC) is an extremely aggressive disease associated with a lack of early symptoms, rapid progression to peritoneal metastases, and poor prognosis for patients. Currently available treatments are not effective in preventing or slowing metastatic spread, and the therapeutic resistance of EOC remains a major unresolved clinical and scientific problem. Cancer stem cells (CSCs) represent the most aggressive part of the tumor. CSCs are drug resistant and are thought to be responsible for the failure of chemotherapy. Earlier, we demonstrated that chemotherapy can lead to selection of CSCs. We hypothesized that malignancy of CSCs was associated with an efficient cytokine network. Method(s): Ovarian CSCs and primary adherent epithelial cultures were established from ascites from ovarian cancer patient with stage III EOC. Ovarian CSCs were isolated using magnetic beads separation columns and human CD133 and CD44 Microbead kits from Miltenyl Biotec and were grown as tumor spheres. The High Content Screening (HCS) and High Content Analysis (HCA) platform from Thermo Scientific Cellomics was applied to study the CSC markers, embryonic markers, transcription factors, epithelial mesenchimal transition markers, cytokines, chemokines, growth and angiogenetic factor receptor expression and intracellular cytokine accumulation. Multiplex xMAP technology was used for the analysis of human cytokines and growth factors in cell culture medium. An in vivo SCID mouse model was used for the analysis of tumorigenity of bulk EOC cells and CSCs. Result(s): We established primary EOC cell lines and CSCs from ascites of 3 EOC patients. We confirmed that cells growing in tumor spheres demonstrate all the properties of CSCs: they express high levels of CSCs markers and low levels of differentiated markers, they have capacity to self-renew and differentiate, and they are highly tumorigenic in SCID mice. The EMT and CSC phenotypes were both exhibited in ovarian CSCs. We found that ovarian CSCs have a specific cytokine microenvironment involving the up-regulation of multiple cytokine-receptor axes. Conclusion(s): Our findings provide new knowledge regarding ovarian CSC biology. They elucidate the important role of the specific cytokine-receptor signaling axis for the self-renewal and proliferation of ovarian CSCs. We concluded that an optimal antitumor efficacy will be achieved by inhibiting both tumor cell populations: CSCs and bulk EOC cells. We suggest that combining two treatment modalities, e.g. RTK inhibitor that targets CSCs, and cisplatin that eradicates bulk tumor cells will represent a novel paradigm in EOC therapy.

Levine, B. L., et al. (2013). "Adoptive transfer of gene-modified T-cells engineered to express high-affinity TCR'S for cancer-testis antigens NY-ESO-1 or lage-1, in multiple myeloma (MM) patients post autologous hematopoietic stem cell transplant (ASCT)." Cytotherapy **1)**: S13.

Adoptive immunotherapy for cancer has been limited by poor antigen specificity, low target antigen expression, and self-tolerance.We hypothesized that genetic engineering of autologous T cells with affinity-enhanced tumor antigen-specific T cell receptors (TCRs) and ex vivo CD3/CD28 costimulation may overcome these limitations.We are conducting a clinical trial (NCT01352286) evaluating T cells engineered with an HLA-A0201 restricted, affinity-enhanced TCR that recognizes an epitope expressed by NY-ESO-1 and LAGE-1 tumor antigens (TCR-T). TCR-T are infused in the setting of profound lymphodepletion that accompanies high-dose chemotherapy followed by aSCT in patients with high risk or relapsed multiple myeloma (MM). TCR-T are manufactured from an apheresis product depleted of monocytes and CD25+ cells, gene-modified by lentivector, and expanded using microbead-based CD3/CD28 costimulation. 15 patients have been infused. 11 more are planned. An average of 8.5 x 10⁹ TCR-T, with transduction efficiency averaging 33%, was administered per patient. 15, 13, and 10 patients have reached the day 42, 100 and 180 MM assessment time points, respectively. At day 100, 10/13 (77%) patients have a best response of VGPR or better and 3/13 (23%) have partial responses. 5 patients have progressed after day 100 and 10 continue to respond to therapy. These results are especially encouraging since 4/15 patients had prior aSCT and 8/15 had high risk cytogenetics. TCR-T expanded through day 14, and persisted in all patients through day 180 and to levels up to 1% at 1yr in blood and marrow by flow cytometry. Patients with progressive disease showed low levels or loss of TCR-T, or loss of target tumor antigen at time of progression, suggesting specific activity of TCR-T. This is the first test of TCR-T in the MM setting, which indicates it is well tolerated and associated with encouraging response rates.

Levine, B. L., et al. (2013). "Safety and correlates of clinical response in an early phase clinical trial in multiple myeloma patients post auto-sct and adoptive immunotherapy with engineered t cells expressing an HLA-A2 restricted affinity-enhanced tcr for lage-1 and ny-ESO-1." Molecular Therapy **1)**: S114.

Immune-based therapy based on the adoptive transfer of engineered-T cells has shown recent and considerable promise against chemotherapy resistant tumors. Engineering of T cells to express tumor-antigen T cell receptors (TCRs) allows for the ability to target both surface and intracellular antigens. Rational affinity enhancement of TCRs allows for the ability to effectively overcome the limitations associated with central tolerance and generate potent T cells to target self-antigens expressed by tumors. We are conducting an early phase clinical trial (NCT01352286) to investigate the safety, feasibility and anti-tumor activity of T cells engineered to express an affinity-enhanced TCR which recognizes the NY-ESO-1/LAGE-1 peptide complex HLA-A*0201-SLLMWITQC. Under this protocol, patients with high risk or relapsed, NY-ESO-1 and/or LAGE-1 positive multiple myeloma (MM), are infused with autologous TCRengineered T cells, 2 days after autologous stem cell transplantation (aSCT). Engineered T cells are activated and expanded using anti- CD3/28 antibody conjugated microbeads, and gene modified to express affinity-enhanced TCR using lentivirus gene transfer. Disease response is evaluated in accordance with the IMWG criteria at 6 weeks, and 3 and 6 months post infusion. Patient blood and marrow is monitored for the persistence and phenotype of gene modified cells and marrow is monitored for expression of NY-ESO-1 and LAGE-1 antigen. 17 patients have been infused with an average of 2.7 x 109 gene modified cells (range 4.5 x 108 - 4.2 x 109). Infusions were well tolerated. At 3 months, 77% of patients experienced a very good partial response (VGPR) or better. In all patients, engineered T cells expanded robustly in vivo, and were detectable in peripheral blood and marrow at 180 days by both Q-PCR and flow-cytometry-based approaches in all but one case. In a subset of patients, robust and long-term persistence of engineered T

cells was observed in periphery and marrow, accompanied by ongoing strong clinical responses and absence of target antigen expression in marrow. Conversely, disease progression has been accompanied by loss of engineered T cells and re-expression of target antigen in marrow.

Levitan, I., et al. (2000). "A Chamber to Permit Invasive Manipulation of Adherent Cells in Laminar Flow with Minimal Disturbance of the Flow Field." Annals of Biomedical Engineering **28**(10): 1184-1193.

An obstacle to real-time in vitro measurements of endothelial cell responses to hemodynamic forces is the inaccessibility of the cells to instruments of measurement and manipulation. We have designed a parallel plate laminar flow chamber that permits access to adherent cells during exposure to flow. The "minimally invasive flow device" (MIF device) has longitudinal slits (1 mm wide) cut in the top plate of the chamber to allow insertion of a recording, measurement, or stimulating instrument (e.g., micropipette) into the flow field. Surface tension forces at the slit openings are sufficient to counteract the hydrostatic pressure generated in the chamber and thus prevent overflow. The invasive probe is brought near to the cell surface, makes direct contact with the cell membrane, or enters the cell. The slits provide access to a large number (and choice) of cells. The MIF device can maintain physiological levels of shear stress (<1-15 dyn/cm super(2)) without overflow in the absence and presence of fine instruments such as micropipettes used in electrophysiology, membrane aspiration, and microinjection. Microbead trajectory profiles demonstrated negligible deviations in laminar flow near the surface of target cells in the presence of microscale instruments. Patch-clamp electrophysiological recordings of flow-induced changes in membrane potential were demonstrated. The MIF device offers numerous possibilities to investigate real-time endothelial responses to well-defined flow conditions in vitro including electrophysiology, cell surface mechanical probing, local controlled chemical release, biosensing, microinjection, and amperometric techniques. Lewis, R. (1999). "Vinyl chloride and polyvinyl chloride." Occupational Medicine **14**(4): 719-742.

Polyvinyl chloride (PVC) is an important plastic resin for construction, pipe and tubing, siding, and other uses. Exposures to vinyl chloride monomer during the early years of production resulted in an important sentinel health event: the recognition of an excess of a rare liver cancer, hepatic angiosarcoma, at facilities throughout the world. Several other syndromes, including acro-osteolysis, also have been associated with PVC, but less clearly with vinyl chloride. Extensive research ranging from large-scale epidemiologic studies to biomarker research into molecular mechanisms continues to provide valuable insight into the pathogenesis of occupational cancer. [References: 151]

Lewis, S. E., et al. (2019). "Upcycling aromatic polymers through C-H fluoroalkylation." Chemical Science **10**(25): 6270-6277.

The unique properties imparted by planar, rigid aromatic rings in synthetic polymers make these macromolecules useful in a range of applications, including disposable packaging, aerospace materials, flexible electronics, separation membranes, and engineering thermoplastics. The thermal and chemical stability of aromatic polymers, however, makes it difficult to alter their bulk and/or surface properties and results in challenges during recycling. In response, we report a platform approach for the C-H functionalization of aromatic polymers by taking advantage of their innate reactivity with electrophilic radical intermediates. The method uses mild reaction conditions to photocatalytically generate electrophilic fluoroalkyl radicals for the functionalization of an array of commercially relevant polyaromatic substrates, including post-industrial and post-consumer plastic waste, without altering their otherwise attractive thermomechanical properties. The density of fluorination, and thus the material properties, is tuned by either increasing the reagent concentration or incorporating longer perfluoroalkyl species. Additionally, the installation of versatile chemical functionality to aromatic polymers is demonstrated through the addition of a bromodifluoromethyl group, which acts as an initiator for atom transfer radical polymerization (ATRP) grafting of vinyl polymers. The method described herein imparts new and versatile chemical functionality to aromatic polymers, enabling an efficient approach to diversify the properties of these otherwise recalcitrant commodity plastics and demonstrating a viable pathway to upcycle post-consumer plastic waste.

Lewis, S. J. and K. W. Heaton (1997). "The intestinal effects of bran-like plastic particles: is the concept of 'roughage' valid after all?" European Journal of Gastroenterology & Hepatology **9**(6): 553-557.

OBJECTIVE: The mechanisms by which dietary fibre exerts is laxative action are not fully understood. Studies using sliced plastic tubing as a fibre substitute showed a decrease in both small and large bowel transit time. The significance of these studies is hard to interpret. We set out to compare the effects on intestinal function of wheat bran with plastic flakes similar in size and flaky shape to wheat bran (and devoid of plasticizers).

DESIGN AND METHODS: Volunteers consumed coarse wheat bran then, after a washout period, plastic flakes of the same size and shape as the bran. Before and after each intervention whole-gut transit time (WGTT), defecation frequency, stool form, stool water content, stool beta-glucuronidase activity and dietary intake were assessed.

RESULTS: Twenty-nine volunteers consumed a mean of 27.1 g of raw wheat bran and 24 g of plastic flakes a day. Baseline WGTT, interdefecatory intervals (IDI), stool form, weight, output, water content, and beta-glucuronidase were similar before both interventions. Both led to a decrease in mean faecal beta-glucuronidase activity, median WGTT (bran 25.8%, plastic 28.6%) and IDI (bran 23.3% plastic 25.0%). Both also increased stool form score (bran 28.6%, plastic 21.2%) and stool output (bran 67.1%, plastic 79.0%). Stool water content only rose with wheat bran (72%-75%, P = 0.014).

CONCLUSION: Overall, plastic 'pseudobran' was as effective at altering colonic function as wheat bran at a similar dosage but with fewer particles. The mechanism is not by increased faecal water. Reduction in enzyme activity with plastic flakes suggests that the plastic led to qualitative and, probably, beneficial changes in the bacterial flora or their metabolic processes. The concept of roughage deserves to be revived.

Lewis, S. J. and K. W. Heaton (1999). "Roughage revisited: the effect on intestinal function of inert plastic particles of different sizes and shape." Digestive Diseases & Sciences **44**(4): 744-748.

The mechanisms by which dietary fiber exerts its laxative action are not fully understood. Finely grinding wheat bran reduces its effect. Inert plastic particles are equipotent to bran if they consist of flakes or sliced tubing. It is not known whether altering the size or shape of inert particles alters their effect on intestinal function. In a randomized crossover study, 18 volunteers swallowed 24 g/day of plastic as branlike flakes or as small granules for 10-12 days with a two-week washout period between interventions. Whole-gut transit time (WGTT), orocecal transit time (OCTT), defecation frequency, stool form, stool water content, stool pH, and dietary intake were assessed. The plastic flakes caused a 24% (P < 0.001) reduction in WGTT and a 19% (P = 0.002) fall in OCTT.

Leyendeckers, H., et al. (2003). "Memory B cells specific for the NC16A domain of the 180 kDa bullous pemphigoid autoantigen can be detected in peripheral blood of bullous pemphigoid patients and induced in vitro to synthesize autoantibodies." Journal of Investigative Dermatology **120**(3): 372-378.

Bullous pemphigoid is a subepidermal blistering disease characterized by the synthesis of autoantibodies against the 180 kDa and the 230 kDa bullous pemphigoid antigens. Whether autoimmunity is also reflected by the presence of circulating autoantigen-specific memory B cells is still a matter of debate. We used a new assay combining two-step immunomagnetic enrichment with multiparameter flow cytometry to detect and characterize bullous pemphigoid 180 kDa-specific IgG+ B cells in blood of bullous pemphigoid patients. In a first magnetic separation, B cells were isolated from peripheral blood mononuclear cells using releasable microbeads conjugated to a CD19 antibody. From pre-enriched B cells, bullous pemphigoid 180 kDa-specific cells were then positively selected using microbeads directly conjugated with a recombinant N-terminal fragment of the bullous pemphigoid 180 kDa ectodomain, containing the noncollagenous 16A domain, which was recently shown to harbor major epitopes of autoantibodies in bullous pemphigoid sera. Noncollagenous 16A domain-specific IgG+ B cells were detectable in blood of most, if not all patients with serum autoantibodies against the noncollagenous 16A domain. The specificity of the cells was confirmed by in vitro differentiation into antibody-forming cells and analysis of the culture supernatant for the presence of noncollagenous 16A domain-specific IgG antibodies. All noncollagenous 16A domain-specific IgG+ B cells showed a clear memory immunophenotype. Noncollagenous 16A domain-specific IgG+ memory B cells may be crucial for continuous noncollagenous 16A domain-specific autoantibody production and/or play a part as antigen-presenting cells for priming and restimulation of bullous pemphigoid 180 kDa-specific T helper cells.

Lezehari, M., et al. (2012). "Fixed-bed column studies of pentachlorophenol removal by use of alginate-encapsulated pillared clay microbeads." Journal of Colloid and Interface Science **379**(1): 101-106.

Columns were packed with two alginate/pillared clays microbeads (aluminium-pillared clay and surfactant-modified aluminium-pillared clay). Pentachlorophenol sorption performance was assessed under variable operating conditions: different bed heights, influent pentachlorophenol concentrations and flow rates. These conditions greatly influenced the breakthrough time/volume, the saturation time/volume and the uptake capacity. Higher values of experimental uptake capacities were obtained for the encapsulated surfactant-modified aluminium-pillared clay compared with the encapsulated aluminium-pillared clay, and the values were compared with those obtained with other low-cost sorbents. The experimental breakthrough curves were modelled using Bed Depth Service Time (BDST), Wolborska and Thomas models. Linear relationship was obtained for the BDST model, indicating the suitability of this model; bed capacity increased sharply with the introduction of CTAB in the inorgano-pillared clay. Wolborska model was applied only to the initial part of the curves. Thomas model was no doubt the most suitable description of the adsorption mechanisms for the entire breakthrough curves. Experimental and Thomas model-predicted equilibrium uptake capacities were in accordance. © 2012 Elsevier Inc.

Li, A. Y., et al. (2019). "Insights into the feeding behaviors and biomechanics of Varroa destructor mites on honey bee pupae using electropenetrography and histology." Journal of Insect Physiology **119**: 103950.

Feeding behaviors and biomechanics of female Varroa destructor mites are revealed from AC-DC electropenetrography (EPG) recordings of mites feeding from Apis mellifera honey bee pupae and histology of mite internal ingestion apparatus. EPG signals characteristic of arthropod suction feeding (ingestion) were identified for mites that fed on pupae during overnight

recordings. Ingestion by these mites was confirmed afterwards by observing internally fluorescent microbeads previously injected into their hosts. Micrographs of internal ingestion apparatus illustrate the connection between a gnathosomal tube and a pharyngeal lumen, which is surrounded by alternating dilator and constrictor muscles. Inspection of EPG signals showed the muscularized mite pharyngeal pump operates at a mean repetition rate of 4.5cycles/s to ingest host fluids. Separate feeding events observed for mites numbered between 23 and 33 over approximately 16h of recording, with each event lasting ~10s. Feeding events were each separated by ~2min. Consecutive feeding events separated by either locomotion or prolonged periods of quiescence were grouped into feeding bouts, which ranged in number from one to six. Statistical analyses of EPG data revealed that feeding events were prolonged for mites having lower pharyngeal pump frequencies, and mites having prolonged feeding events went unfed for significantly more time between feeding events. These results suggest that mites may adjust behaviors to meet limitations of their feeding apparatus to acquire similar amounts of food. Data reported here help to provide a more robust view of Varroa mite feeding than those previously reported and are both reminiscent of, as well as distinct from, some other acarines and fluid-feeding insects.

Li, B., et al. (2019). "Polyethylene microplastics affect the distribution of gut microbiota and inflammation development in mice." Chemosphere **244**: 125492.

Environmental pollution caused by plastics has become a public health problem. However, the effect of microplastics on gut microbiota, inflammation development and their underlying mechanisms are not well characterized. In the present study, we assessed the effect of exposure to different amounts of polyethylene microplastics (6, 60, and 600 mug/day for 5 consecutive weeks) in a C57BL/6 mice model. Treatment with a high concentration of microplastics increased the numbers of gut microbial species, bacterial abundance, and flora diversity. Feeding groups showed a significant increase in Staphylococcus abundance alongside a significant decrease in Parabacteroides abundance, as compared to the blank (untreated) group. In addition, serum levels of interleukin-1alpha in all feeding groups were significantly greater than that in the blank group. Of note, treatment with microplastics decreased the percentage of Th17 and Treg cells among CD4⁺ cells, while no significant difference was observed between the blank and treatment groups with respect to the Th17/Treg cell ratio. The intestine (colon and duodenum) of mice fed high-concentration microplastics showed obvious inflammation and higher TLR4, AP-1, and IRF5 expression. Thus, polyethylene microplastics can induce intestinal dysbacteriosis and inflammation, which provides a theoretical basis for the prevention and treatment of microplastics-related diseases.

Li, B., et al. (2019). "The release and earthworm bioaccumulation of endogenous hexabromocyclododecanes (HBCDDs) from expanded polystyrene foam microparticles." Environmental Pollution **255**(Pt 1): 113163.

Hexabromocyclododecanes (HBCDDs) are common chemical additives in expanded polystyrene foam (EPS). To evaluate the bioaccumulation potential of endogenous HBCDDs in EPS microparticles by earthworms, two ecologically different species of earthworms (Eisenia fetida and Metaphire guillelmi) were exposed to soil added with EPS microparticles of different particle sizes (EPS₂₀₀₀, 830-2000mum and EPS₈₃₀, <830mum). To clarify the accumulation mechanisms, leaching experiments using EPS microparticles in different solutions were conducted. After exposure to EPS microparticles-amended soils (S-EPS) for 28d, the total concentrations of HBCDDs reached 307-371ngg⁻¹ dw in E. fetida and 90-133ngg⁻¹ dw in M. guillelmi, which were higher than those in earthworms

exposed to the soil that was artificially contaminated with a similar level of HBCDDs directly (ACS). The accumulation of HBCDDs in earthworms was significantly influenced by EPS microparticles' size and earthworms' species. The total concentrations of HBCDDs in earthworms' cast were significantly higher than the theoretical concentration of HBCDDs in S-EPS, which suggested that EPS microparticles can be ingested by earthworms. The release rate of HBCDDs from EPS₅₀₀₀ (2000-5000mum) into water-based solutions (<1%) after a 3.5-h incubation was far lower than that into earthworm digestive fluid (7%). These results illustrated that the ingestion of EPS microparticles and consequent solubilization of HBCDDs by digestive fluid play an important role in the accumulation of HBCDDs contained in EPS microparticles in earthworms. After a 28-d incubation with the soil solution, 4.9% of the HBCDDs was accumulatively leached from the EPS₅₀₀₀, which indicated that HBCDDs can be released from EPS microparticles to soil environment, and then accumulated by earthworms. Moreover, similar to those exposed to ACS, the diastereoisomer- and enantiomer-specific accumulation of HBCDDs in earthworms occurred when exposed to S-EPS. This study provides more evidence for the risk of microplastics to the soil ecosystem.

Li, C., et al. (2019). "Assessment of microplastics in freshwater systems: A review." Science of the Total Environment: 135578.

The reliance on plastic for a vast number of consumer products, many of them single-use, results in their continuous entry into aquatic environments. Plastic waste can fragment into smaller debris, some with a diameter < 5 mm (microplastics). Microplastics are of growing concern especially since 2014, however to date research on microplastic pollution has mainly focused on marine environments, partly because it has been mistakenly thought that sewage treatment plants could remove all plastic debris. To understand the impact of microplastic pollution in freshwater environments, an assessment of research on the sources, distribution and effects of microplastics, and trends in their analysis and policy has been carried out. Main sources of microplastic found in freshwater environments include synthetic textiles, personal care products, industrial raw materials and the improper disposal of plastic waste. Microplastic pollution is a global issue that presents with a broad range of concentration: for example, 3.5 x 10^³ microplastic units.L⁻¹ were reported in sediment of Lake Huron, in the US and as low as 1.2x10⁻⁴ units.L⁻¹ in countries with sparse population such as Mongolia. The main polymer constituents of microplastics found in freshwaters have been identified as polyethylene (PE), polypropylene (PP), polystyrene (PS), and polyethylene terephthalate (PET), accounting for 70% of the total, each with a very similar frequency of occurrence. Despite microplastics being relatively inert, they are found to cause some effects in aquatic organisms. Future work should focus on monitoring microplastic pollution in regions from where there is currently scarce published data (e.g. South America, Africa and North Asia) and the study of their sources, stability, transport and effects to freshwater ecosystems. The establishment of standardized monitoring methods will allow for the comparison of data from different geographic areas. This information will inform measures to reduce the release and occurrence of microplastics in aquatic environments.

Li, C., et al. (2012). "Extraction of plasma from whole blood using a deposited microbead plug (DMBP) in a capillary-driven microfluidic device." Biomedical Microdevices **14**(3): 565-572.

We presented a depositedmicrobead plug (DMBP)- based microfluidic device capable of extracting plasma from whole blood by capillary forces. This device was fabricated by reversibly bonding a PDMS slab with a straight channel to a hydrophilic glass substrate. The DMBP was easily constructed at the inlet of the channel within 2 min by a method of natural deposition of microbeads without the need of weirs or photopolymerization. Capillary forces generated mainly on the hydrophilic glass substrate provided a driving force during the fabrication of the DMBP and plasma extraction, resulting in simplicity of operations. The DMBP only allows blood plasma to pass through but blocks blood cells, which was demonstrated experimentally using sheep blood. The DMBP enabled to remain in its initial configuration during plasma extraction. The high quality plasma was obtained without contamination of microbeads and blood cells. This easy-to-use, easy-to-integrate, disposable the DMBP-based microfluidic device has the potential to be integrated with on-chip bioanalytical units for the applications of point-of-care diagnostics ©Springer Science+Business Media, LLC 2012.

Li, C., et al. (2012). "A power-free deposited microbead plug-based microfluidic chip for whole-blood immunoassay." Microfluidics and Nanofluidics **12**(5): 829-834.

We present a deposited microbead plug (DMBP)-based microfluidic chip capable of performing plasma extraction and on-chip immunoassay. The DMBP used as a porous blood filter provides pure blood plasma without the contamination of blood cells or beads. Capillary- driven flow eliminates the requirement of external pumps. The human IgG and goat anti-human IgG sampleto- answer assay was performed in this chip within 600 s using only a 10 µl whole-blood sample. This easy-to-use, rapid, inexpensive, and disposable DMBP-based chip holds a great promise for point-of-care application. © Springer-Verlag 2011.

Li, C., et al. (2011). Simulation & prediction of pacific plastic pollution. Applied Mechanics and Materials. **50-51:** 890-895.

The Great Pacific Garbage Patch which characterized by exceptionally high concentrations of suspended plastic, chemical sludge, and other debris, has a variety of severe influence on the marine life and human beings. Therefore, cleaning up the patch immediately is a matter of great urgency. To solve the problem, three models which are based on different differential equations to predict the amount of waste plastic poured into the ocean are established. According to the basic model, in about next 20 years, the Pacific Ocean will be unable to hold more garbage. Based on the fact that salvaging the waste plastic in the ocean contributes to controlling marine pollution, in accordance with the better model, the Pacific Ocean still has the ability to accommodate garbage before 2060. By improving the better model, a series of results are obtained. Around 2060, the area of the Pacific Ocean Garbage Patch will reach relatively steady state; meanwhile, the annual emissions of the plastic will reach 32,397,273.47 tons. To keep a relatively stable state the area which should be cleaned up will reach about 3,601,672 square kilometers per year. To compare the effect of government increasing taxation and plastic salvaging, a conclusion is reached that the huge economic losses caused by taxes are far more than the amount of money spent in salvaging the plastic garbage. © (2011) Trans Tech Publications.

Li, F., et al. (2019). "Size effects of magnetic beads in circulating tumour cells magnetic capture based on streptavidin-biotin complexation." IET Nanobiotechnology IET **13**(1): 6-11.

Circulating tumour cells (CTCs) draw significant attention as a promising biomarker for cancer prognosis, status monitoring, and metastasis diagnosis. However, the concentration of CTCs in peripheral blood is usually extremely low, thereby requiring enrichment followed by isolation of CTCs prior to detection. An immunomagnetic separation is a promising tool for CTCs enrichment. In this study, a cost-effective magnetic separation method, based on streptavidin-biotin complexation, was developed and the effects of magnetic beads' size in CTCs capture were compared. Magnetic nanobeads which were 25 nm in diameter lead to highest capture efficiency (82.2%) compared with 150 nm magnetic beads and 1 micro m microbeads. Based on the streptavidin-biotin system, 25 nm magnetic nanobeads could capture model CTCs over 80% efficiency even at concentrations as low as ~25 cells/mL that may represent the actual level of CTCs in peripheral blood of cancer patients. Furthermore, the isolated cells remained robust and healthy showing insignificant changes in morphology and behaviour when cultured for 24 h immediately after capture and isolation. The magnetic nanobeads based on streptavidin-biotin complexation showed promise for the easy and efficient capture and isolation of healthy CTCs for further diagnosis and analysis.

Li, H., et al. (2011). "Hydrogel droplet microarrays with trapped antibody-functionalized beads for multiplexed protein analysis." Lab on a Chip **11**(3): 528-534.

Antibody microarrays are a powerful tool for rapid, multiplexed profiling of proteins. 3D microarray substrates have been developed to improve binding capacity, assay sensitivity, and mass transport, however, they often rely on photopolymers which are difficult to manufacture and have a small pore size that limits mass transport and demands long incubation time. Here, we present a novel 3D antibody microarray format based on the entrapment of antibody-coated microbeads within alginate droplets that were spotted onto a glass slide using an inkjet. Owing to the low concentration of alginate used, the gels were highly porous to proteins, and together with the 3D architecture helped enhance mass transport during the assays. The spotting parameters were optimized for the attachment of the alginate to the substrate. Beads with 0.2 micro m, 0.5 micro m and 1 micro m diameter were tested and 1 micro m beads were selected based on their superior retention within the hydrogel. The beads were found to be distributed within the entire volume of the gel droplet using confocal microscopy. The assay time and the concentration of beads in the gels were investigated for maximal binding signal using one-step immunoassays. As a proof of concept, six proteins including cytokines (TNFalpha, IL-8 and MIP/CCL4), breast cancer biomarkers (CEA and HER2) and one cancer-related protein (ENG) were profiled in multiplex using sandwich assays down to pg mL(-1) concentrations with 1 h incubation without agitation in both buffer solutions and 10% serum. These results illustrate the potential of beads-in-gel microarrays for highly sensitive and multiplexed protein analysis.

Li, H., et al. (2013). "Multiplex profiling of glycoproteins using novel bead-based lectin array." Glycoconjugate Journal **30 (4)**: 361.

Lectin array is becoming important in profiling targeted glycan/glycoprotein, but weak interaction between lectin and glycan causes low sensitivity of the approach. This study aims to develop a bead-based lectin array for improving the sensitivity of glycosylation profiling. Lectins are chemically coupled to fluorescent dye coated microbeads, and glycanlectin recognition is carried out three-dimensionally. The performance of this platform was evaluated, and the limit of detection of lectin Ricinus communis agglutinin 120 (RCA120) was 50 pg/mL (1 pM) of asialofetuin, providing the bead based lectin microarray with the highest sensitivity among the reported lectin microarrays. Furthermore, multiplexed assay was performed, which allowed the simultaneous detection of multiple carbohydrate epitopes in a single reaction vessel. The glycosylation patterns of hepatocellular carcinoma associated immunoglobulin G were analyzed, and increased (alpha-1, 6) core fucosylation and (alpha-2, 6) sialylation patterns were observed, which may provide significant clinical evidence for disease diagnosis.

Li, H. S., et al. (2005). "Characterization of endocytic vesicles using magnetic microbeads coated with signalling ligands." Traffic **6**(4): 324-334.

Iron microbeads coated with the protein ligands insulin and EGF (Fe-INS and Fe-EGF) were prepared. Examination of the traffic of these ligand-coated microbeads demonstrated their internalization via clathrin-coated vesicles. Using magnetic methods, we have purified vesicles derived from the endocytic pathway. Vesicles prepared by this method are essentially free of contamination with other endomembrane compartments. Examination of the vesicles derived from cells treated with Fe-INS beads demonstrated the presence of the components of the Ras/Erk cascade on their surface. We conclude that the coupling of the Erk-signalling cascade induced by insulin takes place on the surface of endocytic vesicles derived from the internalization of the insulin receptor.

Li, J., et al. (2018). "Microplastics in mussels sampled from coastal waters and supermarkets in the United Kingdom." Environmental Pollution **241**: 35-44.

Global contamination of the marine environment by plastic has led to the discovery of microplastics in a range of marine species, including those for human consumption. In this study, the presence of microplastics and other anthropogenic debris in seawater and mussels (Mytilus edulis) from coastal waters of the U.K., as well as supermarket sources, was investigated. These were detected in all samples from all sites with spatial differences observed. Seawater samples taken from 6 locations (in triplicates) displayed 3.5+/-2.0 debris items/L on average (range: 1.5-6.7 items/L). In wild mussels sampled from 8 locations around the U.K. coastal environment, the number of total debris items varied from 0.7 to 2.9 items/g of tissue and from 1.1 to 6.4 items/individual. For the supermarket bought mussels, the abundance of microplastics was significantly higher in pre-cooked mussels (1.4 items/g) compared with mussels supplied live (0.9 items/g). Micro-FT-IR spectroscopy was conducted on 136 randomly selected samples, with 94 items characterized. The spectra found that 50% of these debris items characterized were microplastic, with an additional 37% made up of rayon and cotton fibers. The microplastic levels detected in the supermarket bought mussels present a route for human exposure and suggests that their quantification be included as food safety management measures as well as for environmental monitoring health measures.

Li, J., et al. (2018). "Microplastics in freshwater systems: A review on occurrence, environmental effects, and methods for microplastics detection." Water Research **137**: 362-374.

The continuous increase in synthetic plastic production and poor management in plastic waste have led to a tremendous increase in the dumping into our aqueous environment. Consequently, microplastics commonly defined as sizes less than 5 mm are produced and stay in both seawater and freshwater environment. The presence of microplastics as a new type of emerging contaminant has become a great issue of concerns from public and government authorities. The sources of microplastics to freshwater systems are many with the largest portion from wastewater treatment plants. The abundance of microplastics varies with the location, from above 1 million pieces per cubic meter to less than 1 piece in 100 cubic meters. Microplastics can cause several harmful physical effects on humans and living organisms through such mechanisms as entanglement and ingestion. The microplastics can act as carriers of various toxins such as additives from industrial production processes and persistent contaminants by the sorption in waters. Those toxins may cause great health problems to humans. A few studies on the fishes demonstrated that the microplastics and the associated toxins are bio-accumulated and cause such problems as intestinal damage and change in metabolic profiles. In studies of microplastics, fresh water is first sampled by the nets with typical mesh size of 330 mum for collection of microplastics. After the volume reducing process, the samples will then go through the purification process including density separation by such inorganic salts as sodium chloride and digestion process by oxidizing agents or enzymes. The sequence of these two processes (namely purification and digestion) is dependent on the sample type. The purified samples can be studied by several analytical methods. The commonly used methods for the qualification studies are FTIR spectroscopy, Raman spectroscopy, pyrolysis-GC/MS, and liquid chromatography. A tagging method can be used in the quantification study. Our literature study finds that there is still no universal accepted quantification and qualification tools of microplastics in fresh waters. More work is anticipated so as to obtain accurate information on microplastics in freshwater, which can then be used for the better assessment of the environmental risk. Li, J., et al. (2019). "Using mussel as a global bioindicator of coastal microplastic pollution." Environmental Pollution **244**: 522-533.

The ubiquity and high bioavailability of microplastics have an unknown risk on the marine environment. Biomonitoring should be used to investigate biotic impacts of microplastic exposure. While many studies have used mussels as indicators for marine microplastic pollution, a robust and clear justification for their selection as indicator species is still lacking. Here, we review published literature from field investigations and laboratory experiments on microplastics in mussels and critically discuss the suitability and challenges of mussels as bioindicator for microplastic pollution. Mussels are suitable bioindicator for microplastic pollution because of their wide distribution, vital ecological niches, susceptibility to microplastic uptake and close connection with marine predators and human health. Field investigations highlight a wide occurrence of microplastics in mussels from all over the world, yet their abundance varies enormously. Problematically, these studies are not comparable due to the lack of a standardized approach, as well as temporal and spatial variability. Interestingly, microplastic abundance in field-collected mussels is closely related to human activity, and there is evidence for a positive and quantitative correlation between microplastics in mussels and surrounding waters. Laboratory studies collectively demonstrate that mussels may be good model organisms in revealing microplastic uptake, accumulation and toxicity. Consequently, we propose the use of mussels as target species to monitor microplastics and call for a uniform, efficient and economical approach that is suitable for a future large-scale monitoring program.

Li, J., et al. (2016). "Microplastics in mussels along the coastal waters of China." Environmental Pollution **214**: 177-184.

Microplastic has been confirmed as an emerging pollutant in marine environments. One of the primary environmental risks of microplastics is their bioavailability for aquatic organisms. Bivalves are of particular interest because their extensive filter-feeding activity exposes them directly to microplastics present in the water column. In the present study, we investigated microplastic pollution in mussels (Mytilus edulis) from 22 sites along 12,400 mile coastlines of China in 2015. The number of total microplastics varied from 0.9 to 4.6 items/g and from 1.5 to 7.6 items/individual. M. edulis contained more microplastics (2.7 items/g) in wild groups than that (1.6 items/g) in farmed groups. The abundance of microplastics was 3.3 items/g in mussels from the areas with intensive human activities and significantly higher than that (1.6 items/g) with less human activities. The most common microplastics were fibers, followed by fragments. The proportion of microplastics less than 250 mum in size arranged from 17% to 79% of the total microplastics. Diatom was distinguished from microplastics in mussels for the first time using Scanning Electron Microscope. Our results suggested that the numbers of microplastic kept within a relatively narrow range in mussels and were closely related to the contamination of the environments. We proposed that mussels could be used as a potential bioindicator of microplastic pollution of the coastal environment.

Li, J., et al. (2019). "Focus topics on microplastics in soil: Analytical methods, occurrence, transport, and ecological risks." Environmental Pollution: 113570.

Microplastics with extremely high abundances are universally detected in marine and terrestrial systems. Microplastic pollution in the aquatic environment, especially in ocean, has become a hot topic and raised global attention. However, microplastics in soils has been largely overlooked. In this paper, the analytical methods, occurrence, transport, and potential ecological risks of microplastics in soil environments have been reviewed. Although several analytical methods have been established, a universal, efficient, faster, and low-cost analytical method is still not available. The absence of a suitable analytical method is one of the biggest obstacles to study microplastics in soils. Current data on abundance and distribution of microplastics in soils are still limited, and results obtained from different studies differ significantly. Once entering into surface soil, microplastics can migrate to deep soil through different processes, e.g. leaching, bioturbation, and farming activities. Presence of microplastics with high abundance in soils can alter fundamental properties of soils. But current conclusions on microplastics on soil organisms are still conflicting. Overall, research on microplastics pollution in soils is still in its infancy and there are gaps in the knowledge of microplastics pollution in soil environments. Many questions such as pollution level, ecological risks, transport behaviors and the control mechanisms are still unclear, which needs further systematical study.

Li, J., et al. (2015). "Tribo-charging properties of waste plastic granules in process of tribo-electrostatic separation." Waste Management **35**: 36-41.

Plastic products can be found everywhere in people's daily life. With the consistent growth of plastic consumption, more and more plastic waste is generated. Considering the stable chemical and physics characteristics of plastic, regular waste management methods are not suitable for recycling economic strategy of each government, which has become a serious environmental problem. Recycling plastic waste is considered to be the best way to treat it, because it cannot only deduce the waste but also save the energy to produce new virgin plastic. Tribo-electrostatic separation is strongly recommended for plastic separation as it can preserve the original properties of plastic and has little additional pollution. In this study, plastic granules are generated by crushing plastic waste in waste electric and electronic equipment. The tribo-charging properties of plastic waste were studied by vibrating tribo-charging and cyclone tribo-charging. The triboelectric series obtained by vibrating was: (-)-PE-PS-PC-PVC-ABS-PP-(+), while the triboelectric series obtained by cyclone was (-)-PE-PS-PC-PVC-ABS-PP-(+). Further, the cyclone charging was more effective and stable than vibrating charging. The impact factors experiments showed that small particle size was better changed than large ones and were more suitable recycled by tribo-electrostatic separation. High relative humidity was identified as impede charging effect. The results of this study will help defining the operating parameters of subsequent separator.

Li, J., et al. (2015). "Microplastics in commercial bivalves from China." Environmental Pollution **207**: 190-195.

We investigated microplastic pollution in 9 commercial bivalves from a fishery market in China. Multiple types of microplastics, including fibers, fragments and pellets, occurred in the tissue of all bivalves. The number of total microplastics varied from 2.1 to 10.5 items/g and from 4.3 to 57.2 items/individual for bivalves. Scapharca subcrenata contained on average 10.5 items/g and exhibited the highest levels of microplastics by weight. Fibers were the most common

microplastics and consisted of more than half of the total microplastics in each of the 8 species. In Alectryonella plicatula, pellets accounted for 60% of the total microplastics. The most common size class was less than 250 micro m and accounted for 33-84% of the total microplastics calculated by species. Our results suggest that microplastic pollution was widespread and exhibited a relatively high level in commercial bivalves from China. More intensive investigations on microplastics should be conducted in seafood.

Li, J., et al. (2018). "Characterization, source, and retention of microplastic in sandy beaches and mangrove wetlands of the Qinzhou Bay, China." Marine Pollution Bulletin **136**: 401.

Severe microplastic pollution from anthropogenic activities in coastal zones presents an imminent risk to marine ecosystems. In this study, abundant microplastics (15–12,852 items kg−1) with sizes ranging between 0.16 and 5.0 mm were extracted from 17 sediment samples collected in sandy beaches and mangrove wetlands of the Qinzhou Bay, Guangxi Province, Southwest China. Three types of microplastics (i.e. polystyrene, polypropylene, and polyethylene) were identified with Fourier transform infrared (FTIR) spectroscopy analysis. These detected microplastics were characterized by different colors (white, transparent, yellow, green, red, and blue) and shapes (fragment, fiber, and sphere). Microplastics were concentrated on supratidal beaches and wetlands outside of mangrove, and less abundant on intertidal beaches and inside of mangrove wetlands. Meanwhile, high microplastic concentrations were observed near mollusk farms. The spatial distribution and chemical speciation indicated that microplastics were derived from disintegration of large plastic debris (e.g., Styrofoam buoys used to support mollusk rafts) abandoned by aquaculture industry. Further, coastal vegetation (e.g. mangrove) could trap microplastic particles.

Li, J., et al. (2018). "Adsorption of antibiotics on microplastics." Environmental Pollution **237**: 460-467.

Microplastics and antibiotics are two classes of emerging contaminants with proposed negative impacts to aqueous ecosystems. Adsorption of antibiotics on microplastics may result in their long-range transport and may cause compound combination effects. In this study, we investigated the adsorption of 5 antibiotics [sulfadiazine (SDZ), amoxicillin (AMX), tetracycline (TC), ciprofloxacin (CIP), and trimethoprim (TMP)] on 5 types of microplastics [polyethylene (PE), polystyrene (PS), polypropylene (PP), polyamide (PA), and polyvinyl chloride (PVC)] in the freshwater and seawater systems. Scanning Electron Microscope (SEM) and X-ray diffractometer (XRD) analysis revealed that microplastics have different surface characterizes and various degrees of crystalline. Adsorption isotherms demonstrated that PA had the strongest adsorption capacity for antibiotics with distribution coefficient (K<inf>d</inf>) values ranged from 7.36 +/- 0.257 to 756 +/- 48.0 L kg⁻¹ in the freshwater system, which can be attributed to its porous structure and hydrogen bonding. Relatively low adsorption capacity was observed on other four microplastics. The adsorption amounts of 5 antibiotics on PS, PE, PP, and PVC decreased in the order of CIP > AMX > TMP > SDZ > TC with K<inf>f</inf> correlated positively with octanol-water partition coefficients (Log K<inf>ow</inf>). Comparing to freshwater system, adsorption capacity in seawater decreased significantly and no adsorption was observed for CIP and AMX. Our results indicated that commonly observed polyamide particles can serve as a carrier of antibiotics in the aquatic environment. Copyright © 2018 Elsevier Ltd

Li, J., et al. (2009). "Stimulation of specific cytokines in human conjunctival epithelial cells by defensins HNP1, HBD2, and HBD3." Investigative Ophthalmology & Visual Science **50**(2): 644-653.

PURPOSE: To investigate the effect of human defensins HNP1, HBD2, and HBD3 on human conjunctival epithelial cell cytokine secretion.

METHODS: HNP1, HBD2, and HBD3 were used to test cytotoxicity (1-50 microg/mL) and to stimulate (1-20 microg/mL) primary cultured and immortalized human conjunctival epithelial (IOBA-NHC) cells. Cytokine concentrations in the culture medium were measured by cytokine array and a multiplexed microbead analysis. Protein kinase activation was determined by Western blot analysis after defensin stimulation and with specific inhibitors.

RESULTS: HBD3, but not HNP1 or HBD2, killed more than 50% of IOBA-NHC cells at concentrations greater than 12.5 microg/mL. Only IL-6, IL-8, and RANTES were detected in the culture medium in the absence of defensins. All three cytokines increased in the presence of HNP1, HBD2, and HBD3 at concentrations of 5 to 20 microg/mL and between 2 and 8 hours and further accumulated at 24 hours Stimulation with HBD2 and HBD3 increased the secretion of IL-2 and MIP-1beta in IOBA-NHC cells but only of MIP-1beta in primary cultured cells. Activation of p42/44 mitogen-activated protein (MAP) kinase, Akt, and STAT3 was observed in primary and IOBA-NHC cells after defensin stimulation. Cytokine secretion was significantly decreased by the inhibition of p42/44 MAPK in IOBA-NHC cells.

CONCLUSIONS: HNP and HBD selectively increase the secretion of specific proinflammatory cytokines in conjunctival epithelial cells in a time- and concentration-dependent manner, suggesting a supporting role to the innate immune system of the ocular surface.

Li, K. C., et al. (2014). "Melting analysis on microbeads in rapid temperature-gradient inside microchannels for single nucleotide polymorphisms detection." Biomicrofluidics **8**(6): 064109.

A continuous-flow microchip with a temperature gradient in microchannels was utilized to demonstrate spatial melting analysis on microbeads for clinical Single Nucleotide Polymorphisms (SNPs) genotyping on animal genomic DNA. The chip had embedded heaters and thermometers, which created a rapid and yet stable temperature gradient between 60 degreeC and 85 degreeC in a short distance as the detection region. The microbeads, which served as mobile supports carrying the target DNA and fluorescent dye, were transported across the temperature gradient. As the surrounding temperature increased, the fluorescence signals of the microbeads decayed with this relationship being acquired as the melting curve. Fast DNA denaturation, as a result of the improved heat transfer and thermal stability due to scaling, was also confirmed. Further, each individual microbead could potentially bear different sequences and pass through the detection region, one by one, for a series of melting analysis, with multiplex, high-throughput capability being possible. A prototype was tested with target DNA samples in different genotypes (i.e., wild and mutant types) with a SNP location from Landrace sows. The melting temperatures were obtained and compared to the ones using a traditional tube-based approach. The results showed similar levels of SNP discrimination, validating our proposed technique for scanning homozygotes and heterozygotes to distinguish single base changes for disease research, drug development, medical diagnostics, agriculture, and animal production.

Li, L. (2009). Differentiation of embryonic stem cells into neural lineages in an alginate encapsulation microenvironment.

Cell replacement therapies, using renewable stem cell sources, hold tremendous potential to treat a wide range of degenerative diseases. Although many studies have established techniques to successfully differentiate stem cells into different mature cell lineages using growth factors or extracellular matrix protein supplementation in both two and three-dimensional configurations, their practicality is limited by lack of control, low yields of differentiated cells and oftentimes, heterogeneous cell population outcomes. In order to address these issues, we have previously established a murine embryonic stem cell alginate-poly-l-lysine microencapsulation

differentiation system. The three-dimensional alginate microenvironment maintains cell viability, is conducive to ES cell differentiation to hepatocyte lineage cells, and sustains differentiated cellular function. In addition, hepatocyte function was contingent upon aggregate formation within the alginate microbeads. The present studies were designed to determine the feasibility of adapting the alginate encapsulation technique to neuronal lineage differentiation. The results of our studies indicate that by incorporating the soluble inducer, retinoic acid into the permeable microcapsule system, cell aggregation was decreased and neuronal lineage differentiation enhanced. In conjunction with the mechanical and physical characterization of the alginate crosslinking network, we have determined that 2.2% alginate microencapsulation can be optimally adapted to both hepatocyte and neuronal differentiation from embryonic stem cells. However, differentiation could be directed away from the hepatocyte and towards the neural lineage by lowering initial seeding density and physical cell-cell aggregation blocking, even in the absence of RA. This study promises to offer insights into targeting cellular differentiation towards both endodermal and ectodermal cell lineages, and could potentially be generalizable and adaptable to the differentiation of other stem cell types given the correct inducible factors and material properties.

Li, L., et al. (2011). "Neural lineage differentiation of embryonic stem cells within alginate microbeads." Biomaterials **32**(20): 4489-4497.

Cell replacement therapies, using renewable stem cell sources, hold tremendous potential to treat a wide range of degenerative diseases. Although many studies have established techniques to successfully differentiate stem cells into different mature cell lineages using growth factors or extracellular matrix protein supplementation in both two and three-dimensional configurations, they are often limited by lack of control and low yields of differentiated cells. Previously, we developed a scalable murine embryonic stem cell differentiation environment which maintained cell viability and supported ES cell differentiation to hepatocyte lineage cells. Differentiated hepatocyte function was contingent upon aggregate formation within the alginate microbeads. The present studies were designed to determine the feasibility of adapting the alginate encapsulation technique to neural lineage differentiation. The results of our studies indicate that by incorporating the soluble inducer, retinoic acid (RA), into the permeable microcapsule system, cell aggregation was decreased and neural lineage differentiation enhanced. In addition, we demonstrated that even in the absence of RA, differentiation could be directed away from the hepatocyte and toward the neural lineage by physical cell-cell aggregation blocking. In conjunction with the mechanical and physical characterization of the alginate crosslinking network, we determined that 2.2% alginate microencapsulation can be optimally adapted to ES neural differentiation. This study offers insights into targeting cellular differentiation toward both endodermal and ectodermal cell lineages, and could potentially be adaptable to differentiation of other stem cell types given the correct inducible factors and material properties. © 2011 Elsevier Ltd.

Li, L., et al. (2020). "Effect of microplastic on anaerobic digestion of wasted activated sludge." Chemosphere **247**: 125874.

Over 90% of microplastics that enter wastewater treatment plants end in the wasted activated sludge. The effect of microplastic abundance on the activated sludge anaerobic digestion has been rarely reported. This study investigated the methane production performance during anaerobic digestion with different abundance of microplastic doses (0, 1,000, 3,000, 6,000, 10,000, 30,000, 60,000, 100,000 and 200,000 polyester particle/kg activated sludge). The methane production was reduced to 88.53 +/- 0.5%, 90.09 +/- 1.2%, 89.95 +/- 4.7%, 95.08 +/-

0.5%, 90.29 +/- 0.5%, 93.16 +/- 0.8%, 92.92 +/- 1.3%, and 92.72 +/- 0.6% as compared with control after digestion for 59 days. The methane production of all conditions was fitted with the logarithm model (R² > 0.95) and one-substrate model (R² > 0.99). The predicted and actual methane production values of digestion for 59 days had high correlation in all conditions with R² > 0.95. The analysis based on the biochemical methane potential test model indicated that the methane production potential (B₀) and hydrolysis coefficient (k) decreased at nearly all tested conditions. The reactor digestate with microplastics retained higher organic matter and nutrient concentration and had slightly lower dewaterability than the control. The inhibition of methane production potential could be attributed to the incomplete digestion with the existence of microplastics. The microbial community showed no significant difference with and without microplastics.

Li, L., et al. (2019). "Microplastics contamination in different trophic state lakes along the middle and lower reaches of Yangtze River Basin." Environmental Pollution **254**(Pt A): 112951.

Microplastics can enter freshwater lakes through many sources. They can act as carriers to adsorb bacteria, virus, or pollutants (e.g., heavy metal and toxic organic compounds) that threaten human health through food chain. Microplastics can exist in surface water and sediments in freshwater lakes after they enter the lakes through discharge points. Wastewater discharge is the main cause of lake eutrophication and is the main emission source of microplastics. The correlation between lake trophic state and microplastic abundance has been rarely reported. This study investigated the microplastic contamination in surface water and sediments of 18 lakes along the middle and lower reaches of the Yangtze River Basin in the period of August-September 2018. The correlation between lake trophic state and microplastic abundance in surface water and sediments was investigated and discussed. The microplastic abundance in surface water was approximately two orders of magnitude lower than that in sediments in all 18 lakes. Hong Lake had the highest microplastic abundance in surface water sample, and Nantaizi Lake had the highest microplastic abundance in sediment sample. The dominant microplastic shape was fiber of 93.81% in surface water sample and 94.77% in sediment sample. Blue-colored microplastics were dominant in nearly all lakes in surface water sample (around 40%-60%) and sediment sample (around 60%-80%), followed by purple- and green-colored ones. The microplastics size <1mm was dominant in surface water sample (around 40%-60%) and sediment sample (around 50%-80%). The dominant material was polypropylene in surface water sample (around 60%-80%) and sediment sample (around 40%-60%).

Li, L., et al. (2020). "Performance evaluation of MBR in treating microplastics polyvinylchloride contaminated polluted surface water." Marine Pollution Bulletin **150**: 110724.

The microplastics removal and its effects on membrane fouling in membrane bioreactor (MBR) for treating polluted surface water in drinking purpose was investigated in this study. Typical microplastics polyvinylchloride (PVC) with concentration 10 particles/L was added in the feed water. MBR was effective in treating organic matters and ammonia with removal rate over 80% and 95%, respectively. The removal performance was immediately inhibited with the microplastics PVC added into the MBR system, and recovered after operated for few days. The membrane fouling and cleaning results indicated that microplastics contamination could led to higher membrane fouling, and also the irreversible membrane fouling. The main contributor of rejection is the membrane module and the adsorption onto bio-carrier. The microbial community of the system before and after PVC addition did not show obvious difference. MBR has the potential to be used as effective technology in treating microplastics contaminated

polluted surface water.

Li, L., et al. (2008). "Enhancement of thermal stability of poly(divinylbenzene) microspheres." Materials Letters **62**(2): 179-182.

In order to enhance the thermal stability and prepare a new kind of carbon microbeads from poly(divinylbenzene) microspheres (PDM), air oxidation treatment was introduced to modify the pristine PDM. The results showed that the spherical shape of PDM was preserved via the air oxidation and further carbonization at 700 super(o)C. The changes of morphology, especially the surface functional groups and the thermal properties of PDM after air oxidation were investigated in detail by SEM, IR and TG/DSC measurements, respectively. The possible mechanism of oxidation treatment was elucidated.

Li, L., et al. (2019). "Effect evaluation of microplastics on activated sludge nitrification and denitrification." Science of the Total Environment **707**: 135953.

A large amount of microplastics have entered conventional wastewater treatment plants, and their effects on activated sludge nitrification and denitrification are rarely reported. This study investigated the effects of microplastics on activated sludge nitrification and denitrification using five typical microplastics, namely, polyvinyl chloride (PVC), polypropylene, polyethylene, polystyrene, and polyester (PES) with concentrations of 0, 1000, 5000, and 10,000 particles/L.

Li, L., et al. (2019). "The uptake of microfibers by freshwater Asian clams (Corbicula fluminea) varies based upon physicochemical properties." Chemosphere **221**: 107-114.

Microplastic is an umbrella term that covers particles with various physical and chemical properties. However, microplastics with a consistent shape, polymer type and size are generally used in exposure studies (e.g., spherical polyethylene or polystyrene beads 1-100 micro m in size). In the present study, we exposed freshwater Asian clams (Corbicula fluminea) to microfibers with different physicochemical properties at concentrations of 100 and 1000 fibers/L. The first experiment in this study exposed clams to microfibers made from six different polymers, demonstrating that Asian clams uptake more polyester (PET) (4.1 items/g) relevant to other polymers. The next experiment exposed clams to PET fibers of different size classes, demonstrating that uptake in the size range 100-250 micro m (1.7 items/g) was greater than other size classes. These results suggest that physicochemical properties such as polymer and size play important roles in the uptake of microfibers by organisms. Thus, we strongly suggest that the properties of microplastics used in future laboratory exposure experiments be considered, with the aim of being "environmentally relevant", i.e., similar to what is found in nature.

Li, L., et al. (2019). "Uptake and accumulation of microplastics in an edible plant." Kexue Tongbao/Chinese Science Bulletin **64**(9): 928-934.

Microplastic (MP, 100 nm-5 mm) may present an attributable risk to ecosystem and human health, and its pollution has become a global environmental concern. Despite a wealth of information on the accumulation of MPs in aquatic species, there is no information on the uptake and accumulation of MPs by higher plants. Terrestrial edible plants are directly exposed to MPs when agricultural soil was applied with organic manure, sewage sludge as fertilizer or plastic mulching. In this paper, the uptake of two sizes of polystyrene (PS) microbeads (0.2 and 1.0 µm) and then their distribution and migration in an edible plant lettuce were firstly investigated based on laboratory experiments. We used fluorescent markers to track PS microbeads in plant tissues and found fluorescence to be a sensitive and reliable detection method. Sections from untreated control lettuce showed no autofluorescence. When roots were treated with fluorescently labeled PS microbeads, the microbeads could be identified by its fluorescence. Our main study investigated the uptake of 0.2 μm beads, as few luminescence signals were observed in lettuce roots for 1.0 μm beads in our experiment. We observed that 0.2 μm fluorescent microbeads were extracellularly trapped in the root cap mucilage (which is a highly hydrated polysaccharide) and a "dark green tip" (which was typical of lettuce roots exposed to label PS beads) was usually visible to the naked eye. Confocal images revealed that the PS luminescence signals were mainly located in the vascular system and on the cell walls of the cortex tissue of the roots, indicated that the beads passed through the intercellular space via the apoplastic transport system. Once inside the central cylinder, the 0.2 μm PS beads were transferred from the roots to the stems and leaves via the vascular system following the transpiration stream. We also observed that the PS beads adhered to one another and self-assembled systematically into "grape-like" and "(chain) string-like" clusters in the intercellular space of the root and stem vascular tissue of lettuce plant. In contrast to the root and stem, PS beads were dispersed in the leaf tissue. Here, for the first time we provide evidence of the adherence, uptake, accumulation, and translocation of submicrometer MPs within an edible plant. Our findings highlight the previously underappreciated human exposure pathway to MPs through the consumption of contaminated crops and emphasize the need for new management strategies to control the release of MPs waste products into the terrestrial environment. Ultimately, the potential impacts of low range sized MPs on food safety of crop plants and human health need to be urgently considered. © 2019, Science Press. All right reserved.

Li, M., et al. (2010). "Blockage of TRAF6 by dominant negative peptides to inhibit multiple myeloma (MM) cell proliferation and osteoclast formation through NF-kappaB, JNK and Akt signal transduction pathways." Blood. Conference: 52nd Annual Meeting of the American Society of Hematology, ASH **116**(21).

Several members of the tumor necrosis factor receptor-associated factor (TRAF) family, including TRAF1, TRAF2, TRAF3, TRAF5, and TRAF6 have been implicated in regulating signal transduction from various TRAF family members. However, the unique biological function of TRAF6 is largely determined by its TRAF-C domain, which does not interact with peptide motifs that are recognized by TRAF1, -2, -3 or -5. We have reported inhibition of MM cell proliferation and increase of apoptosis through regulation of the NF-kappaB and JNK pathways through silencing TRAF6 C-domain mRNA and the dominant negative peptide expression vector (Chen H. et al, Oncogene, 2006; Li M. et al, Blood 2009). TRAF6 have been recently found as a ligase for Akt ubiquitination (Yang WL et al, Science, 2009). Akt signaling plays a central role in many biological functions, such as cell proliferation and apoptosis. In this study, we first investigated whether TRAF6 is over-expressed in MM tumor cells. Twelve MM fresh bone marrow (BM) aspirates derived from MM patients were assessed using Western blot analysis and immunohistochemical staining with anti-TRAF6 antibody. We found that TRAF6 protein was highly expressed in tumor cells from MM patients compared to normal human BM samples. Based on TRAF6, CD40, and RANKL sequences and crystal structures, we targeted the TRAF6 C-domain binding residues. We found that TRAF6 dominant negative binding peptide (TRAF6dn) significantly inhibited MM cell proliferation maximally at 72 hours using the MTS cell proliferation assay whereas effects on inducing MM cell apoptosis were most prominent at 48 hours as assessed with Annexin V staining with flow cytometric analysis. The decrease in cell proliferation and increase in cell apoptosis occurred in a concentration peptide-dependent fashion. Furthermore, phosphorylation of both AKT and NF-kappaB were also reduced using our

human TRAF6dn or decoy peptides. We also examined the effect of the TRAF6dn peptide on the JNK pathway since this signaling pathway is also associated with cell cycle effects in MM. We measured JUN kinase kinase (JNKK), which activates the MAP kinase homologues SAPK and JNK in response to IL-1 receptor stimulation. The results showed that the phosphorylation of JNKK is markedly reduced after treatment with the TRAF6dn peptide. Furthermore, we examined c-Jun, a component of the transcription factor complex AP-1, which binds and activates transcription at TRE/AP-1 elements. We evaluated the effect of TRAF6dn peptide on osteoclast formation using cells from human monocytes isolated by anti-CD14 micro-bead affinity column from MM patients' BM or peripheral blood mononuclear cells. The monocytes were cultured on slide-culture dishes (2 x 10⁵ cells/well).We found TRAF6dn markedly inhibited osteoclast cell formation from monocytes induced with RANKL and mCSF in a concentration-dependent fashion compared with a control group using tartrate resistant acid phosphatase staining. We further assessed whether TRAF6dn can reduce bone resorption using a dentin bone resorption assay. BM-derived monocytes were isolated as above and were cultured on dentin bone slides (4 x 10⁵ cells/slide). The cells treated with a TRAF6dn peptide or the control peptide, were incubated with 50ng/ml RANKL and 10ng/ml MCSF. All cells were cultured for 21 days. It was found that TRAF6dn significantly inhibited lacunar resorption in a concentration-dependent fashion. These studies suggest that TRAF6 is over-expressed in MM and our TRAF6dn peptide inhibits many signaling pathways critical to the growth of MM and formation of osteoclasts resulting in marked anti-MM effects and reduction in osteoclast formation resulting in marked inhibition of bone resorption. Thus, this novel approach may offer a new therapeutic approach to both treat multiple myeloma and reduce the clinical consequences resulting from enhanced bone loss that commonly occur in these patients.

Li, N., et al. (2010). "Expression level of toll-like receptors and the prognosis of chronic severe hepatitis B." Hepatology International **4 (1)**: 127.

Background: Toll-like receptors (TLRs) play key roles in innate immunity, and are expressed abundantly in dendritic cells. Although TLR has been involved in chronic hepatitis B virus (HBV) infection, its role in HBV-related chronic severe hepatitis (CSHB) is still largely unknown. This study aims to investigate the expression of TLR in monocyte derived dendritic cells (MoDC) from CSHB, to assess the contribution of TLRs in CSHB. Method(s): Peripheral blood was collected from 40 CSHB patients, 30 healthy subjects are as normal controls (NCs). Purified monocytes were isolated by combination of Histopaque-1.077 and CD14 Microbeads. MoDCs were induced with GM-CSF and IL-4 for 6 days from CD14⁺ monocytes. The expression of TLRs in MoDC were measured by Real-time PCR and FACS. Result(s): The expression of TLR1, -2, -7 were significantly higher in MoDC of CSHB than NCs, while decreased level of TLR3 in CSHB patients compared to NCs. We further found that TLR2 was significantly downregulated in CSHB patients with HBeAg⁺ compared to HBeAg⁻. TLR3 level was significantly decreased in nonsurvival patients with CSHB compared to survival, while TLR2 expression was dramatically increased in nonsurvival patients with CSHB. Further linear correlation analysis demonstrated significant correlations between TLR3 level and disease severity markers (total bilirubin, prothrombin activity, creatinine, the count of white blood cells, and maximum depth of ascites) for individual CSHB patients. Conclusion(s): TLR2 and TLR3 may be involved in the pathogenesis of CSHB, and TLR3 may influence on the prognosis of CSHB.

Li, N., et al. (2011). "Correlation of the expression of toll-like receptors in monocyte-derived dendritic cells with prognosis of chronic severe hepatitis B." Journal of Digestive Diseases **12**(2): 117-124.

OBJECTIVE: This study aims to measure the expression of toll-like receptors (TLR) in monocyte-derived dendritic cells (MoDC) from chronic severe hepatitis B (CSHB), to assess the contribution of TLRs in CSHB.

METHODS: Peripheral blood was collected from 40 CSHB patients, 30 chronic hepatitis B (CHB) patients, and 30 healthy individuals who served as healthy controls (HCs). Purified monocytes were isolated by a combination of Histopaque-1.077 and CD14 Microbeads. MoDCs were induced with granulocyte macrophage colony-stimulating factor and interleukin-4 for 6 days from CD14(+) monocytes. The expression of TLRs in MoDC was measured using real-time PCR and flow cytometry.

RESULTS: The expressions of TLR-1, -2, -7 were significantly higher in MoDC of CSHB than that of HCs, of which the level of TLR-3 was decreased. Particularly in CSHB patients, the TLR-3 expression was further decreased compared to CHB patients. In non-survival CSHB patients, TLR-3 level was significantly decreased, while TLR-2 expression was dramatically increased. Linear correlation analysis demonstrated significant correlations between TLR-3 level and disease severity markers (total bilirubin, prothrombin activity, creatinine, white blood cell count, and maximum volume of ascitic fluid) in individual CSHB patients.

CONCLUSIONS: TLR-2 and TLR-3 may be involved in the pathogenesis of CSHB, and TLR-3 may influence the prognosis of CSHB.

Li, P., et al. (2006). "Application of MTS in tumour cell proliferation prohibition studies in loading environment controlled by magnetic microbeads." Journal of Southwest Agricultural University **28**(4): 566-568.

Three methods of cell proliferating measurement were compared with samples of hepatocellular carcinoma (SMCC-7721). The method using trypan blue was not efficient for large samples and was more incidental in error calculation because of similar shapes of microbeads. As the colorimetric reagent of MTT [3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyl-tetrazolium bromide, SIGMA] was not water soluble, it was difficult to control the uniformity in isopropyl alcohol, which might get the result far from the veracity. Floating of microbeads by violent mixture in the solution also affected the veracity. In comparison, MTS [3-(4,5-dimethylthiazol-2-yl)-5(3-carboxymethoxyphenyl)-2-(4-sulopheny)-2H-tetraolium, innersalt] was not only more efficient in cell proliferation study in this loading environment by anti-jamming the effect of microbeads, it also had higher reliability, which showed no observable difference from the traditional method of trypan blue.

Li, P., et al. (2019). "CD4+CD25+ Regulatory T Cells Decreased CD8+IL-4+Cells in a Mouse Model of Allergic Asthma." Iranian Journal of Allergy Asthma & Immunology **18**(4): 369-378.

Interleukin (IL)-4-producing-CD8 (cytotoxic T cells, Tc) contribute to lung eosinophilia and airway hyper-responsiveness (AHR) to an antigen. CD4+CD25+ regulatory T cells (Tregs) attenuate airway inflammation and AHR. This study investigated whether Tregs decrease Tc2frequencies in ovalbumin (OVA)-induced asthma model of mice. Female C57BL/6 mice were sensitized with OVA intraperitoneally and challenged with OVA intranasally to induce allergic asthma model. Tregs were sorted by fluorescence activated cell sorting (FACS) and magnetic activated cell sorting (MACS) microbeads. OVA-sensitized mice were injected with Tregs or phosphate buffer saline (PBS) by tail vein ahead of the first challenge. Airway inflammation and airway hyper-responsiveness (AHR)were evaluated by histological analysis and invasive method, respectively. OVA-specific IgE and cytokine levels were detected by ELISA. Flow cytometry was used to detect the percentages of Tc1 and Tc2. Gata3 and T-bet mRNA was determined by quantitative PCR (qPCR). OVA-sensitized and challenged mice displayed typical asthma features, which included eosinophilic airway inflammation, higher levels of Th2 cytokines and AHR. Gata3 mRNA, Tc2 frequencies and OVA-specific IgE levels were significantly increased in OVA-sensitized and challenged mice. Compared to PBS treatment, Tregs decreased Tc2 frequencies, airway inflammation, Th2 cytokine levels and AHR in OVA-sensitized and challenged mice. IL-13 levels were negatively correlated with Tc1 frequencies and with IFNg levels in experimental mice. Our results demonstrated that Tregs could prevent airway inflammation and AHR by decreasing Tc2 frequencies and cytokine levels in OVA-induced asthma model of mice, supporting Tregmight be as a potent therapeutic target for alleviating airway inflammation and AHR.

Li, P., et al. (2017). "Encapsulation of Autoinducer Sensing Reporter Bacteria in Reinforced Alginate-Based Microbeads." Acs Applied Materials & Interfaces **9**(27): 22321-22331.

Quorum sensing, in which bacteria communities use signaling molecules for inter- and intracellular communication, has been intensively studied in recent decades. In order to fabricate highly sensitive easy-to-handle point of care biosensors that detect quorum sensing molecules, we have developed, as is reported here, reporter bacteria loaded alginate-methacrylate (alginate-MA) hydrogel beads. The alginate-MA beads, which were obtained by electrostatic extrusion, were reinforced by photo-cross-linking to increase stability and thereby to reduce bacteria leaching. In these beads the genetically engineered fluorescent reporter bacterium Escherichia coli pTetR-LasR-pLuxR-GFP (E. coli pLuxR-GFP) was encapsulated, which responds to the autoinducer N-(3-oxododecanoyl)homoserine lactone secreted by Pseudomonas aeruginosa. After encapsulation in alginate-MA hydrogel beads with diameters in the range of 100-300 mum that were produced by an electrostatic extrusion method and rapid photo-cross-linking, the E. coli pLuxR-GFP were found to possess a high degree of viability and sensing activity. The encapsulated bacteria could proliferate inside the hydrogel beads, when exposed to bacteria culture medium. In media containing the autoinducer N-(3-oxododecanoyl)homoserine lactone, the encapsulated reporter bacteria responded with a strong fluorescence signal due to an increased green fluorescent protein (GFP) expression. A prototype dipstick type sensor developed here underlines the potential of encapsulation of viable and functional reporter bacteria inside reinforced alginate-methacrylate hydrogel beads for whole cell sensors for bacteria detection.

Li, P., et al. (2020). "A preliminary study of the interactions between microplastics and citrate-coated silver nanoparticles in aquatic environments." Journal of Hazardous Materials **385**: 121601.

Microplastics and silver nanoparticles (AgNPs) are considered two emerging environmental contaminants that have adverse effects on aquatic environments. Knowledge on the interactions between AgNPs and microplastics may improve our understanding of these pollutants, posing to surrounding environments and public health. However, current knowledge regarding this issue is limited. Here, we investigate, for the first time, the interactions between AgNPs and the microplastics polyethylene (PE), polypropylene (PP), and polystyrene (PS) in aquatic environments.

Li, Q. and M. Prince (2015). "Evaluation of the immunogenicity of aldhhigh human head and neck squamous cell carcinoma cancer stem cells in vitro." Journal for ImmunoTherapy of Cancer. Conference: 30th Annual Scientific Meeting of the Society for Immunotherapy of Cancer, SITC **3**(SUPPL. 2).

Background: Using mouse models we reported that dendritic cells (DC) pulsed with cancer stem cells (CSC) enriched by virtue of their expression of the CSC marker aldehyde dehydrogenase (ALDH) significantly reduced development of pulmonary metastases and prolonged survival. In this recent study, we established the concept that the antigenicity/ immunogenicity of

ALDH^{high} human head and neck squamous cell carcinoma (HNSCC) cancer stem cells is distinct from that of ALDH^{low} non-CSCs. Method(s): Patients with HNSCC enrolled in the University of Michigan Special Project of Research Excellence (SPORE) were recruited to collect tumor and peripheral blood samples. T or B cells were purified from the PBMCs using anti-CD3-coupled or anti-CD19-coupled microbeads respectively with a MACS separator. Primary tumor samples were digested and collected. ALDEFLUOR+/ALDH^{high} or ALDEFLUOR-/ALDH^{low} cells were isolated from tumor cells. ALDH^{low} lysate-pulsed DCs (ALDH^{low} -DC) or ALDH^{high} lysate-pulsed DCs (ALDH^{high}-DC, e.g. CSC-DC) were used as vaccines. To detect T and B cells in PBMCs, PBMCs were stained with PerCP mouse anti-human CD3 and FITC mouse anti-human CD19. Before sensitization in vitro, T or B cells were activated respectively with immobilized anti-human CD3 and anti-human CD28 in complete medium (CM) containing hrIL-2 or lipopolysaccharide plus anti-human CD45. Statistical analyses were performed to compare various interactions of the DC vaccine-primed/sensitized T, B cells with autologous ALDH^{high} CSC vs. ALDH^{low} HNSCC target cells. Result(s): DCs generated from the PBMC and pulsed with the lysate of ALDH^{high} cells isolated from cultured HNSCC cells (CSC-DC) could sensitize autologous T, B lymphocytes in vitro, which was evident by cytokine production, CTL activity, and antibody secretion of these primed T, B cells in response to ALDH^{high} CSCs. In contrast, DCs pulsed with lysate of ALDH^{low} cells from the same HNSCC patient (ALDH^{low}-DC) resulted in limited sensitization/priming of autologous T, B lymphocytes to produce IFNgamma, lyse CSCs, and secrete IgM and IgG in response to ALDH^{high} CSCs. Conclusion(s): These results demonstrated significant differences in the antigenicity/immunogenicity between ALDH^{high} CSCs vs. ALDH^{low} cells isolated from the tumor specimen of patients with HNSCC, which indicates the existence of unique CSC antigens in the ALDH^{high} population. In addition, this study demonstrates that it is feasible to generate DCs from the PBMCs and isolate ALDH^{high} CSCs from tumor cells of the patients with HNSCC to prepare CSC-DC vaccines for clinical application.

Li, Q., et al. (2019). "Fusion of microplastics into the mussel byssus." Environmental Pollution **252**(Part A): 420-426.

Microplastics have been found to adhere to the surface of specific tissues or organs other than being ingested by the organisms. To further test the hypothesis that microplastics might get into specific body parts of organisms, mussel byssus was chosen as a target subject in the present study. In the field investigation, microplastics were found in mussel byssus, and the abundance of microplastics was 0.85-1.02 items/individual mussel and 3.69-9.16 items/g byssus, but the location of microplastics in byssus was not easily determined. Therefore, we simulated environmental conditions in the laboratory for mussels to form fresh byssus in the presence of microplastics. Three types of man-made microplastics (Polystyrene beads, Polyamide fragments, and Polyester fibers) were found in newly formed byssus of mussels after exposure to these test materials. We observed that microplastics not only adhered to the surface but also fused into the byssus of mussels. Since byssus is important for the well-being of mussels, the incorporation of microplastics into the byssus might impair the function of byssus. To the authors' best knowledge, this is the first study to show that microplastics can contact and fuse with the byssus of mussels during their formation, suggesting possible alternations for mussels to grip and interact with microplastics in the aquatic environments.

Li, Q., et al. (2019). "Separation and identification of microplastics from soil and sewage sludge."

Environmental Pollution **254**(Pt B): 113076.

Soil and sludge are important pools for microplastics (MPs), however standard separation methods for MPs from these pools are still missing. We tested the widely used methods for MPs extraction from water and sediment to six agriculture surface soils and three sewage sludges from municipal wastewater treatment plants and included an additional pre-digestion procedure with 30% H₂O₂ before floatation to remove soil or sludge organic matter (OM). Extraction efficiency of MPs were evaluated under different separation conditions, including floatation solution (NaCl, ZnCl₂, and NaI), filtration membrane, and oxidation solution.

Li, Q.-T., et al. (2010). "Human Health Risk Assessment on Contaminants in Recycled Plastic Bags Packaged Foods." Huanjing Kexue yu Jishu / Environmental Science & Technology **33**(11): 181-185.

Recycled plastic bags which are made from plastic waste contain many toxic and hazardous substances. However, because of its cheapness, the recycled plastic bags occupy large market share. Two kinds of simulated tests were designed, and amount of harmful substances moved from different colors of recycled plastic bags to food stimulants under certain conditions were designed. To make use of health risk assessment framework of EPA, health risks of human body was done for recycled plastic bags to package food. Based on assessment results, total carcinogenic risk and non-carcinogenic risk values of blue, yellow and white bags are less than 1, showing that the hazardous substances will not produce a significant hazard on human health. But the risk assessment of black and red plastic bags, risk values of Pb both exceed the critical value 1, showing that hazardous substances of black and red recycled plastic bags arouse a non-carcinogenic health risk to human body.

Li, R., et al. (2019). "Fluorometric lateral flow immunoassay for simultaneous determination of three mycotoxins (aflatoxin B₁, zearalenone and deoxynivalenol) using quantum dot microbeads." Mikrochimica Acta **186**(12): 748.

A fluorometric lateral flow immunoassay (LFA) is described for the simultaneous determination of the mycotoxins aflatoxin B₁ (AFB₁), zearalenone (ZEN) and deoxynivalenol (DON). The method is based on the use of CdSe/SiO₂ quantum dot microbeads (QBs) with a mean diameter of 106 nm. These have strong red luminescence (with excitation/emission peaks at 365/622 nm) which results in enhanced sensitivity. The QBs binding with monoclonal antibodies (mAbs) as the signal probes can react specifically with AFB₁, ZEN and DON, respectively. There is an inverse correlation between the fluorescence signal intensity of test line and the analyte content, which can realize the quantitative analysis of analytes within 15 min. The limits of detection in solution are 10, 80 and 500 pg mL⁻¹ for AFB₁, ZEN and DON, respectively. Besides, the average recoveries from spiked feed range from 85.5 to 119.0%, and the relative standard deviations are less than 16.4% for both intra- and inter-day assays. The method was used to analyze naturally contaminated feedstuff, and this resulted in a good agreement with data obtained by LC-MS/MS. Graphical abstractSchematic representation of a fluorometric method for the simultaneous determination of three mycotoxins. Quantum dot microbeads (QBs) binding with monoclonal antibodies (mAbs) are signal probes. There is an inverse correlation between the fluorescence intensity of test line and the analyte concentration.

Li, R., et al. (2020). "The distribution, characteristics and ecological risks of microplastics in the mangroves of Southern China." Science of the Total Environment **708**: 135025.

During the production, use and disposal of plastic products, microplastics (MPs) are dispersed into the surrounding environment and have inevitable impacts on mangrove ecosystems in estuaries and offshore areas. In the mangroves of Southern China, the systematic evaluation of the distribution, characteristics and ecological risks of MPs is lacking. In this study, surface sediments (0-5cm depth) were collected from six representative mangroves in China to explore MP contamination and its associated ecological risk. Based on the results, MP concentrations of MPs in mangrove sediments were as follows: FT (2249+/-747 items/kg), ZJ (736+/-269 items/kg), DF (649+/-443 items/kg), DZG (431+/-170 items/kg), YX (424+/-127 items/kg), and FCG (227+/-173 items/kg). The higher MP concentration in the Futian mangrove was mainly related to inputs from the Pearl River, the third largest river in China. The predominant shape, colour, and size of MPs were fibrous, white-transparent, and 500-5000mum, respectively. The main MP polymer types were polypropylene, polyethylene, and polystyrene. Degradation artefacts were present on surface of MPs as well as metallic and non-metallic elements. MPs concentration in mangrove sediments increased with increasing social-economic development of surrounding districts, which indicated the clear influence of anthropogenic activity on MP pollution in these mangroves. Furthermore, total organic carbon (TOC) and silt content were positively associated with MPs (P<0.01), indicating a facilitatory role in deposition of MPs in mangroves. Based on a comprehensive evaluation using the potential ecological risk factor (E_i), potential ecological risk (RI), polymer risk index (H) and pollution load index (PLI), MPs were found to present ecological risks in these mangroves, with the highest risk occurring in the Futian mangrove.

Li, S., et al. (2012). "Electrochemical performances of two kinds of electrolytes based on lithium bis(oxalate)borate and sulfolane for advanced lithium ion batteries." Journal of Power Sources **209**: 295-300.

Lithium bis(oxalato)borate (LiBOB) is a promising salt for lithium ion batteries. However, to achieve better electrochemical performance of LiBOB, the development of appropriate electrolytes is essential. In this work, the electrochemical behaviors of sulfolane (SL) with LiBOB were studied by employment of dimethyl sulfite (DMS) and diethyl sulfite (DES) as mixed solvents, respectively. Both of the LiBOB-based electrolytes show high oxidation potentials (>5.5 V), and good conductivities. When used in Li/MCMB (mesophase carbon microbeads) cells, these two kinds of novel electrolytes exhibit not only excellent film-forming characteristics, but also low impedances of the interface films. Besides, when used in LiFePO4/Li cells, compared to the cell with the electrolyte system of 1 M LiPF6-EC/DMC (1: 1, v/v), both of the LiBOB-based electrolytes exhibit several advantages, such as more stable cycle performance even at elevated temperature, and higher mean voltage.

Li, S., et al. (2018). "Aggregation kinetics of microplastics in aquatic environment: Complex roles of electrolytes, pH, and natural organic matter." Environmental Pollution **237**: 126-132.

Microplastics are an emerging contaminants of concern in aquatic environments. The aggregation behaviors of microplastics governing their fate and ecological risks in aquatic environments is in need of evaluation. In this study, the aggregation behavior of polystyrene microspheres (micro-PS) in aquatic environments was systematically investigated over a range of monovalent and divalent electrolytes with and without natural organic matter (i.e., Suwannee River humic acid (HA)), at pH 6.0, respectively. The zeta potentials and hydrodynamic diameters of micro-PS were measured and the subsequent aggregation kinetics and attachment efficiencies (alpha) were calculated. The aggregation kinetics of micro-PS exhibited reaction- and diffusion-limited regimes in the presence of monovalent or divalent electrolytes with distinct critical coagulation concentration (CCC) values, followed the

Derjaguin-Landau-Verwey-Overbeek (DLVO) theory. The CCC values of micro-PS were14.9, 13.7, 14.8, 2.95 and 3.20mM for NaCl, NaNO₃, KNO₃, CaCl₂ and BaCl₂, respectively. As expected, divalent electrolytes (i.e., CaCl₂ and BaCl₂) had stronger influence on the aggregation behaviors of micro-PS as compared to monovalent electrolytes (i.e., NaCl, NaNO₃ and KNO₃). HA enhanced micro-PS stability and shifted the CCC values to higher electrolyte concentrations for all types of electrolytes. The CCC values of micro-PS were lower than reported carbonaceous nanoparticles CCC values. The CCC[Ca²⁺]/CCC [Na⁺] ratios in the absence and presence of HA at pH 6.0 were proportional to Z^{-2.34} and Z^{-2.30}, respectively. These ratios were in accordance with the theoretical Schulze-Hardy rule, which considers that the CCC is proportional to z⁻⁶-z⁻². These results indicate that the stability of micro-PS in the natural aquatic environment and the possibility of significant aqueous transport of micro-PS.

Li, S., et al. (2014). "Studies on electrochemical performances of novel electrolytes for wide-temperature-range lithium-ion batteries." Acs Applied Materials & Interfaces **6**(7): 4920-4926.

Wide-temperature electrochemical behaviors of sulfolane (SL) with lithium difluoro(oxalato)borate (LiODFB) are studied using dimethyl sulfite (DMS) and diethyl sulfite (DES) as mixed solvents, respectively. In LiFePO4/Li cells, LiODFB-SL/DMS and LiODFB-SL/DES electrolytes always exert several advantages over a wide temperature range, such as stable cycling performance and good rate performance. Besides, in Li/mesophase carbon microbead cells, these novel electrolytes respectively exhibit excellent film-forming characteristics at both +60 and -20 degreeC, such as the formation of a stable and conductive SEI layer. It suggests that LiODFB-SL/DMS and LiODFB-SL/DES electrolytes are alterative candidate electrolytes for wide-temperature-range lithium-ion batteries.

Li, S. Y., et al. (2015). "Research on Environmental Impact Evaluation and Recycling Systematic Assessment of Plastic Waste in China." Applied Mechanics and Materials **768**(Selected Proceedings of the Ninth International Conference on Waste Management and Technology): 240-248.

With the increasing of plastic consumption, the recycling of plastic waste has become an important problem with huge environmental impact. In order to analyze the environmental impact of plastic waste recycling, this study presents a systematic evaluation framework for plastic waste's recycling process in China. Based on the framework, theoretical analysis and experimental research are made to evaluate the relationship of scale volume and environmental impact of plastic waste recycling. Cost and energy consumption of typical processing of plastic wastes have been calculated. And an optimization research is made to reduce the environmental impact, and increase recycling output efficiency for enterprise and local region.

Li, T., et al. (2018). "A review on phthalates removal using adsorption in aqueous environments." Journal of Agro Environment Science **37**(8): 1565-1573.

Phthalate esters (PAEs) are widely-used plasticizers added to plastic products, rubber materials, medical implements, and toys to improve plasticity. Over the last decades, the occurrence of PAEs in drinking water, surface water, and ground water is largely due to wastewater discharge, dry and wet deposition, and leachates from plastic waste. PAE-contaminated water has been linked to teratogenesis, mutagenicity and endocrine disruption in the reproduction system of fish and mammals, and has known carcinogenic effects. This work presents a review of current and future adsorptive materials used for phthalate removal from aquatic environments. Adsorbents include activated carbon and its derivatives, chitosan and modified chitosan, biochar, clay minerals, polymer resin, membrane, nanomaterials, molecular imprinted polymers (MIPs), as well as other emerging materials. Additionally, adsorbent efficiency, adsorption mechanisms, and costs have been summarized; generally, adsorption capacity increases with PAE hydrophobicity for most adsorbents. Langmuir and Freundlich's isotherm models are useful in describing adsorption data. Adsorption processes can be attributed to hydrophobic interaction, hydrogen bonding, electrostatic interaction, pi - pi stacking, and pore filling. Moreover, research advances suggest that modified chitosan, clay mineral and biochar of activated sludge and bacteria are promising adsorbents as they are low cost, environmentally friendly, and highly efficient.

Li, W., et al. (2019). "Colonization Characteristics of Bacterial Communities on Plastic Debris Influenced by Environmental Factors and Polymer Types in the Haihe Estuary of Bohai Bay, China." Environmental Science & Technology **53**(18): 10763-10773.

The colonization characteristics of bacterial communities on microplastics or plastic debris (PD) have generated great concern in recent years. However, the influence of environmental factors and polymer types on the formation of bacterial communities on PD in estuarine areas is less studied. To gain additional insights, five types of PD (polyvinyl chloride, polypropylene, polyethylene, polystyrene, and polyurethane) were exposed for three-time periods (two weeks, four weeks, and six weeks) in the Haihe Estuary. 16S rRNA gene sequencing was used to identify the bacterial communities on PD, in seawater, and in sediment samples. The results indicate that the average growth rate of a biofilm is affected by nutrients (total nitrogen and total phosphorus) and salinity. Furthermore, salinity is the primary factor affecting bacterial diversity of the colonies on PD. In addition, genera of bacteria show selectivity toward the PD polymer type and tend to colonize their preferred substrate. Compared with seawater and sediment, PD could be carriers for enrichment of Vibrio in the estuarine environment with salinity >=26 (+/-2), which might increase the ecological risk of PD in marine environments.

Li, W. C., et al. (2016). "Plastic waste in the marine environment: A review of sources, occurrence and effects." Science of the Total Environment **566-567**: 333-349.

This review article summarises the sources, occurrence, fate and effects of plastic waste in the marine environment. Due to its resistance to degradation, most plastic debris will persist in the environment for centuries and may be transported far from its source, including great distances out to sea. Land- and ocean-based sources are the major sources of plastic entering the environment, with domestic, industrial and fishing activities being the most important contributors. Ocean gyres are particular hotspots of plastic waste accumulation. Both macroplastics and microplastics pose a risk to organisms in the natural environment, for example, through ingestion or entanglement in the plastic. Many studies have investigated the potential uptake of hydrophobic contaminants, which can then bioaccumulate in the food chain, from plastic waste by organisms. To address the issue of plastic pollution in the marine environment, governments should first play an active role in addressing the issue of plastic waste by introducing legislation to control the sources of plastic debris and the use of plastic additives. In addition, plastics industries should take responsibility for the end-of-life of their products by introducing plastic recycling or upgrading programmes.

Li, W.-J., et al. (2019). "Effect of Preparation Solvent and Calcination Atmosphere on Ni@SiO2 Catalyst for Simultaneous Production of Hydrogen and Carbon Nanotubes from Simulated Plastic Waste Syngas." Energy Technology **7**(3): N.PAG-N.PAG.

SiO2 core supports are prepared via the Stöber method with various synthesizing solvents. Then,

a Ni shell is deposited on SiO2 by a deposition–precipitation method. The results illustrate that using isopropanol as the solvent governs the catalyst particle size with a superior dispersion and a high catalytic activity. Thus, the calcination atmosphere of the catalyst directly affects both the chemical state and the catalytic performance of the active sites. The Ni@SiO2-I-air (isopropanol) catalyst calcined by air with more Ni2+ facilitates the highest H2 production of 142.2 mmol g−1 h−1 but provides a carbon nanotube (CNT) yield of only 7.6%. Most importantly, the Ni@SiO2-I-H2 catalyst calcined by ambient H2 is prone to form Ni0 species, thus providing the best crystalline conversion and metal–support interaction, which benefits the production of CNTs to a maximum yield of 19.8% with a H2 production of 122.8 mmol g−1 h−1. Monodispersed Ni@SiO2 core-shell catalysts facilitate the catalytic conversion of simulated syngas from plastic waste to hydrogen and carbon nanotubes. [ABSTRACT FROM AUTHOR]

Li, X., et al. (2019). "Effects of chemical pretreatments on microplastic extraction in sewage sludge and their physicochemical characteristics." Water Research **171**: 115379.

Sewage sludge is a primary pathway for microplastics (MPs) entering into terrestrial ecosystems. However, a standardized method to analyze MP in sludge is lacking due to its high organic matter. This study investigated the extraction efficiency of six MPs in five solid matrices, i.e. sewage sludge, cattle manure, soil, sediment and silicon dioxide.

Li, X., et al. (2017). "Regulation of intraocular pressure by microRNA cluster miR-143/145." Scientific Reports **7**(1): 915.

Glaucoma is a major cause of irreversible blindness worldwide. Elevated intraocular pressure (IOP), which causes optic nerve damage and retinal ganglion cell death, is the primary risk factor for blindness in glaucoma patients. IOP is controlled by the balance between aqueous humor secretion from the ciliary body (CB) and its drainage through the trabecular meshwork (TM). How microRNAs (miRs) regulate IOP and glaucoma in vivo is largely unknown. Here we show that miR-143 and miR-145 expression is enriched in the smooth muscle and trabecular meshwork in the eye. Targeted deletion of miR-143/145 in mice results in significantly reduced IOP, consistent with an ~2-fold increase in outflow facilities. However, aqueous humor production in the same mice appears to be normal based on a microbeads-induced glaucoma model. Mechanistically, we found that miR-143/145 regulates actin dynamics and the contractility of TM cells, consistent with its regulation of actin-related protein complex (ARPC) subunit 2, 3, and 5, as well as myosin light chain kinase (MLCK) in these cells. Our data establish miR-143/145 as important regulators of IOP, which may have important therapeutic implications in glaucoma.

Li, Y., et al. (2014). "Asynchronous Magnetic Bead Rotation (AMBR) Microviscometer for Label-Free DNA Analysis." Biosensors **4**(1): 76-89.

We have developed a label-free viscosity-based DNA detection system, using paramagnetic beads as an asynchronous magnetic bead rotation (AMBR) microviscometer. We have demonstrated experimentally that the bead rotation period is linearly proportional to the viscosity of a DNA solution surrounding the paramagnetic bead, as expected theoretically.

Simple optical measurement of asynchronous microbead motion determines solution viscosity precisely in microscale volumes, thus allowing an estimate of DNA concentration or average fragment length. The response of the AMBR microviscometer yields reproducible measurement of DNA solutions, enzymatic digestion reactions, and PCR systems at template concentrations across a 5000-fold range. The results demonstrate the feasibility of viscosity-based DNA detection using AMBR in microscale aqueous volumes.

Li, Y., et al. (2011). "Chemiluminescence aptasensor for cocaine based on double-functionalized gold nanoprobes and functionalized magnetic microbeads." Analytical & Bioanalytical Chemistry **401**(1): 213-219.

A novel chemiluminescence (CL) aptasensor for highly sensitive detection of small-molecule targets using cocaine as a model analyte was developed in the present study. For the proposed aptasensor, the aptamers were immobilized on the surface of gold nanoparticles (AuNPs) functionalized magnetic microbeads (MB-AuNPs) and then hybridized with the signal DNA on the double-functional gold nanoprobes (DF-AuNPs) modified with horseradish peroxidase (HRP). When cocaine was introduced, a competition for the aptamer between cocaine and the signal DNA occurred and the gold nanoprobes were forced to dissociate from the MB-AuNPs surface based on the structure switching of the aptamer. The CL signals of Luminol-H(2)O(2)-HRP-PIP system were proportional to the concentration of cocaine. A linear range was obtained when the concentrations of cocaine were from 1 x 10(-9) to 1 x 10(-8) M with the detection limit of 0.48 nM (3sigma), much lower than those achieved by other methods. This new system can be easily extended to a variety of small-molecules, protein, and tumor cell analysis.

Li, Y., et al. (2019). "Effects of particle size and solution chemistry on Triclosan sorption on polystyrene microplastic." Chemosphere **231**: 308-314.

PS microplastic particle (<5mm) is an emerging contaminant of concern in aquatic and sediment systems with reported negative impacts on environmental and human health. TCS is a broad-spectrum antimicrobial which can affect ecosystems and result in long-term human health risks. The interaction between TCS and PS microplastic, partly determines the behavior and dispersion of TCS in the environment. In this study, the sorption kinetics and isotherms for TCS and PS microplastic were investigated. The influences of temperature, pH, ionic strength and coexisting heavy metals were assessed in batch experiments. The pseudo-second-order model (PSOM) was found to effectively describe the sorption kinetics of TCS on PS. TCS sorption on PS was found to be higher within the pH range of 3.0-6.0, while a decrease occurred at pH>6.0. This result indicates that TCS⁰ was the major species contributing to the sorption process through hydrophobic interaction. Temperature did not affect the sorption of TCS on polystyrene, with sorption K_d values of 0.15, 0.16, 0.18 and 0.17L/g at 288, 298, 308 and 318K, respectively. Furthermore, the sorption amount of TCS showed no obvious variation with NaCl concentrations varying between 0.001 and 0.1M. Finally, the coexistence of Cu(II)/Zn(II) had no significant influence on TCS sorption on PS, as Cu(II)/Zn(II) and TCS had different mechanisms of sorption on PS.

Li, Y., et al. (2019). "Ecological influences of the migration of micro resin particles from crushed waste printed circuit boards on the dumping soil." Journal of Hazardous Materials: 121020.

About 0.8 million tons of resin particles, which were generated from the recovery of waste printed circuit boards, were dumped on soil at Qingyuan city of China. Resin particles not only belong to micro plastic but also contain brominated flame retardants and heavy metals. There is little information about soil pollution caused by the dumped resin particles. This study found

resin particles would transfer from soil surface into soil at least 10 mm downward for six months. Average content of bromine in soil within 10 cm exceeded 2500 mg/kg. The highest content of Pb, Zn, and Cu was 3450, 1143 and 1450 mg/kg, which were approximately 6.9, 2.3 and 3.6 times as much as Grade III soil standard of China. Micro plastic, brominated flame retardants, and heavy metals made significant effects on soil bacterial community. Bacterial diversity was destroyed and the number of resistant bacteria increased obviously such as Acinetobacter, Pseudomonas and Paracoccus. This paper presented the ecological destroy of soil when the resin particles were deposited on soil surface. It also suggested the government to urgently manage the resin particles produced in the recovery of waste printed circuit boards.

Li, Y., et al. (2019). "Airborne fiber particles: Types, size and concentration observed in Beijing." Science of the Total Environment **705**: 135967.

Airborne fibers are of public concern because of their potential threat to the environment, however their physical and chemical properties are poorly understood. Fibers are defined as having an aspect ratio >3:1. Fiber particles were collected in the near surface air, surface deposited dust and building materials in Beijing. They were examined using analytical scanning electron microscopy. The particles were initially classified into two categories: organic and inorganic. Organic fibers comprised microplastic and natural organic fiber particles. Inorganic fibers were mainly man-made mineral fibers (MMMFs), asbestos (represented by chrysotile), calcium sulfate and metal fiber particles. Microplastic and MMMFs fibers were most abundant, accounting for 34.6% and 40.3% in total, respectively, followed by asbestos (7.8%), calcium sulfate (7.2%), metal fibers (5.6%) and natural organic fiber particles (4.5%). The number-concentration of these particles was about 16.7 x 10⁻³ fibers/ml at 1.5 m above the ground and about 14.1 x 10⁻³ fibers/ml at about 18 m, suggesting the particles were mainly derived from surface and were re-suspended. Approximately 80% of the airborne fiber were smaller than 20 mum in length, which is possibly the critical size for fiber particles to re-suspend into the air. Surface dust and construction sites were speculated to be the major contributors of the fiber particles.

Li, Y., et al. (2020). "Low level of polystyrene microplastics decreases early developmental toxicity of phenanthrene on marine medaka (Oryzias melastigma)." Journal of Hazardous Materials **385**: 121586.

Microplastics (MPs) have become global environmental concern. However, the effects of environmental concentrations of MPs, singly or in combination with organic pollutants, on the early development of marine fish remain unclear. In this study, fertilized eggs of marine medaka (Oryzias melastigma) were exposed to polystyrene MPs (0, 2, 20, 200mug/L) and/or phenanthrene (Phe, 50mug/L) for 28 days. The results revealed that MPs were accumulated on the chorion and ingested by larvae from 2 days post-hatching. High levels of MPs (20 and 200mug/L) decreased the hatchability, delayed the hatching time, and suppressed the growth, whereas Phe inhibited hatching and caused malformations in larvae. The presence of MPs at 20 and 200mug/L did not alter the toxicity of Phe. By contrast, combined exposure to 2mug/L MPs and Phe increased the hatchability by 25.8%, decreased malformation and mortality rates, and restored Phe-induced abnormal expressions of cardiac development-related genes. The reduced early developmental toxicity could be attributed to the decreased bioavailability and bioaccumulation of Phe by the low level of MPs. These findings contradicted the view that MPs would aggravate the toxicity of organic pollutants, and future studies are warranted to elucidate the ecological risks of marine MPs.

Li, Y., et al. (2019). "Interactions between nano/micro plastics and suspended sediment in water:

Implications on aggregation and settling." Water Research **161**: 486-495.

Interactions between nano/microplastics and suspended sediment (SS) in natural waters are important for the environmental fate of plastic particles. This study investigated the effect of heteroaggregation between nano/microplastics and SS on the settling of aggregates. In NaCl solutions (0.05-0.5M), large SS (100-500mum in diameter) significantly increased the settling ratio of polystyrene nanoplastics (PSNPs) with an average diameter of 100nm due to the formation of PSNPs-SS aggregates. The settling ratio of the heteroaggregates increased significantly when the NaCl concentration increased from 50 to 200mM. This was primarily because higher ionic strength reduced the electrostatic repulsion between large SS and PSNPs, and subsequently increased the heteroaggregation rate. No obvious differences in settling ratios were observed in 200 or 500mM NaCl solutions because the heteroaggregation entered the diffusion-controlled regime. However, in HA solutions (10-50mgL⁻¹), the surface adsorption of HA on PSNPs and large SS reduced the heteroaggregation of PSNPs-SS and thus led to the low co-settling ratio due to the steric hindrance according to the DLVO theory. In contrast, polyethylene microplastics (PEMPs) with diameters of 1.0-1.2mm were found to always float on water surface (up to 8 months), even after addition of 500mgL⁻¹ small SS (<10mum in diameter). Clearly, the heteroaggregation of PEMPs and small SS had minor effect on the settling of PEMPs due to the overwhelming boyanccy. These results provided new insight into the fate and distribution of nano/microplastics in aquatic environment, which affect the bioavailability of plastic particles in natural waters.

Li, Y.-X., et al. (2009). "Effects of glycerol and ethylene-acrylic acid on composition optimization of PVOH/starch-blended biodegradable resin using response surface methodology." Journal of Applied Polymer Science **114**(5): 2915-2921.

Response surface methodology was used to analyze the effect of glycerol (X1) and ethylene-acrylic acid (EAA) level (X2) on the objective (water solubility index (WSI), water absorption index (WAI), and tensile strength) attributes of a poly(vinyl alcohol) (PVOH)/starch-blended plastic resin. A rotable central composite design was used to develop models for the objective responses. The experiments were run with different barrel temperatures, such as zone 1: 100 degree C, zone 2: 100 degree C, zone 3: 105 degree C, and zone 4: 105 degree C, respectively, with a feed rate of 20 g/min and screw speed of 25 rpm. Responses were most affected by changes in glycerol level (X1) and to a lesser extent by EAA level (X2). Individual contour plots of the different responses were overlaid, and regions meeting the optimum WSI of 6.10%, WAI of 5.57 g gel/g dry wt, and tensile strength of 62.14 MPa were identified at the glycerol level of 72.41 mL and the EAA level of 36.03 g, respectively. [copy 2009 Wiley Periodicals, Inc. J Appl Polym Sci, 2009

Li, Z., et al. (2020). "Evaluating the effect of different modified microplastics on the availability of polycyclic aromatic hydrocarbons." Water Research **170**: 115290.

Microplastics (MPs) discharged into the natural environment undergo various wearthering pathways, such as mechanical abrasion and ultraviolet (UV) irradiation. However, little is known about the effects of such aged MPs on the bioavailability of hydrophobic organic compounds (HOCs) in aqueous environments. To simulate the natural oxidation and UV-ageing process of MPs, three kinds of modified polyethylene MPs were obtained by plastic etching processes common in industry and UV irradiation, namely, etched MPs (EMPs), UV-aged MPs (UV-MPs), and etched MPs followed by UV ageing (UV-EMPs). The modified MPs showed a higher content of surface oxygen-containing groups than the pristine MPs, and the specific surface area and pore volume increased significantly after etching and ultraviolet ageing, especially for the EMPs

(1.67m²g⁻¹ and 0.0049cm3 g⁻¹) and UV-EMPs (2.37m²g⁻¹ and 0.0089cm3 g⁻¹). The effect of modified MPs on the availability of 10 polycyclic aromatic hydrocarbons (PAHs, logK_{ow} 4.18-6.20) was evaluated by negligible-depletion solid-phase microextraction (nd-SPME). The free concentrations (C_{free}) of most PAHs (except for less hydrophobic PAHs, logK_{ow} 4.18 and 4.56) decreased with an increasing concentration of MPs. The logarithms of the sorption coefficients of PAHs with various MPs (logK_{MPs}, logK_{UV-MPs}, logK_{EMPs} and logK_{UV-EMPs}) were linearly correlated with logK_{ow}, suggesting that the sorption is hydrophobicity dependent. Compared with the results for pristine MPs (logK_{MP} 3.80-4.95), UV ageing only slightly enhanced the sorption of PAHs by MPs (logK_{UV-MPs} 3.71-4.98), whereas the plastic etching processes significantly enhanced sorption (logK_{EMPs} 3.85-5.18 and logK_{UV-EMPs} 3.90-5.28). The sorption of PAHs to MPs is mainly based on partitioning; however, a mechanism of adsorption also likely takes place in EMPs and UV-EMPs due to hydrogen bonding and pi-pi interactions. Desorption study indicated that PAH desorption from MPs are dominated by film diffusion. However, intraparticle diffusion also takes great part for the EMPs. These results suggest that modification of MPs in the natural environment will change the availability of HOCs.

Li, Z., et al. (2019). "Combined effect of polystyrene microplastics and dibutyl phthalate on the microalgae Chlorella pyrenoidosa." Environmental Pollution: 113604.

The combined effect of polystyrene microplastics (mPS) and dibutyl phthalate (DBP), a common plastic additive, on the microalgae Chlorella pyrenoidosa was investigated in the present study. The 96 h-IC₅₀ value of DBP was 2.41mgL⁻¹. Polystyrene microplastics exhibited size-dependent inhibitory effect to C. pyrenoidosa, with the 96 h-IC₅₀ at 6.90 and 7.19mgL⁻¹ for 0.1 and 0.55mum mPS respectively, but little toxicity was observed for 5mum mPS. The interaction parameter rho based on the response additive response surface (RARS) model varied from -0.309 to 5.845, indicating the interaction pattern varying with exposure concentrations of chemical mixtures. A modified RARS model (taking rho as a function of exposure concentration) was constructed and could well predict the combined toxicity of mPS and DBP. More than 20% reduction of DBP was observed at 20mgL⁻¹ mPS, while 1mgL⁻¹ mPS had no significant effect on the bioavailability of DBP at different sampling time points. Volume, morphological complexity and chlorophyll fluorescence intensity of microalgal cells were disturbed by both DBP and mPS. The antagonistic effect of high concentrations of mPS might be partially attributed to the combination of hetero- and homo-aggregation and the reduced bioavailability of DBP. The overall findings of the present study profiled the combined toxic effects of mPS and DBP on marine phytoplankton species which will be helpful for further evaluation of ecological risks of mPS and DBP in marine environment.

Lian, J., et al. (2019). "Effects of microplastics on wheat seed germination and seedling growth." Journal of Agro Environment Science **38**(4): 737-745.

To explore the effects of microplastics on seed germination and seedling growth of wheat (Triticum aestivum L.), three widely detected microplastics in agroecosystems Ethylene-vinyl acetate compolymer (EVA), Linear low-density polyethylene (LLDPE) and Poly (methyl methacrylate)(PMMA) were investigated by seed germination experiments. The results showed that all microplastics inhibited wheat seed germination at low and medium concentrations (<500 mg.L⁻¹) with inhibition rates ranging from 2.86% to 20%. At high concentrations (1000 mg.L⁻¹), the microplastics substantially promoted germination compared with that of the control group. In particular, the inhibitory effect of microplastics on wheat seed vigor index decreased in the following order: LLDPE > EVA > PMMA. The mean germination time of wheat seeds exposed to EVA and LLDPE at low and medium concentrations was higher than that at high concentration, and PMMA had no significant effect on wheat seed growth aspects. Overall, microplastics had no significant effect on wheat seedling length, root length and dry weight, but LLDPE significantly inhibited wheat bud length at 10 mg.L⁻¹ concentration.

Lian, J., et al. (2020). "Impact of polystyrene nanoplastics (PSNPs) on seed germination and seedling growth of wheat (Triticum aestivum L.)." Journal of Hazardous Materials **385**: 121620.

Microplastics and nanoplastics are emerging pollutants of global concern. However, the understanding of their ecological effects on terrestrial plants is still limited. We conducted the systematic research to reveal the impact of polystyrene nanoplastics (PSNPs) (0.01-10mg/L) on seed germination and seedling growth of wheat (Triticum aestivum L.). The results showed that PSNPs had no discernible effect on seed germination rate whereas significantly (p<0.01) increased root elongation by 88.6 %-122.6 % when compared with the control. Similarly, remarkable increases in carbon, nitrogen contents, and plant biomass were also observed after exposure to PSNPs. Moreover, PSNPs could reduce the shoot to root biomass ratio (S:R ratio) of wheat seedlings. Furthermore, the imagings of a 3D laser confocal scanning microscopy (LCSM) and scanning electron microscopy (SEM) indicated that PSNPs were taken up and subsequently down-top transported to shoot. The absorption and accumulation of four micronutrients (Fe, Mn, Cu and Zn) in wheat were generally reduced in varying degrees. Notably, metabolomics analysis revealed that all PSNPs treatments altered the leaf metabolic profiles mainly by regulating energy metabolisms and amino acid metabolisms. These findings are expected to provide new insights into the effects of PSNPs on crop plants.

Liang, C.-H. (2007). Biological applications of nanoscale materials.

The objective of my research work is to synthesize, characterize, design, and apply nanocrystals for biomedical use. Gold nanoparticles were synthesized in the presence of chitosan via reduction of HAuCl4 with sodium borohydride. The average particle size of gold nanoparticles was significantly affected with the concentration of chitosan added and was ranged between 5 and 30 nm. The gold-chitosan nanocomposites were formed by adsorbing chitosan molecules on the gold nanoparticles. CdSe/ZnS quantum dots were prepared by a solution phase synthetic method. A new route for the phase transfer of CdSe/ZnS quantum dots from non-polar solvents into aqueous solution was developed using hydrophobically modified polysaccharides, both chitosan and alginate. In addition, it was shown that CdSe/ZnS based polysaccharide nanoparticles effectively inhibited the proliferation of human ovarian cancer cell line SKOV-3 in vitro. The findings suggest that CdSe/ZnS quantum dot based polysaccharide nanoparticles not only act as a long-term biomarker but also have potential value in cancer therapy. A novel method for extracting magnetite nanoparticles from magnetotactic bacteria was developed by using co-surfactant. The problem of mass cultivation was solved by growing AMB-1 in Ca super(2+)-alginate microbeads. To apply magnetotactic bacterial in biomedical applications, uptake of chitosan-capped CdSe/ZnS quantum dots on magnetotactic bacteria and introducing fluorescent magnetotactic bacteria into mouse macrophage cells was achieved. A general strategy is described which allows for constructing multifunctional magnetic nanocomposites based on bacterial magnetite nanoparticles. Specifically, core-shell structures of bacterial magnetite-CdSe/ZnS and bacterial magnetite-gold nanocomplexes have been built in this way.

Furthermore, design and synthesis multimodal contrast agents which are ultrasound and photoacoustic active are achieved by utilizing biocompatible gold nanorods self assembling on liquid perfluorocarbon particles. The probe is likely to provide richer information for a better understanding of the target and subsequent diagnosis. In summary, nanocrystals including gold, CdSe/ZnS quantum dots, and bacterial magnetite and nanocomplexes including bacterial magnetite-quantum dots, bacterial magnetite-gold, gold-perfluorocarbon, quantum dots-chitosan, and quantum dots-alginate were successful synthesized. Some potential applications of these nanoparticles and nanocomplexes in biomedical engineering are explored.

Liang, P., et al. (2014). "Rapid and reagentless detection of microbial contamination within meat utilizing a smartphone-based biosensor." Scientific Reports **4**(1).

A smartphone-utilized biosensor was developed for detecting microbial spoilage on ground beef, without using antibodies, microbeads or any other reagents, towards a preliminary screening tool for microbial contamination on meat products, and potentially towards wound infection. Escherichia coli K12 solutions (10¹-10⁸ CFU/mL) were added to ground beef products to simulate microbial spoilage. An 880 nm near infrared LED was irradiated perpendicular to the surface of ground beef, and the scatter signals at various angles were evaluated utilizing the gyro sensor and the digital camera of a smartphone. The angle that maximized the Mie scatter varied by the E. coli concentration: 15 degrees for 10⁸ CFU/mL, 30 degrees for 10⁴ CFU/mL, and 45 degrees for 10 CFU/mL, etc. SEM and fluorescence microscopy experiments revealed that the antigens and cell fragments from E. coli bonded preferably to the fat particles within meat, and the size and morphologies of such aggregates varied by the E. coli concentration.

Liang, T. W., et al. (2016). "Application of Chitinous Materials in Production and Purification of a Poly(l-lactic acid) Depolymerase from Pseudomonas tamsuii TKU015." Polymers **8**(3): 22.

The management of fishery residues and plastics is considered to be a vital strategy for conserving resources and maintaining the quality of the environment. Poly(l-lactic acid) (PLA) is a commercially promising, renewable, and biodegradable plastic. In this study, a PLA depolymerase was produced in a squid pen powder (SPP) and recycled plastic waste (PLA powder)-containing medium by Pseudomonas tamsuii TKU015, a bacterial strain isolated from Taiwanese soil. This PLA depolymerase had a molecular weight of 58 kDa and was purified to homogeneity from the supernatant of a TKU015 culture. The optimum pH of TKU015 PLA depolymerase is 10, and the optimal temperature of the enzyme is 60 degreeC. In addition to PLA, TKU015 PLA depolymerase degraded fibrinogen and tributyrin, but did not hydrolyze casein, triolein, and poly(beta-hydroxybutyrate). Taken together, these data demonstrate that P. tamsuii TKU015 produces a PLA depolymerase to utilize SPP and polylactide as carbon/nitrogen sources.

Liang, Y., et al. (2019). "Increasing Temperature and Microplastic Fibers Jointly Influence Soil Aggregation by Saprobic Fungi." Frontiers in Microbiology **10**: 2018.

Microplastic pollution and increasing temperature have potential to influence soil quality; yet little is known about their effects on soil aggregation, a key determinant of soil quality. Given the importance of fungi for soil aggregation, we investigated the impacts of increasing temperature and microplastic fibers on aggregation by carrying out a soil incubation experiment in which we inoculated soil individually with 5 specific strains of soil saprobic fungi. Our treatments were temperature (ambient temperature of 25degreeC or temperature increased by 3degreeC, abruptly versus gradually) and microplastic fibers (control and 0.4% w/w). We evaluated the percentage of water stable aggregates (WSA) and hydrolysis of fluorescein diacetate (FDA) as an indicator of fungal biomass. Microplastic fiber addition was the main factor influencing the WSA, decreasing the percentage of WSA except in soil incubated with strain RLCS 01, and mitigated the effects of temperature or even caused more pronounced decrease in WSA under increasing temperature. We also observed clear differences between temperature change patterns. Our study shows that the interactive effects of warming and microplastic fibers are important to consider when evaluating effects of global change on soil aggregation and potentially other soil processes.

Liao, Q., et al. (2011). "Simultaneous detection of antibodies to five simian viruses in nonhuman primates using recombinant viral protein based multiplex microbead immunoassays." Journal of Virological Methods **178**(1-2): 143-152.

Routine screening for infectious agents is critical in establishing and maintaining specific pathogen free (SPF) nonhuman primate (NHP) colonies. More efficient, higher throughput, less costly reagent, and reduced sample consumption multiplex microbead immunoassays (MMIAs) using purified viral lysates have been developed previously to address some disadvantages of the traditional individual enzyme-linked immunosorbent assay (ELISA) methods. To overcome some of the technical and biosafety difficulties in preparing antigens from live viruses for viral lysate protein based MMIAs, novel MMIAs using recombinant glycoprotein D precursor (gD) protein of herpesvirus B and four viral gag proteins of simian immunodeficiency virus (SIV), simian T Cell lymphotropic virus (STLV), simian foamy virus (SFV), and simian betaretrovirus (SRV) as antigens have been developed in the current study. The data showed that the recombinant viral protein based MMIAs detected simultaneously antibodies to each of these five viruses with high sensitivity and specificity, and correlated well with viral lysate based MMIAs. Therefore, recombinant viral protein based MMIA is an effective and efficient routine screening method to determine the infection status of nonhuman primates. © 2011 Elsevier B.V.

Liao, Y., et al. (2017). "A high-performance and robust membrane with switchable super-wettability for oil/water separation under ultralow pressure." Journal of Membrane Science **543**: 123-132.

To separate oil/water mixtures and emlusions, superwetting membranes have been developed via synergy between surface chemistry and topography. However, challenges remain as most of them exhibit unsatisfactory performance, limited strength and durability. Herein, we report a novel membrane with switchable super-wettability for oil and water. This novel composite membrane was developed by electrospinning a hierarchically porous polyvinylidene fluoride (PVDF)-silica composite nano/micro-beaded top layer and a PVDF nanofibrous intermediate layer on a non-woven support. The surface of the composite membrane was modified to exhibit high surface free energy. The membrane is in-air superamphiphilic, underwater superoleophobic and under-oil superhydrophobic. It can treat various types of oil/water mixtures, from simple layered solutions to emulsions (including surfactant-free or surfactant-stabilized oil-in-water and water-in-oil emulsions) without external driving force or under an ultralow pressure (0.1 bar) in a cross-flow filtration process. It shows a flux up to 2000 L/m² h and high separation efficiency (> 99.99% in terms of water and oil purities in the permeation) in the cross-flow filtration process. The membrane also exhibits an excellent robustness under harsh conditions, including strong acidic or alkaline solutions, hot water and petroleum. In addition, it presents remarkable antifouling and easy-cleaning properties, which were demonstrated in a 50-h continuous operation. Copyright © 2017 Elsevier B.V.

Liao, Y. C., et al. (2019). "[Effects of Microplastics on the Growth, Physiology, and Biochemical Characteristics of Wheat (Triticum aestivum)]." Huanjing Kexue/Environmental Science **40**(10): 4661-4667.

The toxicological effects of microplastics in the soil environment have gradually attracted widespread attention, while less is known about the influence of microplastics on plants. The growth of wheat, photosynthetic pigment content, soluble protein content, and the antioxidant enzyme activities of leaves were investigated to explore the toxic effects of microplastics on wheat (Triticum aestivum). In this study, 100 nm and 5 mum polystyrene microplastics (PS-MPs) were used for soil culture treatment combined with hydroponic growth. The results showed that in hydroponic experiment, high concentrations (200 mg.L⁻¹) of PS-MPs significantly inhibited the elongation of wheat roots and stems, and 5 mum PS-MPs showed a greater toxicity effect than 100 nm PS-MPs. Roots and stem length inhibition rates were 67.15% and 56.45%, respectively. In the soil culture tests, 10 mg.kg⁻¹ PS-MPs had the most significant effect on wheat growth. Within the test content range (0-100 mg.kg⁻¹), with an increase in PS-MPs exposure, the content of photosynthetic pigment and soluble protein in wheat leaves increased first and then decreased. This indicated that PS-MPs damaged the photosynthetic pathway of wheat leaves and inhibited protein synthesis. SOD activity decreased, and CAT decreased first and then increased, indicating that the possible mechanism of toxicity to wheat involves oxidative stress. The results provide a basis for the ecological risk assessment of microplastics in the soil environment.

Liao, Y. L. and J. Y. Yang (2020). "Microplastic serves as a potential vector for Cr in an in-vitro human digestive model." Science of the Total Environment **703**: 134805.

Microplastics (MPs), polymer particles capable of adsorbing heavy metals from ambient environment, have been found in diverse human food resources. Through the consumption of MPs, heavy metals adsorbed on MPs might be transported into human body. This study aims to explore the behavior of heavy metal-contaminated MPs in human digestive system which is not previously researched. Firstly, a chromium (Cr) adsorption/desorption study was conducted with four commonly used nondegradable MPs [polyethylene (PE), polypropylene (PP), polyvinyl chloride (PVC) and polystyrene (PS)] as well as one degradable MP (polylactic, PLA). Then, the whole digestive system in-vitro method (WDSM), a systematic model including mouth, gastric, small intestine, and large intestine digestive phases, was conducted on the Cr-loaded MPs. Additionally, the bioaccessibilities and hazard quotients (HQs) of Cr(VI) and Cr(III) were evaluated. Among five MPs, although PLA showed the weakest adsorption capacity for Cr, the Cr(VI) bioaccessibilities for PLA reached the highest values of 19.9%, 15.6% and 3.9% in gastric, small intestinal and large intestinal phases, respectively. The bioaccessibilities of Cr(VI) in gastric phase were significantly higher than those in other phases, while no Cr release from MPs was detected in the mouth phase. In gastric phase, the bioaccessibilities of Cr(VI) were significantly higher than those of Cr(III) in the gastric phase, and both of them approached to a similar level in intestinal phases. In the WDSM, the HQs of Cr(VI) and Cr(III) on MPs were lower than the critical level for both adults and children. Based on the measured bioaccessibilities, the maximum daily total Cr intake for different human groups (female children, male children, female adults and male adults) through MP consumption was estimated from 0.50 to 1.18mug/day. In general, the five tested MPs were potential to serve as Cr vectors in the WDSM.

Liao, Z., et al. (2017). "Application of upconversion luminescent-magnetic microbeads with weak background noise and facile separation in ochratoxin A detection." Journal of Nanoparticle Research **19 (2) (no pagination)**(60).

Ochratoxin A (OTA), the most harmful and abundant ochratoxin, is chemically stable and commonly existed in foodstuffs. In this work, upconversion luminescent-magnetic microbeads (UCLMMs) -based cytometric bead array for OTA detection with a less reagent consumption and high sensitivity has been established and optimized. In UCLMMs, upconversion nanocrystals (UCNs) for optical code present a weak background noise and no spectral cross talk between the encoding signals and target labels under two excitation conditions to improve detection sensitivity. While the superparamagnetic Fe<inf>3</inf>O<inf>4</inf> nanoparticles (Fe<inf>3</inf>O<inf>4</inf> NPs) aim for rapid analysis. The results show that the developed method has a sensitivity of 9.553 ppt below HPLC with a 50-muL sample and can be completed in <2 h with good accuracy and high reproducibility. Therefore, different colors of UCLMMs will become a promising assay platform for multiple mycotoxins after further improvement. Liboiron, M., et al. (2016). "Low plastic ingestion rate in Atlantic cod (Gadus morhua) from Newfoundland destined for human consumption collected through citizen science methods." Marine Pollution Bulletin **113**(1-2): 428-437.

Marine microplastics are a contaminant of concern because their small size allows ingestion by a wide range of marine life. Using citizen science during the Newfoundland recreational cod fishery, we sampled 205 Atlantic cod (Gadus morhua) destined for human consumption and found that 5 had eaten plastic, an ingestion prevalence rate of 2.4%. This ingestion rate for Atlantic cod is the second lowest recorded rate in the reviewed published literature (the lowest is 1.4%), and the lowest for any fish in the North Atlantic. This is the first report for plastic ingestion in fish in Newfoundland, Canada, a province dependent on fish for sustenance and livelihoods. Copyright © 2016 Elsevier Ltd

Liboiron, M., et al. (2019). "Low incidence of plastic ingestion among three fish species significant for human consumption on the island of Newfoundland, Canada." Marine Pollution Bulletin **141**: 244-248.

This study reports the first baselines of plastic ingestion for three fish species that are common commercial and sustenance food fish in Newfoundland. Species collections occurred between 2015 and 2016 for Atlantic cod (Gadus morhua), Atlantic salmon (Salmo salar), and capelin (Mallotus villosus). The frequency of occurrence (%FO) of plastic ingestion for both Atlantic salmon (n = 69) and capelin (n = 350) was 0%. Of the 1010 Atlantic cod individuals collected over two years, 17 individuals had ingested plastics, a %FO of 1.68%. This is the only multi-year investigation of plastic ingestion in Atlantic cod for the Northwest Atlantic, and the first baseline of plastic ingestion in Atlantic salmon and capelin on the island of Newfoundland. Considering the ecological, economic, and cultural importance of these fish species, this study is the beginning of a longitudinal study of plastic ingestion to detect any future changes in contamination levels. Liebezeit, G. and F. Dubaish (2012). "Microplastics in beaches of the East Frisian islands Spiekeroog and Kachelotplate." Bulletin of Environmental Contamination & Toxicology **89**(1): 213-217.

Microplastic particles were quantified in beach transects of the East Frisian islands Spiekeroog and Kachelotplate and in two samples from a tidal flat. Both granules and fibres were present while fragments and polystyrene pellets were completely absent. On the Kachelotplate the highest number of granules (496/10 g sediment) was observed at the high water line while on Spiekeroog a sample from the dune area had the highest value (38/10 g sediment). The tidal flat samples hat 36 and 136 granules/10 g sediment with the higher number being associated with a blue mussel bank. Fibres were more homogeneously distributed and did not show any particular enrichment. In comparison with data from the Belgian coast the total numbers are higher which might be related to the exposure situation of the island beaches.

Liebezeit, G. and E. Liebezeit (2014). "Synthetic particles as contaminants in German beers." Food Additives and Contaminants - Part A Chemistry, Analysis, Control, Exposure and Risk Assessment **31**(9): 1574-1578.

A total of 24 German beer brands was analysed for the contents of microplastic fibres, fragments and granular material. In all cases contamination was found. Counts ranged from 2 to 79 fibres L⁻¹, from 12 to 109 fragments L⁻¹ and from 2 to 66 granules L⁻¹. The results show a high variability between individual samples and samples from different production dates. Possible sources of this contamination with foreign materials are discussed. © 2014 Taylor & Francis.

Liebmann, B., et al. (2008). "Formulation of poorly water-soluble substances using self-assembling spider silk protein." Colloids and Surfaces A: Physicochemical and Engineering Aspects **331**(1-2): 126-132.

In nature self-assembly of soluble monomeric proteins to defined supramolecular structures is an essential process in the formation of morphologically distinct biological materials like cells, tissues, diatoms or mollusk shells. Using these proteins, complex structures in the nanometer and micrometer scale can be generated that are hardly obtainable by other methods. The engineered ADF4(C16) spider silk protein is mimicking the sequence of the dragline silk protein ADF4 of the spider Araneus diadematus and can be synthesized by a biotechnological production process using Escherichia coli (E. coli) as host organism. From the soluble ADF4(C16) monomers assembly of nanofibers, microbeads and films is possible. The purified monomeric ADF4(C16) strongly interacts with hydrophobic surfaces and particles of poorly water-soluble substances. Based on this effect ADF4(C16) could be used for colloidal stabilization of hydrophobic particles in aqueous environment. Poorly water-soluble substances can also be encapsulated in ADF4(C16) microbeads during self-assembly. The release of the encapsulated ingredients was induced by proteolytic cleavage of the microbead structure. These results show that ADF4(C16) protein microbeads have a high potential as a storage and delivery system for poorly water-soluble active ingredients in several application fields like cosmetics, pharma or nutrition.

Liedermann, M., et al. (2018). "A methodology for measuring microplastic transport in large or medium rivers." Water **10**(4).

Plastic waste as a persistent contaminant of our environment is a matter of increasing concern due to the largely unknown long-term effects on biota. Although freshwater systems are known to be the transport paths of plastic debris to the ocean, most research has been focused on marine environments. In recent years, freshwater studies have advanced rapidly, but they rarely address the spatial distribution of plastic debris in the water column. A methodology for measuring microplastic transport at various depths that is applicable to medium and large rivers is needed. We present a new methodology offering the possibility of measuring microplastic transport at different depths of verticals that are distributed within a profile. The net-based device is robust and can be applied at high flow velocities and discharges. Nets with different sizes (41 micro m, 250 micro m, and 500 micro m) are exposed in three different depths of the water column. The methodology was tested in the Austrian Danube River, showing a high heterogeneity of microplastic concentrations within one cross section. Due to turbulent mixing, the different densities of the polymers, aggregation, and the growth of biofilms, plastic transport cannot be limited to the surface layer of a river, and must be examined within the

whole water column as for suspended sediments. These results imply that multipoint measurements are required for obtaining the spatial distribution of plastic concentration and are therefore a prerequisite for calculating the passing transport. The analysis of filtration efficiency and side-by-side measurements with different mesh sizes showed that 500 micro m nets led to optimal results.

Lien, K. Y., et al. (2010). "Rapid isolation and detection of cancer cells by utilizing integrated microfluidic systems." Lab on a Chip **10**(21): 2875-2886.

The present study reports a new three-dimensional (3D) microfluidic platform capable of rapid isolation and detection of cancer cells from a large sample volume (e.g. ~1 mL) by utilizing magnetic microbead-based technologies. Several modules, including a 3D microfluidic incubator for the magnetic beads to capture cancer cells, a microfluidic control module for sample transportation and a nucleic acid amplification module for genetic identification, are integrated into this microsystem. With the incorporation of surface-modified magnetic beads, target cancer cells can be specifically recognized and conjugated onto the surface of the antibody-coated magnetic microbeads by utilizing a swirling effect generated by the new 3D microfluidic incubator, followed by isolating and purifying the magnetic complexes via the incorporation of an external magnet and a microfluidic control module, which washes away any unbound waste solution. Experimental results show that over 90% of the target cancer cells can be isolated from a large volume of bio-samples within 10 min in the 3D microfluidic incubator. In addition, the expressed genes associated with ovarian and lung cancer cells can also be successfully amplified by using the on-chip nucleic acid amplification module. More importantly, the detection limit of the developed system is found to be 5 x 10(1) cells mL(-1) for the target cancer cells, indicating that this proposed microfluidic system may be adapted for clinical use for the early detection of cancer cells. Consequently, the proposed 3D microfluidic system incorporated with immunomagnetic beads may provide a promising automated platform for the rapid isolation and detection of cancer cells with a high sensitivity.

Lien, K. Y., et al. (2009). "Microfluidic system for detection of alpha-thalassemia-1 deletion using saliva samples." Analytical Chemistry **81**(11): 4502-4509.

This current study presents a new miniature, integrated system capable of rapid detection of genetic deletion from saliva samples. Several critical modules including a genomic DNA (gDNA) extraction module, a polymerase chain reaction (PCR) module, and an external optical detection module are integrated into the system. Silica-modified magnetic beads are first incubated with saliva in an extraction chamber with a cell lysis solution. This is followed by the collection of released gDNA onto the surface of the microbeads, which is then further purified and concentrated utilizing a magnetic field generated by an on-chip array of microcoils. Then, genetic deletion of human genes can be specifically amplified by the on-chip PCR module and is immediately detected using the optical detection module. Experimental results show that high-quality gDNA with an average concentration of 50.45 ng/microL can be extracted from 100 microL of saliva. The detection of a mutated alpha-globin gene associated with alpha-thalassemia-1 of southeast Asian (SEA)-type deletion can be completed within less than 1 h. Moreover, the detection limit of the system is found to be 12.00 pg/microL with a high sensitivity up to 90%. Consequently, the proposed saliva-based miniature system can provide a powerful platform for rapid DNA extraction and detection of genetic diseases.

Lien, K.-Y., et al. (2009). "Microfluidic system for detection of -thalassemia-1 deletion using saliva samples." Analytical Chemistry **81**(11): 4502-4509.

This current study presents a new miniature, integrated system capable of rapid detection of genetic deletion from saliva samples. Several critical modules including a genomic DNA (gDNA) extraction module, a polymerase chain reaction (PCR) module, and an external optical detection module are integrated into the system. Silica-modified magnetic beads are first incubated with saliva in an extraction chamber with a cell lysis solution. This is followed by the collection of released gDNA onto the surface of the microbeads, which is then further purified and concentrated utilizing a magnetic field generated by an on-chip array of microcoils. Experimental results show that highquality gDNA with an average concentration of 50.45 ng/L can be extracted from 100 L of saliva. The detection of a mutated -globin gene associated with -thalassemia-1 of southeast Asian (SEA)-type deletion can be completed within less than 1 h. Moreover, the detection limit of the system is found to be 12.00 pg/L with a high sensitivity up to 90%. Consequently, the proposed saliva-based miniature system can provide a powerful platform for rapid DNA extraction and detection of genetic diseases. 2009 American Chemical Society.

Liffourrena, A. S. and G. I. Lucchesi (2018). "Alginate-perlite encapsulated Pseudomonas putida A (ATCC 12633) cells: Preparation, characterization and potential use as plant inoculants." Journal of Biotechnology **278**: 28-33.

Microbial immobilization can be used to prepare encapsulated inoculants. Here, we characterize and describe the preparation of Ca-alginate-perlite microbeads loaded with cells of plant growth-promoting Pseudomonas putida A (ATCC 12633), for their future application as agricultural inoculants. The microbeads were prepared by dropwise addition of a CaCl₂-paraffin emulsion mixture to an emulsion containing alginate 2% (w/v), perlite 0.1-0.4% (w/v) and bacterial suspension in 0.9% NaCl (10¹⁰CFU/mL). For all perlite concentrations used, microbead size was 90-120mum, the trapped population was 10⁸CFU/g microbeads and the increase in mechanical stability was proportional to perlite concentration. Microbeads containing 0.4% (w/v) perlite were able to release bacteria into the medium after 30 days of incubation. When we evaluated how P. putida A (ATCC 12633) entrapped in Ca-alginate-perlite (0.4% (w/v)) microbeads colonized the Arabidopsis thaliana rhizosphere, an increase in colonization over time was detected (from an initial 2.1x10⁴ to 9.2x10⁵CFU/g soil after 21 days). With this treatment, growth promotion of A. thaliana occurred with an increase in the amount of proteins, and in root and leaf biomass. It was concluded that the microbeads could be applied as possible inoculants, since they provide protection and a controlled release of microorganisms into the rhizosphere.

Lighthart, B., et al. (2000). "Bees Scavenge Airborne Bacteria." Microbial Ecology **39**(4): 314-321.

An air conditioned wind tunnel system was designed, fabricated, and tested to determine whether tethered bees scavenge microbeads or Bacillus subtilis var. niger spores from aerosols. Tests showed that microbeads and spores were scavenged by bumblebees and honeybees, respectively. Five independent variables and their interactions were used in a stepwise multiple regression. Two of them, the cube root of the electrostatic charge on the honeybee and the dose of the spore aerosol, accounted for most of the statistically significant fit to the model's two dependent variables: the percentage of the dose adsorbed by honeybees and the number of spores adsorbed by the same bees. Both dependent variables increased directly so that an increase in electrostatic charge on the bee (i.e., cube root 32 pC) resulted in an increase (i.e., approximately 1%) in the spore dose adsorbed and the number of spores adsorbed by the bees.

It was theorized that the spores were in an adsorption/desorption equilibrium that responded to the concentration "pressure" of the spore aerosol. Further, the charge on the bee affected the adsorption force on the bee's surface, as well as increasing the effective aerosol volume accessible for the bee's scavenging. In short, relating these findings to bees scavenging bacteria from the ambient atmosphere, it appears that the spore exposure (where exposure means the product of the ambient concentration, the time the bee is exposed, and air volume through which the bee flies) controls the number of spores adsorbed by a bee, and the static charge on the bee controls the adsorption/desorption equilibrium and presumably the scavenging volume.

Lim, M. C., et al. (2011). "Microbead-assisted PDA sensor for the detection of genetically modified organisms." Analytical & Bioanalytical Chemistry **400**(3): 777-785.

A simple and sensitive approach for the detection of marker protein, phosphinothricin acetyltransferase, from genetically modified crops was developed based on the colorimetric transition of polydiacetylene (PDA) vesicles in combination with silica microbeads. PDAs have attracted a great deal of interests as a transducing material due to their special features that allow colorimetric response to sensory signals, as well as their inherent simplicity. However, most PDA-based biosensors require additional analytical equipment such as a fluorescence microscope or UV-Vis spectrometer. In this study, we report a new approach to increase the degree of color transition by coupling antibody-conjugated PDA vesicles with silica microbeads in an effort to monitor the results with the unaided eye or simple RGB analysis. By immobilizing PDA vesicles on silica microbeads, we were able to overcome the disadvantages of colloidal PDA-based sensors and increase the degree of colorimetric changes in response to target molecules to a concentration as low as 20 nM. The additional stresses were given to PDA vesicles by antigen-antibody bridging of PDA vesicles coupled with microbeads, resulting in enhanced blue-red color transition. All the results showed that PDA vesicles in conjunction with silica microbeads will be a promising transducing material for the detection of target proteins in diagnostic and biosensing applications.

Lim, S. L., et al. (2019). "Targeted metabolomics reveals differential biological effects of nanoplastics and nanoZnO in human lung cells." Nanotoxicology **13**(8): 1117-1132.

Engineered nanomaterials are of public health concern. Recently, there has been an increasing attention on the toxicity of nanoplastics and nanoZnO because of their increasing utilization and presence in the environment. However, knowledge of their toxicological behavior and metabolic interactions with the cellular machinery that determine their potential health effects are extremely limited. In this study, the cellular uptake, cytotoxic effects, and metabolic responses of bronchus epithelial (BEAS-2B) cells exposed to nanopolystyrene (nanoPS) and a widely used metallic nanoparticle, nanoZnO, were investigated using a tandem mass spectrometry-based metabolomics approach. The results revealed that even with low cytotoxicity, these nanoparticles (NPs) affected cell metabolism. NanoPS exposure showed autophagic- and endoplasmic reticulum (ER) stress-related metabolic changes such as increased in amino acids and tricarboxylic acid cycle (TCA) intermediate metabolites, a process known to play a critical role in regulating cell resistance to cytotoxic effects. Both metabolomics profiling and ER-stress pathway, together with quantitative real-time RT-polymerase chain reaction (qRT-PCR) analyses, demonstrated that autophagy was reciprocally regulated to couple metabolic and transcriptional reprograming. In contrast, nanoZnO-induced ROS-mediated cell death was associated with mitochondrial dysfunction and interference in regulating energy metabolism. Collectively, these two types of NPs were observed to cause perturbations albeit differential in cellular metabolism associated with their cytotoxic effects. Our findings provided an in depth understanding of metabolic changes influenced by two different types of NPs, with contrasting molecular mechanisms for the adverse effects observed.

Lim, Y. F., et al. (2014). "Determination of Villous Rigidity in the Distal Ileum of the Possum (Trichosurus vulpecula)." PLoS ONE **9**(6).

We investigated the passive mechanical properties of villi in ex vivo preparations of sections of the wall of the distal ileum from the brushtail possum (Trichosurus vulpecula) by using a flow cell to impose physiological and supra-physiological levels of shear stress on the tips of villi. We directly determined the stress applied from the magnitude of the local velocities in the stress inducing flow and additionally mapped the patterns of flow around isolated villi by tracking the trajectories of introduced 3 µm microbeads with bright field micro particle image velocimetry (mPIV). Ileal villi were relatively rigid along their entire length (mean 550 µm), and exhibited no noticeable bending even at flow rates that exceeded calculated normal physiological shear stress (>0.5 mPa). However, movement of villus tips indicated that the whole rigid structure of a villus could pivot about the base, likely from laxity at the point of union of the villous shaft with the underlying mucosa. Flow moved upward toward the tip on the upper portions of isolated villi on the surface facing the flow and downward toward the base on the downstream surface. The fluid in sites at distances greater than 150 µm below the villous tips was virtually stagnant indicating that significant convective mixing in the lower intervillous spaces was unlikely. Together the findings indicate that mixing and absorption is likely to be confined to the tips of villi under conditions where the villi and intestinal wall are immobile and is unlikely to be greatly augmented by passive bending of the shafts of villi.

Lima, A. R. A., et al. (2015). "Seasonal distribution and interactions between plankton and microplastics in a tropical estuary." Estuarine, Coastal and Shelf Science **165**: 213-225.

The seasonal migration of a salt wedge and rainfall were the major factors influencing the spatiotemporal distribution of ichthyoplankton and microplastics along the main channel of the Goiana Estuary, NE Brazil. The most abundant taxa were the clupeids Rhinosardinia bahiensis and Harengula clupeola, followed by the achirid Trinectes maculatus (78.7% of the catch). Estuarine and mangrove larvae (e.g. Anchovia clupeoides, Gobionellus oceanicus), as well as microplastics were ubiquitous. During drier months, the salt wedge reaches the upper estuary and marine larvae (e.g. Cynoscion acoupa) migrated upstream until the zones of coastal waters influence. However, the meeting of waterfronts in the middle estuary forms a barrier that retains the microplastics in the upper and lower estuary most part of the year. During the late dry season, a bloom of zooplankton was followed by a bloom of fish larvae (12.74 ind. 100 m-3) and fish eggs (14.65 ind. 100 m-3) at the lower estuary. During the late rainy season, the high freshwater inflow flushed microplastics, together with the biota, seaward. During this season, a microplastic maximum (14 items 100 m-3) was observed, followed by fish larvae maximum (14.23 ind. 100 m-3) in the lower estuary. In contrast to fish larvae, microplastics presented positive correlation with high rainfall rates, being more strictly associated to flushing out/into the estuary than to seasonal variation in environmental variables. Microplastics represented half of fish larvae density. Comparable densities in the water column increase the chances of interaction between microplastics and fish larvae, including the ingestion of smaller fragments, whose shape and colour are similar to zooplankton prey.

Lima, A. R. A., et al. (2016). "Seasonal-Dial Shifts of Ichthyoplankton Assemblages and Plastic Debris around an Equatorial Atlantic Archipelago." Frontiers in Environmental Science.

Seasonality was a stronger influence in the ichthyoplankton assemblages around the Saint Peter

and Saint Paul Archipelago (SPSPA) than distance from the islands. Plastic debris were ubiquitous and although it presented diel trends, no other spatiotemporal patterns was showed. Larval Oxyporhamphus micropterus was the most important taxa (29.37% of the total catch), followed by Ceratoscopelus warmingii and Entomacrodus vomerianus. Exocoetidae eggs represented 41.01%. Mesopelagic fish larvae dominated the community. Myctophidae had the highest species richness (15). Four larval fish assemblages occured: (1) nighttime demersal/bathydemersal (Anguillidae, Congridae); (2) daytime mesopelagic/bathypelagic/epipelagic (Myctophidae, Cyclothone acclinidens); (3) daytime epipelagic (Exocoetidae, Coryphaena hippurus, Thunnus albacares) and (4) nighttime reef and demersal (Blennidae, Pomacentridae, Lutjanidae). The dry season (lower temperature, higher chlorophyll a and higher SW wind velocity) influenced the first two assemblages. The rainy season (higher temperatures and lower NW wind velocity) influenced the last two. Nighttime abundance of dominant species in the rainy season suggests diel vertical migration nearshore. Plastics were 2.12 times more abundant than the most abundant fish larvae. Comparable amounts of larvae and plastics in the water column increase the chances of interaction between these two compartments and might disturb the local marine food web and promote the transfer of microplastic from one habitat to another, especially when smaller taxa contaminated by ingested fragments are preyed by migratory animals such as marine birds and tuna. A study around the area concluded that at least a part of the plastic debris can have local source due to fishing activities. Small-scale oceanographic mechanisms such as the interaction between the topography and currents (SEC and EUC) seem to be responsible for the retention of fish eggs, fish larvae and plastics around SPSPA.

Lima, A. R. A., et al. (2014). "Distribution patterns of microplastics within the plankton of a tropical estuary." Environmental Research **132**: 146-155.

Abstract: The Goiana Estuary was studied regarding the seasonal and spatial variations of microplastics (<5mm) and their quantification relative to the zooplankton. The total density (n 100m^{-3}) of microplastics represented half of the total fish larvae density and was comparable to fish eggs density. Soft, hard plastics, threads and paint chips were found in the samples (n=216). Their origins are probably the river basin, the sea and fisheries (including the lobster fleet). In some occasions, the amount of microplastics surpassed that of Ichthyoplankton. The highest amount of microplastics was observed during the late rainy season, when the environment is under influence of the highest river flow, which induces the runoff of plastic fragments to the lower estuary. The density of microplastics in the water column will determine their bioavailability to planktivorous organisms, and then to larger predators, possibly promoting the transfer of microplastic between trophic levels. These findings are important for better informing researchers in future works and as basic information for managerial actions. [Copyright &y& Elsevier]

Limonta, G., et al. (2019). "Microplastics induce transcriptional changes, immune response and behavioral alterations in adult zebrafish." Scientific Reports **9**(1): 15775.

Microplastics have become pervasive environmental pollutants in both freshwater and marine

ecosystems. The presence of microplastics have been recorded in the tissues of many wild fish species, and laboratory studies have demonstrated that microplastics can exert adverse health effects. To further investigate the biological mechanisms underlying microplastics toxicity we applied an integrated approach, analyzing the effects of microplastics at transcriptomic, histological and behavioral level. Adult zebrafish have been exposed to two concentrations of high-density polyethylene and polystyrene microplastics for twenty days. Transcriptomic results indicate alterations in the expression of immune system genes and the down-regulation of genes correlated with epithelium integrity and lipid metabolism. The transcriptomic findings are supported by tissue alterations and higher occurrence of neutrophils observed in gills and intestinal epithelium. Even the daily rhythm of activity of zebrafish appears to be affected, although the regular pattern of activity is recovered over time. Considering the transcriptomic and histological findings reported, we hypothesize that the effects on mucosal epithelium integrity and immune response could potentially reduce the organism defense against pathogens, and lead to a different utilization of energy stores.

Lin, A., et al. (2013). "Multilaboratory validation of a luminex microbead-based suspension array for the identification of the 11 most clinically relevant Shiga toxin-producing Escherichia coli O serogroups." Journal of Food Protection **76**(5): 867-870.

Rapid and high-throughput identification and serotyping of Shiga toxin-producing Escherichia coli (STEC) O serogroups is important for detecting, investigating, and controlling STEC infection outbreaks and removing hazardous products from commerce. A Luminex microbead-based suspension array has been developed to identify the 11 most clinically relevant STEC serogroups: O26, O45, O91, O103, O104, O111, O113, O121, O128, O145, and O157. Here we present results of a blinded multilaboratory collaborative study involving 10 participants from nine laboratories using 55 unknown strains. From the total 495 analyses, two false-positive and three false-negative results were obtained, indicating the assay to be a rapid, high-throughput, and robust method for identifying clinically relevant STEC serogroups.

Lin, A., et al. (2011). "Rapid O serogroup identification of the ten most clinically relevant STECs by Luminex microbead-based suspension array." Journal of Microbiological Methods **87**(1): 105-110.

Identification and serotyping of Shiga toxin-producing Escherichia coli during foodborne outbreaks can aid in matching clinical, food, and environmental isolates when trying to identify the source of illness and ultimately food contamination. Herein we describe a Luminex microbead-based suspension array to identify the O serogroup of the ten most clinically relevant STECs: O26, O45, O91, O103, O111, O113, O121, O128, O145, and O157. The use of PCR followed by Luminex xMAP technology enables the detection of multiple analytes in a single multiplex reaction with high throughput capabilities. One hundred and fourteen STEC isolates were correctly identified with no false positives among forty-six other organisms using this assay. Assay performance was tested in multiple laboratories using a panel of eleven different STEC serogroups on the Bio-Plex 200 and MAGPIX instruments. The STEC microbead-based suspension array can be performed in a 96-well plate format for high throughput screening in less than 4h. Furthermore, it is expandable, allowing for the addition of O serogroups should the need arise.

Lin, C. H., et al. (2009). "Medium- to high-throughput SNP genotyping using VeraCode microbeads." Methods in Molecular Biology **496**: 129-142.

Recent breakthroughs in multiplexed SNP (single nucleotide polymorphism) genotyping technology have enabled global mapping of the relationships between genetic variation and disease. Discoveries made by such whole-genome association studies often spur further interest in surveying more focused subsets of SNPs for validation or research purposes. Here we describe a new SNP genotyping platform that is flexible in assay content and multiplexing (up to 384 analytes), and can serve medium- to high-throughput applications. The Illumina BeadXpress platform supports the GoldenGate Genotyping Assay on digitally inscribed VeraCode microbeads to allow streamlined workflow, rapid detection, unparalleled data reproducibility and consistency. Thus, it is a highly valuable tool for biomarker research and validation, pharmaceutical development, as well as the development of molecular diagnostic tests. [References: 6]

Lin, H., et al. (2019). "A novel nanoscaled chemo dye-based sensor for the identification of volatile organic compounds during the mildewing process of stored wheat." Food Analytical Methods **12**(12): 2895-2907.

This work presents a novel colorimetric sensor based on nanoscaled chemo dyes which can detect inert volatile organic compounds (VOCs) during the mildewing process of stored wheat. 1-Octen-3-ol and 3-octanone were selected as the marked compounds by gas chromatography mass spectrometry (GC-MS) analysis. In this work, poly(styrene-co-acrylic acid) microbeads were prepared by soap-free emulsion copolymerisation. Boron-dipyrromethene dyes with PSA were fabricated as a novel sensor to obtain digital data before and after exposure to VOCs, and the correlation coefficients (R²) between the digital data and the concentration of VOCs were 0.8078 and 0.8324, respectively. And root mean square errors (RMSEs) were 3.05 g L⁻¹ and 1.65 g L⁻¹, respectively. The data based on the identification of mouldy wheat samples were processed by principal component analysis (PCA) and linear discriminant analysis (LDA). The optimal performance obtained for the LDA model was 83.33% in the prediction set and 90% in the calibration set.

Lin, H.-T., et al. (2010). "Hydrocarbon fuels produced by catalytic pyrolysis of hospital plastic wastes in a fluidizing cracking process." Fuel Processing Technology **91**(11): 1355-1363.

A mixture of post-consumer polyethylene/polypropylene/polystyrene (PE/PP/PS) with polyvinyl chloride (PVC) waste was pyrolyzed over cracking catalysts using a fluidizing reaction system operating isothermally at ambient pressure. The influences of catalyst types and reaction conditions including reaction temperatures, ratios of catalyst to plastic feed, flow rates of fluidizing gas and catalyst particle sizes were examined. Experiments carried out with various catalysts gave good yields of valuable hydrocarbons with differing selectivity in the final products dependent on reaction conditions. A model based on kinetic and mechanistic considerations associated with chemical reactions and catalyst deactivation in the acid-catalyzed degradation of plastics has been developed. The model gives a good representation of experimental results from the degradation of commingled plastic waste. The results of this study are useful for determining the effects of catalyst types and reaction conditions on both the product distribution and selectivity from hospital plastic waste, and especially for the utilization of post-use commercial FCC catalysts for producing valuable hydrocarbons in a fluidizing cracking process.

Lin, K., et al. (2011). "Multiplex method for simultaneous serological detection of porcine reproductive and respiratory syndrome virus and porcine circovirus type 2." Journal of Clinical Microbiology **49**(9): 3184-3190.

Porcine circovirus type 2 (PCV2) and porcine reproductive and respiratory syndrome virus (PRRSV) are major contributors to the porcine respiratory disease complex (PRDC). Routine

serological diagnosis and surveillance play an important role in the prevention of PRDC, as it is a leading cause of economic losses to the swine industry. We herein describe an advanced microsphere-based immunoassay that permits the simultaneous detection of antibodies to PCV2 and PRRSV, thereby reducing the time and effort involved in testing. Recombinant PRRSV nucleoprotein antigen and the PCV2 capsid antigen were coupled to fluorophore-dyed beads with distinct spectral addresses. Weekly serum samples from 72 pigs that were experimentally exposed to either PCV2, PRRSV, or both PCV2 and PRRSV were used to validate the microbead assay (MBA) in comparison with the "gold standard" enzyme-linked immunosorbent assays. The kinetics of the PCV2- and PRRSV-specific antibody responses measured by the microbead assay were comparable to those of the standard assays; Spearman's rank correlations were 0.72 (P < 0.001) for PRRSV and 0.80 (P < 0.001) for PCV2. Diagnostic sensitivity and specificity were determined using field sera whose positive or negative status was determined by the standard tests. The diagnostic sensitivity and specificity were both 98% for PCV2 and were 91% and 93%, respectively, for PRRSV (kappa coefficients, 0.85 and 0.67 for PCV2 and PRRSV, respectively). Multiplexing did not interfere with assay performance or diagnostic sensitivity. Therefore, the described study demonstrates proof of concept for the development of more versatile and economical microbead array-based multiplex serological test panels for veterinary use. Lin, K., et al. (2017). "Establishment of a novel quantum dots-encoded microbead-based flow cytometric method for quantification of soluble FcepsilonRIalpha in serum." Cytometry Part A: The Journal of the International Society for Analytical Cytology **91**(7): 686-693.

The soluble form of the transmembrane glycoprotein, FcepsilonRIalpha which corresponds to the high-affinity receptor for IgE, is found in serum. Growing evidence suggests the pathogenic role of IgE and FcepsilonRI in systemic lupus erythematosus (SLE). The goal of this study is to develop a sensitive and standardized cytometric assay for quantification of sFcepsilonRIalpha. A membrane emulsification technique was utilized to incorporate CuInS₂ /ZnS quantum dots and Fe₃ O₄ nanoparticles into poly (styrene-co-maleic anhydride) microbeads. The beads were then carboxylated and coated with capture antibody monoclonal anti-human FcepsilonRIalpha. This antibody binds to FcepsilonRIalpha but does not block the binding of FcepsilonRIalpha to IgE. After incubation with standards or serum samples, the microbeads were incubated with excessive native human IgE, followed by incubation with Phycoerythrin (PE) conjugated anti-human IgE. The resulting quantum dot microbeads were gated, and sFcepsilonRIalpha quantification was analyzed based on PE fluorescence intensity. The method exhibited good linearity (R² > 0.99), and the limit of detection was established at 0.29 ng/mL with the dynamic range of up to 200 ng/mL. The precision of the assay validated by intra- and inter-assay variability met the acceptance criteria with the mean recovery falling within 80-110% of the theoretical concentration and a corresponding CV < 20%. We tested 149 serum samples which 89 were from SLE patients and 60 were from healthy volunteers. For the first time, we detected an increased sFcepsilonRIalpha level in the serum of SLE patients, which was confirmed by a commercial ELISA kit. Compared to ELISA, this novel method is more sensitive and efficient. It allows for the simple comparative analysis of sFcepsilonRIalpha levels in health and disease. © 2017 International Society for Advancement of Cytometry.

Lin, K. N., et al. (2018). "Chemotherapeutic Drug-Conjugated Microbeads Demonstrate Preferential Binding to Methylated Plasmid DNA." Biotechnology Journal **13**(11): e1700701.

Plasmid DNA (pDNA) is an attractive therapeutic biomolecule in several diseases including

cancer, AIDS, cystic fibrosis, Parkinson's disease, and Alzheimer's disease. Increasing demand for plasmid DNA as a therapeutic biomolecule for transgene expression or vaccine applications necessitate novel approaches to bioprocessing. The synthesis, characterization and evaluation of aminoglycoside-derived hydrogel microbeads (Amikabeads) for pDNA binding is described previously. Here, the generation and evaluation of novel chemotherapeutic drug-conjugated microbeads for application in pDNA binding and recovery is described. Chemotherapeutic drug-conjugated Amikabeads demonstrate higher binding of methylated pDNA compared to unmethylated pDNA in presence of high salt concentrations. Desorption of plasmids from drug-conjugated microbeads is facilitated by the use of organic modifiers. The observed differences in binding methylated versus unmethylated DNA can make drug-conjugated microbeads useful in diagnostic as well as therapeutic applications. These results demonstrate that anti-cancer drugs represent a diverse set of ligands that may be exploited for molecular engineering of novel DNA binding materials for applications in delivery, diagnostics, and biomanufacturing.

Lin, L., et al. (2018). "Occurrence and distribution of microplastics in an urban river: a case study in the Pearl River along Guangzhou City, China." Science of the Total Environment **644**: 375-381.
Microplastics, as emerging contaminants in the global environment, have become a cause for concern for both academics and the public. The present understanding of microplastic pollution is primarily focused on marine environments, and less attention has been given to freshwater environments, in particular, to urban rivers. In this study, microplastics were sampled from surface water and sediments in 14 sites located in the lower course of the Pearl River. These sampling sites are located along Guangzhou of South China, with built-up areas being the dominant land use. The abundances of microplastics in surface water and sediments ranged from 379 to 7924 items.m⁻³ and 80 to 9597 items.kg⁻¹, respectively. Polyethylene and polypropylene were the common types of microplastics, together accounting for 64.3% and 73.8% of surface water and sediment samples, respectively. Fibers were the dominant microplastic shapes in both water and sediment samples. The abundances of microplastics varied in surface water and sediments with each site, which might be affected by multiple factors. Our results indicated that wastewater treatment plants (WWTP) could reduce microplastics from municipal sewage which was finally discharged into the Pearl River along Guangzhou.

Lin, M. X., et al. (2013). "Continuous labeling of circulating tumor cells with microbeads using a vortex micromixer for highly selective isolation." Biosensors & Bioelectronics **40**(1): 63-67.
Circulating tumor cells (CTCs) are identified in transit within the blood stream of cancer patients and have been proven to be a main cause of metastatic disease. Current approaches for the size-based isolation of CTCs have encountered technical challenges as some of the CTCs have a size similar to that of leukocytes and therefore CTCs are often lost in the process. Here, we propose a novel strategy where most of the CTCs are coated by a large number of microbeads to amplify their size to enable complete discrimination from leukocytes. In addition, all of the microbead labeling processes are carried out in a continuous manner to prevent any loss of CTCs during the isolation process. Thus, a microfluidic mixer was employed to facilitate the efficient and selective labeling of CTCs from peripheral blood samples. By generating secondary vortex flows called Taylor-Gortler vortices perpendicular to the main flow direction in our microfluidic device, CTCs were continuously and successfully coated with anti-epithelial cell adhesion molecule-conjugated beads. After the continuous labeling, the enlarged CTCs were perfectly trapped in a micro-filter whereas all of the leukocytes escaped.

Lin, Q. B., et al. (2011). "Determination of silver in nano-plastic food packaging by microwave digestion coupled with inductively coupled plasma atomic emission spectrometry or inductively coupled plasma mass spectrometry." Food Additives & Contaminants: Part A - Chemistry, Analysis, Control, Exposure & Risk Assessment **28**(8): 1123-1128.

The detection of silver in nano-plastic food packaging by microwave digestion coupled with either inductively coupled plasma atomic emission spectrometry (ICP-AES) or inductively coupled plasma mass spectrometry (ICP-MS) was investigated. Microwave digestion was optimised by trialling different acid mixtures. Both ICP-AES and ICP-MS showed good reproducibility, repeatability and recovery. For ICP-AES the limit of detection of the method (LODm) was 25.0 mu g g-1, the limit of detection of the instrument (LODi) was 30.0 ng ml-1, the linear range was 0.10-10.0 mu g ml-1. The average recoveries for blank samples spiked with silver at 100, 250 and 500 mu g g-1 ranged from 82.53% to 87.60%, and the relative standard deviations (RSDs) were from 1.79% to 8.30%. For ICP-MS analysis the LODm was 0.75 mu g g-1, the LODi was 0.04 ng ml-1, the linear range was 0.20-500.0 ng ml-1, the RSDs were 2.26-4.79%, and the recoveries were 78.09-92.72% (spiked concentrations of 2.5, 5.0 and 10.0 mu g g-1). These results indicate that the proposed method could be employed to analyse silver in nano-plastic food packaging.

Lin, V. S. (2016). "Research highlights: Impacts of microplastics on plankton." Environmental Sciences: Processes and Impacts **18**(2): 160-163.

Each year, millions of metric tons of the plastic produced for food packaging, personal care products, fishing gear, and other human activities end up in lakes, rivers, and the ocean. The breakdown of these primary plastics in the environment results in microplastics, small fragments of plastic typically less than 1-5 mm in size. These synthetic particles have been detected in all of the world's oceans and also in many freshwater systems, accumulating in sediment, on shorelines, suspended in surface waters, and being ingested by plankton, fish, birds, and marine mammals. While the occurrence of plastics in surface waters has been surveyed in a number of studies, the impacts of microplastics on marine organisms are still being elucidated. This highlight features three recent publications that explore the interactions of microplastics with planktonic organisms to clarify the effects of these pollutants on some of the ocean's smallest and most important inhabitants. Lin, W., et al. (2019). "Investigating the toxicities of different functionalized polystyrene nanoplastics on Daphnia magna." Ecotoxicology and Environmental Safety **180**: 509-516.

Nanoplastics (NPs) spread widely with water and air current, and they can accumulate in aquatic organisms, even penetrating biofilms, which may cause persistent toxicity and potential hazards. This current study aimed to reveal the toxicological mechanism of different functionalized polystyrene (PS) NPs on Daphnia magna (D. magna) by investigating toxicity endpoints in individual level and biochemical level. In this study, acute toxicity, behavioral parameters and biomarker responses of D. magna was measured in the exposure of different functionalized PS NPs (plain PS, PS-p-NH₂, PS-n-NH₂ and PS-COOH). The results indicated that when exposed to the plain PS, ROS induction would activate MAPKs, thereby causing lethality and adverse behavior effects on D. magna; while the functionalized PS NPs were less toxic than the plain PS, especially for PS-p-NH₂ which was severely flocculated after exposure, thus showing no immobilization at the investigated concentrations. Also, the antioxidant system was mainly stimulated due to the direct interaction with the cell

surface receptor, which was different from the plain PS. Consequently, this work suggests significant effects of functional groups on NPs for environmental toxicity studies, and provides a better understanding of the toxicological mechanism on the toxicity of PS NPs toward D. magna.

Lin, W., et al. (2019). "Sorption properties of hydrophobic organic chemicals to micro-sized polystyrene particles." Science of the Total Environment **690**: 565-572.

It has been reported that microplastics (MPs) have strong affinity for hydrophobic organic chemicals (HOCs) and can be ingested accidentally by aquatic organisms, posing a potential threat to the environment. To date, the sorption data used in modelling to clarify the mechanism were mostly obtained in varied sampling durations and regions from different works, which might cause inevitable deviation in modelling results. The current study aimed to illustrate the sorption properties of HOCs to the micro-sized polystyrene (PS). The sorption behaviors of HOCs to the PS were investigated at a certain pre-equilibrium status, and the theoretical analysis was taken into consideration. A bottle-shaped passive dosing system was designed to measure the concentration ratio of HOCs in different phases of the exposure suspension at a certain time (loga_{MP}), including polycyclic aromatic hydrocarbons (PAHs) and polychlorinated biphenyls (PCBs) with logK_{ow} ranging from 3.17 to 10.20, between water and PS MPs with different dimensions (diameters of 100nm, 1mum and 2mum, respectively). The calculated loga_{MP} ranged from 3.73 to 8.34, and a positive correlation was found between loga_{MP} and log1r₀ (r₀ is the MP radius). The results indicated that HOCs would diffuse into the PS particles, but the mass transfers inside the particles were slow and would be negligible in some environmental cases. Under theoretical considerations, the diffusion through the boundary layer of the particle was considered as the dominating process because it was fast, and the contributions of absorbed amounts on the particle surface were larger for smaller PS particles (i.e. 100-nm PS). This study could provide applicable data for further exploring the effects of micro-sized plastics on the HOCs in environmental samples.

Lin, W., et al. (2019). "Quantification of the combined toxic effect of polychlorinated biphenyls and nano-sized polystyrene on Daphnia magna." Journal of Hazardous Materials **364**: 531-536.

It has been reported that nanoplastics (NP) could cause serious toxicity and accumulative effects on aquatic organisms as well as interact with organic pollutants and influence potential hazards when exposed to biota. The current study aimed to quantitatively investigate the combined acute toxic effect of polychlorinated biphenyls (PCBs) and nano-sized polystyrene (PS) plastic on aquatic organisms based on analyte speciation. First, the combined acute toxicity of PCB-18 and 100 nm PS to Daphnia magna (D. magna) in water was evaluated. Then, speciation analysis of the exposure system was conducted by measuring the sorption coefficients (logK_{NP}) of PCBs to nano-sized PS (ranging from 5.28 to 6.56), which demonstrated the PS could substantially decrease the free concentrations of PCBs. The results showed that a low concentration of the PS could decrease the toxicity to D. magna., which might be originated from the decreased free concentration of PCB-18. However, when the PS concentration was high enough, an opposite effect was observed because the PS dominated the lethality instead of PCB-18. The current study is helpful to clarify the PCB occurrence in ecosystems and provide an in-depth understanding of the eco-toxicological effects of nanoscale plastics.

Lin, W., et al. (2018). "Brominated Flame Retardants, Microplastics, and Biocides in the Marine Environment: Recent Updates of Occurrence, Analysis, and Impacts." Advances in Marine Biology **81**: 167-211.

Emerging contaminants (ECs) may pose adverse effects on the marine ecosystem and human health. Based on the analysis of publications filed in recent years, this paper provides a comprehensive overview on three prominent groups of ECs, i.e., brominated flame retardants, microplastics, and biocides. It includes detailed discussions on: (1) the occurrence of ECs in seawater, sediment, and biota; (2) analytical detection and monitoring approaches for these target ECs; and (3) the biological impacts of the ECs on humans and other trophic levels. This review provides a summary of recent advances in the field and remaining knowledge gaps to address, to enable the assessment of risk and support the development of regulations and mitigation technologies for the control of ECs in the marine environment.

Lin, Y. H., et al. (2013). "Integrating solid-state sensor and microfluidic devices for glucose, urea and creatinine detection based on enzyme-carrying alginate microbeads." Biosensors & Bioelectronics **43**: 328-335.

A solid-state sensor embedded microfluidic chip is demonstrated for the detection of glucose, urea and creatinine in human serum. In the presented device, magnetic powder-containing enzyme-carrying alginate microbeads are immobilized on the surface of an electrolyte-insulator-semiconductor (EIS) sensor by means of a step-like obstacle in the microchannel and an external magnetic force. The sample is injected into the microchannel and reacts with the enzyme contained within the alginate beads; prompting the release of hydrogen ions. The sample concentration is then evaluated by measuring the resulting change in the voltage signal of the EIS sensor. The reaction time and alginate bead size are optimized experimentally using a standard glucose solution. The experimental results show that the device has a detection range of 2-8mM, 1-16mM and 10(-2)-10mM for glucose, urea and creatinine, respectively. Furthermore, it is shown that the device is capable of sequentially measuring all three indicators in a human serum sample. Finally, it is shown that the measured values of the glucose, urea and creatinine concentrations obtained using the device deviate from those obtained using a commercial kit by just 5.17%, 6.22% and 13.53%, respectively. This method can be extended to sequentially measure multiple blood indicators in the sample chip by replacing different types of enzyme in alginate bead and can address the enzyme preservation issue in the microfluidic device. Overall, the results presented in this study indicate that the microfluidic chip has significant potential for blood monitoring in point-of-care applications.

Lindmark, R., et al. (1982). "Immobilization of proteins by entrapment in polyacrylamide microbeads." Journal of Immunological Methods **49**(2): 159-177.

The immobilization of protein A and IgG by entrapment in polyacrylamide microbeads with a diameter of 1 mum was studied with the aim of optimizing the yield of immobilized protein. The microbeads were prepared by a modified emulsion polymerization technique. The small size of the beads resulted in an increase in immobilized protein available for interaction at the bead surface when compared with beads of larger diameter (100 mum). The increase was approximately proportional to the increase of the total bead surface. The increase in total bead surface was, however, accompanied by a slight decrease in the degree of immobilization. Optimal immobilization of protein A and IgG was obtained at monomer compositions of T-C 10-5 and 20-5, respectively (for definitions of T and C, see below). The fraction of immobilized protein available for interaction at the bead surface was almost constant over a wide range of protein concentrations tested. The yield of immobilized protein is generally rather low. The immobilization of IgG could be increased, by the presence of urea or by increasing the apparent molecular weight of IgG by addition of soluble protein A, thus forming soluble IgG protein A complexes. A large fraction of the non-immobilized protein (20-90%) could be recovered from

the washings by affinity chromatography. The entrapment seemed to be more related to the molecular weight than to the hydrodynamic properties of the protein. The density of the microbeads was determined in Percoll and was found to be dependent on the total monomer concentration (T). At high concentrations of cross-linker (C) the apparent density was increased, owing to diffusion of the density medium into the large pores of the gel.

Ling, S. D., et al. (2018). "Pollution signature for temperate reef biodiversity is short and simple." Marine Pollution Bulletin **130**: 159-169.

Pollution increasingly impacts healthy functioning of marine ecosystems globally. Here we quantify concentrations of major pollutant types (heavy metals/sewage/petrochemicals/plastics) as accumulated within marine sediments on and/or immediately adjacent to shallow reefs for 42 sites spanning coastal population centres across south-eastern Australia. Gradients in pollutants were revealed, but few pollutants co-varied, while increasing wave exposure ostensibly diluted concentrations of all pollutants except microplastics. Examination of reef biodiversity indicators revealed that maximum size of fauna and flora, a key life-history parameter summarised by the Community shortness index, plus declining functional and species richness, were the most sensitive bioindicators of pollutants - for which heavy metals and nutrient-enrichment were most pervasive. Results indicate that assemblages of biogenic habitat formers and associated fauna collapse from "long and complicated" to "short and simplified" configurations in response to increasing pollution, and this community signature may form an effective bioindicator to track human-driven degradation. Copyright © 2018

Ling, S. D., et al. (2017). "Ubiquity of microplastics in coastal seafloor sediments." Marine Pollution Bulletin **121**(1-2): 104-110.

Microplastic pollutants occur in marine environments globally, however estimates of seafloor concentrations are rare. Here we apply a novel method to quantify size-graded (0.038-4.0mm diam.) concentrations of plastics in marine sediments from 42 coastal and estuarine sites spanning pollution gradients across south-eastern Australia. Acid digestion/density separation revealed 9552 individual microplastics from 2.84l of sediment across all samples; equating to a regional average of 3.4 microplastics.ml⁻¹ sediment. Microplastics occurred as filaments (84% of total) and particle forms (16% of total). Positive correlations between microplastic filaments and wave exposure, and microplastic particles with finer sediments, indicate hydrological/sediment-matrix properties are important for deposition/retention. Contrary to expectations, positive relationships were not evident between microplastics and other pollutants (heavy metals/sewage), nor were negative relationships with neighbouring reef biota detected. Rather, microplastics were ubiquitous across sampling sites. Positive associations with some faunal-elements (i.e. invertebrate species richness) nevertheless suggest high potential for microplastic ingestion.

Ling, Y., et al. (2019). "Rapid Method for Detection of Staphylococcus aureus in Feces." Journal of Biomedical Nanotechnology **15**(6): 1290-1298.

Staphylococcus aureus is an opportunistic human pathogen causing food-borne diseases. Therefore, the goal of the present work was to develop a robust protocol for identification of small amounts of S. aureus DNA in order to establish a rapid, sensitive, and simple method of detect whether this species is present in the stool of patients. A protocol was developed for extraction of DNA by Fe3O4 @SiO2 microbeads and subsequent detection of S. aureus-specific DNA sequences by the loop-mediated isothermal amplification (LAMP). The LAMP technique was rapid and sensitive, which allowed the detect for bacteria at concentrations as low as 102 cells/mL. This level of detection was superior to that seen for conventional PCR and real-time PCR. Moreover, the LAMP protocol did not require specialized expensive instrumentation. These features of the novel assay developed here indicate that it may serve as an effective tool for point-of-care diagnosis of acute S. aureus infections.

Linsmaux, D., et al. (1979). "Lung scanning with Krypton 81m. [French]." Revue Medicale de Liege **34**(9): 390-399.

Pulmonary scintigraphy by means of perfusion of micro-beads labelled with Tc^{99m}, combined with ventilation scintigraphy with Kr^{81m} gas, is a brief, simple examination that yields valuable data in lung pathology. It facilitates the diagnosis of pulmonary embolism, and is an important element in the detection of bronchial and pulmonary tumors and the determination of their extension. In these cases, and in chronic bronchopneumopathy, the method is an original and highly valuable supplement to respiratory function testing. It is indicated in particular for the preoperative examination before chest operations. In the near future, use of a computer linked to a gamma camera will permit determination of the ventilation/perfusion ratio and quantitative determination of the regional ventilation and its variations under the influence of treatment. CV.

Liou, T. H. (2003). "Pyrolysis kinetics of electronic packaging material in a nitrogen atmosphere." Journal of Hazardous Materials **103**(1-2): 107-123.

The kinetics of pyrolysis of electronic packaging material are investigated under various heating rates (5, 10, 15, 20K/min) in an inert atmosphere using a thermogravimetric analysis (TGA) technique. The pyrolysis characteristics of samples are examined by SEM, XRD, FTIR, ICP-MS and EA. The effect of heating condition on the surface area and pore structure of samples is discussed. Two reaction stages are involved for the pyrolysis of electronic packaging material when nitrogen is present in the carrier gas. The corresponding kinetic parameters, including activation energy, pre-exponential factor and reaction order are presented. The apparent activation energies can be divided into three groups. The results will be useful in developing pyrolysis or incineration systems for plastic waste from electronic components. © 2003 Elsevier B.V. All rights reserved.

Lithner, D., et al. (2011). "Environmental and health hazard ranking and assessment of plastic polymers based on chemical composition." Science of the Total Environment **409**(18): 3309-3324.

Plastics constitute a large material group with a global annual production that has doubled in 15 years (245 million tonnes in 2008). Plastics are present everywhere in society and the environment, especially the marine environment, where large amounts of plastic waste accumulate. The knowledge of human and environmental hazards and risks from chemicals associated with the diversity of plastic products is very limited. Most chemicals used for producing plastic polymers are derived from non-renewable crude oil, and several are

hazardous. These may be released during the production, use and disposal of the plastic product. In this study the environmental and health hazards of chemicals used in 55 thermoplastic and thermosetting polymers were identified and compiled. A hazard ranking model was developed for the hazard classes and categories in the EU classification and labelling (CLP) regulation which is based on the UN Globally Harmonized System. The polymers were ranked based on monomer hazard classifications, and initial assessments were made. The polymers that ranked as most hazardous are made of monomers classified as mutagenic and/or carcinogenic (category 1A or 1B). These belong to the polymer families of polyurethanes, polyacrylonitriles, polyvinyl chloride, epoxy resins, and styrenic copolymers. All have a large global annual production (1-37 million tonnes). A considerable number of polymers (31 out of 55) are made of monomers that belong to the two worst of the ranking model's five hazard levels, i.e. levels IV-V. The polymers that are made of level IV monomers and have a large global annual production (1-5 million tonnes) are phenol formaldehyde resins, unsaturated polyesters, polycarbonate, polymethyl methacrylate, and urea-formaldehyde resins. This study has identified hazardous substances used in polymer production for which the risks should be evaluated for decisions on the need for risk reduction measures, substitution, or even phase out.

Liu, B., et al. (2019). "MiR-29b/Sp1/FUT4 axis modulates the malignancy of leukemia stem cells by regulating fucosylation via Wnt/beta-catenin pathway in acute myeloid leukemia." Journal of Experimental & Clinical Cancer Research **38**(1): 200.

BACKGROUND: Acute myeloid leukemia (AML) is initiated and maintained by a unique, small subset of leukemia stem cells (LSCs). LSCs are characterized by unrestricted self-renewal and contribute to the malignancy of leukemia. Aberrant protein fucosylation is associated with AML progression. However, it is still less understood that the miR-29b/Sp1/FUT4 crosstalk involved in the fucosylation-mediated LSCs malignancy in AML.

METHODS: AML cell lines were sorted by magnetic microbeads to obtain the CD34 + CD38- sub-population. The key biomarkers for LSCs were identified by flow cytometry. Fucosyltransferase genes were screened by qRT-PCR, and FUT4 was focused. Effect of FUT4 on LSCs malignancy was determined by CCK8 assay, sphere formation assay, immunofluorescence staining, apoptosis and in vivo xenografts experiments. The linkage of FUT4 promoter and Sp1 was confirmed by dual-luciferase reporter gene assay. ChIP-PCR assay was used to show the directly binding of Sp1 and FUT4 promoter. Activity of Wnt//beta-catenin pathway was determined by western blot. Overall survival curves were diagrammed by Kaplan-Meier analysis.

RESULTS: Here, the expressional profiles of 11 fucosyltransferase genes were different comparing LSCs and non-LSCs of KG-1a and MOLM13 cells, whereas CD34 + CD38- cells exhibited higher expression of FUT4. Functionally, alteration of FUT4 in CD34 + CD38- cells modulated LSCs malignant behaviors both in vitro and in vivo. Transcriptional inhibitor actinomycin D (Act D) or translational inhibitor cycloheximide (CHX) prevented LSCs progression, and Sp1 was identified as the efficient regulator of FUT4 transcription. Moreover, miR-29b directly affected the binding of Sp1 and FUT4 promoter region, which further mediated LSCs proliferation, apoptosis and drug-resistance through fucosylated-CD44 via activation of Wnt/beta-catenin pathway. Clinically, Sp1 and FUT4 were up-regulated and positively correlated with poor overall survival of AML patients.

CONCLUSION: These data indicated that miR-29b/Sp1/FUT4 axis promoted the malignant behaviors of LSCs by regulating fucosylated CD44 via Wnt/beta-catenin pathway. Identifying LSCs surface markers and targeting LSCs were important for the development of potential therapies in AML.

Liu, B. T., et al. (2011). "Strength of the interactions between light-scattering particles and resins affects the haze of anti-glare films." Colloids and Surfaces A: Physicochemical and Engineering Aspects **389**(1-3): 138-143.

In this study we evaluated the effects of the surface functional groups of light-scattering particles (LSPs) and the nature of the resin on the haze of anti-glare (AG) films. We fabricated LSPs with amino groups on their surfaces from commercial crosslinked polystyrene microbeads, and LSPs presenting aliphatic chains through reactions of these amino groups with stearic acid. X-ray photoelectron spectroscopy and contact angle analysis revealed that these surface-modified LSPs had different elemental compositions on their surfaces and different wettabilities, respectively. To fabricate AG films, we incorporated the LSPs presenting the different surface functional groups into resins having various affinities. At the same LSP concentration and with the same resin, the AG films incorporating LSPs with aliphatic chains exhibited greater outer haze than did those featuring amino groups. The outer haze increased upon decreasing the ratio of the viscosity of the mixture of LSPs and resin to that of the resin. We speculate that the outer haze was affected by the interactions between the LSPs and the resin. © 2011 Elsevier B.V.

Liu, C., et al. (2008). "Selective removal of copper and lead ions by diethylenetriamine-functionalized adsorbent: behaviors and mechanisms." Water Research **42**(6-7): 1511-1522.

The selective removal of copper and lead ions from aqueous solutions by diethylenetriamine (DETA)-functionalized polymeric adsorbent was investigated. The adsorbent was prepared by amination of the micro-beads synthesized from glycidyl methacrylate and trimethylolpropane trimethacrylate co-polymerization (denoted as P-DETA). In the single metal species system (only copper or lead ions present), P-DETA was found to adsorb copper ions or lead ions significantly (with a slightly higher adsorption uptake capacity for lead ions than copper ions). However, P-DETA displayed an excellent selectivity in the adsorption of copper ions over lead ions in the binary metal species system (with both copper and lead ions present). It was also found that initially (or previously) adsorbed lead ions on P-DETA were displaced, even completely, by subsequently adsorbed copper ions from the solution but the case was not vice versa. The greater electronegativity of copper ions than lead ions was identified as the major factor that caused P-DETA to selectively adsorb copper ions over lead ions during competitive adsorption in the binary metal species system. It was speculated that the displacement of already adsorbed lead ions on P-DETA by subsequently adsorbed copper ions was through an adjacent attachment and repulsion mechanism. P-DETA has been shown to have the potential to be used as an effective adsorbent for the removal as well as selective recovery of heavy metal ions in water or wastewater treatment.

Liu, C., et al. (2019). "Widespread distribution of PET and PC microplastics in dust in urban China and their estimated human exposure." Environment International **128**: 116-124.

Dust is a fate of many contaminants and may be an important medium for the human exposure to these contaminants. Microplastics (MPs) have been observed in dust in previous studies. However, the mass concentrations of dominant MPs in dust and the exposure risk to human remain unclear. In this study, indoor and outdoor dust samples were collected from 39 major cities of China. The mass concentrations of polyethylene terephthalate (PET) and polycarbonate (PC) MPs were determined through alkali-assisted thermal depolymerization-liquid chromatography-tandem mass spectrometry, and the shape and component distribution of MPs were analyzed by optical microscopy and micro-Fourier transform infrared spectroscopy. PET MPs were detected in all the samples at high concentrations of 1550-120,000mg/kg (indoor) and 212-9020mg/kg (outdoor) and PC MPs were detected in approximately 70% of the samples, with median concentrations of 4.6mg/kg (indoor) and 2.0mg/kg (outdoor). Fiber was the main shape of suspected MPs, and polyester (including PET) was identified as an important component in MPs from dust. Indoor dust is a non-negligible source of human exposure to MPs, accounting for a geomean daily intake of 17,300ng/kg-bw of PET MPs in children.

Liu, F., et al. (2019). "Microplastics in urban and highway stormwater retention ponds." Science of the Total Environment **671**: 992-1000.

Urban and highway stormwater runoff seems an obvious pathway for conveying microplastics from land-based sources to the aquatic environment. The significance of this pathway is however largely unknown. This study presents first results on microplastics in urban and highway stormwaters by analysing microplastics (10-2000 mum) in the water phase of stormwater treatment ponds in the North of Jutland, Denmark. The stormwater of seven ponds treating runoff drained from different landscapes were studied. Ponds serving highway and residential areas had the lowest microplastic concentration, while ponds serving areas with industry and commerce had the highest. The stormwater of the ponds contained 490-22,894 items m⁻³, corresponding to an estimated 85-1143 mug m⁻³. The dominating polymers were polypropylene, polyvinylchloride, polyester, polyethylene and polystyrene. There was a tendency towards polyvinylchloride particles being the largest in size, while a mixed group of less common polymers were the smallest. Residential ponds generally held the largest microplastic particles and were in many aspects quite comparable to one another, in terms of concentrations, sizes, and polymer composition. This study shows that land-based sources are significant contributors to MP in the environment. It demonstrates that the stormwater retention ponds act not only as pollution hotspots, but also play a role in the transport of MP from land to the aquatic environment. Copyright © 2019

Liu, F., et al. (2018). "Prolonged inhibition of class I PI3K promotes liver cancer stem cell expansion by augmenting SGK3/GSK-3beta/beta-catenin signalling." Journal of Experimental & Clinical Cancer Research **37**(1): 122.

BACKGROUND: Serum and glucocorticoid-regulated kinase 3 (SGK3) has been reported to play an important role in tumour progression, but its role in cancer stem cells (CSCs) remains obscure. The phosphoinositide 3-kinase (PI3K) pathway is considered a hallmark of cancer. Although many PI3K pathway-targeted therapies have been tested in oncology trials, the results are not satisfactory.

METHODS: We used spheroids cultured in serum-free culture medium and MicroBead isolation to obtain liver CSCs. Spheroid formation assay and flow cytometric analysis were performed to investigate liver CSC expansion. Real-time polymerase chain reaction (PCR), western blot and immunofluorescence were used to assess gene expression in cell lines.

RESULTS: We found that SGK3 is preferentially activated in liver CSCs. Upregulated SGK3 significantly increases the expansion of liver CSCs. Conversely, suppression of SGK3 in human hepatocarcinoma (HCC) cells had an opposite effect. Mechanistically, SGK3 promoted beta-catenin accumulation by suppressing GSK-3beta-mediated beta-catenin degradation in liver CSCs, and then promoting the expansion of liver CSCs. Prolonged treatment of HCC cells with class I PI3K inhibitors leads to activation of SGK3 and expansion of liver CSCs. Inhibition of hVps34 can block SGK3 activity and suppress liver CSC expansion induced by PI3K inhibitors. More importantly, we also found that prolonged treatment of HCC cells with PI3K inhibitors stimulates the beta-catenin signalling pathway via activation of SGK3.

CONCLUSIONS: Prolonged inhibition of class I PI3K promotes liver CSC expansion by augmenting

SGK3-dependent beta-catenin stabilisation, and effective inhibition of SGK3 signalling may be useful in eliminating liver CSCs and in PI3K pathway-targeted cancer therapies.

Liu, F. F., et al. (2019). "Interactions between microplastics and phthalate esters as affected by microplastics characteristics and solution chemistry." Chemosphere **214**: 688-694.

Microplastics have become a major concern in recent years as they can be recognized as the transport vectors for pollutants in environment. In this study, the sorption behavior of two phthalate esters (PAEs), including diethyl phthalate (DEP) and dibutyl phthalate (DBP), onto three types of microplastics (PVC: polyvinyl chloride, PE: polyethylene, and PS: polystyrene) was investigated. The sorption isotherms of both DEP and DBP on microplastics were highly linear, suggesting that the partition was the main sorption mechanism. The K_d values of DBP were much higher than those of DEP, demonstrating that hydrophobic interaction governed the partition mechanism. Sorption of the two PAEs on the three microplastics followed the order of PS>PE>PVC, indicating that chemical properties of microplastics played an important roles in their sorption behaviors. Solution pH and natural organic matter had no significant impact on PAEs sorption by microplastics. However, the presence of NaCl and CaCl₂ enhanced the sorption of both DEP and DBP because of the salting-out effect. The findings of the present study may have significant implications for the fate and transport assessment of both PAEs and microplastics.

Liu, G., et al. (2020). "Microplastic Impacts on Microalgae Growth: Effects of Size and Humic Acid." Environmental Science & Technology **14**: 14.

Research has already demonstrated the toxic effects of microplastics (MPs) on different biota. However, the underlying toxic mechanism of MPs remains to be elucidated, especially the effect of particle size and the presence of dissolved organic matter in water. This study investigated the impact on Scenedesmus obliquus exposed in five types of polystyrene particle suspensions with different sizes and surface charges, in the presence and absence of humic acid (HA).

Liu, G., et al. (2019). "Sorption behavior and mechanism of hydrophilic organic chemicals to virgin and aged microplastics in freshwater and seawater." Environmental Pollution **246**: 26-33.

Virgin microplastics undergo aging and form oxygen-containing functional groups when they enter the environment. Therefore, the sorption of organic pollutants onto microplastics is not limited to hydrophobic organic pollutants and can also occur with hydrophilic organic pollutants. Therefore, understanding the sorption behaviors and mechanism between aged microplastics and hydrophilic organic pollutants is essential for evaluating the real effects of microplastics in the environment. We investigated the impacts of the UV-accelerated aging of polystyrene (PS) and polyvinylchloride (PVC) on their sorption interactions with ciprofloxacin (CIP). The results of infrared spectroscopy (IR) and scanning electron microscopy (SEM) showed significant surface oxidation and localized microcracks on the aged microplastics. The sorption kinetics and isotherms models indicated that the sorption capacity of aged microplastics is higher than that of pristine microplastics, and their physical interactions, including partitioning, electrostatic interactions, and intermolecular hydrogen bonding, were the dominant mechanism, as demonstrated by FTIR analysis. Moreover, the sorption capacity of the pristine microplastics decreased as the degree of crystallinity increased, whereas the opposite trend was observed with aged microplastics, which means that the crystallinity is not the controlling factor. In addition, salinity suppressed adsorption on all the tested microplastics. The pH influences the electrostatic attraction between the microplastics and CIP because CIP has a different charge at different pH values. The results presented herein confirm the importance of studying the

adsorption between hydrophilic organic pollutants and aged microplastics because ultimately, all microplastics become aged. Moreover, the effects of aged microplastics with adsorbed hydrophilic chemicals on organisms need to be further studied.

Liu, H. and C. Ding (2017). "Establishment of an experimental glaucoma animal model: A comparison of microbead injection with or without hydroxypropyl methylcellulose." Experimental & Therapeutic Medicine **14**(3): 1953-1960.

The present study aimed to compare microbead injection with and without hydroxypropyl methylcellulose (HPM) in order to establish an experimental animal model of glaucoma. This model was established in C57BL/6 mice and transgenic mice expressing cyan fluorescent protein (CFP) under the control of the Thy1 promoter in retinal ganglion cells (RGCs). C57BL/6 mice aged between 12 and 20 weeks old were randomly separated into three groups, which received different injections into the anterior chamber of the eye. Group A (microbead) received 2 micro l microbeads (10x106 beads/ml) and 1 micro l air. Group B (microbeads + HPM) received 2 micro l microbeads and 1 micro l HPM. Group C (control group) received 2 micro l PBS and 1 micro l air. The intraocular pressure (IOP) was measured with a tonometer under topical anesthesia daily for 1 month. A single injection of microbeads, with or without HPM, induced consistent IOP elevation when compared with the control group. Thy1-CFP mice received an injection of 2 micro l microbeads and 1 micro l HPM into the anterior chamber of the eyes, and the number of CFP+ RGCs was subsequently assessed in vivo by confocal scanning laser microscopy in the same area of the retina weekly for 6 weeks. The results from in vivo imaging of Thy1-CFP mice were comparable with the immunohistochemical staining results from the C57BL/6 mice. The combined injection of microbeads and HPM induced longer and higher peaks of IOP elevation when compared with the microbeads alone. The rate of RGC loss following the administration of microbeads alone was 25.0+/-1.3% 6 weeks after the initial IOP elevation, while it was 33.2+/-1.9% following the administration of microbeads + HPM. These results indicate that the injection of microbeads + HPM is a more effective method of establishing a mouse model with chronic elevation of IOP. In addition, the in vivo imaging that can be used with this technique provides an effective and noninvasive approach for monitoring the progress of RGC loss.

Liu, H., et al. (2016). "Microfluidic synthesis of QD-encoded PEGDA microspheres for suspension assay." Journal of materials chemistry. B, Materials for biology and medicine. **4**(3): 482-488.

Uniform and size-controllable QD-encoded poly(ethylene glycol) diacrylate (PEGDA) microbeads were produced using a microfluidic device followed by in situ photopolymerization. An S-shaped and gradually widening channel was designed to allow optimized UV exposure for photopolymerization and to prevent coalescence. The as-obtained PEGDA microbeads exhibited well-defined sphericity and excellent monodispersity with a coefficient of variation (CV) below 5%. The size varied from 7 mu m to 120 mu m and can be selectively achieved by simply adjusting the experimental parameters. The fluorescence performance of the QDs was well preserved without significant peak broadening or distortion. Seven barcode libraries were realized with bright fluorescence and distinguishing coding signals which could be conveniently decoded by a flow cytometer. Furthermore, a very facile strategy to conjugate biomolecules on the bead surfaces was developed using polydopamine (PDA). A sandwich immunoassay of rabbit IgG was performed and the applicability of the QD-encoded microbeads for suspension assay was demonstrated.

Liu, H., et al. (2019). "Interactive effects of microplastics and glyphosate on the dynamics of soil dissolved organic matter in a Chinese loess soil." Catena **182**(104177).

The increased use of plastic films and pesticides on agricultural soil leads to the accumulation of plastic debris and pesticide residues in soil. This accumulation has become a serious environmental issue, as it threatens life of earthworms, inhibits the enzyme activities and microbial diversity, and contributes to the loss of soil microbial carbon and nitrogen. However, little information is available regarding the effects of pesticides on soil dissolved organic matter (DOM). It is also unknown how plastic debris, especially small-sized particles called microplastics, influences the effects of pesticides on soil DOM. In this study, we performed a 30-day soil incubation experiment. Three levels of the common herbicide glyphosate were applied to soil: 0 (control, CK), 3.6 kg ha⁻¹ (G1) and 7.2 kg ha⁻¹ (G2). We also tested four levels of glyphosate and microplastics (homopolymer polypropylene powder) co-addition: 3.6 kg ha⁻¹ +7% (w/w) (M1 G1), 3.6 kg ha⁻¹ +28% (w/w) (M2 G1), 7.2 kg ha⁻¹ +7% (w/w) (M1 G2), and 7.2 kg ha⁻¹ +28% (w/w) (M2 G2). Glyphosate addition slightly increased soil fluorescein diacetate hydrolase (FDAse) and phenol oxidase (PO) activities. Although the glyphosate addition significantly promoted the accumulation of dissolved organic phosphorus (DOP) within the first 14 days, the M2 treatment decreased DOP at day 30. M2 G1 and M2 G2 increased soil FDAse activity and promoted the accumulation of DOC and DOP relative to G1 and G2 respectively while M1 G1 and M1 G2 benefited DON accumulation. Our results highlighted that the interaction between glyphosate and low microplastics content negatively affected DOC and DOP dynamics, leading to the loss of bioavailable C and P loss. The interaction between glyphosate and high content microplastics negatively affected DON compared with glyphosate addition, possibly decreasing DON.

Liu, H., et al. (2017). "Response of soil dissolved organic matter to microplastic addition in Chinese loess soil." Chemosphere **185**: 907-917.

Plastic debris is accumulating in agricultural land due to the increased use of plastic mulches, which is causing serious environmental problems, especially for biochemical and physical properties of the soil. Dissolved organic matter (DOM) plays a central role in driving soil biogeochemistry, but little information is available on the effects of plastic residues, especially microplastic, on soil DOM. We conducted a soil-incubation experiment in a climate-controlled chamber with three levels of microplastic added to loess soil collected from the Loess Plateau in China: 0% (control, CK), 7% (M1) and 28% (M2) (w/w). We analysed the soil contents of dissolved organic carbon (DOC), dissolved organic nitrogen (DON), NH₄⁺, NO₃⁻, dissolved organic phosphorus (DOP), and PO₄³⁻ and the activities of fluorescein diacetate hydrolase (FDAse) and phenol oxidase. The higher level of microplastic addition significantly increased the nutrient contents of the DOM solution. The lower level of addition had no significant effect on the DOM solution during the first seven days, but the rate of DOM decomposition decreased in M1 between days 7 and 30, which increased the nutrient contents. The microplastic facilitated the accumulation of high-molecular-weight humic-like material between days 7 and 30. The DOM solutions were mainly comprised of high-molecular-weight humic-like material in CK and M1 and of high-molecular-weight humic-like material and tyrosine-like material in M2. The Microplastic stimulated the activities of both enzymes. Microplastic addition thus stimulated enzymatic activity, activated pools of organic C, N, and P, and was beneficial for the accumulation of dissolved organic C, N and P.

Liu, J., et al. (2018). "Polystyrene Nanoplastics-Enhanced Contaminant Transport: Role of Irreversible

Adsorption in Glassy Polymeric Domain." Environmental Science & Technology **52**(5): 2677-2685.

Nanoplastics (NPs) are becoming an emerging pollutant of global concern. A potential risk is that NPs may serve as carriers to increase the spreading of coexisting contaminants. In this study, we examined the effects of polystyrene nanoplastics (PSNPs, 100 nm), used as a model NP, on the transport of five organic contaminants of different polarity in saturated soil. The presence of low concentrations of PSNPs significantly enhanced the transport of nonpolar (pyrene) and weakly polar (2,2',4,4'-tetrabromodiphenyl ether) compounds, but had essentially no effects on the transport of three polar compounds (bisphenol A, bisphenol F, and 4-nonylphenol). The strikingly different effects of NPs on the transport of nonpolar/weakly polar versus polar contaminants could not be explained with different adsorption affinities, but was consistent with the polarity-dependent extents of desorption hysteresis. Notably, desorption hysteresis was only observed for nonpolar/weakly polar contaminants, likely because nonpolar compounds tended to adsorb in the inner matrices of glassy polymeric structure of polystyrene (resulting in physical entrapment of adsorbates), whereas polar compounds favored surface adsorption. This hypothesis was verified with supplemental adsorption and desorption experiments of pyrene and 4-nonylphenol using a dense, glassy polystyrene polymer and a flexible, rubbery polyethylene polymer. Overall, the findings of this study underscore the potentially significant environmental implication of NPs as contaminant carriers.

Liu, J., et al. (2019). "Aging Significantly Affects Mobility and Contaminant-Mobilizing Ability of Nanoplastics in Saturated Loamy Sand." Environmental Science & Technology **53**(10): 5805-5815.

Plastic debris, in particular, microplastics and nanoplastics, is becoming an emerging class of pollutants of global concern. Aging can significantly affect the physicochemical properties of plastics, and therefore, may influence the fate, transport, and effects of these materials. Here, we show that aging by UV or O₃ exposure drastically enhanced the mobility and contaminant-mobilizing ability of spherical polystyrene nanoplastics (PSNPs, 487.3 +/- 18.3 nm in diameter) in saturated loamy sand. Extended Derjaguin-Landau-Verwey-Overbeek calculations and pH-dependent transport experiments demonstrated that the greater mobility of the aged PSNPs was mainly the result of surface oxidation of the nanoplastics, which increased not only the surface charge negativity, but more importantly, hydrophilicity of the materials. The increased mobility of the aged PSNPs significantly contributed to their elevated contaminant-mobilizing abilities. Moreover, aging of PSNPs enhanced the binding of both nonpolar and polar contaminants, further increasing the contaminant-mobilizing ability of PSNPs. Interestingly, aging enhanced binding of nonpolar versus polar compounds via distinctly different mechanisms: increased binding of nonpolar contaminants (tested using pyrene) was mainly the result of the modification of the polymeric structure of PSNPs that exacerbated slow desorption kinetics; for polar compounds (4-nonylphenol), aging induced changes in surface properties also resulted in irreversible adsorption of contaminants through polar interactions, such as hydrogen bonding. The findings further underline the significant effects of aging on environmental fate and implications of nanoplastics.

Liu, J., et al. (2018). "Application value of TIMP-4 suspension microbead chip in diagnosis of gastric cancer: A validation study." Journal of Digestive Diseases **19 (Supplement 1)**: 97.

Objective Our previous study showed that there was a significant difference in serum TIMP-4 between gastric cancer (GC) and nonneoplastic gastric diseases (NGD) patients. To test its ability and feasibility for the diagnosis of GC, this study was performed. Methods Serum samples from 40 GC and 38 gender and age matched NGD patients were collected from March 2017 to June 2017. TIMP bead-based assay using the Luminex technology was applied to quantitative

measurement of TIMP-4 (Figure 1A-B). Its expression level was compared between the GC and NGD groups and its diagnostic value was assessed by ROC curve. Additionally, the levels of 4 conventional serological tumor markers in GC patients were determined by electrochemiluminescence assay. Results The levels of TIMP-4 in GC and NGD groups were 1101.2+/-703.3 pg/mL and 890.1+/-454.7 pg/mL, respectively. Compared with the NGD group, the level of TIMP-4 tended to increase in the GC group, and the difference was critical statistical significance (t=1.568, P=0.122) (Figure 1C). Its AUC value was 0.574 (95% CI, 0.444-0.704) for the diagnosis of GC. At the optimal cutoff value of 1292.7 pg/mL, its sensitivity, specificity and accuracy were 38.5%, 89.5% and 63.6%, respectively (Figure 1D). Nevertheless, the positive rates of alpha fetoprotein (AFP), carcinoembryonic antigen (CEA), carcinoma antigen 125 (CA125), and carbohydrate antigen 19-9 (CA19-9) for the diagnosis of GC were 0, 18.9%, 8.3% and 10.8%, respectively. Conclusions Serum TIMP-4 has a certain reference value for the diagnosis of GC. Whether it can be used as a novel diagnostic marker for GC requires further investigation.

Liu, J., et al. (2019). "Microdeformation of RBCs under oxidative stress measured by digital holographic microscopy and optical tweezers." Applied Optics **58**(15): 4042-4046.

This paper utilized digital holographic microscopy and optical tweezers to study microdeformation of red blood cells (RBCs) dynamically under oxidative stress. RBCs attached with microbeads were stretched by dual optical tweezers to generate microdeformation. Morphology of RBCs under manipulation were recorded dynamically and recovered by off-axis digital holographic microscopy method. RBCs treated with H₂O₂ at different concentrations were measured to investigate the mechanical properties under oxidative stress. Use of optical tweezers and off-axis digital holographic microscopy enhanced measuring accuracy compared with the traditional method. Microdeformation of RBCs is also more consistent with the physiological situation. This proposal is meaningful for clinical applications and basic analysis of Parkinson's disease research.

Liu, J. Y., et al. (2004). "Bioreactor microcarrier cell culture system (Bio-MCCS) for large-scale production of autologous melanocytes." Cell Transplantation **13**(7-8): 809-816.

Restoration of cutaneous pigmentation can be achieved in stable vitiligo by autologous cultured melanocyte transplantation. It was the goal of this study to construct a bioreactor microcarrier cell culture system (Bio-MCCS) to produce autologous melanocytes in large scale. In this Bio-MCCS, porcine gelatin microbeads were used as microcarriers, spinning bottle as fermented tank. Autologous melanocytes were able to attach to and proliferate on the gelatin microbeads in serum-free melanocyte medium in the Bio-MCCS, reaching up to 24-fold the cells seeded on day 15 (MTT assay). These autologous melanocytes cultured on gelatin microbeads could leave the microbeads and proliferate on the bottom of tissue culture flasks. Although Pluronic F68 has been widely used to protect animal cells from hydrodynamic stress in animal cell bioreactors, Pluronic F68 at a concentration of 0.25-1.0% showed no significant protective effects on the autologous melanocytes cultured on the microbeads and subjected to mechanical stress in the Bio-MCCS. This Bio-MCCS using porcine gelatin microbeads as microcarriers enabled large-scale production of autologous melanocytes, offering a potential treatment for large-area stable vitiligo by direct administration of the melanocytes cultured on the gelatin microbeads to the vitiliginous site.

Liu, J. Y., et al. (2006). "High yields of autologous living dermal equivalents using porcine gelatin microbeads as microcarriers for autologous fibroblasts." Cell Transplantation **15**(5): 445-451.

Permanent skin replacement requires a dermal component to ensure adequate long-term graft stability and to prevent wound contraction. This study was to construct a bioreactor microcarrier cell culture system (Bio-MCCS) to produce autologous living dermal equivalents on a large scale. Autologous fibroblasts were isolated from split-thickness skin biopsy from a leg ulcer patient, inoculated onto macroporous porcine gelatin microbeads, and incubated in a bioreactor (Cellspin) in serum-free fibroblast growth medium or in DMEM medium containing 10% fetal calf serum (FCS). Fibroblasts rapidly adhered to and actively proliferated on the microbeads in the bioreactor in both serum-free and serum-containing medium. MTT assay showed the number of fibroblasts on the microbeads reached up to 5.3- or 4.0-fold the cells seeded in DMEM medium containing 10% FCS or serum-free medium, respectively. When removed from Bio-MCCS and cultured under static conditions, fibroblasts were able to leave the microbeads and proliferate to confluence on the bottom of tissue culture flasks. When stored at room temperature in DMEM containing 10% FBS, fibroblast cultured on the microbeads retained highest viabilities for at least 3 weeks, up to 82% of originals. This Bio-MCCS using porcine gelatin microbeads as carriers for fibroblasts offers a new option of mass production of autologous living dermal equivalents.

Liu, J. Y., et al. (2004). "Autologous cultured keratinocytes on porcine gelatin microbeads effectively heal chronic venous leg ulcers." Wound Repair & Regeneration **12**(2): 148-156.

We have established a specific bioreactor microcarrier cell culture system using porcine gelatin microbeads as carriers to produce autologous keratinocytes on a large scale. Moreover, we have shown that autologous keratinocytes can be cultured on porcine collagen pads, thereby forming a single cell layer. The objective of this study was to compare efficacy and safety of autologous cultured keratinocytes on microbeads and collagen pads in the treatment of chronic wounds. Fifteen patients with recalcitrant venous leg ulcers were assigned to three groups in a single-center, prospective, uncontrolled study: five underwent a single treatment with keratinocyte monolayers on collagen pads (group 1); another five received a single grafting with keratinocyte-microbeads (group 2); and the last five received multiple, consecutive applications of keratinocyte-microbeads 3 days apart (group 3). All patients were followed for up to 12 weeks. By 12 weeks, there was a mean reduction in the initial wound area of 50, 83, and 97 percent in the three groups, respectively. The changes in wound size were statistically significant between the first and third groups (p= 0.0003). Keratinocyte-microbeads proved to be more effective than keratinocyte monolayers on collagen pads when the former were applied every 3 days. Rapid availability within 10-13 days after skin biopsy and easy handling represent particular advantages.

Liu, J. Y., et al. (2004). "Original Research Articles - Clinical Science: Autologous cultured keratinocytes on porcine gelatin microbeads effectively heal chronic venous leg ulcers." Wound Repair and Regeneration **12**(2): 148-156.

Liu, K., et al. (2019). "Source and potential risk assessment of suspended atmospheric microplastics in Shanghai." Science of the Total Environment **675**: 462-471.

A growing body of research has recently revealed that airborne microplastics could be an important source of microplastic pollution in marine environments. However, the origins and spatial distributions of suspended atmospheric microplastics (SAMPs) are poorly understood. Further, SAMPs abundances have only been observed using passive sampling devices that could lead to underestimates of abundances. To address these knowledge-gaps, the current study investigated the potential source and spatial distribution of SAMPs in Shanghai during May 2018 using an active suspended particulate sampler. SAMPs abundances from filtered air ranged from 0 to 4.18 n/m³ (items per cubic meter of air). Microfibers comprised 67% of all SAMPs, followed by fragments and granules comprising 30% and 3% of SAMPs, respectively. mu-FT-IR analysis revealed that the SAMPs consisted of polyethylene terephthalate (PET), polyethylene (PE), polyester (PES), polyacrylonitrile (PAN), poly(N-methyl acrylamide) (PAA), rayon (RY), ethylene vinyl acetate (EVA), epoxy resin (EP), and alkyd resin (ALK). Synthetic compounds comprised 54% of the observed particles, of which PET, PE, PES, PAN, PAA, and RY comprised 91% of the microplastics. Our preliminary evaluation indicated that textile clothes are likely major source of the airborne microplastics. Modeling estimated that approximately 120.7kg of SAMPs are annually transported through Shanghai air. Moreover, an estimation of the ecological risk from SAMPs indicated that a minor ecological consequence was present, necessitating further evaluation of SAMPs pollution. In addition, modeling estimated that approximately 21 particles of microplastics are inhaled daily by people in Shanghai from outdoor environments. Given the prevalence of airborne microfibers, it is critically urgent to reevaluate procedures for sampling, transporting, and processing microplastic field samples. Future investigations should seek to develop more rigorous and conclusive methods to evaluate these types of samples.

Liu, K., et al. (2019). "Accurate quantification and transport estimation of suspended atmospheric microplastics in megacities: Implications for human health." Environment International **132**: 105127.

Although atmospheric microplastics have been found to be ubiquitous even on untraversed mountains and have potential impacts on human health, little information concerning their sampling methodology and transport is currently available. Until a realistic quantification of suspended atmospheric microplastics (SAMPs) is obtained, however, any potential health risk assessment for this pollutant will be open to criticism for using an ambiguous dataset. To address this knowledge gap, in May 2019 a trial experiment was performed to explore the potential relationship between sampling volume and SAMP abundance. A significant logarithmic regression between SAMP abundance and the sampling volume of filtrated air was found and the sufficient volume of filtrated air for accurate SAMP quantification was recommended. Investigation results indicated that fibrous and fragment-shaped SAMPs comprised 91% of all of the identified synthetic particles. Interestingly, for the first time, plastic microbeads were also observed in the collected air, constituting 9% of the all of the SAMPs by quantity. Spectral analysis revealed that these SAMPs consisted of polyethylene terephthalate (PET), epoxy resin (EP), polyethylene (PE), alkyd resin (ALK), rayon (RY), polypropylene (PP), polyamide (PA), and polystyrene (PS). PET, EP, PE, and ALK constituted the majority (90%) of all of the polymer types, with quantitative percentages of 51%, 19%, 12%, and 8%, respectively. Based on our numerical modeling simulation, the approximate transport flux of SAMPs during June in Shanghai was estimated, ranging from 9.94x10⁴n/(m.d) to 6.52x10⁵n/(m.d), with a mean of 3.00+/-1.58x10⁵n/(m.d). The goal of our study was to provide an essential methodological aid for the accurate determination of SAMPs in the environment and a better understanding of terrestrial microplastic transport in megacities.

Liu, K., et al. (2019). "Consistent Transport of Terrestrial Microplastics to the Ocean through Atmosphere." Environmental Science & Technology **53**(18): 10612-10619.

Although atmospheric transport and deposition could be an important pathway of terrestrial pollutants to the ocean, little information concerning the presence and distribution of these suspended atmospheric microplastics in marine air is available. We investigated, for the first time, the occurrence and distribution of suspended atmospheric microplastics (SAMPs) in the west Pacific Ocean. In this study, the spatial distribution, morphological appearance, and chemical composition of suspended atmospheric microplastics were studied through continuous sampling during a cruise. SAMPs abundance ranged from 0 to 1.37 n/m³, the median of 0.01 n/m³. Fiber, fragment, and granule SAMPs quantitively constituted 60%, 31%, and 8% of all MPs, respectively. Interestingly, plastic microbeads with numerical proportion of 5% were also observed. A high suspended atmospheric microplastics abundance was found in the coastal area (0.13 +/- 0.24 n/m³), while there was less amount detected in the pelagic area (0.01 +/- 0.01 n/m³). The amount of suspended atmospheric microplastics collected during the daytime (0.45 +/- 0.46 n/m³) was twice the amount collected at night (0.22 +/- 0.19 n/m³), on average. Our observations provide field-based evidence that suspended atmospheric microplastics are an important source of microplastics pollution in the ocean, especially the pollution caused by textile microfibers.

Liu, L., et al. (2016). "Sorption of polycyclic aromatic hydrocarbons to polystyrene nanoplastic." Environmental Toxicology & Chemistry **35**(7): 1650-1655.

Microplastic has become an emerging contaminant of global concern. Bulk plastic can degrade to form smaller particles down to the nanoscale (<100 nm), which are referred to as nanoplastics. Because of their high surface area, nanoplastic may bind hydrophobic chemicals very effectively, increasing their hazard when such nanoplastics are taken up by biota. The present study reports distribution coefficients for sorption of polycyclic aromatic hydrocarbons (PAHs) to 70 nm polystyrene in freshwater, and PAH adsorption isotherms spanning environmentally realistic aqueous concentrations of 10−5 μg/L to 1 μg/L. Nanopolystyrene aggregate state was assessed using dynamic light scattering. The adsorption isotherms were nonlinear, and the distribution coefficients at the lower ends of the isotherms were very high, with values up to 109 L/kg. The high and nonlinear sorption was explained from π-π interactions between the planar PAHs and the surface of the aromatic polymer polystyrene and was higher than for micrometer-sized polystyrene. Reduction of nanopolystyrene aggregate sizes had no significant effect on sorption, which suggests that the PAHs could reach the sorption sites on the pristine nanoparticles regardless of the aggregation state. Pre-extraction of the nanopolystyrene with C18 polydimethylsiloxane decreased sorption of PAHs, which could be explained by removal of the most hydrophobic fraction of the nanopolystyrene. Liu, L., et al. (2016). "Inclusion of Strep-tag II in design of antigen receptors for T-cell immunotherapy." Nature Biotechnology **34**(4): 430-434.

Adoptive immunotherapy with genetically engineered T cells has the potential to treat cancer and other diseases. The introduction of Strep-tag II sequences into specific sites in synthetic chimeric antigen receptors or natural T-cell receptors of diverse specificities provides engineered T cells with a marker for identification and rapid purification, a method for tailoring spacer length of chimeric receptors for optimal function, and a functional element for selective antibody-coated, microbead-driven, large-scale expansion. These receptor designs facilitate cGMP manufacturing of pure populations of engineered T cells for adoptive T-cell therapies and enable in vivo tracking and retrieval of transferred cells for downstream research applications.

Liu, L., et al. (2016). "Bead-based microarray immunoassay for lung cancer biomarkers using quantum dots as labels." Biosensors & Bioelectronics **80**: 300-306.

In this study, we developed a multiplex immunoassay system that combines the suspension and planar microarray formats within a single layer of polydimethylsiloxane (PDMS) using soft lithography technology. The suspension format was based on the target proteins forming a sandwich structure between the magnetic beads and the quantum dot (QD) probes through specific antibody-antigen interactions. The planar microarray format was produced by fabricating an array of micro-wells in PDMS. Each micro-well was designed to trap a single microbead and eventually generated a microbead array within the PDMS chamber. The resultant bead-based on-chip assay could be used for simultaneously detecting three lung cancer biomarkers-carcinoembryonic antigen (CEA), fragments of cytokeratin 19 (CYFRA21-1) and neuron-specific enolase (NSE)-in 10 mul of human serum, with a wide linear dynamic range (1.03-111 ng/mL for CEA and CYFRA21-1; 9.26-1000 ng/ml for NSE) and a low detection limit (CEA: 0.19 ng/ml; CYFRA21-1: 0.97 ng/ml; NSE: 0.37 ng/ml; S/N=3). Our micro-well chip does not require complex e-beam lithography or the reactive ion etching process as with existing micro-well systems, which rely on expensive focused ion beam (FIB) milling or optical fiber bundles. Furthermore, the current approach is easy to operate without extra driving equipment such as pumps, and can make parallel detection for multiplexing with rapid binding kinetics, small reagent consumption and low cost. This work has demonstrated the importance of the successful application of on-chip multiplexing sandwich assays for the detection of biomarker proteins.

Liu, M., et al. (2018). "Microplastic and mesoplastic pollution in farmland soils in suburbs of Shanghai, China." Environmental Pollution **242**(Pt A): 855-862.

Microplastics are emerging pollutants which have been extensively detected in water environments. However, little is known about microplastic pollution in soil environments. In this study, we investigated microplastics and mesoplastics in farmland soils from twenty vegetable fields around the suburbs of Shanghai. In each site, three duplicate soil samples were collected from shallow (0-3cm) and deep soils (3-6cm), respectively. Microplastics (sizes of 20mum -

5mm) and mesoplastics (5mm - 2cm) were detected using methods of density extraction, 30% H₂O₂ digestion and micro-fourier transform infrared spectroscopy. The abundance of microplastics was 78.00+/-12.91 and 62.50+/-12.97 items kg⁻¹ in shallow and deep soils, respectively. While, mesoplastics were found with abundance of 6.75+/-1.51 and 3.25+/-1.04 items kg⁻¹ in shallow and deep soils. Among these micro(meso)plastics, 48.79% and 59.81% were in size of <1mm in shallow and deep soils. The main morphotypes of microplastics included fiber, fragment and film, mostly in color of black or transparent. Moreover, we found that topsoil contained higher concentrations and larger sizes of micro(meso)plastics than deep soil. In addition, the vast majority of micro(meso)plastics were polypropylene (50.51%) and polyethylene (43.43%). This study reveals occurrence and characteristics of microplastic pollution in typical farmland soils. It provides important data for subsequent research on microplatics in the terrestrial ecosystem.

Liu, M., et al. (2019). "A method for extracting soil microplastics through circulation of sodium bromide solutions." Science of the Total Environment **691**: 341-347.

Microplastics (MP) have been recently found in soil environments. These MP might have adverse effects at high concentrations and thus efficient extraction and analysis of MP from soil is needed. Here we propose a new method of NaBr solution circulation for extracting soil MP. A device for the circular extraction of soil MP was developed. This device included a separation, vacuum filtration, and solution recovery system. It was then utilized to test separation efficiency of soil MP with three economic and environmentally friendly extraction reagents: NaCl, CaCl₂ and NaBr solutions. The separation was tested with ten different types of polymers, three different size classes and three different shapes of MP. Extraction with NaBr showed the highest recovery rates ranging from 85% to 100%. After extraction the samples were treated with H₂O₂ and analyzed by micro-Fourier transform infrared spectroscopy. The developed method was assessed for its potential influence on MP and no significant changes in the integrity of multiple MP were found. Finally, the established method was used to analyze MP in four types of soil: farmland, yellow-brown, paddy and floodplain soil from the suburb of Shanghai.

Liu, N., et al. (2013). "Simultaneous and combined detection of multiple tumor biomarkers for prostate cancer in human serum by suspension array technology." Biosensors and Bioelectronics **47**: 92-98.

Tumor markers (TMs) play an important role in clinical rapid screening and diagnosis for prostate cancer (PCa). In this study, we describe a competitive method to establish the multiplex suspension array by tumor biomarkers coated on distinguishable microbeads which competing with free biomarkers for their complementary antibodies (Ab) in one single reaction system for simultaneous and combined detection of prostate TMs in human serum. The volumes of the targets coupled onto the beads and their complementary Abs were optimized. The suspension array standard curves correlated well with PCa biomarkers (R²>0.9968). PCa biomarker levels were qua2013ntified using median fluorescent intensities. The working ranges of prostate-specific antigen (PSA), prostate stem cell antigen (PSCA), prostate-specific membrane antigen (PSMA) and prostatic acid phosphatase (PAP) were 0.47-502.94, 1.00-923.35, 1.00-524.79, and 1.73-176.07ngmL⁻¹ in serum samples, respectively. This method was compared to indirect competitive enzyme linked immunosorbent assay. It was found that high concordance between the two technologies resulted from serum samples of the eight PCa patients. The multiplex suspension array technology is specific to PCa biomarkers, displayed no significant cross-reactivity, and remains stable for 6 months. We also characterized the bead surface microstructures under different conditions employing a field emission scanning electron microscope. The suspension array is a straightforward and reliable method for analysis of multiple TMs with simple operation, high sensitivity at a low cost. © 2013 Elsevier B.V.

Liu, N., et al. (2018). "Detection of biomarkers of acute myocardial infarction by high-throughput suspension array technology in serum sample." Bioanalysis **10**(1): 47-58.

AIM: In order to assist and support early diagnosis of acute myocardial infarction (AMI), suspension array technology was established for multiplexed, rapid and accurate measurement of AMI biomarkers in serum samples. Methodology & results: It was developed by coating AMI biomarkers on distinguishable microbeads and competing with free biomarkers for complementary antibodies. The limits of detection of three AMI biomarkers were 2.5- to 50-times lower than that of the previous methods and the working ranges were four to five orders of magnitude. Accuracy and stability also met satisfying acceptance criteria in both of the intra- and interbatch testing. The variation coefficients and relative standard deviations were all less than 10%.

CONCLUSION: Suspension array technology is completely applicable for requirements of rapid clinical diagnosis in serum sample.

Liu, P., et al. (2020). "Effect of aging on adsorption behavior of polystyrene microplastics for pharmaceuticals: Adsorption mechanism and role of aging intermediates." Journal of Hazardous Materials **384**: 121193.

In the environment, aging obviously changes physicochemical properties of microplastics (MPs), but the effects of aging process on adsorption behavior of MPs are not fully understood. In this study, the aging of polystyrene (PS) was accelerated by photo-Fenton reaction. The adsorption mechanism of different aged PS toward atorvastatin (ATV) and amlodipine (AML) and the role of PS-derived intermediates in adsorption process were investigated.

Liu, P., et al. (2020). "Effect of weathering on environmental behavior of microplastics: Properties, sorption and potential risks." Chemosphere **242**: 125193.

Microplastic (MP) pollution is a raising global concern in recent years due to its wide distribution. Additionally, most of the MPs have undergone extensive weathering in the environment, and weathered MPs may exhibit different physicochemical properties from pristine ones. The review reveals the change in physicochemical properties (e.g. size, color, crystallinity, mechanical property and oxygen-containing groups) and the release of additives and MP-derived intermediates (i.e. oligomers and oxygenated compounds) during weathering processes. Weathering further affects the sorption behavior of MPs for environmental pollutants because of the changed crystallinity, specific surface area and oxygen functional groups. The interaction mechanisms of pristine and weathered MPs with pollutants are summarized, and how weathering processes affect sorption behavior is critically revealed. Because of the changed size, color and surface charges, weathered MPs might be ingested by aquatic organisms in different ways from the pristine ones. The detailed effects of weathering on the ingestion of MPs are discussed, and the potential toxicity of leachates from weathering processes is evaluated. In addition, the environmental components (e.g. natural organic matter and salinity) and biofilm correlated to the sorption behavior of MPs are reviewed. As for the knowledge gap, further studies should focus on the long-term weathering of MPs and the relationships between weathering properties and sorption capacities toward pollutants. The potential risks of weathered MPs and leachates on organisms should be explored.

Liu, Q. Y., et al. (2011). "Astragalus polysaccharides regulate T cell-mediated immunity via CD11c

^{high}CD45RB^{low} DCs in vitro." <u>Journal of Ethnopharmacology</u> **136**(3): 457-464.

Ethnopharmacological relevance: Astragalus polysaccharides (APS) isolated from one of the Chinese herbs, Astragalus mongholicus, are known to have a variety of immunomodulatory activities. However, it is not yet clear whether APS can induce the activation and differentiation of dendritic cells (DCs) and subsequently activate T cells. Aim of the study: This study was carried out to investigate the effect of APS on the differentiation of splenic DCs and its influence on T cell-mediated immunity through interleukin (IL)-12-producing CD11c^{high}CD45RB^{low} DCs in vitro. Methodology: MACS microbeads were used to isolate splenic DCs, CD11c^{high}CD45RB ^{low} DCs, CD11c^{low}CD45RB^{high} DCs and CD4 ⁺ T cells. Phenotypes were analyzed by flow cytometry, and cytokine levels were determined with cytometric bead array or ELISA. Result(s): The percentage of CD11c^{high}CD45RB^{low} DCs was significantly increased after treatment with APS compared to their counterparts. The cytokine secretion pattern of CD11c^{high}CD45RB^{low} DCs and CD11c ^{low}CD45RB^{high} DCs was detected, and it was found that unlike the stable IL-10 secretion pattern of CD11c^{low}CD45RB ^{high} DCs induced by APS, CD11c^{high}CD45RB^{low} DCs showed a dose-dependent relationship between IL-12 production and APS stimulation. In order to verify whether the activation of CD4⁺ T was associated with the differentiation of splenic DCs mediated by APS to CD11c ^{high}CD45RB^{low} DCs, anti-IL-12 receptor (IL-12R) as well as anti-IL-10R monoclonal antibody was used to inhibit the effect of CD11c ^{high}CD45RB^{low} DCs and CD11c^{low}CD45RB ^{high} DCs in CD4⁺ T mixed lymphocyte reaction culture. After treatment with anti-IL-12R or anti-IL-10 monoclonal antibody in CD4 ⁺ T+CD11c^{high}CD45RB^{low} DCs or CD11c ^{low}CD45RB^{high} DCs mixed lymphocyte reaction, the inductions of these DCs on T cells were inhibited dramatically. Conclusion(s): APS might induce the differentiation of splenic DCs to CD11c ^{high}CD45RB^{low} DCs followed by shifting of Th2 to Th1 with enhancement of T lymphocyte immune function in vitro. Also, the effect of APS on T-cell differentiation to Th1 was not associated with the inhibition of IL-10 production in CD11c^{low}CD45RB^{high} DCs. © 2010 Elsevier Ireland Ltd All rights reserved.

Liu, R., et al. (2015). "Fluorometric flow-immunoassay for alkylphenol polyethoxylates on a microchip containing a fluorescence detector comprised of an organic light emitting diode and an organic photodiode." <u>Talanta</u> **134**: 37-47.

A compact fluorescence detector was constructed on a microchip from an organic light emitting diode (OLED) as the light source and an organic photodiode (OPD) as the photo-detector and was used in an immunoassay for alkylphenol polyethoxylates (APE). The OLED based on a terbium complex emitted a sharp light at the main wavelength of 546 nm with a full width at half maximum of 9 nm. The incident photo-to-current conversion efficiency (IPCE) of the OPD fabricated with Fullerene 70 (C70) and tris[4-(5-phenylthiopen-2-yl)phenyl]-amine (TPTPA) was approximately 44% for light at a wavelength of 586 nm. The performance of the fluorescence detector was evaluated for the determination of resorufin (lambda(em)=586 nm) and the photocurrent of the OPD due to the fluorescence of resorufin was proportional to the concentration of resorufin in the range from 0 to 18 micro M with a detection limit (S/N=3) of 0.6 micro M. The fluorescence detector was successfully utilized in a competitive enzyme-linked immunosorbent assay for APE, where an anti-APE antibody was immobilized on the surface of the channel of the Polydimethylsiloxane (PDMS) microchip or on the surface of magnetic microbeads. After an immunoreaction with a sample solution of APE containing a horse radish peroxidase (HRP)-labeled APE, the fluorescence of resorufin generated just after introduction of a mixed solution of Amplex Red and H2O2 was measured using the fluorescence detector. The calibration curve for the photocurrent signals of the OPD due to the fluorescence of resorufin against the logarithmic concentration of APE was sigmoidal in shape. The detection limits defined as IC80 were ca. 1 ppb and ca. 2 ppb, respectively, for the methods using the anti-APE antibody immobilized on the surface of the microchannel and in the case where the antibody was immobilized on the surface of magnetic microbeads.

Liu, S., et al. (2019). "Research progress on environmental behavior and ecological toxicity of microplastics." Journal of Agro Environment Science **38**(5): 957-969.

The ubiquitous micro-plastics pollution has received global attention in recent years. In this review, the sources, migration, distribution and ecological toxicity challenges of micro-plastics in various environment matrices are discussed and evaluated. Micro-plastics mainly originate from two sources: (1) a significant direct input of primary micro-plastics and (2) secondary micro-plastics resulting from the fragmentation of larger plastic materials. Microplastics can migrate through atmospheric, freshwater, marine and terrestrial environments. In future, uniform methods for monitoring and investigating micro-plastics should be developed and combined with the source tracking technology, to explore its environmental effects. Microplastics (including additives) can be accidentally ingested by organisms, which may cause physical damage, a wide range of biological and physiological behavior and molecular effects. Micro-plastics can pose a combined toxicity to organism, owing to its role as a vector of chemical pollutants in ecosystems. Future studies on microplastics should focus on investigating their bio-accumulation and trophic transfer up the food chain by combined isotope tracing and new molecular biology techniques, especially for the potential health risk of microplastics for human. This review will provide a rationale for the ecological risk assessment of microplastics.

Liu, S., et al. (2019). "Distribution and characteristics of microplastics in the sediments of Poyang Lake, China." Water Science and Technology **79**(10): 1868-1877.

Microplastics are considered to be a widespread environmental contaminant, posing a serious threat to the aquatic environment. We addressed this issue based on field observations and laboratory analysis of samples from Poyang Lake. We collected sediment samples from 10 sites across Poyang Lake during 2017. Data were analyzed by one-way analysis of variance (ANOVA). Results showed that the abundance of microplastics ranged from 11 to 3,153 items/kg dw in the sediment samples. Except at Nanjishan, the amount of microplastics in different periods decreased in the order: December > April > July. Microplastics with a size <1 mm were the most abundant fraction in sediments, reaching over 50%. Observations under microscope revealed four types of microplastics in Poyang Lake: fragments, films, foams and fibers. Fragments were more common in sediments. Microplastics have complex surface topography, typically including rough surfaces, porous structures, cracks and extensive damage. Energy dispersive X-ray analysis indicated that most microplastics contained Si, Na, Ca, Cl and Al. Overall, the results provided strong evidence of high levels of microplastics in Poyang Lake, suggested that the microplastics pollution status in Poyang Lake should continue to be monitored.

Liu, T., et al. (2007). "Construction of eukaryotic expression plasmid human transforming growth factor beta3 and its transfection into precartilaginous stem cells." Chinese Journal of Traumatology - English Edition **10**(5): 288-293.

Objective: To obtain seed cells for cartilage repair through constructing recombinant human transforming growth factor beta3 vector (hTGF-beta3) and transfecting it into rat's precartilaginous stem cells (PSCs). Method(s): Gene engineering technique was introduced to construct eukaryotic expression plasmid pcDNA3. 1 (+)-hTGF-beta3. PSCs of rats were isolated and purified with method of immunomagnetic microbeads. Then PSCs were cotransfected with plasmid hTGF-beta3 and pcDNA3. 1 (+)-enhanced green fluorescence protein (EGFP) by liner polyethyleneimine (PEI). And 48 hours later the transient expression of EGFP was observed under a fluorescence microscope, and the expression of hTGF-beta3 was detected with reverse transcription-polymerase chain reaction (RT-PCR) and enzyme linked immunosorbent assay (ELISA). Result(s): The sequences of the recombinants were consistent with that from Genebank. Cotransfection of EGFP provided fast visual confirmation of successful transduction. The hTGF-beta3 mRNA and protein expression could be detected by RT-PCR and ELISA. Conclusion(s): The recombinant plasmid is correctly constructed and successfully transfected into rat's PSCs, which is an important step to treat epiphyseal injury or other osteo-cartilage diseases with transgenic therapy.

Liu, X. and U. J. Krull (2006). "DNA hybridization on silica microbeads that are physically adsorbed as arrays on glass surfaces." Analytica Chimica Acta **562**(1): 1-8.

Detection of DNA hybridization was done on silica microbeads that were physically adsorbed onto glass surfaces. DNA oligonucleotide probes of approximately 20 mer size were immobilized on beads of 5 mum diameter after the microbeads were first silanized with 3-glycidoxypropyltrimethoxysilane. The suspension of silica microbeads in aqueous solution was spotted on the glass slides. After drying, the glass surface was washed with water and 1 x SSC buffer. Significant numbers of microbeads remained physically adsorbed onto the glass surfaces even after vigorous washing with buffer solution. After hybridization using approximately 200 mer PCR targets strands, the glass slides were scanned using a standard laser confocal fluorescence microscope microarray reader. The total time for completion of hybridization assays was less than 20 min for 100 nM samples of target oligonucleotide. The clinical utility of the method was demonstrated by detection of single base pair mutations in the survival motor neuron gene that is associated with the childhood disease Spinal Muscular Atrophy. The method proved to provide a readily adaptable strategy for immobilization of different probes in an array format, and provided for SNP detection on a disposable slide without cross contamination. © 2006 Elsevier B.V. Liu, X., et al. (2017). "Simultaneous photodegradation of multi-herbicides by oxidized carbon nitride: performance and practical application." Applied Catalysis. B, Environmental **219**: 194.

This work focuses on photodegradation of multi-herbicides simultaneously with series oxidized carbon nitrides (OCN), which were synthesized via a rapid acid-assisted method. Carbon nitrides, after treating with nitric acid solution at several concentrations, revealed variant oxygen content, surface morphology and structure characteristic. The photocatalytic activity was verified by degradation of ten typical herbicides in water. The influence of microplastics on the photocatalytic performance of OCN sample was investigated for the first time. Experimental results showed that microplastics contained in environmental matrix significantly influenced the photodegradation ratio. Moreover, holes (h+) and OW radicals were found to be the main reactive species during this process. The OCN-10 sample demonstrated favourable reusability in recycling tests and exhibited satisfactory degradative capability for ten investigated herbicides both in soil and aqueous phase under simulated diurnal cycle.

Liu, X., et al. (2009). "Fabrication of a microfluidic enzyme reactor utilizing magnetic beads." Electrophoresis **30**(12): 2129-2133.

An enzyme-catalyzed microfluidic assay using magnetic micro-beads is described. Here, diaphorase (DI) (E.C. 1.6.99) is covalently attached to the magnetic micro-beads (2.7 mum) and integrated into a short section of a microchip fabricated from PDMS. DI converts non-fluorescent resazurin to fluorescent resorufin in the presence of nicotinamide adenine dinucleotide phosphate (NADH). In this work, an embedded magnet holds the micro-beads in place within the microchannel while a solution of resazurin and NADH in buffer is flowed through the beads. Incorporation of the micro-beads into the microchannel requires only a few minutes and offers well-defined spatial resolution and reproducibility. At a flow rate of 41.2 microL/h, a stable state for the enzyme reaction in the microfluidic format was achieved within 50 s. The maximum conversion of the reaction was obtained at a concentration of 1.25 mM NADH. The reaction yield is affected by ZnCl(2) and at concentrations in excess of 90.0 mM, the activity of DI was almost double without ZnCl(2). At 5.2 mM potassium chloride, the activity of DI reached its maximum value. Overall, the conversion of resazurin in microfluidic format was more than twice than that in a batch assay.

Liu, X., et al. (2019). "Microplastics as Both a Sink and a Source of Bisphenol A in the Marine Environment." Environmental Science and Technology **53**(17): 10188-10196.

Microplastics were demonstrated to be an environmental sink for hydrophobic organic pollutants, while they can also serve as a potential source of such pollutants. In this study, the sorption and release of bisphenol A in marine water were investigated through laboratory experiments. Sorption and desorption isotherms were developed, and the results reveal that sorption and desorption depend on the crystallinity, elasticity, and hydrophobicity of the polymer concerned. The adsorption and partition of bisphenol A can be quantified using a dual-mode model of the sorption mechanisms. Polyamide and polyurethane were found to exhibit the highest sorption capacity for bisphenol A, and it was almost irreversible, probably due to hydrogen bonding. Polyethylenes and polypropylene exhibited high and reversible sorption without noticeable desorption hysteresis. Glassy polystyrene, poly(vinyl chloride), poly(methyl methacrylate), and poly(ethylene terephthalate) exhibited low sorption capacity and only partial reversibility. Low-density polyethylene and polycarbonate microplastic particles were for the first time proved to be a persistent source releasing bisphenol A into aquatic environments. Salinity, pH, coexisting estrogens, and water chemistry influence the sorption/desorption behaviors to different degrees. Plastic particles can serve as transportation vectors for bisphenol A, which may constitute an ecological risk. Copyright © 2019 American Chemical Society.

Liu, X., et al. (2018). "Construction of High Sensitive CD133 Immune PLGA Magnetic Spheres Platform for Lung Cancer Stem Cells Isolation and Its Property Evaluation." Journal of Biomedical Nanotechnology **14**(6): 1066-1074.

High sensitive immune CD133 PLGA magnetic spheres platform is constructed to isolate and enrich lung cancer stem cells in order to study their biological characteristics, such as their proliferation, self-renewal and invasion and metastasis in vitro. The expression of the specific transcription factors Oct 4 and Nanog genes of stem cells were detected by immunofluorescence and RT-PCR. The tumorigenic capacity of lung cancer cells were studied using the tumorigenesis experiment in nude mice in vivo. The results indicated that the CD133 immune PLGA magnetic beads (with diameter 356.25 +/- 0.64 nm) can effectively separate more lung cancer stem cells under the serum-free suspension culture compared with MACS CD133

MicroBead Kit. Some A549 cells sorted magnetically could form stable tumor suspended spheres that were able to undergo passage stably after 3 to 6 days. The self-renewal, clonal formation and invasion and metastasis capacities of the suspended spheres were higher than those of the parent cells (P < 0.05). The expressions of Oct 4 and Nanog mRNA in stem cells were significantly elevated (P < 0.05), and the A549 suspended spheres could significantly improve the in vivo tumorigenic capacity of nude mice. Among the peripheral blood of 20 patients with lung adenocarcinoma, CD133+ cells were isolated from the peripheral blood of 14 (70%), and CD133+ cells sorted from 11 (55%) patients were cultured into spheres.

Liu, X., et al. (2019). "Hydrophobic sorption behaviors of 17 beta -estradiol on environmental microplastics." Chemosphere **226**: 726-735.

Microplastics (MPs) have been regarded as a vector for contaminants and greatly affect the migration and fate of hydrophobic organic compounds (HOCs) in marine water. In this study, the sorption behavior of 17 beta -estradiol (E2) on MPs was investigated in marine water system. The sorption capacity of E2 varied greatly with the chemical structures of MPs. The adsorption or partition contribution of E2 sorption on MPs was well quantified with adsorption-partition dual-mode model mechanism. The hydrophobic partition dominantly regulates the sorption of E2 due to the high crystallinity of MPs and high accessibility of amorphous domain of rubbery MPs. Smaller particle size benefits the sorption of E2 on same kind of MPs. The salinity and dissolved organic matter (DOM) have minor effect on E2 sorption by MPs in real marine water. The result shows that the MPs greatly influence the transportation of E2 and cause potential environmental risk to marine ecosystem.

Liu, X., et al. (2019). "Transfer and fate of microplastics during the conventional activated sludge process in one wastewater treatment plant of China." Chemical Engineering Journal **362**: 176-182.

Municipal wastewater treatment plants (WWTP) are considered as a significant point source of microplastics (MPs) in the aquatic environment. The objective of this study was to investigate the transport and fate of MPs particles in one WWTP of China based on the conventional activated sludge process. The results exhibited that the abundance of MPs in wastewater declined sharply, from 79.9 n L⁻¹ in the influent to 28.4 n L⁻¹ in the effluent, with a removal rate of 64.4%. MPs removed were mostly transferred and stored into the sludge, and the abundance of MPs in dewatered sludge was 240.3+or-31.4 n g⁻¹ (dry sludge) with an average size of 222.6 micro m. Larger size fraction of MPs in the effluent was reduced compared to that in the influent due to mechanical erosion and sedimentation into sludge. Fiber and fragment were main MPs particles in four wastewater sampling sites, with the average percentage ranged from 33.5 to 56.7% and 30.4 to 45.6%, respectively. An interesting finding is that the ellipses with the size ranged from 100 to 800 micro m (average size of 348.1 micro m), seldom reported before, were abundantly seen in the influent with a percentage of 4.4%, but not observed in the effluent. A higher fraction of microbead and foam in sludge (17.1% and 12.9%) indicates MPs with the smaller size (average size of 90.3 and 240.1 micro m, respectively) in wastewater are prone to be adsorbed and transferred into sludge. Polyamide (nylon) was found to be the main plastic component in wastewater with 54.8% based on Raman spectra, indicating that the MPs particles are primarily originated from the wastewater discharged by washing clothes and polymer manufacturing and processing industries, followed by personal care products.

Liu, X., et al. (2018). "Sorption behaviors of tris-(2,3-dibromopropyl) isocyanurate and hexabromocyclododecanes on polypropylene microplastics." Marine Pollution Bulletin **135**: 581-586.

In recent years, microplastics in oceans have become a serious environmental problem and the focus of attention. In the present study, the sorption of TBC and HBCDs by microplastics in simulated seawater is examined. The effects of particle size, temperature, salinity, and concentration on the adsorption of TBC and HBCDs by microplastics are studied.

Liu, Y., et al. (2017). "Design of a Modular DNA Triangular-Prism Sensor Enabling Ratiometric and Multiplexed Biomolecule Detection on a Single Microbead." Analytical Chemistry **89**(6): 3590-3596.

DNA nanostructures have emerged as powerful and versatile building blocks for the construction of programmable nanoscale structures and functional sensors for biomarker detection, disease diagnostics, and therapy. Here we integrated multiple sensing modules into a single DNA three-dimensional (3D) nanoarchitecture with a triangular-prism (TP) structure for ratiometric and multiplexed biomolecule detection on a single microbead. In our design, the complementary hybridization of three clip sequences formed TP nanoassemblies in which the six single-strand regions in the top and bottom faces act as binding sites for different sensing modules, including an anchor module, reference sequence module, and capture sequence module. The multifunctional modular TP nanostructures were thus exploited for ratiometric and multiplexed biomolecule detection on microbeads. Microbead imaging demonstrated that, after ratiometric self-calibration analysis, the imaging deviations resulting from uneven fluorescence intensity distribution and differing probe concentrations were greatly reduced. The rigid nanostructure also conferred the TP as a framework for geometric positioning of different capture sequences. The inclusion of multiple targets led to the formation of sandwich hybridization structures that gave a readily detectable optical response at different fluorescence channels and distinct fingerprint-like pattern arrays. This approach allowed us to discriminate multiplexed biomolecule targets in a simple and efficient fashion. In this module-designed strategy, the diversity of the controlled DNA assembly coupled with the geometrically well-defined rigid nanostructures of the TP assembly provides a flexible and reliable biosensing approach that shows great promise for biomedical applications.

Liu, Y., et al. (2017). Profiling multiple cytokine levels in a mixing-enhanced microfluidic immunoassay. 2017 IEEE 12th International Conference on Nano/Micro Engineered and Molecular Systems, NEMS 2017.

We report a microfluidic immunoassay consisting of multiple precise and efficient mixing units for transient multi-cytokine detections secreted by lymphocytes. This device has an array of detection micro-chambers with each included a Taylor dispersion-based mixing unit. The sub-pico-liter bio-samples are extracted from cell culture media and mixed with cytokine-sensitive fluorescence micro-beads, which offer fluorescent signals to quantify the bound cytokines on beads, are embedded in the chambers for quantitative detection of the target cytokines. We perform experiments to verify the mixing scheme on its robustness and sensitivity. We first calibrate labeling fluorescence intensity profiles of 6 independent cytokine-sensitive beads, each conjugated with a specific antibody, using a confocal microscope for measuring the intensity. We demonstrate the high detection sensitivity for cytokine concentrations released by a human leukemic cell line (THP-1). We propose a highly integrated microfluidic immunoassay consisting the 4 × 4 independently operated detection micro-chambers that achieve high-Throughput detection functionality. Altogether, further development of this device can lead to the profiling of multiple cytokine dynamics of lymphocytes for deeper understandings of the human immune system as well as the immune diseases. © 2017 IEEE.

Liu, Y., et al. (2019). "Aggregation kinetics of UV irradiated nanoplastics in aquatic environments." Water Research **163**: 114870.

Nanoplastics (NPs) derived from degradation of macroplastics and microplastics possess potential threat to aquatic biota and human health. Their fate and transport in aquatic systems are mainly governed by aging processes and aggregation behavior. In this study, we simulated plastic aging process using UV-irradiation and compared the aggregation kinetics of fresh versus aged polystyrene NPs (PSNPs) under aqueous conditions. The results showed that fresh PSNPs had strong negative surface charge and exhibited both reaction- and diffusion-limited aggregation regimes, in agreement with classic Derjaguin-Landau-Verwey-Overbeek (DLVO) theory. Divalent electrolytes were 10-15 times more effective in inducing PSNP aggregation than monovalent electrolytes. The aging process inhibited PSNP aggregation in NaCl solutions by increasing the negative charge on PSNP surface and the organic matter content in solution, while promoted PSNP aggregation in CaCl₂ solutions due to interactions between Ca²⁺ and carboxyl groups formed on aged PSNP surface. Such distinct behaviors were consistent with characterizations by contact angle measurements, potentiometric titration, total organic carbon (TOC) analysis, Fourier Transform Infrared Spectroscopy (FTIR), and X-ray photoelectron spectroscopy (XPS). Hamaker constants obtained from DLVO fitting decreased from 3.5x10⁻²¹J for fresh PSNPs to 1.5x10⁻²¹J for aged PSNPs. This study indicated that UV-irradiation plays a vital role in governing the fate, transport, and potential hazards of PSNPs in aquatic environments.

Liu, Y., et al. (2015). "MiR-200b modulates the properties of human monocyte-derived dendritic cells by targeting WASF3." Life Sciences **122**: 26-36.

AIMS: The aim of the study was to explore the effect of miR-200b on the development of human peripheral blood monocyte-deriveddendritic-cell (DC) and its mechanisms.

MAIN METHODS: Expression levels of miR-200b and its predicted targets were measured by real time-PCR. Protein expression of WASF3 was determined by Western blot and immunohistochemistry. Human peripheral blood mononuclear cells (PBMCs) were isolated by Ficoll-Hypaque density gradient centrifugation from the buffy coat fraction of anticoagulated blood. Monocytes were purified from PBMCs using anti-CD14 microbeads. The immunophenotypes of DCs were tested by flow cytometry.

KEY FINDINGS: A strong reduction in miR-200b expression was associated with human peripheral blood monocyte-derivedDC differentiation. The overexpression of miR-200b significantly reduced the numbers of protruding veils in mature DCs (mDCs) that are critical for promoting antigen-specificT-cell activation. Further experiments showed that miR-200b could regulate the function of DCs by targeting WASF3, a protein involved in cell movement and invasion.

SIGNIFICANCE: Our results define an important function of miR-200b in the negative regulation of DC development and provide a potential form of miRNA-mediated cell therapy for diseases that range from auto-immunity to graft-versus-host disease.

Liu, Y. and Y. Li (2002). "Detection of Escherichia coli O157:H7 using immunomagnetic separation and absorbance measurement." Journal of Microbiological Methods **51**(3): 369-377.

An assay system for detection of Escherichia coli O157:H7 was developed based on immunomagnetic separation of the target pathogen from samples and absorbance measurement of p-nitrophenol at 400 nm from p-nitrophenyl phosphate hydrolysis by alkaline phosphatase (EC 3.1.3.1) on the "sandwich" structure complexes (antibodies coated onto micromagnetic beads--E. coli O157:H7-antibodies conjugated with the enzyme) formed on the microbead surface. The effects of immunoreaction time, phosphate buffer concentration, pH and temperature on the immunomagnetic separation of E. coli O157:H7 from samples were determined and the conditions used for the separation were 1-h reaction time, 1.0 x 10(-2) M PBS, pH 8.0 and 33 degrees C in this system. The effects of MgCl(2) concentration, Tris buffer concentration, pH and temperature on the activity of alkaline phosphatase conjugated on the immuno-"sandwich" structure complexes were investigated after immunomagnetic separation of the target pathogen and the conditions used for the enzymatic amplification were 1.0 x 10(-4) M MgCl(2), 1.0 M Tris buffer, pH 8.0, 28 degrees C and 30-min reaction time during the assay. The selectivity of the system was examined and no interference from the other pathogens including Salmonella typhimurium, Campylobacter jejuni and Listeria monocytogenes was observed. Its working range was from 3.2 x 10(2) to 3.2 x 10(4) CFU/ml, and the relative standard deviation was 2.5-9.9%. The total detection time was less than 2 h.

Liu, Y., et al. (2016). "Quantum-dots-encoded-microbeads based molecularly imprinted polymer." Biosensors & Bioelectronics **77**: 886-893.

Quantum dots encoded microbeads have various advantages such as large surface area, superb optical properties and the ability of multiplexing. Molecularly imprinted polymer that can mimic the natural recognition entities has high affinity and selectivity for the specific analyte. Here, the concept of utilizing the quantum dots encoded microbeads as the supporting material and the polydopamine as the functional monomer to form the core-shell molecular imprinted polymer was proposed for the first time. The resulted imprinted polymer can provide various merits: polymerization can complete in aqueous environment; fabrication procedure is facile and universal; the obvious economic advantage; the thickness of the imprinting layer is highly controllable; polydopamine coating can improve the biocompatibility of the quantum dot encoded microbeads. The rabbit IgG binding and flow cytometer experiment result showed the distinct advantages of this strategy: cost-saving, facile and fast preparation procedure. Most importantly, the ability for the multichannel detection, which makes the imprinted polydopamine modified encoded-beads very attractive in protein pre-concentration, recognition, separation and biosensing.

Liu, Y., et al. (2005). "LPS receptor (CD14): a receptor for phagocytosis of Alzheimer's amyloid peptide." Brain **128**(Pt 8): 1778-1789.

The amyloid beta peptide 42 (Abeta(42)) plays a key role in neurotoxicity in Alzheimer's disease. Mononuclear phagocytes, i.e. microglia, have the potential to clear Abeta by phagocytosis. Recently, the lipopolysaccharide (LPS) receptor CD14 was shown to mediate phagocytosis of bacterial components and furthermore to contribute to neuroinflammation in Alzheimer's disease. Here, we investigated whether this key innate immunity receptor can interact with Abeta(42) and mediate phagocytosis of this peptide. Using flow cytometry, confocal microscopy and two-photon fluorescence lifetime imaging (FLIM) combined with fluorescence resonance energy transfer (FRET), we demonstrated a direct molecular interaction in the range of a few nanometers between Abeta(42) and CD14 in human CD14-transfected Chinese hamster ovary cells. Investigations using cells that were genetically deficient for this receptor showed that in <30 minutes exogenous Abeta(42) added to cultured primary microglial cells was phagocytosed into the cytoplasmic compartment in a CD14-dependent manner. This phagocytosis occurred at Abeta(42) concentration ranges that were considerably lower than the threshold to activate a cellular inflammatory reaction. In contrast, there was no association of CD14 to microglial internalization of microbeads. In complementary clinical experiments, we detected a pronounced CD14 immunoreactivity on parenchymal microglia spatially correlated to characteristic Alzheimer's disease lesion sites in brain sections of Alzheimer's disease patients but not in brain sections of control subjects. By showing a close interaction between CD14 and Abeta(42), demonstrating a direct role of CD14 in Abeta(42) phagocytosis, and detecting CD14-specific staining in brains of Alzheimer's disease patients, our results indicate a role of the LPS receptor in the pathophysiology of Alzheimer's disease, which could be of therapeutic relevance.

Liu, Y., et al. (2019). "Ecotoxicological effects on Scenedesmus obliquus and Danio rerio Co-exposed to polystyrene nano-plastic particles and natural acidic organic polymer." Environmental Toxicology & Pharmacology **67**: 21-28.

The importance of attention to unravel the interaction of nano-plastic particles (NPs) with natural acidic organic polymer (NAOP) in freshwater environment should not be neglected. However, toxicological data available for the interaction between NPs and NAOP remain limited. Here, we investigate the toxicological effects of three model polystyrene (PS) NPs with different functional groups (unmodified, amino- and carboxyl-modified PS NPs) on two freshwater organisms of different trophic levels (Scenedesmus obliquus and Danio rerio) in the absence and presence of two classes of NAOP, namely fulvic acid and humic acid. The NAOP interaction with the NPs is shown to alter oxidative stress and disturb membrane function in S. obliquus cells to a certain extent. Combined oxidative stress responses to the NPs and NAOP in D. rerio as a function of their mixture levels showed inhibition, alleviation, and reinforce. Changes in cellular oxidative stress and membrane function depended on the concentration and types of both NPs and NAOP. Furthermore, the characterization parameters of the NPs were important for the explanation of the ecotoxicological mechanism of the NPs in the presence of NAOP. Our findings emphasized the critical role of NAOP in the fate and toxicity of plastic particles in freshwater environment. [ABSTRACT FROM AUTHOR]

Liu, Y., et al. (2006). "Highly selective determination of methylmercury with methylmercury-imprinted polymers." Analytica Chimica Acta **575**(2): 159-165.

Methylmercury-imprinted and non-imprinted polymers were prepared by formation monomer complex of methylmercury with (4-ethenylphenyl)-4-formate-6-phenyl-2,2'-bipyridine and thermally polymerizing with divinylbenzene (crosslinker) in the presence of 2,2'-azobisisobutyronitrile as initiator and subsequently leached with the acidic thiourea solution (1.0 mol L(-1) of thiourea and 4.0 mol L(-1) of HCl). In the same way, non-imprinted copolymers were prepared without methylmercury chloride added. The separation and preconcentration characteristics of the polymers for methylmercury were investigated by batch and column procedures. The results demonstrated that the methylmercury-imprinted polymers had higher adsorption capacity (170 micromol g(-1) of dry microbeads) and good selectivity for methylmercury compared to non-imprinted polymers. The distribution ratio (D) values of the methylmercury-imprinted polymers increased for methylmercury with respect to both D values of Hg(II), Cu(II), Zn(II), Cd(II) and non-imprinted polymers. The relatively selective factor (alpha(r)) values of CH3Hg+/Hg(II), CH3Hg+/Cu(II), CH3Hg+/Zn(II), and CH3Hg+/Cd(II) are 24.0, 46.7, 50.7, and 40.2, which are greater than 1. The methylmercury-imprinted polymers can be used at least twenty times with recoveries no less than 95%. Based on the packed columns with

methylmercury-imprinted polymers, a highly selective solid-phase extraction (SPE) and preconcentration method for methylmercury was developed. The metal ion imprinted polymer solid-phase extraction (MIIP-SPE) preconcentration procedure showed a linear calibration curve within concentration range from 0.093 to 22 microg L(-1). The detection limit and quantification limit were 0.041 and 0.093 microg L(-1) (3sigma) for cold vapor atomic absorption spectrometry (CVAAS). The relative standard deviation of the 10 replicate determinations was 3.5% for the determination of methylmercury in human hair sample. Determination of methylmercury in certified human hair sample (IAEA-086) and soil certified reference material (CRM 580) demonstrated that the interfering substances in matrix had been almost removed during preconcentration. The methylmercury-imprinted polymers were good enough for methylmercury determination in matrixes containing components with similar chemical property such as Hg(II), Cu(II), Zn(II), and Cd(II).

Liu, Y. Q., et al. (2018). "[Effect of HIF-2alpha on the biological characteristics of breast cancer stem cells]." Chung-Hua i Hsueh Tsa Chih [Chinese Medical Journal] **98**(4): 269-273.

Objective: To explore the effect of hypoxia inducible factor (HIF)-2alpha on biological characteristics of breast cancer stem cells (BCSCs). Methods: Stem cells were isolated and purified from MCF-7 cells by using the immunomagnetic microbeads. HIF-2alpha ORF/shRNA lentiviral vectors were transduced into MCF-7 stem cells respectively, and then the stable stem cell lines were detected and gained. Using the method of Cell Counting Kit-8 (CCK-8) and flow cytometry, the effect of HIF-2alpha on cell vitality and apoptosis of MCF-7 cancer stem cells (CSCs) were tested. Serum-free suspension culture was used on MCF-7 cells to get breast CSCs microspheres. The expression of CD44(+) in different groups were detected by flow cytometry. Tumor-bearing nude mice model was established to compare tumor growth rate and pulmonary metastasis probability of MCF-7 CSC HIF-2alpha knock up/down in vivo. Results: Compared with MCF-7 CSC group, the apoptosis rate of MCF-7 CSCs HIF-2alpha knockup group decreased obviously and cell proliferation activity increased significantly (all P<0.05). However, the MCF-7 CSCs HIF-2alpha knock down group had the opposite trend.

Liu, Z., et al. (2018). "Are exports of recyclables from developed to developing countries waste pollution transfer or part of the global circular economy?" Resources, Conservation and Recycling **136**: 22-23.

CE has benefitted the global economy for years, including China. For example, developed countries benefitted from cost savings associated with exporting waste to China where there were less stringent Chinese environmental laws, but developed countries failed to incorporate true environmental costs. China also benefitted by importing recyclable waste to supplement its domestic manufacturing industries, yet imported plastic waste was considered inferior, and often unusable (i.e., generating more waste), compared to domestic waste by China's manufacturing industries. In future, the key will be to establish fair-trading systems for waste reutilization across countries globally to reduce waste generation. Firstly, we argue that to reduce waste generation in developed countries, reduced consumption is imperative, since current per capita waste generation in developed countries is much higher than in developing countries. Developed countries, like Canada, need to adopt zero plastic waste strategies by reducing and recycling single-use plastics (Walker and Xanthos, 2018). Secondly, developed countries need to help developing countries deal with their environmental issues, caused by waste reutilization, by transferring waste management and recycling technologies, investing in R&D and training local employees to mitigate potential environmental risks. Thirdly, from a global perspective, implementing extended producer responsibility (EPR) systems across developed and developing countries to help reshape and rebalance the global CE should be undertaken. Liu, Z., et al. (2020). "Effects of nanoplastics at predicted environmental concentration on Daphnia pulex after exposure through multiple generations." Environmental Pollution **256**: 113506.

The biological effects of nanoplastics are a growing concern. However, most studies have focused on exposure to high concentrations or short-term exposure. The potential effects of exposure to low environmental nanoplastic concentrations over the long-term and across multiple generations remain unclear. In the present study, Daphnia pulex was exposed over three 21-day generations to a typical environmental nanoplastic concentration (1mug/L) and the effects were investigated at physiological (growth and reproduction), gene transcription and enzyme activity levels. Chronic exposure did not affect the survival or body length of D. pulex, whereas the growth rate and reproduction were influenced in the F2 generation. Molecular responses indicated that environmental nanoplastic concentrations can modulate the response of antioxidant defenses, vitellogenin synthesis, development, and energy production in the F0-F1 generations, and prolongation resulted in inhibitory effects on antioxidant responses in F2 individuals. Some recovery was observed in the recovery group, but reproduction and stress defenses were significantly induced. Taken together, these results suggest that D. pulex recovery from chronic exposure to nanoplastic may take several generations, and that nanoplastics have potent long-term toxic effects on D. pulex. The findings highlight the importance of multigenerational and chronic biological evaluations to assess risks of emerging pollution.

Liu, Z., et al. (2018). "Age-dependent survival, stress defense, and AMPK in Daphnia pulex after short-term exposure to a polystyrene nanoplastic." Aquatic Toxicology **204**: 1-8.

The widespread occurrence and accumulation of micro- and nanoplastics in aquatic environments has become a growing global concern. Generally, natural aquatic populations are characterized by a variety of multi-structured age groups, for which physiological and biochemical responses typically differ. The freshwater cladoceran, Daphnia pulex, is a model species used extensively in environmental monitoring studies and ecotoxicology testing. Here, the effects of a polystyrene nanoplastic on the physiological changes (i.e., survival) and expression levels of stress defense genes (i.e., those encoding antioxidant-mediated and heat shock proteins) in this freshwater flea were measured. Results from acute bioassays were used to determine the respective nanoplastic LC50 values for five age groups (1-, 4-, 7-, 14- and 21-day-old individuals): the obtained values for the 1- and 21-day-old D. pulex groups were similar (i.e., not significantly different). The expression levels of genes encoding key stress defense enzymes and proteins - SOD, CAT, GST, GPx, HSP70, and HSP90 - were influenced by the nanoplastic in all the age groups, but not in the same way for each. Significant differences were observed among all age groups in their expression of the gene encoding the energy-sensing enzyme AMPK (adenosine monophosphate-activated protein kinase) alpha , beta , and gamma following exposure to the nanoplastic. Moreover, the expression of AMPK alpha was significantly increased in the 1-, 7-, and 21-day-old individuals exposed to nanoplastic relative to the control group. Together, these results indicate that age in D. pulex affects the sensitivity of its individuals to pollution from this nanoplastic, primarily via alterations to vital physiological and biochemical processes, such as cellular energy homeostasis and oxidation, which were demonstrated in vivo. We speculate that such age-related effects may extend to other nanoplastics and forms of pollution in D. pulex and perhaps similar marine organisms.

Liu, Z., et al. (2019). "Effects of microplastics on the innate immunity and intestinal microflora of juvenile

Eriocheir sinensis." Science of the Total Environment **685**: 836-846.

The effects of microplastic exposure on the non-specific immune responses and intestinal microflora remain unclear. In this study, juveniles of the Chinese mitten crab (Eriocheir sinensis) were exposed to different concentrations of microplastics (0, 0.04, 0.4, 4, and 40 mg/L) for 7, 14, and 21 days to explore their effects. Under microplastic-induced stress, the contents or activities of most immune-related factors [haemocyanin (Hc), alkaline phosphatase (AKP), phenoloxidase (PO), lysozyme (LSZ), and acid phosphatase (ACP)] decreased after an initial increase in the low-dose or short exposure times in the haemolymph and hepatopancreas. The trends in Hc and LSZ gene expression were consistent with the corresponding changes in enzyme activities. Moreover, the haemocyte expression of caspase and MyD88 in the groups with microplastic-induced stress was higher than that in the control group, whereas the expression levels in the hepatopancreas were first increased and then decreased. Furthermore, the relative abundance of Firmicutes and Bacteroidetes decreased following exposure to 40 mg/L microplastics, whereas that of Fusobacteria and Proteobacteria increased. These results indicate that microplastics affect immune enzyme activity and immune-related gene expression and change the diversity and composition of the intestinal microflora in E. sinensis.

Liu, Z., et al. (2019). "Polystyrene nanoplastic exposure induces immobilization, reproduction, and stress defense in the freshwater cladoceran Daphnia pulex." Chemosphere **215**: 74-81.

The widespread occurrence and accumulation of plastic waste have been globally recognized as a critical issue. However, there is limited information on the adverse effects of nanoplastics on freshwater invertebrates. In this study, the effects of a polystyrene nanoplastic on physiological changes (e.g., survival, growth, and reproduction) and expression levels of stress defense genes (oxidative stress-mediated and heat shock proteins) in the freshwater flea Daphnia pulex were measured. The results showed that the digestive organs of D. pulex were strongly fluorescent after exposure to the nanoplastic particles, and the 48-h median lethal concentration (LC 50) of the nanoplastic was determined to be 76.69 mg/L. In the 21-day chronic toxicity test, dose- and time-dependent relationships were observed for body length, and the time to first eggs was significantly prolonged in the 0.5 and 1 mg/L groups. The time to clutch was delayed, and total offspring per female and number of clutches were decreased in all the treatment groups. In addition, the offspring per clutch were significantly decreased in the 0.1 mg/L group. As the nanoplastic concentration increased, expression of stress defense genes (SOD, GST, GPx, and CAT) was first induced and then inhibited. The gene expressions of heat shock proteins (HSP70 and HSP90) were induced in all the treatment groups. Our results suggest that nanoplastics can be ingested by the freshwater cladoceran D. pulex and affect its growth and reproduction as well as induce stress defense.

Liu, Z., et al. (2010). "Magnetic microbead-based enzyme-linked immunoassay for detection of Schistosoma japonicum antibody in human serum." Analytical Biochemistry **404**(2): 127-134.

A specific and sensitive immunoassay based on magnetic microbead separation for schistosomiasis japonica screening is presented in this article. So far as we know, this is the first time that magnetic microbead-based enzyme-linked immunoassay (MEIA) has been used for the determination of Schistosoma japonicum (Sj) antibody in human serum. Fluorescein isothiocyanate (FITC)-labeled soluble egg antigen (SEA) and polymer-coated magnetic beads, to which anti-FITC monoclonal antibodies were immobilized, were used as separation support in MEIA. Immunoassay parameters were optimized based on a direct immunoreaction of SEA on the magnetic microbead and Sj antibody in serum samples. The laboratory experimental results showed that the MEIA method was more sensitive and more precise than traditional SEA-ELISA

(enzyme-linked immunosorbent assay). In the field test, human sera collected from 513 infected humans and 2260 uninfected humans were tested with indirect hemagglutination assay (IHA), dipstick dye immunoassay (DDIA), and MEIA. IHA and DDIA were then compared with MEIA, and a lower false negative rate (0.97%) was obtained.

Liubartseva, S., et al. (2018). "Tracking plastics in the Mediterranean: 2D Lagrangian model." Marine Pollution Bulletin **129**(1): 151-162.

Drift of floating debris is studied with a 2D Lagrangian model with stochastic beaching and sedimentation of plastics. An ensemble of >10¹⁰ virtual particles is tracked from anthropogenic sources (coastal human populations, rivers, shipping lanes) to environmental destinations (sea surface, coastlines, seabed). Daily analyses of ocean currents and waves provided by CMEMS at a horizontal resolution of 1/16 degrees are used to force the plastics. High spatio-temporal variability in sea-surface plastic concentrations without any stable long-term accumulations is found. Substantial accumulation of plastics is detected on coastlines and the sea bottom. The most contaminated areas are in the Cilician subbasin, Catalan Sea, and near the Po River Delta. Also, highly polluted local patches in the vicinity of sources with limited circulation are identified. An inverse problem solution, used to quantify the origins of plastics, shows that plastic pollution of every Mediterranean country is caused primarily by its own terrestrial sources.

Livun, A., et al. (2010). "Significant up-regulation of CXCR4 in CD34⁺ and CD34⁻ mesenchymal stromal cells in patients with primary myelofibrosis." Haematologica **2)**: 660-661.

Background: Primary myelofibrosis (PMF) is the most aggressive stem cell derived Philadelphia chromosome-negative chronic myeloproliferative neoplasia (MPN), with average survival of 5-7 years and no effective therapy. It is characterized by bone marrow (BM) fibrosis, cytopenias, leukoerythroblastosis, teardrop poikilocytosis, extramedullary hematopoiesis, splenomegaly and elevated number of CD34⁺ cells in peripheral blood (PB). Understanding of biological abnormalities in PMF may lead to the development of new targeted therapies. Discovery of a single point mutation in the tyrosine kinase JAK2 (JAK2V617F) in MPN has revealed an abnormality contributing to the existence to these diseases, and JAK2 inhibitors are being developed clinically. Mobilization of hematopoietic progenitors from BM to spleen and liver in PMF suggests that alternations in the cross talk between hematopoietic and mesenchymal stromal cells (MSC) may also participate in disease biology. Aim(s): To assess the expression of selected group of genes in CD34⁺ BM cells, as well as BM-derived MSC, from patients with PMF, which may have a role in the biology of this disease. The genes examined included those involved in cell-stromal adhesion (SPARC, CXCR4), metabolism (COX-2, HIF1alpha), and differentiation and signaling (Pax5 and Socs3). Materials and methods. Mononuclear cells (MNC) from BM aspirates from 20 PMF patients and five healthy donors (used as a control) were cultured in aMEM medium containing 20% fetal bovine serum for 2 weeks. Adherent MSC, as well as nonadherent cells, were then collected and sorted using CD34 microbeads. Total RNA was isolated from sorted CD34⁺ and CD34⁻ cells and Q-RT-PCR was performed to measure the expression levels of SPARC, COX-2, CXCR4, FOS, Pax5 and HIF1 transcripts, with b-actin as internal control. Results were analyzed using GraphPad Prism (Kruskal-Wallis test and Dunns test). Result(s): (Table 1). There was no significant change in FOS and HIF1a expression between control and patients' MSC. COX-2 was down-regulated in CD34⁺ patients' nonadherent cells in comparison to CD34⁻ adherent patients' MSC, but in comparison to control cells there was no significant change. (Table presented) SPARC was down-regulated in patients' CD34⁺

adherent MSC in comparison to CD34⁻ control nonadherent cells. Pax5 showed statistically significant (P>0.0001) up-regulation in patients' CD34⁻ adherent MSC vs. CD34⁺ nonadherent cells. CXCR4 was significantly (P>0.0001) up-regulated in patients' CD34- and CD34⁺ adherent cells vs. patients' nonadherent MSC CD34- and CD34⁺. Conclusion. The expression ofselected genes differs in CD34⁺ and CD34⁻ adherent MSC and nonadherent cells from patients with PMF as compared to expression in cells from healthy controls. In particular, patients' MSC have significantly higher expression of CXCR4 gene that encodes a CXC chemokine receptor specific for stromal cell-derived factor-1, suggesting its role in the mobilization of hematopoietic progenitors from BM. CXCR4 is also involved in haematopoiesis, angiogenic activity, apoptosis, T-cell differentiation and phagocyte activation. Further investigation of the CXCR4 gene regulation in both adherent MSC and nonadherent mononuclear cells in PMF is warranted.

Lizard, G., et al. (2003). "Microbeads, nanobeads and cytometry: Applications to the analysis and purification of cells and biomolecules. [French]." Pathologie Biologie **51**(7): 418-427.

Nano and microspheres are important tools in cytometry. They have been used in first to optimize fluorescent signals detected by flow cytometry and to evaluate phagocytosis. Some antigens were also detected by using nanospheres covalently coupled to antibodies. Specifically dedicated microspheres are now widely used for antigenic quantitation by flow cytometry, and magnetic nano and micropheres are very usefull for cellular and molecular purifications. To date, analytical methods based on the use of microspheres are developed to detect proteins, nucleic acids, and ions. To this end, antibodies, oligonucleotides, or chelating agents are bound to microspheres characterized by different fluorescences. The applications of these multiplexed microspheres assays allow to identify and quantify simultaneously some macromolecules and ions, but they also permit to analyze enzymatic activities and to perform polymorphism analyses. With microspheres used as reactive support, molecular analyses are therefore possible by flow cytometry. Nano and microspheres are also usefull tools for calibration in confocal microscopy as well as for micromanipulations of biomolecules and of living cells. Inovative methods based on the use of nano and microspheres are expected in the fields of biology, medicine, food industry, and environmental sciences. © 2003 Editions scientifiques et medicales Elsevier SAS. Tous droits reserves.

Llorca, M., et al. (2018). "Adsorption of perfluoroalkyl substances on microplastics under environmental conditions." Environmental Pollution **235**: 680-691.

Plastic debris has become an environmental problem during recent years. Among the plastic debris, microplastics (<5mm; MPLs) imply an extra problem due to their capacity to enter into the fauna through ingestion. In this work, we study the capacity of three MPLs, that include high-density polyethylene (HDPE), polystyrene (PS) and polystyrene carboxylate (PS-COOH), to sorb 18 perfluoroalkyl substances (PFASs; including carboxylic acids, sulphonates and one sulphonamide) from the surrounding waters (freshwater and seawater).

Llorent-Martinez, E. J., et al. (2008). "Fast determination of salicylic acid in pharmaceuticals by using a terbium-sensitized luminescent SIA optosensor." Journal of Pharmaceutical Sciences **97**(2): 791-797.

In this article, we report the coupling of sequential injection analysis (SIA) and solid phase lanthanide-sensitized luminescence as a detection technique; in this technique, the energy absorbed by the analyte (retained on a solid support) is transferred to the lanthanide ion, which finally emits the luminescence signal. By using this automatic system, the determination of salicylic acid (SA) is easily, rapidly, and selectively achieved. Microspheres of commercial solid support, Sephadex-QAE A-25, are used to fill the flow-through cell and retain analyte and terbium ions; after the signal from SA-terbium complex is obtained, the solid support is easily regenerated by using an ethylenediaminetetraacetic acid disodium salt 2-hydrate (EDTA) solution. Over 200 determinations can be carried out without replacing the resin microbeads. The proposed method shows a 0.045 microg mL(-1) detection limit, with an R.S.D. lower than 3% and a sampling frequency up to 30 samples per hour. The system has been applied to the determination of SA in pharmaceuticals obtained from the Spanish Pharmacopoeia, with satisfactory results; an additional recovery study has been carried out with recoveries close to 100%.

Llorent-Martinez, E. J., et al. (2019). "Automated fluorimetric sensor for the determination of zearalenone mycotoxin in maize and cereals feedstuff." Talanta **191**: 89-93.

Zearalenone (ZEA), a mycotoxin produced by several Fusarium molds, can be found in many cereals and related products. The toxicity of ZEA has been reported for both humans and animals. Therefore, many countries have adopted regulations in foods and feed materials to limit the exposure to this contaminant. In this paper, we propose a multicommutated flow-through optosensor to quantify ZEA in different cereal samples. ZEA was retained and pre-concentrated on C₁₈ silica gel, and the use of the multicommutated flow manifold allowed the automated retention/desorption of ZEA on the solid microbeads by the use of appropriate carrier/eluting solutions, hence increasing the selectivity and sensitivity of the system. The native fluorescence of ZEA was recorded on the solid phase at lambda_{exc}/lambda_{em} of 265/465nm/nm. A QuEChERS procedure was used to carry out the extraction of ZEA from different cereal samples (feedstuff materials). Recovery studies were performed to assess the accuracy of the method, obtaining recovery yields between 93% and 107% in all the analyzed samples. LC-MS was employed as reference method. The quantitation limit of the proposed method was low enough to fulfill the maximum residue levels established by the Commission of the European Communities, thus demonstrating its potential use for the analysis of ZEA in feedstuffs.

Lloyd, J. S. (2019). "Expanding safe waste management to public health systems." The Lancet **393**(10168): 225.

Lo, H. and K. Chan (2018). "Negative effects of microplastic exposure on growth and development of Crepidula onyx." Environmental Pollution **233**: 588-595.

Microplastics exposure could be detrimental to marine organisms especially under high concentrations. However, few studies have considered the multiphasic nature of marine invertebrates' life history and investigated the impact of experiencing microplastics during early development on post-metamorphic stages (legacy effect). Many planktonic larvae can feed selectively and it is unclear whether such selectivity could modulate the impact of algal food-sized microplastic. In this two-stage experiment, veligers of Crepidula onyx were first exposed to additions of algae-sized micro-polystyrene (micro-PS) beads at different concentrations, including ones that were comparable their algal diet. These additions were then either halted or continued after settlement. At environmentally relevant concentration (ten 2-micro m microplastic beads ml⁻¹), larval and juvenile C. onyx was not affected. At higher concentrations, these micro-PS fed larvae consumed a similar amount of algae compared to those in control but grew relatively slower than those in the control suggesting that ingestion and/or removal of microplastic was/were energetically costly. These larvae also settled earlier at a smaller size compared to the control, which could negatively affect post-settlement success.

Juvenile C. onyx receiving continuous micro-PS addition had slower growth rates. Individuals only exposed to micro-PS during their larval stage continued to have slower growth rates than those in the control even if micro-PS had been absent in their surroundings for 65 days highlighting a legacy effect of microplastic exposure.

Lo, H. S., et al. (2019). "Spatial distribution and source identification of hydrophobic organic compounds (HOCs) on sedimentary microplastic in Hong Kong." Chemosphere **219**: 418-426.

The spatial distribution, composition and source of hydrophobic organic compounds (HOCs) including polyaromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs) and organochlorinated pesticides (OCPs) of the sedimentary microplastics (0.25-5mm) in Hong Kong were investigated. The concentration of SIGMAPAHs ranged between 70.8 and 1509ngg⁻¹ with inter-site differences although the regional difference was insignificant, indicating localised pyrolytic and petrogenic input of PAHs. The concentration of SIGMAPCBs (13-1083ngg⁻¹) varied with both study sites and regions with higher concentrations obtained in the western waters, possibly due to the input from Pearl River. Significantly higher concentrations of OCPs on eastern shores highlighted fishing and aquaculture activities in South China Sea a potential major source of OCPs. DDT and its metabolites (DDX, ranged from 1.96 to 626ngg⁻¹) were the dominant forms of OCPs (45%-80%). Since most of the DDX existed as DDT, this suggested that there was a fresh input of DDT into the microplastics. As microplastics and HOCs cannot be removed effectively from the environment, reduction of potential ecotoxicological risks should rely on minimizing the use of plastics and HOCs.

Löder, M. G. J., et al. (2017). "Enzymatic Purification of Microplastics in Environmental Samples." Environmental Science & Technology **51**(24): 14283-14292.

Micro-Fourier transform infrared (micro-FTIR) spectroscopy and Raman spectroscopy enable the reliable identification and quantification of microplastics (MPs) in the lower micron range. Since concentrations of MPs in the environment are usually low, the large sample volumes required for these techniques lead to an excess of co-enriched organic or inorganic materials. While inorganic materials can be separated from MPs using density separation, the organic fraction impedes the ability to conduct reliable analyses. Hence, the purification of MPs from organic materials is crucial prior to conducting an identification via spectroscopic techniques. Strong acidic or alkaline treatments bear the danger of degrading sensitive synthetic polymers. We suggest an alternative method, which uses a series of technical grade enzymes for purifying MPs in environmental samples. A basic enzymatic purification protocol (BEPP) proved to be efficient while reducing 98.3 ± 0.1% of the sample matrix in surface water samples. After showing a high recovery rate (84.5 ± 3.3%), the BEPP was successfully applied to environmental samples from the North Sea where numbers of MPs range from 0.05 to 4.42 items m-3. Experiences with different environmental sample matrices were considered in an improved and universally applicable version of the BEPP, which is suitable for focal plane array detector (FPA)-based micro-FTIR analyses of water, wastewater, sediment, biota, and food samples. [ABSTRACT FROM AUTHOR]

Loepp, D. (2009). "Is plastics recycling a cynical strategy?" Plastics News **21**(28): 6-1NULL.

The article presents the author's comments on the issues related to plastics recycling. He refers to the article "Recycling Plastic: What a Waste," by Lisa Kaas Boyle, co-founder of the Plastic Pollution Coalition. He says that Boyle criticizes the American Chemistry Council (ACC) for promoting recycling as the solution to plastic pollution. However, she says that only 5-7 percent of plastics are being recycled and the industry continues to produce single-use products, not designed to be recycled.

Lohmann, R. (2017). "Microplastics are not important for the cycling and bioaccumulation of organic pollutants in the oceans--but should microplastics be considered POPs themselves?" Integrated Environmental Assessment and Management **13**(3): 460-465.

The role of microplastic particles in the cycling and bioaccumulation of persistent organic pollutants (POPs) is discussed. Five common concepts, sometimes misconceptions, about the role of microplastics are reviewed. While there is ample evidence that microplastics accumulate high concentrations of POPs, this does not result in microplastics being important for the global dispersion of POPs. Similarly, there is scant evidence that microplastics are an important transfer vector of POPs into animals, but possibly for plastic additives (flame retardants). Last, listing microplastics as POPs could help reduce their environmental impact. Integr Environ Assess Manag 2017;13:460-465. © 2017 SETAC Key Points Microplastics accumulate POPs relative to their surroundings, acting as passive samplers, yet there are insufficient microplastic particles to affect the global cycling of POPs. Laboratory experiments exposing clean animals to POP-contaminated microplastics observe the transfer of POPs into the animals but cannot demonstrate that this pathway is relevant in the field. Field observations of POPs in animals show little evidence that the ingestion of microplastics contributed much to their body burden with the exception of plastic additives. Microplastics should be considered as POPs as they share persistence, long-range transport, potential for bioaccumulation, and adverse effects with other POPs.

Loisi, R. V., et al. (2017). "Land analysis of agricultural plastic waste production in a South Italy area by means of a geographical information system." Acta Horticulturae.

Plastic materials have been worldwide applied in agriculture for soil mulching, greenhouse covering, irrigation and drainage pipes, bags, containers, pots, and agrochemical containers. All of these plastic materials require, at the end of their lifetime, suitable collection and treatment systems. Agricultural activities in some areas of the Apulia Region, Southern Italy, are characterized by huge quantities of plastic wastes and local authorities and farmers associations have been interested in solving this problem by applying modern land management tools such as Geographical Information System (G.I.S.). In this paper a G.I.S. methodology is applied to an area of 10,200 ha in the Trani municipality, included in the Province of Barletta, Andria, Trani (BAT) - Apulia Region, in order to assess the agricultural plastic waste generation. The use of plastics at the agricultural farms has been investigated and related to the land use by applying statistical analysis, orthophoto analysis and remote sensing surveys. These data were introduced in a specific geo-database, and the agricultural plastic waste quantity and localization were defined. Vineyards and olive groves are scattered in this area, so the agricultural plastic waste mostly consists in irrigation pipes, after-use covering films and anti-hail nets used on vineyards. The analysis carried out showed that up to 614 kg ha⁻¹ of covering films waste are yearly produced in some areas while the estimation of waste from the anti-hail nets was up to 159 kg ha⁻¹ and the waste yearly produced from irrigation pipes was up to 83 kg ha⁻¹. Through the use of the G.I.S., the areas with high density of plastic wastes were pointed out thus allowing to determine the suitable location of temporary storage areas and collecting points, in order to optimize the transport of agricultural plastic waste from the farms to the collecting points and to the recycling firms.

Long, M., et al. (2017). "Interactions between polystyrene microplastics and marine phytoplankton lead to species-specific hetero-aggregation." Environmental Pollution **228**: 454-463.

To understand the fate and impacts of microplastics (MP) in the marine ecosystems, it is essential to investigate their interactions with phytoplankton as these may affect MP bioavailability to marine organisms as well as their fate in the water column. However, the behaviour of MP with marine phytoplanktonic cells remains little studied and thus unpredictable. The present study assessed the potential for phytoplankton cells to form hetero-aggregates with small micro-polystyrene (micro-PS) particles depending on microalgal species and physiological status. A prymnesiophycea, Tisochrysis lutea, a dinoflagellate, Heterocapsa triquetra, and a diatom, Chaetoceros neogracile, were exposed to micro-PS (2 mum diameter; 3.96 mug L⁻¹) during their growth culture cycles. Micro-PS were quantified using an innovative flow-cytometry approach, which allowed the monitoring of the micro-PS repartition in microalgal cultures and the distinction between free suspended micro-PS and hetero-aggregates of micro-PS and microalgae. Hetero-aggregation was observed for C. neogracile during the stationary growth phase. The highest levels of micro-PS were "lost" from solution, sticking to flasks, with T. lutea and H. triquetra cultures. This loss of micro-PS sticking to the flask walls increased with the age of the culture for both species. No effects of micro-PS were observed on microalgal physiology in terms of growth and chlorophyll fluorescence. Overall, these results highlight the potential for single phytoplankton cells and residual organic matter to interact with microplastics, and thus potentially influence their distribution and bioavailability in experimental systems and the water column.

Long, M., et al. (2011). "Advances in experiments and modeling in micro-and nano-biomechanics: A mini review." Cellular and Molecular Bioengineering **4**(3): 327-339.

Recent advances in micro-and nano-technologies and high-end computing have enabled the development of new experimental and modeling approaches to study biomechanics at the micro- and nano-scales that were previously not possible. These new cutting-edge approaches are contributing toward our understanding in emerging areas such as mechanobiology and mechanochemistry. Another important potential contribution lies in translational medicine, since biomechanical studies at the cellular and molecular levels have direct relevance in areas such disease diagnosis, nano-medicine and drug delivery. Thus, the developed experimental and modeling approaches are critical in elucidating important mechanistic insights in both basic sciences and clinical treatment. While it is hard to cover all the recent advances in this mini-review, we focus on several important approaches. For experimental techniques, we review the assays involving shear flow, cellular imaging, microbead, microcontact printing, and micropillars at the micro-scale, and micropipette aspiration, optical tweezers, parallel flow chamber, and atomic force microscopy at the nano-scale. In modeling and simulations, we outline the theoretical modeling for actin dynamics in migrating cell and actin-based cell motility in cellular mechanics, as well as the receptor-ligand binding in cell adhesion and the application of free, steered, and flow molecular dynamics simulations in molecular biomechanics. Relevant scientific issues and applications are also discussed. © 2011 Biomedical Engineering Society.

Long, R. F., et al. (2017). "The effects of weight percent solids and hydrogen ion activity on three

common mucus systems." Pediatric Pulmonology **52 (Supplement 47)**: 279.

Mucociliary clearance (MCC) is diminished in cystic fibrosis patients. Of the many factors that can contribute to poor MCC, we propose an examination of two of the parameters that have been reported to affect the rheological properties of airway mucus; free hydrogen ion activity (pH) and the weight percent solids of the mucus. In these studies, we investigated the effect of a physiological pH range (pH 6-8) over a range of mucus concentrations (% solid) of human bronchial epithelial (HBE) mucus harvested from cultured, donor cells. We anticipate that our data will help to frame the discussion of the relative importance of both factors on MCC, drug delivery and innate immunity. We present the biophysical properties of the mucus systems from the nanoscale, using fluorescence recovery after photobleaching (FRAP), to the microscale with passive microbead rheology data and a modified capillary diffusion experiment, then finally to the macroscale with a traditional rheometer. As a reference on the properties of HBE over these length scales, we also show results from two commercially available mucus research substitutes, porcine gastric mucus (PGM) and bovine submaxillary mucus (BSM) along with industry standards. In these studies, we explored multiple methodologies to adjust the pH in these three mucus systems, each with certain pros and cons that may be exploited. We have demonstrated that each type of mucus can respond drastically to pH changes. However, physiologically-relevant changes in pH (from pH 6 to 8) did not result in appreciable changes in rheology or in the diffusion of microbeads and fluorescently labelled dextrans with masses up to 70 kD. In this work, we show that the complex viscosity of the HBE mucus is largely insensitive to physiological pH changes with minimal bulk rheological property changes. We also show that, of the two parameters investigated, weight percent solids had a greater influence than pH on the bulk complex viscosity, the mean squared displacement of microbeads and the diffusion coefficients of fluorescently labelled complexes. Therefore, we conclude that weight percent solids plays a larger role in the biophysical properties of mucus than pH.

Long, Z., et al. (2019). "Microplastic abundance, characteristics, and removal in wastewater treatment plants in a coastal city of China." Water Research **155**: 255-265.

Studying the abundance, characteristics, and removal of microplastics (MPs) in wastewater treatment plants (WWTPs) in coastal cities is of great significance for understanding the impacts of human activities on the marine environment, but currently, little information on this topic is available in China. Therefore, the abundance, characteristics, and removal of MPs in seven WWTPs of Xiamen, a typical coastal city in China, are studied. Sixty samples were collected using an improved sampling method involving an electromagnetic flowmeter and a fast digital camera. The influent MPs concentration is 1.57-13.69 items/L, and it is reduced to 0.20-1.73 items/L in the effluent, indicating that 79.3-97.8% MPs is removed. Based on the daily effluent discharge and MPs removal rate, it is estimated that ~6.5x10⁸MPs are released from the seven WWTPs into the Xiamen Bay each day. The light microscopic and micro-Raman spectroscopic analysis indicates that ~62.68% of particles are plastic polymers, including polypropylene (31.6%), polyethylene (21.9%), polystyrene (10.1%), propylene/ethylene copolymer (9.2%), and polyethylene terephthalate (7.5%). The color of MPs is mainly composed of white (27.3%) and clears (25.8%). Our results show that granules (41.1%) are the dominant shape of MPs, followed by fragments (31.3%), fibers (23.7%), and pellet (3.9%). The characteristics of MPs such as sizes, shapes, and types affect the MPs removal in WWTPs. Our findings show that MPs concentration in the influent is positively correlated with the suspended solids (SS), however, in the effluent, it is associated with the WWTPs operating load, as reflected by obviously higher MP abundance in overloaded ones.

Longo, B. M. (2019). "NNA Environmental Health Committee. Microplastics & Our Health." Nevada RNformation **28**(4): 8-9.

Lonnstedt, O. M. and P. Eklov (2016). "Environmentally relevant concentrations of microplastic particles influence larval fish ecology." Science **352**(6290): 1213-1216.

Microplastic's triple threatThe billions of tons of plastics that we release into the environment for the most part do not biodegrade. But they do degrade, breaking into ever smaller particles that end up in the oceans. Lonnstedt et al. show that the impacts of these microplastics are multifold (see the Perspective by Rochman). Eurasian perch larvae exposed to microplastics were less active, less responsive to predator cues, more likely to be eaten, and less likely to thrive-preferring to eat plastic rather than their natural prey.Science, this issue p. 1213; see also p. 1172 The widespread occurrence and accumulation of plastic waste in the environment have become a growing global concern over the past decade. Although some marine organisms have been shown to ingest plastic, few studies have investigated the ecological effects of plastic waste on animals. Here we show that exposure to environmentally relevant concentrations of microplastic polystyrene particles (90 micrometers) inhibits hatching, decreases growth rates, and alters feeding preferences and innate behaviors of European perch (Perca fluviatilis) larvae. Furthermore, individuals exposed to microplastics do not respond to olfactory threat cues, which greatly increases predator-induced mortality rates. Our results demonstrate that microplastic particles operate both chemically and physically on larval fish performance and development.

Loo, J. F. C., et al. (2017). "Sample-to-answer on molecular diagnosis of bacterial infection using integrated lab--on--a--disc." Biosensors & Bioelectronics **93**: 212-219.

Sepsis by bacterial infection causes high mortality in patients in intensive care unit (ICU). Rapid identification of bacterial infection is essential to ensure early appropriate administration of antibiotics to save lives of patients, yet the present benchtop molecular diagnosis is time-consuming and labor-intensive, which limits the treatment efficiency especially when the number of samples to be tested is extensive. Therefore, we hereby report a microfluidic platform lab-on-a-disc (LOAD) to provide a sample-to-answer solution. Our LOAD customized design of microfluidic channels allows automation to mimic sequential analytical steps in benchtop environment. It relies on a simple but controllable centrifugation force for the actuation of samples and reagents. Our LOAD system performs three major functions, namely DNA extraction, isothermal DNA amplification and real-time signal detection, in a predefined sequence. The disc is self-contained for conducting sample heating with chemical lysis buffer and silica microbeads are employed for DNA extraction from clinical specimens. Molecular diagnosis of specific target bacteria DNA sequences is then performed using a real-time loop-mediated isothermal amplification (RT-LAMP) with SYTO-9 as the signal reporter. Our LOAD system capable of bacterial identification of Mycobacterium tuberculosis (TB) and Acinetobacter baumanii (Ab) with the detection limits 10³cfu/mL TB in sputum and 10²cfu/mL Ab in blood within 2h after sample loading. The reported LOAD based on an integrated approach should address the growing needs for rapid point-of-care medical diagnosis in ICU.

Loos, U., et al. (2018). "New technology for improvement of sensitivity and specificity of IVDTests." Clinical Chemistry **64 (Supplement 1)**: S124-S125.

Background: Some test systems are lacking of high sensitivity and specificity which otherwise enable early and accurate diagnosis and treatment being beneficial for the course of the

disease. This is known for Graves' disease (GD), which is caused by thyroid stimulating immunoglobulins (TSI) directed against the thyrotropin receptor (TSHR). Current TSH or M22 displacement assays (TDA) quantify indirectly all TSHR autoantibodies (Ab). We developed a direct epitope recognition assay (DERA) for sensitive detection of TSI in which the extracted capture human(h) wtTSHR chimera is anchored on microtiter plates (sTRAb) and stimulatory epitope binding TSI are bridging to a soluble signalling chimeric extracellular domain (ECD) of the hTSHR. Here we show a Bridge assay in which a novel truncated capture hTSHR can be anchored on paramagnetic microbeads (PMB). Method(s): PMB DERA is performed by bridge technology were an antibody anchors to PMB the solitary chimeric ECD of hTSHR-rLH/CG receptor fused with a secretory protein. The TSI binds with one arm to the immobilised chimeric capture hTSHR, and the second arm bridges to a chimeric hTSHR ECD fused with secretory alkaline phosphatase or HRP. Applying chemiluminescence substrate sTRAb were quantified using a plate luminometer. The PMB assay was performed manually with a 12-tube magnet. For further development, we used PMB on microtiter plates. Result(s): The chimeric ECD of hTSHR-rLH/CG receptor shows a functionality/half life of 12/15 days at 4degreeC. ROC analysis of sTRAB DERA with 274 GD positive and 325 GD negative show a criterion for positivity > 0.54 IU/L with a sensitivity of 99.8 % and a specificity of 99.1 % in the assay. The PMB assay performed manually with a 12-tube magnet enabled ROC analysis of 190 samples (136 GD positive, 54 GD negative) and shows a criterion for positivity > 1.5 IU/L with a sensitivity of 94.1% and a specificity of 98.2%. In comparison the sensitivity/specificity/cut off from the following tests: Roche Elecsys, cobas anti-TSHR 97.0%/99.0%/>1.75 IU/L; Thermo Brahms Kryptor: 96.3%/98.1%/>1.80 IU/L; Immunite 2000/XPi TSI: 98.3%/99.7%/>0.55 IU/L; sTRAb-DERA: 99.8%/99.1%/>0.54 IU/L; PMB-Bridge-assay 94.1%/98.2%/>1.50 IU/L. Further preliminary experiments with PMB performed on microtiter plates using the signaling hTSHR-ECD-HRP as detection receptor show a calibration curve reaching a clinical cut off of 0.2 IU/L. These results on microtiter plates are a basis for the development of automation for the PMB Bridge assay. Conclusion(s): For the first time an immobilized chimeric hTSHR ECD is shown to be excellently used on PBM in a Bridge assay which as a further innovation works with two secreted TSHR ECDs. Further improvement of technical statistics (sensitivity and specificity) is expected by transferring this prototype to fully automatic systems. Together with the good stability data automatization will improve sensitivity and specificity in comparison to other current IVD-assays by a novel technology. Further, we wish to apply this method for other autoimmune diseases such as diabetes type 1 in future cooperative studies. Also in diabetes type 1, early diagnosis and treatment will lead to less severe course of the disease.

Lopalco, A., et al. (2020). "Taste masking of propranolol hydrochloride by microbeads of EUDRAGIT R E PO obtained with prilling technique for paediatric oral administration." International Journal of Pharmaceutics **574**: 118922.

The purpose of this study was to develop a new solid paediatric formulation for propranolol hydrochloride (PR). This drug is used to treat various paediatric diseases, and recently received clearance to treat haemangioma. However, PR has a bitter salty taste that does not facilitate high rates of compliance among children, especially in liquid formulations. In addition, the solid formulations are designed for adults and often their dosage is not suitable for children that require a flexible dose based on their weight. Therefore, matrix microbeads of EUDRAGIT R E PO containing PR were manufactured to overcome these limitations. Nine different samples were prepared using the prilling-congealing technique with high yield. Using 2 nozzles, 300 and 450 mum (code n), the diameters obtained of microbeads (from 333 to 699 mum) were homogenous and appropriate to be swallowed by children. In this study, the ratio drug:matrix for the microbeads was also examined in detail: 1:25 (F₁), 1:15 (F₂) and 1:10 (F₃) in aqueous and tert-butyl alcohol/aqueous (code t) media. Most of the examined microbeads were characterized by high percentage of encapsulation efficiency (22-100%) and drug loading (22-77 mg of drug per g of matrix) effective for the administration of low and high doses of PR. SEM analysis revealed a matrix with a radial or a spongy structure, with numerous pores that generated soft floating microbeads in aqueous solution. Release studies confirmed a low release and dissolution of the drug in artificial saliva, mainly F_{1n} > F₁ > F_{2nt}, and a prompt dissolution in simulated gastric media. Finally, electronic tongue measurements revealed the ability of these formulations to mask the bitter drug taste, especially for the sample with a ratio 1:25 (F_{1n} and F₁). These samples were chemically and physically stable for six months. In conclusion, the projected microbeads F₁, and F_{1n} reached the goal of the study, and could be proposed as new solid oral formulations dedicated to use by children.

Lopes, L. B., et al. (2010). "Impact of using different laboratory assays to detect human leukocyte antigen antibodies in female blood donors." Transfusion **50**(4): 902-908.

BACKGROUND: HLA antibodies passively transferred to transfused recipients may cause transfusion reactions such as transfusion-related acute lung injury (TRALI), but in many of the reported TRALI incidents, no white blood cell antibodies have been identified. We investigated whether a higher number of anti-HLA would be detected in donor's plasma by using a method with potential higher sensitivity rate.

STUDY DESIGN AND METHODS: Sera from 300 previously pregnant female blood donors were screened for anti-HLA using a solid-phase mixed-antigen assay (enzyme-linked immunosorbent assay [ELISA]). Samples from 60 women with three or more pregnancies with a negative ELISA were further tested using microbead-flow assays (LABScreen mixed, panel-reactive antibodies [PRA], and single antigen).

RESULTS: Anti-HLA Class I and/or Class II were detected by ELISA in 26.7% (80/300) of all women and in 37.0% (37/100) of women with three or more pregnancies. The LABScreen assays detected additional anti-HLA specificities (44 Class I and 17 Class II) in 28.3% (17/60) of ELISA-negative donors with three or more pregnancies. HLA antibodies were detected in 8.3% (5/60), 18.3% (11/60), and 21.7% (13/60) of ELISA-negative women by LABScreen mixed, PRA, or single antigen, respectively.

CONCLUSION: Our data showed that the microbead-flow detected more HLA antibodies than ELISA, but the clinical significance of these antibodies is currently unknown. Detecting anti-HLA is useful for donor management and could contribute to the decision to definitively defer blood donors involved in TRALI incidents. However, further studies are necessary to better determinate the relative risk of TRALI induced by anti-HLA detected only by techniques with higher sensitivity rate.

Lopes, L. B., et al. (2017). "Evaluation of labscreen multi in the detection of antibodies against the HNA-3 system." Vox Sanguinis **112 (Supplement 1)**: 235.

Background: Antibodies directed to human neutrophil antigens 3a (HNA-3a) have been involved in fatal transfusion-associated acute lung injury (TRALI) reactions. For the HNA-3a antibody detection, the gold-standard method is the Granulocyte Agglutination Test (GAT); however, it is a time-consuming methodology. The new generation LABScreen-MULTI assay (LSM) kit (One Lambda, Inc.) is suitable for high-throughput testing and automating, using microbeads coated with HLA and all HNA antigens, including HNA-3a and -3b. Aim(s): Considering that the LSM is a recently developed commercial platform, this study aimed to evaluate its ability to detect anti-HNA-3a and -3b. Method(s): Thirty-six samples, tested by the LSM (Lots 005 and 007), were included in the study, comprising 13 pregnant women, 12 multiparous blood donors, 4 alloimmunized patients with multiple antibodies, and 7 mothers whose newborns had neonatal neutropenia. The cutoff value was set to 5 NBG (Normalized Background Ratio) for the HNA-3a and -3b beads. Results of the LSM were confirmed by the HNA-3 genotyping and by the GAT, using a panel specific for HNA-3 antigens. Result(s): LSM screening resulted in 31 samples with positive results for 3a and/or 3b beads, and 5 samples with negative results. 28/31 samples were considered falsepositive because they presented negative results in the GAT and, in some cases, also presented discordant results with the genotyping. The false-positive reactions were observed on 3a and -3b beads, and in 10 samples occurred for both beads concomitantly. 24/28 false-positive samples presented NBG of 5 to 15 and Mean Fluorescence Intensity (MFI) values below 1,000; and 4/28 presented high NBG values, between 20 and 80, and MFI values, between 1,150 and 3,900. 3/31 samples were considered true-positive, and the antibodies were confirmed by positive results in 1 sample for anti-HNA-3a, and in 2 samples for anti-HNA-3b in the GAT. It is important to highlight that the anti-HNA-3a sample had a false-positive result with 3b bead (NBG = 17.6, MFI = 1,711), and 1 sample with anti-HNA-3b presented a falsepositive result with 3a bead (NBG = 83, MFI = 4,313). False-negative results in the LSM were observed in 5 samples, since anti-HNA-3b was detected by the GAT, and their results were compatible with the HNA-3 genotyping. Summary/Conclusions: HNA-3 antibodies are highly agglutinating, therefore, the GAT was chosen as a parameter to evaluate the results obtained in the LSM. Anti-HNA-3 was confirmed by the GAT in only 3/36 (8.3%) samples. False-negative results were observed just for the 5/36 (13.9%) samples tested with Lot 005. Considering that most samples (28/36 - 77.8%) presented false-positive reactions, we suggest a careful analysis of the results presenting an NBG variation from 5 to 15 and MFI less than 1,000. The analysis of the discordant results between the GAT and the LSM lead us to two possible conclusions: (i) Really false-positive results in the LSM due to inconsistencies with genotyping; and (ii) False-negative results in the GAT due to low titre and/or low agglutinating capacity. These antibodies cannot be disregarded in view of their possibility to induce TRALI by directly binding to the pulmonary endothelium.

Lopez, C. A., et al. (2010). "Characterization of HIV-1 RNA forms in the plasma of patients undergoing successful HAART." Archives of Virology **155**(6): 895-903.

An assay to characterize plasma human immunodeficiency virus 1 (HIV-1) sequences for patients with low viral loads was developed by combining the selective binding of anti-CD44 MicroBeads with a nested RT-PCR targeting the env C2V4 region. Sequences were obtained from 10 of 20 HIV+ patients who had viral loads below 48 copies/ml. Sequences derived from plasma were compared to those from CD14+ CD16 +monocytes and CD4+ T cells. The plasma sequences were most closely related to those amplified from monocytes, suggesting that during successful antiretroviral therapy, the predominant plasma virus originates from myeloid cells. By characterizing HIV-1 RNA sequences from 8 ml of plasma while avoiding multiple steps, which can lead to contamination and deterioration, this method can help elucidate the viral forms in patients with therapeutically suppressed HIV-1. Understanding the source of residual viremia is crucial in developing approaches for viral eradication.

Lopez de Dicastillo, C., et al. (2016). "Antioxidant films based on cross-linked methyl cellulose and native Chilean berry for food packaging applications." Carbohydrate Polymers **136**: 1052-1060.

Development of antioxidant and antimicrobial active food packaging materials based on biodegradable polymer and natural plant extracts has numerous advantages as reduction of synthetic additives into the food, reduction of plastic waste, and food protection against microorganisms and oxidation reactions. In this way, active films based on methylcellulose (MC) and maqui (Aristotelia chilensis) berry fruit extract, as a source of antioxidants agents, were studied. On the other hand, due to the high water affinity of MC, this polymer was firstly cross-linked with glutaraldehyde (GA) at different concentrations. The results showed that the addition of GA decreased water solubility, swelling, water vapor permeability of MC films, and the release of antioxidant substances from the active materials increased with the concentration of GA. Natural extract and active cross-linked films were characterized in order to obtain the optimal formulation with the highest antioxidant activity and the best physical properties for latter active food packaging application.

Lopez Zambrano, M., et al. (2013). "Thrombin modulates the expression of a set of proinflammatory genes including tissue factor in human monocytes." Journal of Thrombosis and Haemostasis **2)**: 741.

Background: Besides its role in blood coagulation, thrombin is known to act as a cell signaling molecule via activation of protease-activated receptors (PAR), thereby connecting this coagulation protease to specific cellular/inflammatory responses. Previous studies demonstrated that thrombin is capable of modulating chemotaxis of monocytes and also inducing expression of monocyte chemotactic protein (MCP-1), plasminogen activator inhibitor type 2 (PAI-2), matrix metalloproteinase- 9 (MMP-9) or interleukin (IL) eight in monocytes. However, no study has analyzed the gene expression changes of thrombin-stimulated monocytes in a systematic way using microarray experiments. Aim(s): The aim of this work was to evaluate the gene expression profile of thrombin-stimulated monocytes by microarray technology. Method(s): Peripheral blood mononuclear cells (PBMC) were isolated from human blood by density gradient centrifugation using Ficoll- Paque PLUS and affinity adsorption using anti-CD14 monoclonal antibody-coated microbeads combined with a magnetic cell separation system. Monocytes were stimulated with 10 U/mL human alphathrombin at 37 degreeC for 5 h, and after washing cells, total RNA was isolated using the RNeasy mini Kit (Qiagen). Labeled cRNAs were hybridized to the Whole Human Genome Oligo Microarray Kit 4x44K v2), including cRNA fragmentation, hybridization (Agilent Technologies, protocol V5.7). Slides were scanned on the Agilent Micro Array Scanner G2565CA. DAVID database (http://david.abcc. ncifcrf.gov) was used to dynamically assign gene expression data to the Gene Ontology (GO) biological-process categories. Result(s): Eighty-three genes were selected which showed differential expression changes; 68 genes were up-regulated whereas 15 genes were down-regulated. Near 30% of the upregulated genes were related to the inflammatory response. Thus, genes encoding several cytokines and chemokines, associated with the recruitment and activation of leukocytes, were differentially expressed in monocytes in response to thrombin. Moreover, the gene for tissue factor was also up-regulated. Real-time reverse transcriptase polymerase chain reaction (RT-PCR) was used to confirm the microarray results of some of these genes. Moreover, higher expression of tissue factor in monocytes exposed to thrombin was also demonstrated by immunofluorescence and by shortening of clotting time. Conclusion(s): Our results provide new evidences to the thrombin-mediated link between coagulation and inflammation through changes in gene expression in monocytes.

Lopez-Hernandez, R., et al. (2015). "Killer immunoglobulin-like receptor (KIR) repertoire and HLA class i ligands analysis in a caucasian spanish population with inflammatory bowel diseases." Tissue Antigens **85 (5)**: 390.

Alterations in several immunological molecules are implicated in inflammatory disorders, including IBD (Inflammatory Bowel Disease) [Crohn s disease (CD) and ulcerative colitis (UC)]. A further group of genetically variable proteins involved in immune function are the killer cell immunoglobulin-like receptors (KIRs). These are expressed by NK cells and certain T lymphocytes where they regulate specificity and function by interaction with HLA Class I molecules. KIRs may either be inhibitory or activating and are polymorphic both in terms of alleles and haplotype gene content. Genetic associations of activating KIRs with certain autoimmune and inflammatory diseases have been demonstrated. There are several conflicting articles of KIR association with IBD and their relationships seem to be unclear. The aim of this study was to determine the relationship between KIR repertoire and the IBD pathologies in a Spanish population. KIR and HLA-C variability analysis was performed using PCR-SSOP by using a microbeads Luminex assay. We found an increase in activating KIR2DL5 in UC and IBD patient groups respect to Controls (P=0.028 and P=0.01, respectively) and in the same manner an increase in inhibitory KIR2DS1 (P=0.02, UC vs Controls; P=0.001, IBD vs Controls; P=0.01, Controls vs CR), KIR2DS5 (P=0.0028, Controls vs UC; P=0.0001, Controls vs IBD; P=0.01, Controls vs CR) and KIR3DS1 (P=0.012, Controls vs IBD). Our data suggest that the imbalance between activating and inhibitory KIR and HLA ligands may contribute, at least in part, to the differential pathogenesis of these inflammatory bowel diseases.

Lopez-Hernandez, R., et al. (2011). "Study of SNPS (-238G/A and -308G/A) in the tumour necrosis factor alpha (TNF-A) promoter gene and response to the TNF-alpha inhibitor infliximab in patients with inflammatory bowel disease." Tissue Antigens **77 (5)**: 495.

TNF-alpha is a key cytokine known to play a role in inflammatory response, and the locus for the gene is found in the IBD3 region on chromosome 6p21, known to be associated with an increased risk for inflammatory bowel disease (IBD). TNFalpha/ TNF receptor interactions not only play a pivotal role in the pathogenesis of the inflammatory response, but also cause apoptosis, cell proliferation and differentiation. Alterations in the regulation of TNF-alpha, especially TNF-alpha over-production, have been implicated in a variety of symptoms associated with autoimmune disorders, including IBD, and especially Crohn disease (CD). Indeed, a common treatment of CD is the use of TNF-alpha inhibitors such as the monoclonal antibody, infliximab (IFX). Several Single Nucleotide Polymorphisms (SNPs) in the TNF-alpha promoter region are known to affect the level of gene expression (e.g., -238GA and -308GA). Such variations in the TNF-a promoter region have previously been associated with susceptibility to a range of autoimmune disorders, including asthma, psoriasis and rheumatoid arthritis. The -238G/A SNP is associated with lower production of TNF-a in patients with Ulcerative colitis (UC). Conversely, the -308A allele is associated with enhanced TNF-alpha production in cells in vitro and in CD patients. Thus, the aim was to investigate the role that these SNPs in the TNF-a promoter gene play in the risk of IBDs in a Spanish population and the individual response to IFX treatment. DNA samples from 90 patients with IBD and 154 randomly selected controls from the Murcia Region (Spain) were screened for TNF-a -238G/A and -308G/A SNPs by PCR-SSOP method using a microbeads luminex assay (Gen-Probe, San Diego, CA). There were not any statistical differences in individual -238G/A and -308G/A allele and genotype frequencies between patients with CD, UC, IBD and healthy control groups for each studied polymorphism. The study of combinations between the two polymorphisms and the different pathologies were also not statistically significant. Indeed, the comparisons of allele and genotypes frequencies with respect to the treatment with the TNF-a inhibitor, IFX, were also not significant. In conclusion, TNF-a promoter gene polymorphism does not seem play a role in susceptibility and response to TNF-a inhibitor IFX treatment in IBD patients.

Lopez-Hernandez, R., et al. (2015). "Pro- and anti-inflammatory cytokine gene single-nucleotide polymorphisms in inflammatory bowel disease." International Journal of Immunogenetics **42**(1): 38-45.

Anti-inflammatory cytokines have an important role in disease, tumour and transplant processes. Alterations in the regulation of several cytokines have been implicated in a variety of inflammatory disorders, including IBD (inflammatory bowel disease) [Crohn's disease (CD) and ulcerative colitis (UC)]. Cytokine polymorphisms are also known to affect the level of gene expression. Thus, the aim of this study was to determine the relationship between cytokine polymorphisms and the IBD pathologies in a Spanish population. Polymorphisms analysis was performed using PCR-SSOP using a microbeads luminex assay. The following polymorphisms were determined: TNFalpha [-238G/A (rs361525) and -308G/A (rs1800629)], IFNgamma [+874A/T (rs62559044)], TGFbeta [+869C/T (rs1982073) and +915G/C (rs1800471)], IL10 [-1082A/A (rs1800896), -592A/C (rs1800872), -819C/T (rs1800871)], IL6 [-174C/G (rs1800795)], IL12p40 [3'UTR -1188A/C (rs3212227)], IL1alpha [-889C/T (rs1800587)], IL1beta [-511C/T (rs1143634) and +3962C/T (rs1143633)], IL1R [Pst-1 1970C/T] and IL1RA [Mspa-1 11100C/T]. No statistical differences in TNFalpha, IFNgamma, TGFbeta, IL10, IL6, IL1alpha, IL1beta, IL1R and IL1Ra genotypes and allele distributions between the IBD groups and healthy controls were found. However, we observed significant differences in the 3'UTR -1188A/C polymorphism of IL12p40. So -1188A allele was increased in patients with UC and the -1188C allele (high IL12p40 production) was increased in patients with CD with respect to controls. These data are in concordance with the fact that CD has been shown to be associated with a Th1 T-cell-mediated inflammation model and high IL12/IFNgamma production at histological affected sites. These data suggest that cytokine polymorphisms in TNFalpha, IFNgamma, TGFbeta, IL10, IL6 and IL1alpha, IL1beta, IL1R and IL1Ra cytokine gene do not seem to be relevant in IBD susceptibility and IL12p40 3'UTR -1188A/C polymorphism seems to be associated with a differential IBD development.

Lopez-Hernandez, R., et al. (2014). "Genetic polymorphisms of tumour necrosis factor alpha (TNF-alpha) promoter gene and response to TNF-alpha inhibitors in Spanish patients with inflammatory bowel disease." International Journal of Immunogenetics **41**(1): 63-68.

Tumour necrosis factor alpha (TNF-alpha) has an important role in inflammatory response. Alterations in the regulation of TNF-alpha have been implicated in a variety of inflammatory disorders, including Inflammatory bowel disease (IBD). Indeed, a common treatment for IBD is the use of TNF-alpha inhibitors. Polymorphisms in the TNF-alpha promoter region are known to affect the level of gene expression. Our aim was to investigate the influence of these single nucleotide polymorphisms (SNPs) in TNF-alpha promoter gene play in the risk of IBD in a Spanish population and their individual response to anti-TNF-alpha treatment. DNA samples from patients with IBD and controls were screened for TNF-alpha -238G/A (rs361525) and -308G/A (rs1800629) SNPs by PCR-SSOP using a microbeads luminex assay and compared with response to TNF-alpha inhibitors. There were not statistical differences in -238G/A and -308G/A allele and genotype frequencies between patients. However, we found an increased frequency of -308A allele and -308GA genotype in these nonresponders patients to TNF-alpha inhibitors with respect to responders patients ($P_c < 0.05$). This -308GA genotype has been classified as high producer of this cytokine. This fact could actually be interesting to explain the different response of patients with IBD with respect to TNF-alpha inhibitors. TNF-alpha promoter gene polymorphism does not seem to play a role in IBD susceptibility, but particular TNF-alpha genotypes may be involved in the different responses to TNF-alpha inhibitor treatment in Spanish patients with IBD.

Lopez-Iglesias, A. A., et al. (2015). "Prognostic implications of PIM-2 expression in samples from patients with chronic lymphocytic leukemia and impact in the sensitivity to the pan-PIM kinase inhibitor PIM447." Blood **126 (23)**: 2923.

Background and objectives. PIM kinases (PIM1, PIM2, PIM3) are proteins known to be overexpressed in several hematological malignancies. In particular, in chronic lymphocytic leukemia (CLL) they are involved in cell survival, resistance to apoptosis (especially PIM2 and PIM3) and interactions with the microenvironment (PIM1). The aim of this study was dual: I) to evaluate the preclinical efficacy of PIM447, a pan PIM kinase inhibitor, in CLL and to study potential synergies with other drugs; and II) to evaluate the expression of PIM-kinases in different stages of the disease and correlate it with the prognosis and the sensitivity to the drug. Methods. Peripheral blood samples from untreated patients with different stages of the disease (monoclonal B lymphocytosis (MBL), stable CLL not requiring treatment (sCLL), and active CLL requiring treatment (aCLL)) were collected after informed consent. The ex vivo efficacy of PIM447 was analyzed by flow cytometry with annexin V in these samples. Moreover, PIM447 efficacy was also analyzed in two cell lines (MEC-1 and JVM-2) by MTT assay. Synergy with other drugs effective in CLL (bendamustine and fludarabine) was evluated with the calcusyn software. Protein levels of PIM Kinase proteins were evaluated by capillary electrophoresis immunoassay (WESTM ProteinSimple) in monoclonal B cells purified by CD19 selection with anti-CD19 magnetic microbeads and the autoMacs Cell separator (both from Miltenyi Biotec) from a subset of patients. Results. The pan PIM inhibitor, PIM447 was active in both cell lines tested, MEC-1 (IC50 5muM) and JVM2 (IC50 7muM), and also in monoclonal B cells from freshly isolated patients samples (sCLL=11; aCLL=5), with no difference in sensitivity between the different stages of the disease (IC50 of 4,8 muM and 4,7 muM for sCLL and aCLL respectively). There was a clear therapeutic window as treatment with PIM447 at doses toxic for monoclonal B cells, preserved T lymphocytes (figure 1) (median % of apoptosis for B cells and T lymphocytes respectively of 23 vs 20 at 5muM and 87 vs 35 at 10 muM). Moreover, PIM447 demonstrated to potentiate the activity of both bendamustine and fludarabine, being especially synergistic with this last one (combination index 0.1-0.6). A second objective was to analyze PIM2 protein expression by western blot in monoclonal B cells from these samples and correlate it with clinical and biological features. Up to now, it has been evaluated in 18 samples (MBL=4; sCLL=8; aCLL=6,). All of them expressed PIM-2. Expression levels of this protein were significantly higher in active CLL as compared with indolent stages of the disease (p=0,012). Patients with an unmutated IGHV status also displayed higher levels of PIM2 (p=0,01). Finally, samples with high PIM2 levels were slightly more resistant to PIM447 as compared with samples with lower protein levels (IC50 of 7,7 muM vs 5 muM, respectively). We are currently completing the analysis of the PIM2 levels of remaining samples and we are also measuring the levels of PIM1 protein, what will be available at the meeting. Conclusion(s): PIM-Kinase inhibition with PIM447 is effective in vitro in CLL cell lines and ex vivo in samples from patients. It synergizes with other agents especially fludarabine. PIM2 protein levels correlated with the clinical activity of CLL and with the mutational state of IGHV. Although all patients appear sensitive ex vivo to PIM447, further work is required to define PIM2 expression as a marker of sensitivity. (Figure Presented).

Lopez-Marin, J., et al. (2012). "Study of degradable materials for soil mulching in greenhouse-grown lettuce." Acta Horticulturae **952**: 393-398.

The benefits associated with use of plastic mulches include higher yields, earlier harvests, improved weed control and increased efficiency in the use of water and fertilizers. However, the plastic has a negative effect on the environment. After the crop is picked, the plastic waste must be removed from the field. In the last few years, the use of starch-based biodegradable and

oxo-biodegradable films have been introduced as an alternative to conventional mulches. These materials can be incorporated into the soil at the end of the crop season and undergo biodegradation by soil microorganisms. A year study was conducted to determine the response of a lettuce crop to six mulch materials (2 low density polyethylene films (LDPE), 2 oxo-biodegradable and 2 biodegradable) in a greenhouse in South East Spain. Harvest was carried out 45 days after transplanting and the following variables were determined: fresh and dry weight of the aerial part, number of leaves per plant, plant height and the longitudinal and transverse diameters of the plant. Biodegradable and oxo-biodegradable films showed an agronomic behaviour equal to LDPE. The degradation time of oxo-biodegradable films was longer than biodegradable films. The evaluation of the performance in the field showed that the biodegradable films are as suitable for protected cultivation as LDPE.

Lopez-Rojo, N., et al. (2019). "Microplastics have lethal and sublethal effects on stream invertebrates and affect stream ecosystem functioning." Environmental Pollution **259**: 113898.

Microplastics (MPs) are contaminants of increasing concern due to their abundance, ubiquity and persistence over time. However, knowledge about MP distribution in fresh waters and their effects on freshwater organisms is still scarce, and there is virtually no information about their potential influence on ecosystem functioning. We used a microcosm experiment to examine the effects of MPs (fluorescent, 10-mum polystyrene microspheres) at different concentrations (from 0 to 10³ particles mL⁻¹) on leaf litter decomposition (a key process in stream ecosystems) and associated organisms (the caddisfly detritivore Sericostoma pyrenaicum), and the extent to which MPs were attached to leaf litter and ingested and egested by detritivores, thus assessing mechanisms of MP trophic transfer. We found that MPs caused detritivore mortality (which increased 9-fold at the highest concentration) but did not affect their growth. Analysis of fluorescence in samples suggested that MPs were rapidly ingested (most likely through ingestion of particles attached to leaf litter) and egested. Leaf litter decomposition was reduced as a result of increasing MP concentrations; the relationship was significant only in the presence of detritivores, but microbially-mediated decomposition showed a similar trend. Our findings provide novel evidence of harmful effects of MPs on aquatic insects and stream ecosystem functioning, and highlight the need for the standardization of methods in future experiments with MPs in order to allow comparisons and generalizations.

Lorenz, C., et al. (2019). "Spatial distribution of microplastics in sediments and surface waters of the southern North Sea." Environmental Pollution **252**: 1719-1729.

Microplastic pollution within the marine environment is of pressing concern globally. Accordingly, spatial monitoring of microplastic concentrations, composition and size distribution may help to identify sources and entry pathways, and hence allow initiating focused mitigation. Spatial distribution patterns of microplastics were investigated in two compartments of the southern North Sea by collecting sublittoral sediment and surface water samples from 24 stations. Large microplastics (500-5000 mum) were detected visually and identified using attenuated total reflection (ATR) Fourier transform infrared (FTIR) spectroscopy. The remaining sample was digested enzymatically, concentrated onto filters and analyzed for small microplastics (11-500 mum) using Focal Plane Array (FPA) FTIR imaging. Microplastics were detected in all samples with concentrations ranging between 2.8 and 1188.8 particles kg⁻¹ for sediments and 0.1-245.4 particles m⁻³ for surface waters. On average 98% of microplastics were <100 mum in sediments and 86% in surface waters. The most prevalent polymer types in both compartments were polypropylene, acrylates/polyurethane/varnish, and polyamide. However, polymer composition differed

significantly between sediment and surface water samples as well as between the Frisian Islands and the English Channel sites. These results show that microplastics are not evenly distributed, in neither location nor size, which is illuminating regarding the development of monitoring protocols. Capsule: Microplastic concentrations and compositions differ significantly between environmental compartments. Geographic distribution patterns are revealed by a statistical approach. Microplastics <500 mum are more abundant and diverse than >500 mum ones, rendering the exclusive analysis of later ones insufficient for environmental risk assessment. Copyright © 2019 Elsevier Ltd

Lorenzi, L., et al. (2020). "Plastic floating debris along a summer-winter estuarine environmental gradient in a coastal lagoon: how does plastic debris arrive in a conservation unit?" Environmental Science & Pollution Research **15**: 15.

Improper management of plastic waste is an important contributor to the pollution in water bodies. However, how floating plastic debris is transported to coastal lagoons and marine conservation units is still poorly understood. This work determined the level of contamination due to floating plastic debris in Acarai Lagoon by establishing density distribution patterns along the lagoon ecocline in the winter and summer. Four areas were chosen that followed the estuarine gradient of the lagoon (external, lower, middle, and upper), and in each area, three samples of were collected by trawling with a plankton net. The plastic debris was classified into paint fragments, hard solids, plastic filaments, and soft plastics, and the plastic debris density and surface area were determined in each sampling area. The concentrations of the plastics in the downstream and upstream areas resulted from the high density of debris that occurred during the winter due to the absence of rain and the entry of coastal waters into the lagoon. The reduced abundance and surface area of the plastics in the summer were related to the substantial output of water from the interior of the lagoon to the mouth of the lagoon due to high rainfall during this season. The absence of plastic waste management actions and developed areas at the mouth of the lagoon that were associated with the spatial and temporal fluctuations in the environmental variables favored the occurrence and high abundance of plastic debris in the water column, contaminating the entire system of Acarai State Park.

Losada, C., et al. (2012). "Can MACS as a sperm preparation technique improve clinic results in patients with Kartagener syndrome?" Human Reproduction. Conference: 28th Annual Meeting of the European Society of Human Reproduction and Embryology, ESHRE **27**(SUPPL. 2).

Introduction: Kartagener syndrome (KS) is an autosomal recessive genetic disorder, affecting approximately one out of every 15,000 live births. This congenital disease belongs to Ciliary Dyskinesia Syndromes (CDS), characterized by the presence of several symptoms, such as chronic sinusitis, bronchiectasis, situs inversus and infertility, secondary to structural or functional defects in the action of the motile cilia. Male infertility is due to partial or total immotility of the spematozoon flagellum by verified mutations in at least two genes that encode dynein protein, DNAH5 and DNAI1, located on chromosomes 5 and 9 respectively. Recently, a novel procedure called Magnetic-Activated Cell Sorting (MACS) has been used as a non-invasive method in different fields to reduce the percentage of apoptotic cells. This sperm selection technique is based on the high affinity of Annexin V for phosphatidylserine, which is located on pre-apoptotic spermatozoa membrane. This publication describes a case in which an ongoing pregnancy has been achieved for the first time in a patient with KS, after applying the MACS technique to ejaculated sperm. Our aim was to reduce the percentage of apoptotic spermatozoa and DNA fragmentation rate, and thus, increase the chance of selecting sperm with higher viability for intracytoplasmic sperm injection (ICSI). Material(s) and Method(s): A couple with

history of two years of primary infertility due to male factor came to our fertility centre. The male was under suspicion of KS, because of the presence of symptoms such us, situs inversus totalis and abnormal sperm analisys characterized by total astenozoospermy and teratozoospermy (according to Kruger strict criteria). Sperm viability assessed by the Eosin test, revealed 40% of alive spermatozooa. Morphology of sperm flagella was evaluated under electron microscopy showing the absence of dynein connections. Mutations in DNAH5 and DNAI1 genes were not found in the genetic study performed on blood sample. Both Karyotype and FISH sperm were normal. Ovarian stimulation was carried out in October of 2011 using a GnRH antagonist multiple dose protocol and recombinant follicle-stimulating hormone. Ovulation induction was triggered with recombinant chorionic gonadotropin (rCG). MACS technique was applied to eyaculated sperm. Annexin V protein conjugated with super-paramagnetic microbeads is closed to the separation column when exposed to a magnetic field. Non-apoptotic spermatozoa with intact membranes went through the column and were used for ICSI. Result(s): On the day of the oocyte retrieval, fresh semen evaluation showed that sperm count was 32 x 106 /ml and 1.3 ml. Total absence of motility was confirmed even after incubation with pentoxifylline. Vitality test showed 55% of alive spermatozoa. ICSI was performed after applying MACS to sperm aliquot. Ten out of fourteen oocytes recovered were metaphase II (71.4%) and six out of ten oocytes (60%) were appropriately fertilized. Embryos were scored according to classical morphology criteria. Embryo transfer was carried out on day 3 and two even 8 and 6 cells good quality embryos were transferred into the uterus. In addition, one cavitated blastocyst was frozen on day 5. Thirteen days after the embryo transfer beta-hCG blood test was 112.64 IU and nowadays, the pregnancy satisfactorily progresses. Conclussion: To the best of our knowledge this is the first time that MACS is reported to improve the outcome of ICSI procedure using immotile sperm of male with KS. By doing so, we increased the chance of better selection of viable sperm in a case showing total astenozoospermy. Taking this into consideration and based on our good results, we conclude that MACS technique may be an alternative tool in routine IVF practice in these patients, not only improving reproductive outcomes, but also minimizing the need for invasive interventions such as testicular biopsy.

Lots, F. A. E., et al. (2017). "A large-scale investigation of microplastic contamination: Abundance and characteristics of microplastics in European beach sediment." Marine Pollution Bulletin **123**(1-2): 219-226.

Here we present the large-scale distribution of microplastic contamination in beach sediment across Europe. Sediment samples were collected from 23 locations across 13 countries by citizen scientists, and analysed using a standard operating procedure. We found significant variability in the concentrations of microplastics, ranging from 72+/-24 to 1512+/-187 microplastics per kg of dry sediment, with high variability within sampling locations. Three hotspots of microplastic accumulation (>700 microplastics per kg of dry sediment) were found. There was limited variability in the physico-chemical characteristics of the plastics across sampling locations. The majority of the microplastics were fibrous, <1mm in size, and blue/black in colour. In addition, using Raman spectrometry we identified particles as polyester, polyethylene, and polypropylene. Our research is the first large spatial-scale analysis of microplastics on European beaches giving insights into the nature and extent of the microplastic challenge.

Lourenco, P. M., et al. (2017). "Plastic and other microfibers in sediments, macroinvertebrates and shorebirds from three intertidal wetlands of southern Europe and west Africa." Environmental Pollution **231**(Part 1): 123-133.

Microplastics are widespread in aquatic environments and can be ingested by a wide range of

organisms. They can also be transferred along food webs. Estuaries and other tidal wetlands may be particularly prone to this type of pollution due to their particular hydrological characteristics and sewage input, but few studies have compared wetlands with different anthropogenic pressure. Furthermore, there is no information on microplastic transfer to secondary intertidal consumers such as shorebirds. We analysed intertidal sediments, macroinvertebrates and shorebirds, from three important wetlands along the Eastern Atlantic (Tejo estuary, Portugal; Banc d'Arguin, Mauritania and Bijagos archipelago, Guinea-Bissau), in order to evaluate the prevalence and transfer of microplastics along the intertidal food web. We further investigated variables that could explain the distribution of microplastics within the intertidal areas of the Tejo estuary. Microfibers were recorded in a large proportion of sediment samples (91%), macroinvertebrates (60%) and shorebird faeces (49%). micro -FTIR analysis indicated only 52% of these microfibers were composed of synthetic polymers (i.e. plastics). Microfiber concentrations were generally higher in the Tejo and lower in the Bijagos, with intermediate values for Banc d'Arguin, thus following a latitudinal gradient. Heavier anthropogenic pressure in the Tejo explains this pattern, but the relatively high concentrations in a pristine site like the Banc d'Arguin demonstrate the spread of pollution in the oceans. Similar microfiber concentrations in faeces of shorebirds with different foraging behaviour and similar composition of fibres collected from invertebrate and faeces suggest shorebirds mainly ingest microfibers through their prey, confirming microfiber transfer along intertidal food webs. Within the Tejo estuary, concentration of microfibers in the sediment and bivalves were positively related with the percentage of fine sediments and with the population size of the closest township, suggesting that hydrodynamics and local domestic sewage are the main factors influencing the distribution of microfibers.

Loutsios, C., et al. (2015). "SPECT/CT to quantify eosinophil migration into the lungs." Journal of Nuclear Medicine. Conference: Society of Nuclear Medicine and Molecular Imaging Annual Meeting, SNMMI **56**(SUPPL. 3).

Objectives Eosinophils are key mediators of allergic inflammation. The ability to localise and quantify eosinophilic inflammation is important both clinically and to test the efficacy of novel therapeutics. Existing biomarkers are indirect or invasive so there remains a need for a less invasive method to localise eosinophilic inflammation in the lungs. Methods Granulocytes were isolated from autologous peripheral blood by plasma-Percoll density gradient separation. Eosinophils were then isolated by negative selection using anti-CD16 magnetic microbeads, labelled with ^{99m}Tc- HMPAO [1,2] and injected into 9 healthy subjects, 10 asthmatics and 3 patients with focal eosinophilic lung inflammation. Initial cell distribution was monitored by dynamic imaging over the chest for 40 min post-injection. Frequent serial peripheral blood samples were taken and lung activity determined from 3 sequential SPECT images obtained up to 9 h post-injection. Activity was anatomically co-registered from a single low-dose CT scan. The rate of eosinophil clearance into the lungs was measured by Patlak analysis, using peripheral blood for input function, and multiplied by the blood eosinophil count to give the rate of eosinophil migration into the lungs. Results Labelled cells displayed rapid first-pass transit through the lungs before localising in the liver, spleen and bone marrow. Lung eosinophil migration was 194 +/- 66 cells/min/ml in asthmatics (p<0.1) and 6051 +/- 4593 in patients with focal pulmonary inflammation (p<0.01), compared with 46 +/- 22 in healthy subjects. Conclusions Autologous radiolabelled eosinophils coupled to SPECT/CT are able to localise pulmonary eosinophilic inflammation in humans and therefore have the potential for testing novel therapeutics.

Lowry, A. (2013). "Material goals." Green Futures(89): 42-42.

The article offers the author's insights regarding environmental values and their aesthetics, along with management of plastic waste. The author states that the people should choose between their environmental values and their aesthetics. He says that the most toxic products in the grocery store could be found in the cleaning category. He relates that there are billions of tonnes of plastics in circulation; however other brands are rejecting post-consumer waste as a material.

Lu, B., et al. (2018). "Dual-channel-coded microbeads for multiplexed detection of biomolecules using assembling of quantum dots and element coding nanoparticles." Analytica Chimica Acta **1024**: 153-160.

To achieve the dual-channel (analog and digital) encoding, microbeads assembled with quantum dots (QDs) and element coding nanoparticles (ECNPs) have been prepared. Dual-spectra, including fluorescence generated from quantum dots (QDs) and laser induced breakdown spectrum obtained from the plasma of ECNPs, including AgO, MgO and ZnO nanoparticles, has been adopted to provide more encoding amounts and more accurate dual recognition for encoded microbeads in multiplexed utilization. The experimental results demonstrate that the single microbead can be decoded in two optical channels. Multiplexed analysis and contrast adsorption experiment of anti-IgG verified the availability and specificity of dual-channel-coded microbeads in bioanalysis. In gradient detection of anti-IgG, we obtained the linear concentration response to target biomolecules from 3.125 x 10⁻¹⁰ M to 1 x 10⁻⁸ M, and the limit of detection was calculated to be 2.91 x 10⁻¹¹ M. Lu, B. and M. M. Maharbiz (2019). "Ion concentration polarization (ICP) of proteins at silicon micropillar nanogaps." PLoS ONE [Electronic Resource] **14**(11): e0223732.

Fast detection of low-abundance protein remains a challenge because detection speed is limited by analyte transport to the detection site of a biosensor. In this paper, we demonstrate a scalable fabrication process for producing vertical nanogaps between micropillars which enable ion concentration polarization (ICP) enrichment for fast analyte detection. Compared to horizontal nanochannels, massively paralleled vertical nanogaps not only provide comparable electrokinetics, but also significantly reduce fluid resistance, enabling microbead-based assays. The channels on the device are straightforward to fabricate and scalable using conventional lithography tools. The device is capable of enriching protein molecules by >1000 fold in 10 min. We demonstrate fast detection of IL6 down to 7.4 pg/ml with only a 10 min enrichment period followed by a 5 min incubation. This is a 162-fold enhancement in sensitivity compared to that without enrichment. Our results demonstrate the possibility of using silicon/silica based vertical nanogaps to mimic the function of polymer membranes for the purpose of protein enrichment.

Lu, H., et al. (2007). "[Hyperinsulinemia induced immune maturation of human monocyte derived dendritic cells: bridging between diabetes and atherosclerosis]." Chung-Hua Hsin Hsueh Kuan Ping Tsa Chih [Chinese Journal of Cardiology] **35**(12): 1151-1154.

OBJECTIVE: Dendritic cells an hyperinsulinemia are both implicated in the pathogenesis of atherosclerosis. The aim of this study is to explore the effect of high concentration of insulin on the maturation of monocyte-derived dendritic cells (MoDCs) and related signal transduction pathways.

METHODS: Human monocytes were purified (over 98%) using Anti-CD14 micro-beads and cultured for 5 days with DC Cellgro medium containing rhGM-CSF (100 microg/L) and rhIL-4 (20 microg/L). Immature DC were then incubated with insulin of various concentrations (0, 1, 10, 100 nmol/L)

for 24 hours in the presence or absence of LY294002 (PI3K inhibitor) or PD98059 (MAPK inhibitor). Immunophenotypic expression of CD86 and CD83 were detected using flow cytometry. Endocytosis function of the MoDCs was evaluated using FITC-Dextran and MoDCs secretion IL-12, IFN-gamma and TNF-alpha were measured by ELISA.
RESULTS: Insulin induced significantly higher CD83 and CD86 expressions on MoDCs in a dose-dependent manner. The endocytosis function of MoDCs were significantly inhibited and cytokine secretions of IL-12, IFN-gamma and TNF-alpha significantly increased by 10 nmol/L and 100 nmol/L insulin. These effects could be blocked by the LY294002 and PD98059.
CONCLUSION: Hyperinsulinemia contributed to atherosclerosis via stimulating immune maturation of MoDCs via both PI3K and MAPK pathways.

Lu, J., et al. (2020). "Adsorption and Desorption of Steroid Hormones by Microplastics in Seawater." Bulletin of Environmental Contamination & Toxicology **07**: 07.

This study evaluated the adsorption and desorption of 17beta-estradiol (E2) and 17alpha-ethynylestradiol (EE2) on microplastics in seawater. The effects of microplastic materials and particle sizes on adsorption of E2 and EE2 were explored. Moreover, effects of salinity, pH, humic acid (HA) concentrations, and initial E2/EE2 concentrations on adsorption were also discussed. Increase in salinity, HA concentration, and initial E2/EE2 concentration would enhance adsorption of E2/EE2 on microplastics. Adsorption capacity of E2/EE2 firstly increased to reach the highest at pH of 8.0 and then decreased when pH further increased. Pseudo-second-order kinetics better fitted adsorption data of E2 while pseudo-first-order model yielded better fitting results for EE2. Freundlich isotherm was better to fit the adsorption data of E2 while Langmuir isotherm yielded better fitting results for EE2. Desorption capacity of E2/EE2 on microplastics was over 40% of its adsorption capacity. This study provides new insights on microplastics and endocrine disrupting chemicals.

Lu, J., et al. (2019). "Effects of microplastics on distribution of antibiotic resistance genes in recirculating aquaculture system." Ecotoxicology and Environmental Safety **184**(109631).

Microplastics and antibiotic resistance genes (ARGs) are two kinds of emerging contaminants with frequent detection in coastal regions. However, rare information on co-occurrence of microplastics and ARGs in coastal recirculating aquaculture system (RAS) is available. This study performed field sampling and laboratory analysis to investigate the distribution of microplastics and ARGs in a typical RAS farm. The results showed that microplastics were detected in all water samples with the abundances ranging from 58 to 72 items/m³. Absolute abundances of total 10 ARGs in water samples ranged from 3.24x10⁵ to 7.83x10⁵ copies/mL while those on microplastic samples were in the range of 1.59x10⁹-1.83x10⁹ copies/g. Microbial communities of microplastics and water showed significant difference at both phylum and genus levels. Microbial community diversity of microplastics was higher than that of water. ARGs including tetG, qnrS, sul1, sul2, and ermF possessed relatively more active relationships with bacterial community in water and on microplastics of the RAS farm. The results suggested that microplastics might be an important reservoir of ARGs in RAS farms. The findings of this study will provide useful information on pollution control and environmental management for both microplastics and ARGs in coastal aquaculture systems.

Lu, K., et al. (2018). "Influence of microplastics on the accumulation and chronic toxic effects of cadmium in zebrafish (Danio rerio)." Chemosphere **202**: 514-520.

As the accumulation of microplastics (MPs) in the environment continues to rise, more concerns

focus on the health risk of combined exposure to MPs and other contaminants. The aim of this study is to investigate the influences of MPs on the tissue-accumulation of cadmium (Cd) in zebrafish and explore the related chronic toxic effects induced by combined exposure of Cd and MPs. After co-exposure to MPs and Cd for 3 weeks, 20 and 200 micro g/L MPs increased the accumulation of Cd in zebrafish livers (46% and 184%), guts (10% and 25%) and gills (9% and 46%). The Cd accumulation was gill > gut > liver. Comprehensive analyzes of biochemical biomarkers, histopathological observation and functional gene expression firstly demonstrated that the presence of MPs enhanced the toxicity of Cd on zebrafish and the combined exposure caused oxidative damage and inflammation in zebrafish tissues. Collectively, our results highlight the chronic effects of combined exposure to MPs and heavy metals.

Lu, L., et al. (2019). "Interaction between microplastics and microorganism as well as gut microbiota: A consideration on environmental animal and human health." Science of the Total Environment **667**: 94-100.

Microplastics (MPs) has gradually become a global environmental pollution problem and may harm human and animal health. In recent years, a large number of studies had shown that MPs had various toxicological effects on different organisms. At the same time, a number of studies had also shown that gut microbiota was closely related to host health and as a toxicity target for certain environmental pollutants including MPs. The fact is that more and more studies proved that MPs not only could interact with microorganism directly but also serve as a carrier for other pollutants and interacted with microorganism indirectly. In this review, we summarized the interactions between MPs and microorganisms as well as gut microbiota, and considered the possible impacts of MPs on environmental animal and human health, suggesting that the environmental microorganisms and the gut microbiota of animals were also the very important target for MPs. We hope that more studies pay more attention to focus on the relationship between MPs, gut microbiota, and environmental animals and human health in the future.

Lu, L., et al. (2018). "Polystyrene microplastics induce gut microbiota dysbiosis and hepatic lipid metabolism disorder in mice." Science of the Total Environment **631**(632): 449-458.

Microplastic (MP) has become a concerning global environmental problem. It is toxic to aquatic organisms and can spread through the food chain to ultimately pose a threat to humans. In the environment, MP can interact with microbes and act as a microbial habitat. However, effects of polystyrene MP on the gut microbiota in mammals remain unclear. Here, male mice were exposed to two different sizes of polystyrene MP for 5 weeks to explore its effect. We observed that oral exposure to 1000 micro g/L of 0.5 and 50 micro m polystyrene MP decreased the body, liver and lipid weights in mice. Mucus secretion in the gut decreased in both sizes of polystyrene MP-treated groups. Regarding the gut microbiota, at the phylum level, polystyrene MP exposure decreased the relative abundances of Firmicutes and alpha -Proteobacteria in the feces. Furthermore, high throughput sequencing of the V3-V4 region of the 16S rRNA gene revealed significant changes in the richness and diversity of the gut microbiota in the cecums of polystyrene MP-treated mice. At the genus level, a total of 6 and 8 types of bacteria changed in the 0.5 and 50 micro m polystyrene MP-treated groups, respectively. Furthermore, an operational taxonomic unit (OTU) analysis identified that 310 and 160 gut microbes were changed in the 0.5 and 50 micro m polystyrene MP-treated groups, respectively. In addition, the hepatic triglyceride (TG) and total cholesterol (TCH) levels decreased in both 1000 micro g/L 0.5 and 50 micro m polystyrene MP-treated groups. Correspondingly, the relative mRNA levels of some key genes related to lipogenesis and TG synthesis decreased in the liver and epididymal fat. These results indicated that polystyrene MP could modify the gut microbiota composition and induce hepatic lipid disorder in mice; while the mouse is a common mammal model, consequently, the health risks of MP to animals should not be ignored.

Lu, P., et al. (2012). "The inhibitory effect of CD8 alpha ⁻CD11c⁺ dendritic cells on asthma in schistosoma japonicum infected mice." Tianjin Medical Journal **40**(7): 695-697.

Objective: To study the inhibitory effect of CD8 alpha ⁻CD11c⁺ dendritic cells (DC) on allergic asthma in schistosoma japonicum-infected mice.

Lu, S., et al. (2019). "Prevalence of microplastics in animal-based traditional medicinal materials: Widespread pollution in terrestrial environments." Science of the Total Environment **709**: 136214.

Microplastics (MPs) pollution is an emerging environmental and health concern. MPs have been extensively observed in the aquatic environment, yet rarely investigated in the terrestrial ecosystem, especially in relation to health risks. To evaluate potential MPs pollution in land-dwelling animal medicine materials, we collected 20 types of small animal-based medicinal materials and 10 types of available fresh terrestrial animals from eight different regions in China. MPs were found in all medicinal materials with an average incidence rate of 94.67%. The abundance of MPs was in the range of 1.80 +/- 0.38 to 7.80 +/- 0.83 items/individual or 1.59 +/- 0.33 to 43.56 +/- 9.22 items/g (dry weight), with polymer distribution by polyethylene terephthalate (40.45%), rayon (30.64%), polyethylene (10.11%), nylon (7.35%), polypropylene (5.93%), and polyvinyl chloride (5.52%). The majority of MPs were microfibers (84.68%), with 15.32% of fragments. Moreover, MPs were directly observed in the intestine, detected in all ten types of fresh medicinal animals with the abundance of 0.83 +/- 0.35 to 3.42 +/- 0.46 items/individual. Furthermore, significant positive correlations (R: 0.32-0.99, p < 0.05) of MPs characteristics were found between medicinal materials and fresh animals, including shape, size, color, and polymer distribution of MPs. The results support that MPs in the medicinal materials were likely derived from living animals. This study demonstrates the prevalence of MPs in animal-based, traditional medicinal materials, and also suggests widespread MPs pollution in terrestrial environments and latent health risks.

Lu, S., et al. (2018). "Impact of water chemistry on surface charge and aggregation of polystyrene microspheres suspensions." Science of the Total Environment **630**: 951-959.

The discharge of microplastics into aquatic environment poses the potential threat to the hydrocoles and human health. The fate and transport of microplastics in aqueous solutions are significantly influenced by water chemistry. In this study, the effect of water chemistry (i.e., pH, foreign salts and humic acid) on the surface charge and aggregation of polystyrene microsphere in aqueous solutions was conducted by batch, zeta potentials, hydrodynamic diameters, FT-IR and XPS analysis. Compared to Na⁺ and K⁺, the lower negative zeta potentials and larger hydrodynamic diameters of polystyrene microspheres after introduction of Mg²⁺ were observed within a wide range of pH (2.0-11.0) and ionic strength (IS, 0.01-500mmol/L). No effect of Cl⁻, HCO₃⁻ and SO₄²⁻ on the zeta potentials and hydrodynamic diameters of polystyrene microspheres was observed at low IS concentrations (<5mmol/L), whereas the zeta potentials and hydrodynamic diameters of polystyrene microspheres after addition of SO₄²⁻ were higher than that of Cl⁻ and HCO₃⁻ at high IS concentrations (>10mmol/L). The zeta potentials of polystyrene microspheres after HA addition were decreased at pH2.0-11.0, whereas the lower hydrodynamic diameters were observed at pH<4.0. According to FT-IR and XPS analysis, the change in surface properties of polystyrene microspheres after addition of hydrated

Mg²⁺ and HA was attributed to surface electrostatic and/or steric repulsions. These investigations are crucial for understanding the effect of water chemistry on colloidal stability of microplastics in aquatic environment.

Lu, X. M., et al. (2019). "Fate and abundance of antibiotic resistance genes on microplastics in facility vegetable soil." Science of the Total Environment **709**: 136276.

Microplastics (MPs) and antibiotic resistance genes (ARGs) coexist widely in farmland soils, but the fate and abundance of ARGs on MPs is rarely explored. In this study, high-throughput fluorescent quantitative polymerase chain reaction was used to determine ARGs on MPs in facility vegetable soil. The results indicated that when the particle size of the MPs was larger, the weathering was more serious, or the MPs came from soils with a long vegetable cultivation period, the levels of antibiotics and heavy metals on the MPs were higher. The distribution of the detected ARGs types on distinct MPs showed changes. Compared with weakly weathered MPs, the detected beta lactamase and aminoglycoside resistance genes on strongly weathered MPs were decreased by 2.6% and 1.7%, while the detected sul-ARGs and Macrolide-Lincosamide-Streptogramin B (MLSB) resistance genes were increased by 1.5% and 2.8%. Compared with smaller MPs, the detected MLSB and vancomycin resistance genes on larger MPs were decreased by 2.0% and 1.4%, while the detected fluoroquinolone, quinolone, florfenicol, chloramphenicol, and amphenicol (FCA) resistance genes and sul-ARGs were increased by 1.2% and 1.0%. Compared with MPs in soil after three years of vegetable cultivation, the detected FCA resistance genes and sul-ARGs on MPs in soil after ten years of vegetable cultivation were decreased by 1.3% and 1.6%, while the detected beta lactamase and aminoglycoside resistance genes were increased by 1.0% and 1.7%. This study suggests that MPs with larger size, stronger weathering or from soil after long-term vegetable cultivation adsorb more antibiotics and heavy metals and cause more mobile genetic elements, which can contribute to antibiotic resistance on the MPs.

Lu, Z., et al. (2016). "Amplified voltammetric detection of miRNA from serum samples of glioma patients via combination of conducting magnetic microbeads and ferrocene-capped gold nanoparticle/streptavidin conjugates." Biosensors & Bioelectronics **86**: 502-507.

MicroRNA (miRNA) plays a key regulatory role in many biological processes, emerging as an important biomarker for a large variety of cancer diseases. Employing gold nanoparticle (AuNP)-coated magnetic microbeads (AuNP-MMBs) as an immobilization matrix for higher loading density of hairpin-structured DNA probes and then ferrocene (Fc)-capped gold nanoparticle/streptavidin conjugates, amplified electrochemical assay of miRNA has been performed. In the presence of target miRNA, a novel assembly was formed via linking biotinylated hairpin DNA probe-covered AuNP-MMBs with Fc-capped gold nanoparticle/streptavidin conjugates and then collected by magnetic electrodes for voltammetric detection. The enlarged surface area, good conductivity of AuNP-MMBs and the multiple Fc tags on the electrode surface ensure high sensitivity of the method. The oxidation peak current of Fc tags is proportional to the concentrations of miRNA ranging from 5 fM to 100 fM, and a detection limit of 0.14 fM was achieved. The proposed assay is highly selective and reproducible, serving as a viable alternative for the detection of miRNA-182 from serum samples of glioma patients.

Luca, G., et al. (2007). "Encapsulation, in vitro characterization, and in vivo biocompatibility of sertoli cells in alginate-based microcapsules." Tissue Engineering **13**(3): 641-648.

A method for microencapsulation of isolated neonatal porcine Sertoli cells is described. Using a

conventional alginate-poli-L-ornithine encapsulation procedure, which has been used in our laboratory for almost two decades to envelop pancreatic islets, we observed significant loss of Sertoli cell viability, possibly due to excessive Ca²⁺ ion exposure. Replacing calcium with barium, or shortening the incubation period in the presence of Ca ions, we obtained barium or calcium alginate gel microbeads that did not alter morphology and viability of the encapsulated Sertoli cells. The procedure might permit access to a novel approach to immunologically alter cell graft acceptance. © Mary Ann Liebert, Inc.

Lucas, D., et al. (2018). "Methods of Responsibly Managing End-of-Life Foams and Plastics Containing Flame Retardants: Part II." Environmental Engineering Science **35**(6): 588-602.

This is Part II of a review covering the wide range of issues associated with all aspects of the use and responsible disposal of foam and plastic wastes containing toxic or potentially toxic flame retardants. We identify basic and applied research needs in the areas of responsible collection, pretreatment, processing, and management of these wastes. In Part II, we explore alternative technologies for the management of halogenated flame retardant (HFR) containing wastes, including chemical, mechanical, and thermal processes for recycling, treatment, and disposal. © Copyright 2018, Mary Ann Liebert, Inc. 2018.

Luchese, C. L. (2019). "Intelligent packaging for monitoring food quality." CAB Reviews **14**(049): 1-11.

Synthetic plastics derived primarily from fossil carbon sources (such as crude oil and natural gas) are one of the main constituents of urban solid waste that present an increasing problem of disposal and environmental pollution due to its recalcitrant nature. Growing environmental concerns over the uncontrolled use of traditional synthetic plastics and a desire related to reducing the use of non-renewable resources have led to several looking for alternative packaging materials. An alternative to minimize the problem related to plastic waste disposal is the production of biodegradable films. Currently, dynamic information and constant monitoring of food quality, shelf life, safety and convenience are required for the most demanding consumer news. Intelligent packaging systems are those that monitor the condition of packaged foods to provide information about die quality of packaged food during transportation and storage. In the current context, smart (active and intelligent) packaging is a potential area for future research. The development and improvement of processing technologies and the raw materials used in the manufacture of this type of packaging can help to preserve products of animal origin (chicken meat, beef and pork) and vegetables (minimally processed), as the different characteristic of the material can be obtained.

Lucia, G. A. d., et al. (2018). "Sea water contamination in the vicinity of the Italian minor islands caused by microplastic pollution." Water **10**(8).

The abundance and distribution of microplastics (MP) were evaluated in six "clean" sites (Italian minor islands) and in two "polluted" areas (near the mouth of two major Italian rivers). Samples of MP, plankton and persistent organic pollutants (POPs) were collected using a manta trawl (MA) and a plankton net (WP2), both lined with a 333 micro m mesh net. MP have been confirmed to be ubiquitous since they were found at each site, showing an average density of 0.3+or-0.04 items/m³ (values ranged from 0.641 to 0.119). When comparing the clean sites with the polluted ones, a significantly higher value of MP was found near the river mouths. The most common types of MP were synthetic filaments (50.24%), followed by fragments (30.39%), thin plastic films (16.98%) and spheres (2.39%). Infrared spectroscopy analysis highlighted that the most abundant polymers were polyethylene (PE-26%), polypropylene (PP-11%), polyethylene-terephthalate/polyester (PET/PEST-8%) and

ethylene-vinyl-acetate (EVA-5%). Polychlorinated biphenyls and organochlorine pesticides were detected in all the samples with a high variability among sites and depths. This study adds to the existing information on the distribution of contaminants across the Mediterranean Sea, and is useful to policy makers who wish to implement effective measures to reduce MP pollution.

Luciani, M., et al. (2016). "Rapid detection and isolation of Escherichia coli O104:H4 from milk using monoclonal antibody-coated magnetic beads." Frontiers in Microbiology **7**(June).

Monoclonal antibodies (MAbs) specific for the lipopolysaccharide (LPS) of Escherichia coli O104:H4 were produced by fusion of Sp2/O-Ag-14 mouse myeloma cells with spleen cells of Balb/c mice, immunized with heat-inactivated and sonicated E. coli O104:H4 bacterial cells. Four MAbs specific for the E. coli O104:H4 LPS (1E6 G6, 1F4C9, 3 G6 G7, and 4 G10D2) were characterized and evaluated for the use in a method for the detection of E. coli O104:H4 in milk samples that involves antibody conjugation to magnetic microbeads to reduce time and increase the efficiency of isolation. MAb 1E6 G6 was selected and coupled to microbeads, then used for immuno-magnetic separation (IMS); the efficiency of the IMS method for E. coli O104:H4 isolation from milk was evaluated and compared to that of the EU RL VTEC conventional culture-based isolation procedure. Milk suspensions also containing other pathogenic bacteria that could potentially be found in milk (Campylobacter jejuni, Listeria monocytogenes, and Staphylococcus aureus) were also tested to evaluate the specificity of MAb-coated beads. Beads coated with MAb 1E6 G6 showed a good ability to capture the E. coli O104:H4, even in milk samples contaminated with other bacteria, with a higher number of E. coli O104:H4 CFU reisolated in comparison with the official method (121 and 41 CFU, respectively, at 10³ E. coli O104:H4 initial load; 19 and 6 CFU, respectively, at 10² E. coli O104:H4 initial load; 1 and 0 CFU, respectively, at 10¹ E. coli O104:H4 initial load). The specificity was 100%.

Luck, S., et al. (2016). "Tailored and biodegradable poly(2-oxazoline) microbeads as 3D matrices for stem cell culture in regenerative therapies." Biomaterials **79**: 1-14.

We present the synthesis of hydrogel microbeads based on telechelic poly(2-oxazoline) (POx) crosslinkers and the methacrylate monomers (HEMA, METAC, SPMA) by inverse emulsion polymerization. While in batch experiments only irregular and ill-defined beads were obtained, the preparation in a microfluidic (MF) device resulted in highly defined hydrogel microbeads. Variation of the MF parameters allowed to control the microbead diameter from 50 to 500 mum. Microbead elasticity could be tuned from 2 to 20 kPa by the POx:monomer composition, the POx chain length, net charge of the hydrogel introduced via the monomer as well as by the organic content of the aqueous phase. The proliferations of human mesenchymal stem cells (hMSCs) on the microbeads were studied. While neutral, hydrophilic POx-PHEMA beads were bioinert, excessive colonization of hMSCs on charged POx-PMETAC and POx-PSPMA was observed. The number of proliferated cells scaled roughly linear with the METAC or SPMA comonomer content. Additional collagen I coating further improved the stem cell proliferation. Finally, a first POx-based system for the preparation of biodegradable hydrogel microcarriers is described and evaluated for stem cell culturing.

Luczkowska, K., et al. (2017). "The role of neurotrophins and angiogenic cytokines in the pathophysiology of peripheral neuropathy in patients with multiple myeloma." Haematologica **102 (Supplement 2)**: 773.

Background: The introduction of new treatment modalities have changed significantly the prognosis of multiple myeloma (MM) patients. The novel drugs and schemes of treatment of

MM have contributed to substantial extend of the overall survival time of patients. However, the administration of some of the treatments, e.g. thalidomide or bortezomib, is also associated with occurrence of a serious and common side-effect problem, which is the drug-induced peripheral neuropathy. The mechanism of the development of the peripheral neuropathy is poorly understood. Nevertheless, one of its potential cause, could be inadequate concentrations of crucial trophic factors, including neurotrophic and/or angiogenic factors, which are responsible for proliferation, differentiation, survival and death of neuronal and nonneuronal cells. Aim(s): The aim of this study was to elucidate the potential relationship between concentration of neurotrophic and angiogenic factors and development of peripheral neuropathy in the natural clinical course of the disease and, especially, induced by treatment regimen: VMP (bortezomib, melphalan, prednisone) or VTD (bortezomib, thalidomide,dexamethason) in patients with MM. Method(s): Peripheral blood samples were collected from patients classified into two groups: i) patients with multiple myeloma, without neuropathy and before therapy; and ii) patients with peripheral neuropathy 3oor 4o induced in the course of VMP or VTD therapy. The control group consisted healthy aged matched subjects. Assessment of concentrations of neurotrophins (BDNF, NSE) and angiogenic factor (PDGF) were performed using Luminex technology, which utilize microbeads coated with fluorescently labeled antibodies. Result(s): Concentration of BDNF, PDGF and NSE were significant decreased in patients after treatment regimen involving VMP or VTD who have developed peripheral neuropathy grade 3 or 4, compared with patients with newly diagnosed MM without neuropathy, before therapy and control healthy group. Additionally, plasma levels of both neurotrophins and PDGF in patients before therapy were higher, then in control group. Obtained results may be caused by the changes in an activity of the transcription factor NF-kappaB during the treatment of MM, since reduction of NF-kB concentration is associated with decrease in the transcription of genes encoding BDNF, NSE and PDGF. Summary/Conclusions: Alterations in the concentration of BDNF, PDGF and NSE suggest the cause and effect relationship between these factors and the development of neuropathy in patients with MM. Comprehensive elucidation of this phenomenon may contribute to the extension of the knowledge concerning the pathogenesis of neuropathy, and might well lead to reduction of the incidence of polyneuropathy in MM patients in the future.

Luijsterburg, B. J., et al. (2016). "Solid-state drawing of post-consumer isotactic poly(propylene): Effect of melt filtration and carbon black on structural and mechanical properties." Waste Management **54**: 53-61.

Post-consumer plastic waste obtained via mechanical recycling is usually applied in thick-walled products, because of the low mechanical strength due to the presence of contaminants. In fact, sorted post-consumer isotactic poly(propylene) (i-PP) can be considered as a blend of 95% i-PP and 5% poly(ethylene), with traces of poly(ethylene terephthalate) (PET). By applying a treatment such as solid-state drawing (SSD) after melt extrusion, the polymer chains can be oriented in one direction, thereby improving the stiffness and tensile strength. In this research, molecular processes such as crystal break-up and chain orientation of these complex blends were monitored as a function of draw ratio. The melt filter mesh size - used to exclude rigid PET particles - and the addition of carbon black (CB) - often added for coloration in the recycling industry - were varied to investigate their influence on the SSD process. This research shows that despite the blend complexity, the molecular processes during SSD compare to virgin i-PP and that similar draw ratios can be obtained (lambdamax=20), albeit at reduced stiffness and strength as a result of the foreign polymers present in post-consumer i-PP. It is observed that the process stability improves with decreasing mesh size and that higher draw ratios can be obtained. The addition of carbon black, which resides in the dispersed PE phase, also stabilizes the SSD process. Compared to isotropic post-consumer i-PP, the stiffness can be improved by a factor 10 to over 11GPa, while the tensile strength can be improved by a factor 15-385MPa, which is approx. 70% of the maximum tensile strength achieved for virgin i-PP.

Luis, L. G., et al. (2015). "Does the presence of microplastics influence the acute toxicity of chromium(VI) to early juveniles of the common goby (Pomatoschistus microps)? A study with juveniles from two wild estuarine populations." Aquatic Toxicology **164**: 163-174.

Toxicological interactions between microplastics (MP) and other environmental contaminants are of grave concern. Here, the potential influence of MP in the short-term toxicity of chromium to early juveniles of Pomatoschistus microps was investigated. Three null hypotheses were tested: (1) exposure to Cr(VI) concentrations in the low ppm range does not induce toxic effects on juveniles; (2) the presence of microplastics in the water does not influence the acute toxicity of Cr(VI) to juveniles; (3) the environmental conditions of the natural habitat where fish developed do not influence their sensitivity to Cr(VI)-induced acute stress. Fish were collected in the estuaries of Minho (M-est) and Lima (L-est) Rivers (NW Iberian Peninsula) that have several abiotic differences, including in the water and sediment concentrations of various environmental contaminants. After acclimatization to laboratory conditions, two 96 h acute bioassays were carried out with juveniles from both estuaries to: (i) investigate the effects of Cr(VI) alone; (ii) investigate the effects of Cr(VI) in the presence of MP (polyethylene spheres 1-5 micro m O). Cr(VI) alone induced mortality (96 h-LC₅₀s: 14.4-30.5 mg/l) and significantly decreased fish predatory performance (<=74%). Thus, in the range of concentrations tested (5.6-28.4 mg/l) Cr(VI) was found to be toxic to P. microps early juveniles, therefore, we rejected hypothesis 1. Under simultaneous exposure to Cr(VI) and MP, a significant decrease of the predatory performance (<=67%) and a significant inhibition of AChE activity (<=31%) were found. AChE inhibition was not observed in the test with Cr(VI) alone and MP alone caused an AChE inhibition <=21%. Mixture treatments containing Cr(VI) concentration >=3.9 mg/l significantly increased LPO levels in L-est fish, an effect that was not observed under Cr(VI) or MP single exposures. Thus, toxicological interactions between Cr(VI) and MP occurred, therefore, we rejected hypothesis 2. In the presence of MP, the negative effect caused by high concentrations of Cr(VI) on the predatory performance was significantly reduced in L-est fish but not in M-est fish, and Cr(VI) concentrations higher than 3.9 mg/l caused oxidative damage in L-est fish but not in M-est fish. The acclimatization and test conditions were similar for fish from the two estuaries and these ecosystems have environmental differences. Thus, long-term exposure to distinct environmental conditions in the natural habitat during previous developmental phases influenced the sensitivity and responses of juveniles to Cr(VI), therefore, we rejected hypothesis 3. Overall, the results of this study indicate toxicological interactions between MP and Cr(VI) highlighting the importance of further investigating the combined effects of MP and other common contaminants.

Lukic, A., et al. (2006). "Production of interleukin-8 in vitro by mononuclear cells isolated from human periapical lesions." Oral Microbiology & Immunology **21**(5): 296-300.

INTRODUCTION: Interleukin-8 (IL-8) is an important mediator of inflammation. However, little is known about its production in chronic dental periapical lesions and this was the main aim of this work.

METHODS: Inflammatory cells were isolated from clinically different periapical lesions and analyzed by morphological criteria. The mononuclear cells were isolated, phenotypically analyzed by immunocytochemistry and cultivated in vitro. IL-8 was measured in culture supernatants of

these periapical lesion mononuclear cells (PL-MNC) using a microbeads fluorescence assay.
RESULTS: We found a relatively high production of IL-8 in 19 out of 21 periapical lesions included in the study. The level of IL-8 and the proportion of neutrophil granulocytes were significantly higher in the group of symptomatic lesions, compared to the asymptomatic lesions, but there was no statistically significant correlation between these parameters. According to the predominance of CD3(+) T cells and Ig(+)/CD19(+) B cells and plasma cells, lesions were divided into T-type and B-type lesions, respectively. The levels of IL-8 were significantly higher in the culture supernatants of PL-MNC in the T-type lesions and were positively correlated with the proportion of macrophages/dendritic cells (CD11c(+) cells) and CD4(+) T cells. Such a correlation was not shown in B-type lesions.
CONCLUSION: These results suggest that PL-MNC are a significant source of IL-8, which is probably an important chemokine for the migration and function of different cell types at the site of chronic inflammation.

Lum, F., et al. (2017). "Zika virus infects human fetal brain microglia and induces inflammation." Clinical Infectious Diseases **64**(7): 914-920.
Background. The unprecedented reemergence of Zika virus (ZIKV) has startled the world with reports of increased microcephaly in Brazil. ZIKV can infect human neural progenitors and impair brain growth. However, direct evidence of ZIKV infection in human fetal brain tissues remains elusive. Methods. Investigations were performed with brain cell preparations obtained from 9 donors. Virus infectivity was assessed by detection of virus antigen by flow cytometry together with various hematopoietic cell surface markers. Virus replication was determined by viral RNA quantification. Cytokine levels in supernatant obtained from virus-infected fetal brain cells were measured simultaneously in microbead-based immunoassays. Results. We also show that ZIKV infection was particularly evident in hematopoietic cells with microglia, the brain-resident macrophage population being one of the main targets. Infection induces high levels of proinflammatory immune mediators such as interleukin 6 (IL-6), tumor necrosis factor alpha (TNF- alpha), interleukin 1 beta (IL-1 beta), and monocyte chemotactic protein 1 (MCP-1). Conclusions. Our results highlight an important role for microglia and neuroinflammation during congenital ZIKV pathogenesis.

Lum, F. M., et al. (2018). "Longitudinal Study of Cellular and Systemic Cytokine Signatures to Define the Dynamics of a Balanced Immune Environment During Disease Manifestation in Zika Virus-Infected Patients." Journal of Infectious Diseases **218**(5): 814-824.
Background: Since its unexpected reemergence, Zika virus (ZIKV) has caused numerous outbreaks globally. This study characterized the host immune responses during ZIKV infection.
Methods: Patient samples were collected longitudinally during the acute, convalescence and recovery phases of ZIKV infection over 6 months during the Singapore outbreak in late 2016. Plasma immune mediators were profiled via multiplex microbead assay, while changes in blood cell numbers were determined with immunophenotyping.
Results: Data showed the involvement of various immune mediators during acute ZIKV infection accompanied by a general reduction in blood cell numbers for all immune subsets except CD14+ monocytes. Importantly, viremic patients experiencing moderate symptoms had significantly higher quantities of interferon gamma-induced protein 10, monocyte chemotactic protein 1, interleukin 1 receptor antagonist, interleukin 8, and placental growth factor 1, accompanied by reduced numbers of peripheral CD8+ T cells, CD4+ T cells, and double-negative T cells. Levels of T-cell associated mediators, including interferon gamma-induced protein 10, interferon gamma, and interleukin 10, were high in recovery phases of ZIKV infection, suggesting a functional role

for T cells. The identification of different markers at specific disease phases emphasizes the dynamics of a balanced cytokine environment in disease progression.

Conclusions: This is the first comprehensive study that highlights specific cellular changes and immune signatures during ZIKV disease progression, and it provides valuable insights into ZIKV immunopathogenesis.

Lumachi, F., et al. (2017). "Predictive markers of survival in patients with pulmonary metastases and malignant pleural effusion." Annals of Oncology **28 (Supplement 2)**: iii53-iii54.

Background: Lung metastases (LMs) can be identified in up to 30-50% of all cancer patients and represent the result of metastatic spread to the lungs from the several cancers. The presence of LMs seriously affects overall survival (OS), and the onset of pleural effusion further reduces the life expectancy of the patients. The aim of this retrospective study was to evaluate the usefulness of carcinoembryonic antigen (CEA), lactate dehydrogenase (LDH), and C-reactive protein (CRP) measurement in the pleural fluid of patients with LMs and malignant pleural effusion (MPE). Method(s): The medical records of 22 patients (median age 68 years, range 46-86) with LMs (mainly from breast, urinary tract, and colorectal cancers) and MPE were analyzed. There were 13 (59.1%) males and 9 (40.9%) females. All patients underwent video-assisted thoracoscopic (VAT)-assisted thoracentesis and subsequent pleural fluid examination, including CEA, LDH, and CRP, which were measured using a chemiluminescent (CLIA) immunoassay (sandwich CLIA with native CEA coated to magnetic microbeads), a spectrophotometric assay (L-lactate as substrate), and an immunonephelometric assay (polystyrene particles coated with anti-human CRP monoclonal antibodies), respectively. Result(s): The OS was 6.765.2 months (range 1-23 months), and the levels of pleural markers were 10.4621.6 ng/mL (CEA), 418.46342.9 U/L (LDH), and 6.269.1 mg/L (CRP). No relationship was found between OS and the age of the patients (R=0.14 p=0.542), LDH (R=-0.31, p=0.169) or CRP (R=-0.33, p=0.136). There was a significant direct correlation between OS and CEA (R=0.66, p=0.0007). The relative regression line equations are reported in the table. Conclusion(s): In patients with MPE and LMs, only CEA pleural levels significantly related to OS, and can be considered a useful predictive factor. Further studies will eventually confirm our results.

Luna-Jorquera, G., et al. (2019). "Marine protected areas invaded by floating anthropogenic litter: An example from the South Pacific." Aquatic Conservation **29**: 245-259.

Oceanic marine protected areas (MPAs) that are close to the litter accumulation zones in the subtropical gyres receive large amounts of plastic litter, both as micro- and as macroplastics.The macro-litter accumulating on the islands in the Easter Island Ecoregion (Rapa Nui and Salas y Gómez) can be traced back to the high seas industrial fishery operating in the South Pacific.Seabirds nesting in the MPAs in the South Pacific are affected by both microplastic ingestion and macroplastic in their nests, but there was no evidence of entangled birds.Conservation of seabirds (and other species) in these oceanic MPAs requires efficient measures to reduce plastic contamination in the ocean.Observations made in the South Pacific coincide with those from other oceanic MPAs, calling for global actions. [ABSTRACT FROM AUTHOR]

Lund, A. W. (2009). The three-dimensional microenvironment as a regulatory cue during mesenchymal stem cell osteogenic differentiation.

The bidirectional interaction between cells and their surrounding matrix provides structural and organizational cues for tissue development. It is this intimate interaction that is required for the appropriate and controlled functioning of stem cells within both natural and engineered three dimensional (3D) environments. Elucidation of the mechanisms that govern this interaction are required to guide the induction and maintenance of specific stem cell differentiation in engineered tissues. 3D culture facilitates external mechanical cues, solute concentration gradients and cell-mediated remodeling of the extracellular matrix (ECM) that are required to form many physiologic structures. This work demonstrates that mesenchymal stem cell (MSC) osteogenic differentiation potential is enhanced in 3D type I collagen hydrogel culture as a result of an increase in expression and localization of the discoidin domain receptor 1 (DDR1) that suppresses ERK phosphorylation and enhances type I collagen remodeling. Knockdown of DDR1 results in the reversion of stem cells from a physiologic 3D morphology to a two dimensional (2D) one, thereby inhibiting their ability to upregulate their osteogenic potential in response to the 3D environment. Given its inductive role in MSC differentiation, the ECM can be applied as an instructive cue for differentiating stem cells to promote their ability to regenerate tissue in vivo. To demonstrate this application we created defined protein microenvironments using a microbead encapsulation procedure. MSC encapsulated within these environments exhibited osteogenic potential both in vitro and in vivo and presents a way to engineer the local microenvironment of the stem cell niche for specific lineage commitment. External remodeling and internal signaling, therefore, couple to promote 'tissue' morphogenesis by generating crosstalk between signaling pathways that are geometrically separate in 2D. MSC use DDR1 to sense the three dimensionality of their microenvironment; and changes in cell shape that result from these dynamic matrix adhesions allow cells to integrate their signals in response to local changes in the ECM. MSC responding to injury and the disorganized matrix that they encounter within the wound site must interact through an iterative feedback loop to robustly regenerate mature tissue structure and function. Engineering of MSC function will consequently require continued elucidation of biological mechanisms and novel biomaterial development to define local, 3D microenvironments that replicate the control present in native tissue.

Luo, H., et al. (2019). "Effects of accelerated aging on characteristics, leaching, and toxicity of commercial lead chromate pigmented microplastics." Environmental Pollution: 113475.

It is of environmental significance to study the leaching performance of additives from microplastics (MPs) and further evaluate the toxicity of leachate to microalgae. Here, we investigated the effects of accelerated aging on characteristics, leaching, and toxicity of commercial lead chromate pigmented MPs.

Luo, H., et al. (2019). "Leaching behavior of fluorescent additives from microplastics and the toxicity of leachate to Chlorella vulgaris." Science of the Total Environment **678**: 1-9.

Chemical additives leaching from microplastics and their effects on physiology of microalgae are of environmental significance. So far, these issues remain unclear. Here, the leaching behavior of fluorescent additives from polyurethane sponge microplastics in simulated (acidic, saline, and basic water) and natural waters (river, lake, wetland, and sea water) was investigated. Release amount of additives increased with increasing solution pH and leaching time. The maximum release amount was reached at the leaching time of 12-24h and the 3,3'-diaminobenzidine-like substances were identified in the leachate. The leached concentrations of fluorescent additives

in simulated and natural waters followed the order of basic water>saline water>seawater>West Lake>River>Wetland. Effects of leachate and microplastics on growth and photosynthesis of Chlorella vulgaris were further evaluated. The maximum quantum efficiency of photosystem II (F_v/F_m) decreased with increasing leachate concentrations. Only high content (1.6gL⁻¹) of microplastics exerted significant inhibitory influence on cell photosynthesis when microalgae were exposed to microplastics alone. Retention of algal cells inside the porous sponge microplastics did not change their photosynthetic efficiency. These findings indicate that leaching process of additives from microplastics depends mainly on water environments and the leached chemicals may pose ecological risks to aquatic organisms.

Luo, T., et al. (2019). "Maternal Polystyrene Microplastic Exposure during Gestation and Lactation Altered Metabolic Homeostasis in the Dams and Their F1 and F2 Offspring." Environmental Science & Technology **53**(18): 10978-10992.

Microplastics (MPs) are considered as a pollutant of marine environments and have become a global environmental problem in recent years. A number of studies have demonstrated that MPs can enter the human food chain, and MPs have even been detected in human stools. Therefore, there is increasing concern about the potential risks of MPs to human and animal health. Here, we investigated maternal polystyrene MPs exposure during gestation and lactation and evaluated the potential effects on dams and the F1 (both PND 42 and 280) and F2 (PND 42) generations. The results of transcriptome and 16S rRNA sequencing indicated that MPs caused the metabolic disorder in maternal MPs associated with gut microbiota dysbiosis and gut barrier dysfunction. Simultaneously, maternal MPs exposure also had the intergenerational effects and even caused long-term metabolic consequences in the F1 and F2 generations. In addition, in F1 (PND 42), the composition of gut microbiota did not change significantly, while the hepatic transcriptome and serum metabolite changes showed the potential risk in metabolic disorder. Then, the potential of hepatic lipid accumulation was observed in adult F1 mice (PND 280), especially in the female mice. Our results demonstrated that maternal MPs exposure during gestation and lactation increases the risk of metabolic disorder, and these results provide new insight into the potential long-term hazards of MPs.

Luo, T., et al. (2019). "Maternal exposure to different sizes of polystyrene microplastics during gestation causes metabolic disorders in their offspring." Environmental Pollution **255**(Pt 1): 113122.

Microplastics (MPs) are highly concerned environmental pollutants that are ubiquitous in the environmental and might affect human and animal health. In this study, we exposed pregnant mice to 0.5 and 5mum with 100 and 1000 mug/L polystyrene MPs, then investigated maternal MPs exposure during gestation and evaluated the potential effects on the mice offspring (PND42). In the F1 offspring, the serum triglyceride (TG), total cholesterol (TC), high-density lipoprotein cholesterol (HDL-C) and low-density lipoprotein cholesterol (LDL-C) levels and hepatic TC, TG levels were altered, while some of them were only significant in 5mum MPs-treated group. Various serum metabolites including amino acids and acyl-carnitines were carried out by nonderivatized tandem mass spectrometry, there were 11 and 15 kinds of metabolites changes significantly in 0.5 and 5 mum MPs-treated groups, respectively. Furthermore, the changes of C0 and C0/(C16 + 18) indicators suggested the potential risk of fatty acid metabolism disorder, which was verified by hepatic genes expression. These results indicated that maternal exposure of two different sizes of polystyrene MPs increased risks of metabolic disorder in their offspring, and greater effects were observed in 5 mum MPs-treated groups. The data provides a preliminary exploration of the potential relationship between MPs and the risk metabolic disorder even in the next generation, which might offer new insights into the health risk assessment of MPs.

Luo, W., et al. (2018). "miR-27a is highly expressed in H1650 cancer stem cells and regulates proliferation, migration, and invasion." Journal of Cancer Research & Therapeutics **14**(Supplement): S1004-S1011.

Background: Cancer stem cells (CSCs) are responsible for tumor relapse after chemotherapy and radiotherapy in non-small cell lung cancer (NSCLC). The aim of this study is to explore the profile and role of microRNA (miRNA) in CSC of NSCLC.

Materials and Methods: We studied the expression of stem cell marker in side population cells and serum-free cultured spheres of NSCLC. We identified that CD133⁺ CD34⁻ cells are NSCLC stem cell. We isolated CD133⁺ CD34⁻ cells and CD133⁻ CD34⁺ cells with MicroBead Kit. We verified that H1650 CD133⁺ CD34⁻ cells have CSC characteristics with doxorubicin, radiation, and xenograft. We studied miRNA expression profile in H1650 and HCC827 CD133⁺ CD34⁻ cells with microarray analysis. We detected proliferation, migration, and invasion with 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide assay, scratch test, and Transwell chamber invasion assay, respectively.

Results: CD133 and CD34 are CSC markers in H1650. We demonstrated that H1650 CD133⁺ CD34⁻ cells have CSC characteristics and found that miR-27a was highly expressed in H1650 CD133⁺ CD34⁻ cells. In addition, we showed that miR-27a regulates proliferation, migration, and invasion in H1650 cell line and demonstrated that miR-27a expression was positively related to epidermal growth factor receptor in NSCLC cell lines.

Conclusions: CD133⁺ CD34⁻ is a CSC marker in H1650. miR-27a is highly expressed in H1650 CSCs and regulates cancer development in H1650. miR-27a may be a potential target for NSCLC therapy.

Luo, Y., et al. (2014). "IL-37, an inhibitor of innate inflammation and adaptive immunity, is elevated in the blood of melanoma patients and is related with poor prognosis." Journal of Investigative Dermatology **1)**: S100.

Developing methodologies to identify biomarkers in easily accessible body fluids is valuable for the early diagnosis and management of cancer patients. Here, using microarray analysis, we identified 6 highly upregulated transcripts in melanoma blood samples compared with healthy blood samples (>5-fold; P<0.01). Of particular interest was IL-37, a member of IL-1 family. IL-37 reduces innate inflammation and adaptive immune responses. We examined IL-37 gene expression of whole blood cells from 14 healthy individuals and 45 melanoma patients (5 from stage I, 8 from stage II, 11 from stage III and 21 from stage IV). While IL-37 expression was very low in healthy individuals, the level was 6.3-fold increased in melanoma patient samples (P<0.001). IL-37 levels among melanoma patients from different stages were overall constant. Fourteen melanoma patients whose blood samples were analyzed for IL-37 levels were clinically followed for up to 22 months. Whereas 100% (5 out of 5) of melanoma patients whose IL-37 expression was high showed disease progression, 66.7% (6 out of 9) of melanoma patients whose IL-37 expression was low remained stable, suggesting that elevated IL-37 levels were related with poor prognosis. To understand cell subsets responsible for the elevated IL-37 in blood, we used microbeads to fractionate blood samples into CD3, CD14, CD15, CD19, CD45 and CD56. IL-37 was almost exclusively expressed in CD45+ cells but undetectable in CD45- cells. Among CD45+ cells, higher levels of IL-37 were detected in CD3+ cells and CD19+ cells in melanoma blood samples, suggesting IL-37-mediated suppression of adaptive immunity in

melanoma patients. In conclusion, IL-37 may not only be a biomarker of melanoma but also serve as a therapeutic target in melanoma.

Luo, Y. D., et al. (2019). "Distribution Characteristics of Microplastics in Qingdao Coastal Beaches. [Chinese]." Huan jing ke xue= Huanjing kexue **40**(6): 2631-2638.

Microplastics (MPs, plastic fibers, debris, or particles that are generally smaller than 5 mm in diameter) can serve as carriers for hazardous substances, which are ingested by organisms in the ocean and can affect their growth and metabolism. Moreover, MPs will spread with ocean currents, and MP pollution has become a global problem. In this study, the MP abundance distribution of four typical beaches near the coast of Qingdao was studied by the combination of ordinary microscope and fluorescence microscope methods. In addition, the distribution of MPs collected from various beaches in different particle size ranges, shapes, and chemical compositions was discussed. Abundances on the sea surface varied between 5.05x103 particles.m-3 and 1.25x104 particles.m-3, and the concentration of MPs in sand varied between 1.91x103 particles.m-2 and 4.35x103 particles.m-2, with no significant differences detected among the four beaches examined. The results show the pervasiveness of MP pollution in coastal environments of Qingdao. The size of particles found in this study ranged from 5 mm to 50 mum, and increases in abundance were detected with the decreasing particle size. Polypropylene (PP), polyethylene (PE), polystyrene (PS), polyethylene terephthalate (PET), polyvinyl chloride (PVC), 96% polystyrene+4% butadiene copolymer (SB), polymethyl acrylate (PMA), and polyamide (PA) were present in seawater in coastal environments of Qingdao, and compared with the seawater samples, no PA or PMA were found in sand. Research results indicated that fiber was dominant in seawater and sand. MPs in the sand were similar to those in seawater in terms of the particle size, shape, and composition, thus indicating that the seawater and sand of the bathing beaches in Qingdao may have the same pollution sources, e. g., the packaging industry, clothing textile industry, and tourism. This paper studies the distribution and sources of MPs in the bathing beaches of Qingdao, and it provides basic data for research and supervision of environmental MP pollution in Chinese coastal zones.

Luo, Y. D., et al. (2019). "[Distribution Characteristics of Microplastics in Qingdao Coastal Beaches]." Huanjing Kexue/Environmental Science **40**(6): 2631-2638.

Microplastics (MPs, plastic fibers, debris, or particles that are generally smaller than 5 mm in diameter) can serve as carriers for hazardous substances, which are ingested by organisms in the ocean and can affect their growth and metabolism. This paper studies the distribution and sources of MPs in the bathing beaches of Qingdao, and it provides basic data for research and supervision of environmental MP pollution in Chinese coastal zones.

Luostarinen, A., et al. (2017). "Low IL-2 concentration favors generation of early memory T cells over terminal effectors during CAR T-cell expansion." Cytotherapy **19 (5 Supplement 1)**: S8.

Adoptive T-cell therapy offers new options for cancer treatment. The therapeutic efficacy of T-cell therapy is linked to the persistence of administrated T cells, which is dependent on T-cell memory. Hence, the need for cells possessing early memory phenotypes in T-cell products is evident. The amount of interleukin-2 (IL-2) supplementation during in vitro expansion affects T-cell proliferation and effector differentiation. Here, we present a simplified and costeffective expansion method for the production of chimeric antigen receptor (CAR) T cells with potentially improved therapeutic capacity. Lymphocytes were transduced with third generation lentiviral vectors encoding CD19-targeted CARs, and expanded using CD3/CD28 microbeads and differing IL-2 concentrations (range from 0 to 300 IU/mL). After expanding the cells for 10 to 20-days, the effects of altering IL-2 levels and duration of expansion on the phenotype and functionality of the T-cell products were assessed. High IL-2 concentrations favored the generation of more differentiated effector T-cell phenotypes and decreased the proportion of early T memory (TM) cells. TM stem cells (TSCM, CD95+CD45RO-CD45RA+CD27+), which represent the most primitive T-cell memory phenotype with possibly the highest potential to provide long-term persistence, were not present in all expansions, but their existence was independent of IL-2 and could be linked to expansion kinetics. All CD19-CAR T-cell products demonstrated in vitro response against CD19+ leukemia cell lines, and the effector function was enhanced when T cells were expanded in high IL-2 concentration. In summary, production of CAR T cells without any cytokine supplementation yielded the highest proportion of early TM cells, provided a tenfold cell expansion, and the cells were functionally potent. The memory T cell composition of T-cell preparations can be adjusted to favor of TM cells by limiting the length of expansion and using a low level of supplemental IL-2 in T-cell expansion. This method yields early memory T cells with potentially improved in vivo effectiveness. These findings are significant for robust and cost-effective T-cell manufacturing.

Luoto, T. P., et al. (2019). "Biogeochemical cycling and ecological thresholds in a High Arctic lake (Svalbard)." Aquatic Sciences **81**(2): 1-16.

Lakes are a dominant feature of the Arctic landscape and a focal point of regional and global biogeochemical cycling. We collected a sediment core from a High Arctic Lake in southwestern Svalbard for multiproxy paleolimnological analysis. The aim was to find linkages between the terrestrial and aquatic environments in the context of climate change to understand centennial-long Arctic biogeochemical cycling and environmental dynamics. Two significant thresholds in elemental cycling were found based on sediment physical and biogeochemical proxies that were associated with the end of the cold Little Ice Age and the recent warming. We found major shifts in diatom, chironomid and cladoceran communities and their functionality that coincided with increased summer temperatures since the 1950s. We also discovered paleoecological evidence that point toward expanded bird (Little Auk) colonies in the catchment alongside climate warming. Apparently, climate-driven increase in glacier melt water delivery as well as a prolonged snow- and ice-free period have increased the transport of mineral matter from the catchment, causing significant water turbidity and disappearance of several planktonic diatoms and clear-water chironomids. We also found sedimentary accumulation of microplastic particles following the increase in Little Auk populations suggesting that seabirds potentially act as biovectors for plastic contamination. Our study demonstrates the diverse nature of climate-driven changes in the Arctic lacustrine environment with increased inorganic input from the more exposed catchment, larger nutrient delivery from the increased bird colonies at the surrounding mountain summits and subsequent alterations in aquatic communities.

Lupo, B., et al. (2014). "Preparation of alginate microspheres by emulsification/internal gelation to encapsulate cocoa polyphenols." Food Hydrocolloids **38**: 56-65.

Encapsulation of cocoa extract was performed by emulsification/internal gelation in alginate microspheres. A suitable gelling was determined with a minimum of 1.8x10⁻⁴ mol of Ca⁺²/g alginate. The pH influence in alginate gels showed similar viscoelastic properties in the range of pH 3.5-10. Citrate and carbonate salts were uses as calcium sources, obtaining smaller spheres with citrate source. Moreover, SEM of microbeads made with citrate show uniform surface while the carbonate ones seem rough. Emulsions were formulated with several concentrations of Span 80, Span 85, Span 80-Tween 80 and polyglycerol polyricinoleate (PGPR). The most stable, also with the smallest microspheres were that prepared with PGPR. A shrinkage gelation factor of 0.8 was observed between drop size of emulsions and blank microspheres obtained, maintaining the shape and size distribution. When cocoa extract was encapsulated in microspheres, around 60% of retention was easily reached. The Peppas-Sahlin model fitted polyphenols release from microbeads, suggesting the existence of a relaxation/dissolution mechanism. The obtained cocoa microbeads could increase the daily intake of antioxidants when implemented in a food product.

Lusher, A. L., et al. (2018). "Incidence of marine debris in cetaceans stranded and bycaught in Ireland: recent findings and a review of historical knowledge." Environmental Pollution **232**: 467-476.

Interactions between marine mammals and plastic debris have been the focus of studies for many years. Examples of interactions include entanglement in discarded fishing items or the presence of ingested debris in digestive tracts. Plastics, including microplastics, are a form of marine debris globally distributed in coastal areas, oceanic waters and deep seas. Cetaceans which strand along the coast present a unique opportunity to study interactions between animals with macro- and microplastics. A combination of novel techniques and a review of historical data was used to complete an extensive study of cetaceans interacting with marine debris within Irish waters. Of the 25 species of marine mammals reported in Irish waters, at least 19 species were reported stranded between 1990 and 2015 (n=2934). Two hundred and forty-one of the stranded cetaceans presented signs of possible entanglement or interactions with fisheries. Of this number, 52.7% were positively identified as bycatch or as entangled in fisheries items, 26.6% were classified as mutilated and 20.7% could not be related to fisheries but showed signs of entanglement. In addition, 274 cetaceans were recorded as by-catch during observer programmes targeting albacore tuna. Post-mortem examinations were carried out on a total of 528 stranded and bycaught individuals and 45 (8.5%) had marine debris in their digestive tracts: 21 contained macrodebris, 21 contained microdebris and three had both macro- and microdebris. Forty percent of the ingested debris were fisheries related items. All 21 individuals investigated with the novel method for microplastics contained microplastics, composed of fibres (83.6%) and fragments (16.4%). Deep diving species presented more incidences of

macrodebris ingestion but it was not possible to investigate this relationship to ecological habitat. More research on the plastic implications to higher trophic level organisms is required to understand the effects of these pollutants.

Lusher, A. L., et al. (2015). "Microplastic and macroplastic ingestion by a deep diving, oceanic cetacean: the True's beaked whale Mesoplodon mirus." Environmental Pollution **199**: 185-191.
When mammals strand, they present a unique opportunity to obtain insights into their ecology. In May 2013, three True's beaked whales (two adult females and a female calf) stranded on the north and west coasts of Ireland and the contents of their stomachs and intestines were analysed for anthropogenic debris. A method for identifying microplastics ingested by larger marine organisms was developed. Microplastics were identified throughout the digestive tract of the single whale that was examined for the presence of microplastics. The two adult females had macroplastic items in their stomachs. Food remains recovered from the adult whales consisted of mesopelagic fish (Benthosema glaciale, Nansenia spp., Chauliodius sloani) and cephalopods, although trophic transfer has been discussed, it was not possible to ascertain whether prey were the source of microplastics. This is the first study to directly identify microplastics <5 mm in a cetacean species.

Lusher, A. L., et al. (2013). "Occurrence of microplastics in the gastrointestinal tract of pelagic and demersal fish from the English Channel." Marine Pollution Bulletin **67**(1-2): 94-99.
Microplastics are present in marine habitats worldwide and laboratory studies show this material can be ingested, yet data on abundance in natural populations is limited. This study documents microplastics in 10 species of fish from the English Channel. 504 Fish were examined and plastics found in the gastrointestinal tracts of 36.5%. All five pelagic species and all five demersal species had ingested plastic. Of the 184 fish that had ingested plastic the average number of pieces per fish was 1.90. +/-. 0.10. A total of 351 pieces of plastic were identified using FT-IR Spectroscopy; polyamide (35.6%) and the semi-synthetic cellulosic material, rayon (57.8%) were most common. There was no significant difference between the abundance of plastic ingested by pelagic and demersal fish. Hence, microplastic ingestion appears to be common, in relatively small quantities, across a range of fish species irrespective of feeding habitat. Further work is needed to establish the potential consequences. © 2012 Elsevier Ltd.

Lusher, A. L., et al. (2016). "Microplastic interactions with North Atlantic mesopelagic fish." ICES Journal of Marine Science **73**(4): 1214-1225.
Microplastics in the marine environment are well documented, and interactions with marine biota have been described worldwide. However, interactions with vertically migrating fish are poorly understood. The diel vertical migration of mesopelagic fish represents one, if not the largest, vertical migration of biomass on the planet, and is thus an important link between the euphotic zone, transporting carbon and other nutrients to global deep sea communities. Knowledge of how mesopelagic fish interact and distribute plastic as a marine contaminant is required as these populations have been identified as a potential global industrial fishery for fishmeal production. Ingestion of microplastic by mesopelagic fish in the Northeast Atlantic was studied. Approximately 11% of the 761 fish examined had microplastics present in their digestive tracts. No clear difference in ingestion frequency was identified between species, location, migration behaviour, or time of capture. While ingesting microplastic may not negatively impact individual mesopelagic fish, the movement of mesopelagic fish from the euphotic zone to deeper waters could mediate transfer of microplastics to otherwise unexposed species and regions of the world's oceans.

Lusher, A. L., et al. (2017). "Sampling, isolating and identifying microplastics ingested by fish and invertebrates." Analytical Methods **9**(9): 1346-1360.

Microplastic debris (5 mm) is a prolific environmental pollutant, found worldwide in marine, freshwater and terrestrial ecosystems. Interactions between biota and microplastics are prevalent, and there is growing evidence that microplastics can incite significant health effects in exposed organisms. To date, the methods used to quantify such interactions have varied greatly between studies. Here, we critically review methods for sampling, isolating and identifying microplastics ingested by environmentally and laboratory exposed fish and invertebrates. We aim to draw attention to the strengths and weaknesses of the suite of published microplastic extraction and enumeration techniques. Firstly, we highlight the risk of microplastic losses and accumulation during biotic sampling and storage, and suggest protocols for mitigating contamination in the field and laboratory. We evaluate a suite of methods for extracting microplastics ingested by biota, including dissection, depuration, digestion and density separation. Lastly, we consider the applicability of visual identification and chemical analyses in categorising microplastics. We discuss the urgent need for the standardisation of protocols to promote consistency in data collection and analysis. Harmonized methods will allow for more accurate assessment of the impacts and risks microplastics pose to biota and increase comparability between studies. 2017 The Royal Society of Chemistry.

Luz, M. R., et al. (2014). "Abiotic and Biotic Degradation of Oxo-Biodegradable Plastic Bags by Pleurotus ostreatus: e107438." PLoS ONE **9**(11).

In this study, we evaluated the growth of Pleurotus ostreatus PLO6 using oxo-biodegradable plastics as a carbon and energy source. Oxo-biodegradable polymers contain pro-oxidants that accelerate their physical and biological degradation. These polymers were developed to decrease the accumulation of plastic waste in landfills. To study the degradation of the plastic polymers, oxo-biodegradable plastic bags were exposed to sunlight for up to 120 days, and fragments of these bags were used as substrates for P. ostreatus. We observed that physical treatment alone was not sufficient to initiate degradation. Instead, mechanical modifications and reduced titanium oxide (TiO_2) concentrations caused by sunlight exposure triggered microbial degradation. The low specificity of lignocellulolytic enzymes and presence of endomycotic nitrogen-fixing microorganisms were also contributing factors in this process.

Luz, M. R., et al. (2013). "Degradation of Oxo-Biodegradable Plastic by Pleurotus ostreatus. e69386." PLoS ONE **8**(8).

Growing concerns regarding the impact of the accumulation of plastic waste over several decades on the environmental have led to the development of biodegradable plastic. These plastics can be degraded by microorganisms and absorbed by the environment and are therefore gaining public support as a possible alternative to petroleum-derived plastics. Among the developed biodegradable plastics, oxo-biodegradable polymers have been used to produce plastic bags. Exposure of this waste plastic to ultraviolet light (UV) or heat can lead to breakage of the polymer chains in the plastic, and the resulting compounds are easily degraded by microorganisms. However, few studies have characterized the microbial degradation of oxo-biodegradable plastics. In this study, we tested the capability of Pleurotus ostreatus to degrade oxo-biodegradable (D2W) plastic without prior physical treatment, such as exposure to UV or thermal heating. After 45 d of incubation in substrate-containing plastic bags, the oxo-biodegradable plastic, which is commonly used in supermarkets, developed cracks and small holes in the plastic surface as a result of the formation of hydroxyl groups and carbon-oxygen bonds. These alterations may be due to laccase activity. Furthermore, we observed the degradation of the dye found in these bags as well as mushroom formation. Thus, P. ostreatus degrades oxo-biodegradable plastics and produces mushrooms using this plastic as substrate.

Lv, L., et al. (2019). "A simple method for detecting and quantifying microplastics utilizing fluorescent dyes - safranine T, fluorescein isophosphate, Nile red based on thermal expansion and contraction property." Environmental Pollution **255**(Part 2).

Microplastics (particle size <5 mm) are an emerging contaminant for aquatic environmental, which have attracted increasing attention in worldwide range. In this study, an improved fluorescent staining method for detection and quantification of microplastics was developed based on thermal expansion and contraction. This method is effective in detection of polyethylene, polystyrene, polyvinyl chloride and polyethylene terephthalate plastic particles. In order to avoid error statistics caused by pretreatment, various characterizations of microplastics were measured after heated, such as microstructure, compositions and thermostability. The results showed that there was no significant damage to microplastics even under heating condition at 75 degrees C for 30 min, and the stained microplastics had strong stability for up to two months. Moreover, this method has been successfully applied to the quantification of microplastics in biological samples and result showed there were about 54 particles g⁻¹ (dry weight) microplastics in the Sipunculus nudus. This new method provides a reliable method for quantitative analysis of microplastics in environment and biological tissue.

Lv, S., et al. (2018). "Physicochemical evolutions of starch/poly (lactic acid) composite biodegraded in real soil." Journal of Environmental Management **228**: 223-231.

Plastic pollution is a major environmental problem and the waste disposal is a challenge in this case. Poly (lactic acid) (PLA) based biodegradable materials is one of the most attractive polymers which can fulfill the current demand. In this work, the degradation of starch/PLA composite was investigated in real soil environment. The weight loss results demonstrated that the degradation rate of PLA could be accelerated by starch. Scanning electrical microscopy (SEM) and Fourier transform infrared (FTIR) results showed that the samples degraded faster with the presence of starch. The mechanical strengths had an abrupt decrease for the starch/PLA composite while that of PLA only decreased in a low degree. The distribution of carboxyl group intensity and carbon atomic percent reflected the heterogeneity of biodegradation for starch/PLA composite in soil. Moreover, the variation of internal carbon atomic percent was higher than that on the surface, demonstrating that the degradation of starch/PLA composite was bulk degradation. Based on the role of starch played in starch/PLA composite and the physicochemical performance evolutions during biodegradation, it should create a scientific basis for people interested in studying the biodegradation of PLA, and provide some knowledge about controlling the biodegradation rate of PLA through adjusting the content of starch in the composite.

Lv, W., et al. (2019). "Microplastic pollution in rice-fish co-culture system: a report of three farmland stations in Shanghai, China." Science of the Total Environment **652**: 1209-1218.

Microplastics are emerging contaminants of increasing concern. Despite the occurrence of microplastics in farmland soils, the knowledge on microplastics in rice-fish co-culture ecosystems is limited. In this study, we investigated the distribution of microplastics in three rice-fish culture stations in Shanghai. During non-rice and rice-planting periods, microplastics in water, soils and aquatic animals (eel, loach and crayfish) were systematically assayed using

methods of NaCl density extraction, H₂O₂ digestion and micro-Fourier transform infrared spectroscopy. Results showed that average microplastic abundances were 0.4+or-0.1 items L⁻¹, 10.3+or-2.2 items kg⁻¹, 1.7+or-0.5 items individual⁻¹ in water, soils and aquatic animal samples, respectively. We found an increasing trend in microplastic abundances in water, soil and animal samples from non-rice period to rice-planting period. Almost all of microplastics were found in digestive tracts of animals. Major microplastics were small (<1 mm) polyethylene and polypropylene fibers, with color of white and translucent. Size, shape, color and polymer type distributions of microplastics were similarly found in environmental and animal samples. Moreover, microplastic abundances in aquatic animals correlated to abundance in farmland soils. This study, for the first time, reveals the occurrence and characteristics of microplastic pollution in rice-fish culture ecosystem which suggests the potential ecological risks of microplastics in the agroecosystem.

Lwanga, E. H., et al. (2017). "Incorporation of microplastics from litter into burrows of Lumbricus terrestris." Environmental Pollution **220**(Part A): 523-531.

Pollution caused by plastic debris is an urgent environmental problem. Here, we assessed the effects of microplastics in the soil surface litter on the formation and characterization of burrows built by the anecic earthworm Lumbricus terrestris in soil and quantified the amount of microplastics that was transported and deposited in L. terrestris burrows. Worms were exposed to soil surface litter treatments containing microplastics (Low Density Polyethylene) for 2 weeks at concentrations of 0%, 7%, 28%, 45% and 60%. The latter representing environmentally realistic concentrations found in hot spot soil locations. There were significantly more burrows found when soil was exposed to the surface treatment composed of 7% microplastics than in all other treatments. The highest amount of organic matter in the walls of the burrows was observed after using the treatments containing 28 and 45% microplastics. The highest microplastic bioturbation efficiency ratio (total microplastics (mg) in burrow walls/initial total surface litter microplastics (mg)) was found using the concentration of 7% microplastics, where L. terrestris introduced 73.5% of the surface microplastics into the burrow walls. The highest burrow wall microplastic content per unit weight of soil (11.8+or-4.8 g kg⁻¹) was found using a concentration of 60% microplastics. L. terrestris was responsible for size-selective downward transport when exposed to concentrations of 7, 28 and 45% microplastics in the surface litter, as the fraction <=50 micro m microplastics in burrow walls increased by 65% compared to this fraction in the original surface litter plastic. We conclude that the high biogenic incorporation rate of the small-fraction microplastics from surface litter into burrow walls causes a risk of leaching through preferential flow into groundwater bodies. Furthermore, this leaching may have implications for the subsequent availability of microplastics to terrestrial organisms or for the transport of plastic-associated organic contaminants in soil.

Lwanga, E. H., et al. (2018). "Decay of low-density polyethylene by bacteria extracted from earthworm's guts: a potential for soil restoration." Science of the Total Environment **624**: 753-757.

Low-density polyethylene (LDPE) is the most abundant source of microplastic pollution worldwide. A recent study found that LDPE decay was increased and the size of the plastic was decreased after passing through the gut of the earthworm Lumbricus terrestris (Oligochaeta). Here, we investigated the involvement of earthworm gut bacteria in the microplastic decay. The bacteria isolated from the earthworm's gut were Gram-positive, belonging to phylum Actinobacteria and Firmicutes. These bacteria were used in a short-term microcosm experiment performed with gamma-sterilized soil with or without LDPE microplastics (MP). We observed that the LDPE-MP particle size was significantly reduced in the presence of bacteria. In addition,

the volatile profiles of the treatments were compared and clear differences were detected. Several volatile compounds such as octadecane, eicosane, docosane and tricosane were measured only in the treatments containing both bacteria and LDPE-MP, indicating that these long-chain alkanes are byproducts of bacterial LDPE-MP decay.

Lyons, B. P., et al. (2020). "Marine plastic litter in the ROPME Sea Area: Current knowledge and recommendations." Ecotoxicology & Environmental Safety **187**: N.PAG-N.PAG.
The impact of marine litter, particularly plastic waste, is widely acknowledged as a growing global concern. Marine litter is an understudied issue in the Regional Organisation for Protection of the Marine Environment (ROPME) Sea Area where rapid economic growth has already placed considerable stress on infrastructure and coastal ecosystems. This paper outlines some of the drivers for waste generation in region and reviews the available literature to summarise the current state of knowledge on the environmental fate, behaviour and impact of marine litter within the ROPME Sea Area. While data is limited, those studies conducted demonstrate marine litter is posing a clear and growing threat to the environmental and socioeconomic prosperity of the ROPME Sea Area. The development of regional and national marine litter reduction plans are clearly a priority to focus and coordinate activity across multiple stakeholders. Discussion of the potential environmental impacts arising as a result of marine litter are presented together with a roadmap for establishing and implementing a ROPME Sea Area Marine Litter and Single-Use Plastic Action Plan. • Marine litter is understudied across the Regional Organisation for Protection of the Marine Environment (ROPME) Sea Area. • Economic growth and poor waste management in region has led to an increase in marine litter, particularly plastic based. • Small, but growing body of scientific literature now showing widespread plastic contamination of the ROPME Sea Area. • A roadmap for establishing and implementing a ROPME Sea Area Marine Litter and Single-Use Plastic Action Plan is presented. [ABSTRACT FROM AUTHOR]

Lyu, R., et al. (2015). "Leaching characteristics and groundwater health risk assessment of PBDEs from consumer plastic product waste." Environmental Chemistry - Huanjing Huaxue **34**(1): 37-43.
Leaching characteristics of PBDEs from some consumer plastic product waste and health risk were investigated in a typical disposal scenario. The results showed that after reaching the equilibrium, the concentrations of the capital sigma sub(21), PBDEs leached from the crushed plastic waste were 20.00 mu g times kg super(-1), 63.65 mu g times kg super(-1), 125.60 mu g times kg super(-1) in solutions of sulfuric acid/ nitric acid, acetic acid and humic acid respectively, and BDE209 was the dominant congener. The dissolution rate of the capital sigma sub(21), PBDEs in waste landfill site was higher than those in stockpiling and non-standard landfill site. The highest concentration of the capital sigma sub(21), PBDEs in groundwater 500 meters downstream the landfill was 39.67 mu g times L super(-1). The non-cancer risk from PBDEs was 2.11 x 10 super(-1) when the waste was put into the landfill, while the non-cancer risk from BDE209 was 1.85 x 10 super(-1). The non-cancer risk (hazard index, HI) were below the value accepted from the US EPA (1.0). This consumer plastic product waste could he put into the waste landfill site.

Ma, B., et al. (2019). "Removal characteristics of microplastics by Fe-based coagulants during drinking water treatment." Journal of Environmental Sciences (China) **78**: 267-275.

Microplastics have caused great concern worldwide recently due to their ubiquitous presence within the marine environment. Up to now, most attention has been paid to their sources, distributions, measurement methods, and especially their eco-toxicological effects. With microplastics being increasingly detected in freshwater, it is urgently necessary to evaluate their behaviors during coagulation and ultrafiltration (UF) processes. Herein, the removal behavior of polyethylene (PE), which is easily suspended in water and is the main component of microplastics, was investigated with commonly used Fe-based salts.

Ma, B., et al. (2019). "Characteristics of microplastic removal via coagulation and ultrafiltration during drinking water treatment." Chemical Engineering Journal **359**: 159-167.

Microplastics have garnered much attention worldwide as a new emerging pollutant, especially because of their eco-toxicological effects in marine environments. As they are gradually detected in freshwaters, understanding how microplastics, with their small particle size and low density, will behave during current drinking water treatment processes is urgently needed. In this study, Al- and Fe-based salts were used in the presence of polyethylene (PE), which is suspended/floats easily in water and is the main constituent of microplastics. Results showed that Al-based salts performed better in PE removal efficiency than Fe-based salts. The smaller the PE particle size, the higher the removal efficiency. However, a low removal efficiency was observed, even with a high Al-based salt dosage of 15 mM (below 40%). Additionally, water conditions, such as ionic strength, turbidity level, barely influenced the removal efficiency. In comparison to pH, polyacrylamide (PAM) addition played an important role in removing PE; especially anionic PAM addition, because of the positively charged Al-based flocs it generates under neutral conditions. For ultrafiltration, although PE particles can be completely rejected, slight membrane fouling was induced after coagulation with conventional Al-based salts. With increasing dosage, membrane fouling was gradually aggravated owing to the thick cake layer formed. However, the larger the PE particles, the greater the roughness of the Al-based floc cake layer, leading to less severe membrane fouling. Based on this investigation, the microplastic removal behaviors exhibited during coagulation and ultrafiltration processes have potential application in drinking water treatment.

Ma, D., et al. (2018). "Quantitative detection of exosomal microRNA extracted from human blood based on surface-enhanced Raman scattering." Biosensors & Bioelectronics **101**: 167-173.

Since the nature of the exosomal lipid bilayer can allow miRNAs to be protected from degradation by cellular RNAses in body fluids, exosomal microRNA (miRNA) has become an ideal source of non-invasive biomarkers for the early diagnosis and prognosis. In this paper, a new surface-enhanced Raman scattering (SERS) analysis strategy combining stable SERS reporter element and duplex-specific nuclease (DSN)-assisted signal amplification for quantitative detection of exosomal miRNA extracted from human blood is proposed. Firstly, we prepared SERS signal reporter of Au@R6G@AgAu nanoparticles (R6G attachment on the gold nanoparticles, then encapsulated in AgAu alloy shell nanoparticles named as ARANPs) with an inter small nanogap to generate stable SERS signal. Then, ARANPs and separating substrate of silicon microbead (SiMB) were then covalently attached to the 3'- and 5'- end of capture probe (CP) targeting exosomal miRNA. Upon target miRNA binding, DNA in heteroduplexes could be specifically cleaved by DSN and resulted in the release of ARANPs from the surface of SiMB. Meanwhile, target miRNA remained intact and subsequently involved in the next round of target-recycling amplification. The combination of stable SERS intensity and signal amplification

significantly improved the sensitivity of the sensing systems, resulting in detection limits of 5 fM. More importantly, this method also could be used for the detection of exosomal miRNAs extracted from the blood collected from patients of recurrence in non-small-cell lung cancer (NSCLC), with a detection of 5.0muL of sample volume, which has potential for point-of-care testing (POCT) in clinical analysis.

Ma, J., et al. (2020). "Do combined nanoscale polystyrene and tetracycline impact on the incidence of resistance genes and microbial community disturbance in Enchytraeus crypticus?" Journal of Hazardous Materials **387**: 122012.

It has been proved that nanoplastics can effectively adsorb pollutants and thus influence their behavior and availability. The combined toxic effects of nanoplastic and its adsorbed pollutant on the soil fauna are still not well known. We used high-throughput quantitative PCR to explore the effects of oral nanoscale polystyrene and tetracycline exposure on antibiotic resistance genes in the soil invertebrate Enchytraeus crypticus, and used bacterial 16S rRNA gene amplification sequencing to examine the response of the microbiome of E. crypticus. After 14 days of tetracycline and nanoscale polystyrene exposure, we terminated exposure and monitored the restoration of ARGs and microbiome in the E. crypticus.

Ma, J., et al. (2019). "Effect of microplastic size on the adsorption behavior and mechanism of triclosan on polyvinyl chloride." Environmental Pollution **Part B. 254 (no pagination)**(113104).

Microplastics in water environment and its ability to load various environmental pollutants have attracted wide attention in recent years. However, effect of microplastic size on the adsorption behavior of environmental pollutants and interaction mechanism has not been thoroughly explored. In this study, triclosan (TCS) was selected as model pollutant, and polyvinyl chloride (PVC) with different particle sizes (small size (<1 mum) is recorded as PVC-S and PVC-L means large particle size of about 74 mum) were used as the typical microplastics, the adsorption behavior of TCS on PVC was investigated by studying kinetics, isotherms, and other influencing factors, such as pH and salinity. The results indicate PVC-S has greater distribution coefficient k<inf>d</inf> values of TCS (1.35 L/g > 1.05 L/g) and stronger adsorption capacity (12.7 mg/g > 8.98 mg/g) compared with PVC-L, which may be due to higher specific surface area, stronger hydrophobicity and relatively small electronegative property of PVC-S. Moreover, the initial pH value and salinity of the solution played crucial role in the adsorption process. The distribution diffusion mechanisms (including liquid-film diffusion and intra-particle diffusion), hydrophobic interaction, electrostatic interaction, halogen bonding, and hydrogen bonding may be the important reasons for adsorption. These findings show that MPs with different particle sizes have vary adsorption behaviors and load capacities for environmental pollutants, which deserve our further concerned. Ma, X., et al. (2015). "Safety and efficacy of third-party umbilical cord blood-derived regulatory T cells." Xenotransplantation **1)**: S89.

Background: More and more studies have shown the potential clinical application of Treg from umbilical cord blood (UCB) could not only to reduce the risk of acute GvHD after allogeneic transplantation but also to suppress graft rejection after solid organ transplantation and the treatment of autoimmune disease. If Treg from third party UCB would not induce immune response by themselves it would make UCB as an excellent source of regulatory T cells. The goal of our study is to demonstrate the safety and efficacy of third-party, ex-vivo-expanded, UCBderived Treg in cell therapies. Method(s): Treg was isolated from UCB with one step way and the phenotyping was analyzed by flow cytometry (FACS). Fresh isolated Treg was then cultured with CD3/CD28 microbeads in vitro for 3 weeks. MLR assay was used to identify the function of Treg in vitro. To determine the immunogenicity of Treg from UCB stimulation assay was performed. In stimulation assay T responder cells and Treg were human leukocyte antigen (HLA) mismatch or partial match. A xenogenic GvHD mouse model was used to test whether Treg from the third party could prevent GvHD. Result(s): With the use of magnetic cell sorting, natural Treg was isolated from CD25 by one step positive selection and the range of CD25+ cells were 2.4%~5% among cord blood mononuclear cells (CBMC). For 60 ml cord blood 5~9 x 106 Treg could be enriched. The phenotype of fresh isolated Treg was with high expression of CD4, CD25 and Foxp3. After 3 weeks expansion UCB derived Treg retained Treg phenotype but had a significantly increased expression of HLA-DR, and CD45RO when compared with the fresh isolated Treg. MLR assay also showed remarkably higher suppression ability of expanded Treg in vitro compared to the fresh isolated Treg. By luminex-R-SSO assay the expanded Treg from cord blood or adult PBMC and T responder cells from adult PBMC were distributed into partial match or mismatch group. At partial match group Treg and T responder cells were at least 2-4/6 HLA-A, B, DR match. At mismatch group there was only 1-0/6 HLA-A, B, DR match. CFSE labeled T responder cells were stimulated by irradiated Treg at low responder: Treg ratio of 1 : 1 and high responder: Treg ratio of 10 : 1. The results showed at low responder: Treg ratio the proliferation of T responder cells stimulated by partial matched Treg isolated from PBMC was 11.34%. However its proliferation was only 0.28% when stimulated by partial matched Treg from cord blood. In mismatch group the proliferation of T responder cells was 12.54% and 8.03%, respectively stimulated by Treg isolated from PBMC and CBMC. At high responder: Treg ratio of 10 : 1, the proliferation of T responder cells stimulated by Treg from PBMC or CBMC was very low and showed no difference not only in partial match group but also in mismatch group. NOD-SCID IL-2Rcnull mice with sublethal irradiation followed by injection of 1 x 107 PBMC was explored as GvHD model. In our NOD-SCID IL-2Rcnull model of GvHD, Treg from third party cord blood has more potent at improving GvHD score and significantly superior overall survival compared to Treg from the third party PBMC. Conclusion(s): Third party umbilical cord blood derived Treg would be a viable source of human Treg for cellular therapy not only because of its high yield and good suppressive ability but also for its low immunogenicity.

Ma, Y., et al. (2016). "Effects of nanoplastics and microplastics on toxicity, bioaccumulation, and environmental fate of phenanthrene in fresh water." Environmental Pollution **219**: 166-173.

Contamination of fine plastic particles (FPs), including micrometer to millimeter plastics (MPs) and nanometer plastics (NPs), in the environment has caught great concerns. FPs are strong adsorbents for hydrophobic toxic pollutants and may affect their fate and toxicity in the environment; however, such information is still rare. We studied joint toxicity of FPs with phenanthrene to Daphnia magna and effects of FPs on the environmental fate and bioaccumulation of ¹⁴C-phenanthrene in fresh water. Within the five sizes particles we tested (from 50 nm to 10 micro m), 50-nm NPs showed significant toxicity and physical damage to D. magna. The joint toxicity of 50-nm NPs and phenanthrene to D. magna showed an additive effect. During a 14-days incubation, the presence of NPs significantly enhanced bioaccumulation of phenanthrene-derived residues in daphnid body and inhibited the dissipation and transformation of phenanthrene in the medium, while 10- micro m MPs did not show significant effects on the bioaccumulation, dissipation, and transformation of phenanthrene. The differences may be attributed to higher adsorption of phenanthrene on 50-nm NPs than 10- micro m MPs. Our findings underlined the high potential ecological risks of FPs, and suggested that NPs should be given more concerns, in terms of their interaction with hydrophobic pollutants in the environment.

Maass, S., et al. (2017). "Transport of microplastics by two collembolan species." Environmental Pollution **225**: 456-459.

Plastics, despite their great benefits, have become a ubiquitous environmental pollutant, with microplastic particles having come into focus most recently. Microplastic effects have been intensely studied in aquatic, especially marine systems; however, there is lack of studies focusing on effects on soil and its biota. A basic question is if and how surface-deposited microplastic particles are transported into the soil. We here wished to test if soil microarthropods, using Collembola, can transport these particles over distances of centimeters within days in a highly controlled experimental set-up. We conducted a fully factorial experiment with two collembolan species of differing body size, Folsomia candida and Proisotoma minuta, in combination with urea-formaldehyde particles of two different particle sizes. We observed significant differences between the species concerning the distance the particles were transported. F. candida was able to transport larger particles further and faster than P. minuta. Using video, we observed F. candida interacting with urea-formaldehyde particles and polyethylene terephthalate fibers, showing translocation of both material types. Our data clearly show that microplastic particles can be moved and distributed by soil microarthropods. Although we did not observe feeding, it is possible that microarthropods contribute to the accumulation of microplastics in the soil food web.

Mabilleau, G., et al. (2004). "Biodegradability of poly (2-hydroxyethyl methacrylate) in the presence of the J774.2 macrophage cell line." Biomaterials **25**(21): 5155-5162.

The degradation of cross-linked and linear poly(2-hydroxyethyl methacrylate) (pHEMA), was examined in vitro with J774.2 cells. pHEMA microbeads were prepared with both types of polymers. Only cells in contact with the microbeads increased their production of lysosomal enzymes (TRAcP and ANAE) and released large amounts of reactive oxygen species with both types of pHEMA microbeads. Electron microscopy showed that macrophages were able to erode the surface of linear pHEMA but unable to erode the surface of the cross-linked polymer. Cells appeared wrapped by the linear pHEMA surface, but those cultured on the cross- linked polymer were only laying at the surface. After cell culture, the surface roughness of pHEMA slices was observed by atomic force microscopy (AFM). There was a significant increase in roughness (R sub(a)) of the surface of linear pHEMA slices cultured with J774.2 cells whereas no difference in R sub(a) between the surface of cross-linked pHEMA slices could be measured. AFM image of the hydrated materials were done: the surface of linear pHEMA swelled considerably in saline whereas the hydrated cross-linked polymer did not differ from the air-dried appearance. In conclusion, linear pHEMA swells in biological fluids, activates macrophages in close contact with the polymer and can be progressively eroded.

Macali, A., et al. (2018). "Episodic records of jellyfish ingestion of plastic items reveal a novel pathway for trophic transference of marine litter." Scientific Reports **8**(1).

Invertebrates represent the most plentiful component of marine biodiversity. To date, only few species have been documented for marine litter intake. Here, we report for the first time the presence of macroplastic debris in a jellyfish species. Such novel target to plastic pollution highlights an under studied vector of marine litter along marine trophic web, raising further concern over the impact on marine wildlife.

Machado, A. A. d. S., et al. (2018). "Microplastics as an emerging threat to terrestrial ecosystems." Global Change Biology **24**(4): 1405-1416.

Microplastics (plastics <5 mm, including nanoplastics which are <0.1 micro m) originate from the fragmentation of large plastic litter or from direct environmental emission. Their potential impacts in terrestrial ecosystems remain largely unexplored despite numerous reported effects on marine organisms. Most plastics arriving in the oceans were produced, used, and often disposed on land. Hence, it is within terrestrial systems that microplastics might first interact with biota eliciting ecologically relevant impacts. This article introduces the pervasive microplastic contamination as a potential agent of global change in terrestrial systems, highlights the physical and chemical nature of the respective observed effects, and discusses the broad toxicity of nanoplastics derived from plastic breakdown. Making relevant links to the fate of microplastics in aquatic continental systems, we here present new insights into the mechanisms of impacts on terrestrial geochemistry, the biophysical environment, and ecotoxicology. Broad changes in continental environments are possible even in particle-rich habitats such as soils. Furthermore, there is a growing body of evidence indicating that microplastics interact with terrestrial organisms that mediate essential ecosystem services and functions, such as soil dwelling invertebrates, terrestrial fungi, and plant-pollinators. Therefore, research is needed to clarify the terrestrial fate and effects of microplastics. We suggest that due to the widespread presence, environmental persistence, and various interactions with continental biota, microplastic pollution might represent an emerging global change threat to terrestrial ecosystems.

Machado, N. P., et al. (2007). "Plastic packages and cold storage on the postharvest preservation of jabuticaba fruits." Revista Brasileira de Fruticultura **29**(1): 166-168.

The objective of this study was to evaluate the efficiency of the plastic packages use in cold storage on the preservation of jabuticabas (Myrciaria spp.) for fresh consumption and processing. Two experiments were carried out at Embrapa Clima Temperado Research Centre, Pelotas, Rio Grande do Sul, with the following treatments: T₁ - control (open package); T₂ - 200 g capacity plastic box (dimensions: 18 cm of length, 12 cm of width and 3 cm of height) with perforated cover (two holes of 1 mm diameter each one); and T₃ - 15 micro thick perforated plastic sac (0,5 mm holes). In the Experiment 1, the fruits (for fresh consumption) with these packaging treatments were kept during eight days in a cold storage chamber under temperature of 0 degrees C and 90% relative humidity (RH) containing 0.03-0.09 ppm of ionized oxygen, and after being taken out from the cold storage, the fruits of the three pack kinds were left two days in room temperature (20-22 degrees C) and 70-75% RH. In the Experiment 2 (fruit for processing), it were evaluated the same treatments and cold storage conditions as it was referred in the first experiment, except that it was not simulated shelf life of the fruits which, in this experiment, were kept in the cold storage chamber of 0 and 90 degrees C RH for 10 days, since the fruits were supposed to be used for processing. In both experiments, the variables evaluated were: loss of weight (%); total soluble solids (TSS); pH; tritable acidity, TA (% citric acid); and ratio TSS/TA. It was concluded that for both purposes of fruit consumption the best packing treatment was the 15 micro plastic sac, which maintained the quality better during eight days in cold storage plus two days of simulated shelf life, as well as the quality of fruits for processing kept in cold storage for 10 days.

Maciel, A. d. S., et al. (2004). "Particleboards of Pinus elliottii Engelm. wood, polystyrene and polyethylene therephthalate particles." Revista Arvore **28**(2): 257-266.

This study determined the properties of wood particleboards containing particles of polystyrene (PS) and polyethylene therephthalate (PET). Three amounts of polystyrene (0, 25 and 50%), two amounts of PET/PS (5/20 and 10/40%), three amounts (0, 4 and 6%) of urea-formaldehyde or

phenol-formaldehyde adhesive and three amounts of polystyrene in toluene solution (0, 4 and 6%), combined with 50, 75 or 100% of particles of Pinus elliottii wood were used. Layer boards measuring approximately 400x400x10 mm with density approximately equal to 0.60 g/cm³ were produced. Internal bond, modulus of rupture and modulus of elasticity, screw withdrawal, water absorption and thickness swelling after 24 h of immersion were determined. The mechanical properties of all the boards were superior to the established by ANSI/A 208.1-1993 standard. All wood/plastic particleboards absorbed more water than those observed in commercial boards. However, the observed thickness swelling was quite similar to the values of commercial wood particleboards. Boards in which the solution of polystyrene was applied presented, in general, the best values for all the properties.

Macintosh, A., et al. (2020). "Plastic bag bans: Lessons from the Australian Capital Territory." Resources, Conservation and Recycling **154 (no pagination)**(104638).

Bans on single-use plastic shopping bags are amongst the most popular policy interventions taken by governments to address the harms associated with plastics. Yet, there are few published studies on their effectiveness and durability. This article addresses this gap, presenting the results of a study on the impacts of a ban on single-use plastic bags introduced in the Australian Capital Territory in 2011. The study assessed whether the ban has reduced plastic bag consumption and litter, and whether community support for the ban was sustainable. The results suggests the ban has not been overly effective in reducing plastic bag consumption or litter. Over the almost seven-year study period, between 2011 and 2018, the ban reduced consumption of single-use conventional polyethylene bags by ~2600 tonnes. However, these reductions were largely offset by increases in the consumption of other bags. The net effect of the ban on plastic consumption over the period was relatively minor; a 275 t reduction. Notwithstanding this, the ban is widely supported. When it was first introduced, 58 % of the community supported the ban. By 2018, this had increased to 68 %. The article explores the implications of the results and the need for better information on plastic bag consumption. Copyright © 2019 Elsevier B.V.

Maczko, J. (1988). "Extrusion system recycles contaminated plastic waste." Plastics Engineering **44**(6): 39-41.

The scarcity and cost of raw materials, as well as the environmental issue, make reclamation of plastics an attractive consideration. Recycling contaminated plastics waste, commercial and consumer, into a broad-based material addresses all three issues and opens new retail markets for the plastics industry.

Madsen, H. and O. Winding (1996). "Release of foreign bodies (particles) by clinical use of intravenous infusion sets." Biomaterials **17**(7): 663-666.

In clinical practice, stripping the plastic tubes of intravenous (i.v.) infusion sets with a scissor blade is a commonly used method for re-establishing flow in malfunctioning i.v. sets. The present investigation concludes that this procedure results in release of plastic particles from the luminal wall of the tube. Particles are subsequently flushed into the patient. The average amount of particles released exclusively from the i.v. infusion sets under these circumstances may exceed the standards for acceptable particle content per millilitre in large volume i.v. injectable fluids, according to the British Pharmacopoeia and the United States Pharmacopoeia.

Madsen, J. L. and L. Hendel (1992). "Gastrointestinal transit times of radiolabeled meal in progressive systemic sclerosis." Digestive Diseases & Sciences **37**(9): 1404-1408.

Gastrointestinal transit times were measured in 12 patients with progressive systemic sclerosis. The CREST syndrome (calcinosis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia) was found in all patients. None of the patients reported complaints referable to specific gastric, small intestinal, or colonic involvement. The patient group had an increased mean gastric emptying time of 99mTc-labeled cellulose fiber when compared with 16 healthy controls [1.17 (0.89-1.38) hr [median (range)] vs 0.84 (0.56-1.88) hr; P less than 0.02], whereas mean gastric emptying time of 2- to 3-mm 111In-labeled plastic particles was unaffected [1.86 (0.99-2.74) hr vs 1.50 (0.92-2.51) hr; NS]. No difference was observed in mean small intestinal transit time of cellulose fiber [4.33 (0.50-7.04) hr vs 3.74 (2.09-7.59) hr; NS] or plastic particles [4.21 (2.00-6.25) hr vs 3.53 (1.50-6.70) hr; NS] between patients and controls. The patient group had an increased mean colonic transit time of plastic particles [47 (24-116) hr vs 29 (18-46) hr; P less than 0.01]. These findings suggest that asymptomatic delay in gastric emptying and colonic transit is frequent in patients with progressive systemic sclerosis.

Madsen, J. L. and M. Jensen (1989). "Gastrointestinal transit of technetium-99m-labeled cellulose fiber and indium-111-labeled plastic particles." Journal of Nuclear Medicine **30**(3): 402-406.

We introduce two new nondigestible solid markers for gastrointestinal transit measurements. One is technetium-99m-labeled cellulose fiber [^{99m}Tc]CF, the other is indium-111-labeled plastic particles [¹¹¹In]PP of 2- to 3-mm diameter. In six healthy male volunteers gastric emptying and small intestinal transit of the two markers were obtained simultaneously. Large intestinal transit of [¹¹¹In]PP was also obtained. Technetium-99m CF had acceptable stability properties in the proximal gastrointestinal segments. Indium-111 PP was almost completely stable in all segments. Mean gastric emptying time was 1.13 +/- 0.24 hr (mean +/- s.d.) for [^{99m}Tc]CF and 1.94 +/- 0.78 hr for [¹¹¹In]PP. The difference was significant (p < 0.05). Mean small intestinal transit time was 3.85 +/- 0.61 hr (mean +/- s.d.) for [^{99m}Tc]CF and 4.03 +/- 0.34 hr for [¹¹¹In]PP. The difference was not significant (p < 0.5). Mean large intestinal transit time of [¹¹¹In]PP was 23 +/- 11 hr (mean +/- s.d.) We also suggest a simple deconvolution principle for the interpretation of the small intestinal and the large intestinal transit data.

Madzovska, I., et al. (2012). "Investigation of copper-alginate microbeads as antimicrobial materials for potential biomedical applications." Journal of Tissue Engineering and Regenerative Medicine **1)**: 325.

Alginate hydrogels cross-linked with copper ions are promising biomaterials for biomedical applications due to their biocompatibility, bioinductivity and antimicrobial properties. While highly-hydrophilic alginate matrices can serve as cell carriers or wound dressing, Cu ions provide antimicrobial activity and as essential micronutrients and cofactors for many enzymes, promote angiogenesis and healing processes. In this study, we have optimized production of Cu-alginate microbeads (~ 500 lm) by electrostatic extrusion of 1.9%w/v Naalginate solution into 0.135 M CuSO<inf>4</inf> gelling solution. Release kinetics of Cu ions in saline solution (0.9% w/v NaCl) as well as in distilled water were investigated in conjunction with studies of antimicrobial activity of the microbeads in suspensions of E. coli and S. aureus. Experiments were performed in shaken flasks at 37degreeC for 24 h (4 g of microbeads in 10 ml of solution). It was found that Cu ions quickly induced alginate gelation resulting in the Cu concentration of 0.157 mM/g in the hydrogel. However, when Cu-alginate microbeads were placed in water or saline solution, Cu ions were released over 5 h period to the final concentration in solution of ~20 mM. This release trend was found to be very efficient inducing quick bactericidal effects in both cultures even after 1 h of incubation. These results suggest that copper release rate and antimicrobial activity

of Cu-alginate could be optimized for each particular application.

Madzovska-Malagurski, I., et al. (2016). "Towards antimicrobial yet bioactive Cu-alginate hydrogels." Biomedical Materials (Bristol) **11 (3) (no pagination)**(035015).

The simplest approach to enhance alginate hydrogel characteristics and functional properties is to replace the calcium in the process of alginate gelation with other metallic ions which are essential for living systems. Gelling of alginate with other ions and using modern encapsulation techniques can provide new delivery systems with required properties. Hence, in this study Cu-alginate hydrogels in the form of microbeads were produced by electrostatic extrusion using gelling solutions with Cu(II) concentrations in the range 13.5-270 mM and comprehensively characterized in vitro. The variation of gelling solution concentration influenced the microbead Cu(II) content, size, biomechanical properties, Cu(II) release and subsequently potential biomedical application. The formulations chosen for biomedical evaluation showed potential for antimicrobial and tissue engineering applications. Microbeads with higher Cu(II) loading (~100 mumol g⁻¹) induced immediate bactericidal effects against Escherichia coli and Staphylococcus aureus. Conversely, Cu(II) release from microbeads with the Cu(II) content of ~60 mumol g⁻¹ was slower and they were suitable for promoting and maintaining chondrogenic phenotype of bovine calf chondrocytes in 3D culture. Results of this study have shown possibilities for tuning Cu-alginate properties for potential biomedical applications such as antimicrobial wound dressings, tissue engineering scaffolds or articular cartilage implants. Maeng, Y. J., et al. (2010). "Culture of human mesenchymal stem cells using electrosprayed porous chitosan microbeads." Journal of Biomedical Materials Research. Part A **92**(3): 869-876.

The aim of this study was to fabricate porous chitosan microbeads using an electrospraying method into liquid nitrogen, then thawing and refreezing. The microbeads were then used to evaluate their potential for tissue engineering of human mesenchymal stem cells (hMSCs). Scanning electron microscopy (SEM) and a mercury porosimeter were used to show the morphology of the scaffolds formed and to determine their pore size and porosity. As the chitosan concentration increased (0.5, 1, 1.5, and 2 wt %), the diameter of the porous microbead increased from 350 to 890 microm, and the average pore size and the porosity decreased from 65 to 21 microm and 95 to 38%, respectively. The hMSCs were cultured onto the porous microbeads in a spinner flask. SEM images and methyl tetrazolium salt assays at 3, 7, 14, and 21 days of culture revealed that hMSCs had successfully attached and proliferated inside the porous microbeads. This study demonstrated that electrosprayed porous chitosan microbeads can be used as three-dimensional scaffolds for tissue engineering.

Maes, T., et al. (2018). "Below the surface: Twenty-five years of seafloor litter monitoring in coastal seas of North West Europe (1992-2017)." Science of the Total Environment **630**: 790-798.

Marine litter presents a global problem, with increasing quantities documented in recent decades. The distribution and abundance of marine litter on the seafloor off the United Kingdom's (UK) coasts were quantified during 39 independent scientific surveys conducted between 1992 and 2017. Widespread distribution of litter items, especially plastics, were found on the seabed of the North Sea, English Channel, Celtic Sea and Irish Sea. High variation in abundance of litter items, ranging from 0 to 1835 pieces km⁻² of seafloor, was observed. Plastic tems such as bags, bottles and fishing related debris were commonly observed across all areas. Over the entire 25-year period (1992-2017), 63% of the 2461 trawls contained at least one plastic litter item. There was no significant temporal trend in the percentage of

trawls containing any or total plastic litter items across the long-term datasets. Statistically significant trends, however, were observed in specific plastic litter categories only. These trends were all positive except for a negative trend in plastic bags in the Greater North Sea - suggesting that behavioural and legislative changes could reduce the problem of marine litter within decades. Magara, G., et al. (2018). "Single contaminant and combined exposures of polyethylene microplastics and fluoranthene: accumulation and oxidative stress response in the blue mussel, Mytilus edulis." Journal of Toxicology and Environmental Health. Part A **81**(16): 761-773.

The microplastic "vector effect" has received increasing attention. The aim of this study was to investigate the influence of polyethylene microplastic beads (PE MP) on accumulation and associated oxidative stress responses attributed to fluoranthene (Flu) in blue mussels, Mytilus edulis. Blue mussels were exposed for 96 h to four treatment groups: Flu-only, MP-only, Flu and MP coexposure, and Flu-incubated MP. Treatments were conducted at a low and high concentration (50 micro g/L and 100 Flu micro g/L and 100, and 1000 MP/mL). Results demonstrated that in both the gill and digestive gland, coexposure did not markedly affect Flu uptake, but this treatment significantly decreased tissue Flu concentrations. Antioxidant responses including activities of superoxide dismutase (SOD), catalase (CAT), glutathione peroxidases (GPx), and levels of total glutathione (GSH) in both gills and digestive glands were significantly altered suggesting a perturbation of redox state induced by the exposure conditions. Although individual biomarkers varied, the biomarker profile enabled certain generalizations to be made. Antioxidant responses occurred more likely in gill tissue than in digestive gland. Individual contaminant exposures to Flu or MP led to varying responses, but coexposures and incubated exposures did not result in additive or synergistic effects. Exposure concentrations (i.e., low or high treatments) were not a consistent a predictor of response; and the internal Flu dose did not consistently predict outcome of various biomarkers. Importantly, MP-only exposure appeared to be capable of eliciting direct effects on the oxidative stress system as demonstrated by the activities of CAT and GPx. These findings warrant further investigation.

Magara, G., et al. (2019). "Effects of combined exposures of fluoranthene and polyethylene or polyhydroxybutyrate microplastics on oxidative stress biomarkers in the blue mussel (Mytilus edulis)." Journal of Toxicology & Environmental Health Part A **82**(10): 616-625.

A growing interest in developing and commercialization of new eco-friendly plastic polymers is occurring attributed to the impact of marine plastics debris and microplastics that result from the degradation of oil-based polymers as these substances adversely affect ecosystem health. Recently, polyhydroxybutyrate (PHB) has become of interest due to its biodegradability and physicochemical properties. However, biological consequences resulting from bioplastics exposure remain to be determined. Further, few data are apparently available regarding the potential for bioplastics to act as a vector for exogenous chemicals in the environment. The aim of the study was to compare the effects of polyethylene (PE MPs) and polyhydroxybutyrate (PHB MPs) microplastics administered alone or in combination with fluoranthene (Flu) on detoxifying enzymes in digestive glands and gills of Mytilus edulis. Blue mussels were exposed for 96h to eight experimental groups: control, Flu-only, PE MPs-only, PHB MPs-only, PE MPs-Flu co-exposure, PHB MPs-Flu co-exposure, Flu-incubated PE MPs, and Flu-incubated PHB MPs. Activities of superoxide dismutase (SOD), catalase (CAT), glutathione peroxidases (GPx), glutathione S-transferase (GST), and glutathione reductase (GR) were found to be significantly susceptible to Flu and plastics in both tissues. Interestingly, a single exposure to PHB MPs led to decreased activity levels of CAT and GST in gills, SOD in digestive glands and SeGPx in both tissues. In co-exposure and incubation treatments, biochemical responses were generally comparable with those exerted by PE MPs or PHB MPs only, suggesting an apparent absence of combined effects of microplastics with the pollutant. Data demonstrated the ecotoxicological impact of bioplastics materials on digestive glands and gills of Mytilus edulis.

Magni, S., et al. (2019). "First evidence of protein modulation by polystyrene microplastics in a freshwater biological model." Environmental Pollution **250**: 407-415.

Microplastics (MPs) are now one of the major environmental problems due to the large amount released in aquatic and terrestrial ecosystems, as well as their diffuse sources and potential impacts on organisms and human health. Still the molecular and cellular targets of microplastics' toxicity have not yet been identified and their mechanism of actions in aquatic organisms are largely unknown. In order to partially fill this gap, we used a mass spectrometry based functional proteomics to evaluate the modulation of protein profiling in zebra mussel (Dreissena polymorpha), one of the most useful freshwater biological model. Mussels were exposed for 6 days in static conditions to two different microplastic mixtures, composed by two types of virgin polystyrene microbeads (size=1 and 10mum) each one. The mixture at the lowest concentration contained 5x105MP/L of 1mum and 5x105MP/L of 10mum, while the higher one was arranged with 2x106MP/L of 1mum and 2x106MP/L of 10mum. Proteomics' analyses of gills showed the complete lack of proteins' modulation after the exposure to the low-concentrated mixture, while even 78 proteins were differentially modulated after the exposure to the high-concentrated one, suggesting the presence of an effect-threshold. The modulated proteins belong to 5 different classes mainly involved in the structure and function of ribosomes, energy metabolism, cellular trafficking, RNA-binding and cytoskeleton, all related to the response against the oxidative stress.

Magni, S., et al. (2018). "Evaluation of uptake and chronic toxicity of virgin polystyrene microbeads in freshwater zebra mussel Dreissena polymorpha (Mollusca: Bivalvia)." Science of the Total Environment **631**(632): 778-788.

Microplastics (MPs), plastic debris smaller than 5 mm, are widely found in both marine and freshwater ecosystems. However, few studies regarding their hazardous effects on inland water organisms, have been conducted. For this reason, the aim of our research was the evaluation of uptake and chronic toxicity of two mixtures (MIXs) of virgin polystyrene microbeads (PMs) of 10 micro m and 1 micro m in size (MIX 1, with 5x10⁵ of 1 micro m size PMs/L and 5x10⁵ of 10 micro m size PMs/L, and MIX 2 with 2x10⁶ of 1 micro m size PMs/L and 2x10⁶ of 10 micro m size PMs/L) on freshwater zebra mussel Dreissena polymorpha (Mollusca: Bivalvia) during 6 exposure days. The PM uptake in the mussel body and hemolymph was assessed using confocal microscopy, while the chronic toxicity of PMs was evaluated on exposed mussels using a comprehensive battery of biomarkers of cellular stress, oxidative damage and neuro- genotoxicity. Confocal microscopy analyses showed that MPs concentrated in the gut lumen of exposed mussels, absorbed and transferred firstly in the tissues and then in the hemolymph. The results revealed that PMs do not produce oxidative stress and genetic damage, with the exception of a significant modulation of catalase and glutathione peroxidase activities in mussels exposed to MIX 1. Regarding neurotoxicity, we observed only a significant increase of dopamine concentration in mussels exposed to both MIXs, suggesting a possible implication of this neurotransmitter in an elimination process of accumulated PMs. This research represents a first study about the evaluation of virgin MP toxicity in zebra mussel and more research is warranted concerning the long term neurological

effects of virgin MPs.

Magri, D., et al. (2018). "Laser Ablation as a Versatile Tool To Mimic Polyethylene Terephthalate Nanoplastic Pollutants: Characterization and Toxicology Assessment." Acs Nano **12**(8): 7690-7700.

The presence of micro- and nanoplastics in the marine environment is raising strong concerns since they can possibly have a negative impact on human health. In particular, the lack of appropriate methodologies to collect the nanoplastics from water systems imposes the use of engineered model nanoparticles to explore their interactions with biological systems, with results not easily correlated with the real case conditions. In this work, we propose a reliable top-down approach based on laser ablation of polymers to form polyethylene terephthalate (PET) nanoplastics, which mimic real environmental nanopollutants, unlike synthetic samples obtained by colloidal chemistry. PET nanoparticles were carefully characterized in terms of chemical/physical properties and stability in different media. The nanoplastics have a ca. 100 nm average dimension, with significant size and shape heterogeneity, and they present weak acid groups on their surface, similarly to photodegraded PET plastics. Despite no toxic effects emerging by in vitro studies on human Caco-2 intestinal epithelial cells, the formed nanoplastics were largely internalized in endolysosomes, showing intracellular biopersistence and long-term stability in a simulated lysosomal environment. Interestingly, when tested on a model of intestinal epithelium, nano-PET showed high propensity to cross the gut barrier, with unpredictable long-term effects on health and potential transport of dispersed chemicals mediated by the nanopollutants.

Mahadappa, P., et al. (2020). "Effect of plastic foreign body impaction on rumen function and heavy metal concentrations in various body fluids and tissues of buffaloes." Ecotoxicology & Environmental Safety **189**: 109972.

Rumen impaction by plastic waste (PW) is a common condition in the developing countries where ruminants are reared under extensive grazing. As heavy metals (HM) are used in the manufacture of plastic, we hypothesized that buffaloes with PW impaction would have suboptimal rumen function and higher content of HM in the rumen fluid, sera and body tissues. Buffaloes at an abattoir were categorized into impacted with PW or not (Group C and B, respectively; n = 30/group). From the animals of group C and B, rumen fluid and sera were collected ante-mortem, while muscle, liver and kidney were collected after exsanguination. Blood and rumen fluid of stall-fed buffaloes (Group A; n = 15) served as known negative control. Rumen function was assessed by protozoal density, motility, pH, methylene blue reduction time (MBRT) and sedimentation activity time (SAT). Concentration of HM such as mercury (Hg), lead (Pb), cadmium (Cd), chromium (Cr) and copper (Cu) in the body fluids, tissues and impacted PW was estimated by atomic absorption spectrometry (AAS). A significant decrease in the rumen protozoal density, motility and increase ($P < 0.05$) in the rumen fluid pH, MBRT and SAT were observed in group C as compared to group A and B. Concentration of Pb, Hg and Cd showed a moderate to strong significant negative correlation with rumen function indicators. Quantitatively, Cu content (ppm) was highest in PW with 0.9 +/- 0.04. The concentration of HM in the body fluids and tissues was significantly ($P < 0.05$) elevated in group C, but was below the toxic levels. In stall-fed buffaloes, Hg, Pb and Cd were undetectable in body fluids. Collectively, the results indicate that long term exposure of buffaloes to HM from PW affect the health, productivity and increase the risk of entering the food chain.

Mahalakshmi, V., et al. (2012). "Analysis of polyethylene degrading potentials of microorganisms isolated from compost soil." International Journal of Pharmaceutical and Biological Archives **3**(5):

1190-1196.

Plastic play important role for many "short live" applications such as packaging, disposable gloves, garbage bags etc and these represent the major part of plastic waste. Because of their persistence in our environment, improperly disposed plastic materials are significant source of environment pollution, potentially harming life. Among the synthetic plastics, one of the most problematic plastics in this regard is polyethylene (PE). In the absence of appropriate disposal methods polyethylene waste is usually burned, causing grave air pollution. Polyethylene-considered to be inert-can be biodegraded if the right microbial strains are used. In the present study microorganisms able to degrade polyethylene were isolated from compost soil and characterized. Physicochemical analysis of PE was done by Scanning electron Microscopy (SEM) & Fourier Infrared Spectroscopy (FTIR). The degraded products were analyzed by Gas Chromatography-Mass-Spectrometer (GC-MS).

Maharana, D., et al. (2019). "Assessment of micro and macroplastics along the west coast of India: Abundance, distribution, polymer type and toxicity." Chemosphere **246**: 125708.

Considering the magnitude of pollution caused by marine plastics, the present study assessed their abundance, distribution, surface morphology and polymer type in ten sandy beaches spread across three states (Maharashtra, Karnataka and Goa) along the west coast of India (WCI). The total abundance of plastics (~1-100 mm) in the studied beaches ranged from 4.1 to 23.4% (19+/-1-346 +/- 2 items/m²). Location-wise, the abundances of both micro (43.6 +/- 1.1-346 +/- 2 items/m²) and macroplastics (21.6+/-3-195 +/- 6 items/m²) were relatively higher in beaches along the Maharashtra coast. Surface morphology-wise, fragments were predominantly abundant in both micro (76+/-2-346 +/- 2 items/m²) and macroplastics (50.6 +/- 1.5-195 +/- 6 items/m²) followed by pellets (43.3 +/- 2.5-245.6 +/- 2 items/m²). Fourier-transform infrared spectroscopy (FT-IR) analysis of plastics revealed a dominance of polyethylene (PE) followed by polypropylene (PP). IR spectra of the collected plastics at absorption band at 1750-1700 cm⁻¹ reflect minimal surface oxidation. White-colored plastics were observed most frequently, followed by pale-yellow, dark-brown, green, blue, transparent and red. A short-term (72 h) experimental study to assess the toxicity of PE microbeads (~1 mm) in a commercially important shrimp species, Litopenaeus vannamei revealed toxicological changes. An elevated level of lipid peroxidation (LPX)-the tagged biochemical marker, was recorded only at the maximum dose (0.15 mg/L) of PE microbeads. A moderate increase in the levels of enzymatic antioxidants (catalase and glutathione S-transferase) was also recorded at the same dose. Comprehensive information on marine plastics, including ecotoxicity provided in this study, would help in evolving strategies in minimizing plastic pollution along the WCI.

Mahesh Kumar, G., et al. (2016). "Waste management in food packaging industry." Environmental Science and Engineering (Subseries: Environmental Science) **0**(9783319272269): 265-277.

The increasing amount of food packaging waste is perceived as a problem in urgent need of solution in all industrialized countries. According to the environment protection act, waste is any substance which constitutes scrap material, an effluent, unwanted surplus substance, article which requires disposing of as being broken, worn out, contaminated or otherwise spoiled. Waste leads to the production of significant greenhouse gas, methane which is over 20 times more potent than carbon dioxide. Source reduction, reuse and recycle are the most powerful and effective thing we can do to manage waste. Plastic Waste Management has assumed great significance in view of the urbanization activities. Plastic waste generated by the polymer manufacturers at the production, extrusion, quality control and laboratory testing etc., stages, as well as, by the consumers require urgent disposal and recycling to avoid health hazards. Various strategies are being devised to mitigate the impact of plastic waste in India. 2016, Springer International Publishing Switzerland.

Mahmoodi, F., et al. (2012). "An experimental evaluation of an effective medium based compaction equation." European Journal of Pharmaceutical Sciences **46**(1-2): 49-55.

Tablet production involves compression of free flowing powder in an enclosed cavity of defined geometry. The complexity of the powder bed system necessitates that a way be found to better understand what occurs during compression. One such approach is by means of compaction equations, of which, the Heckel and Kawakita equations are the best known. This work attempts to experimentally evaluate the applicability of the effective medium (EM) equation introduced by Frenning et al. (2009) to powder systems. Two powder types (sodium chloride and lactose monohydrate), each consisting of three size fractions (<40, 125-212 and 212-300mum) were characterised and compressed to a pressure of 500MPa. These powders were chosen because of their differing mechanical properties. An invariance which is inherent in the EM equation is exposed by varying the starting points of compression, and can yield insights into compression mechanisms. Such invariant regions were observed once plastic particle deformation started to dominate the compression behaviour, and enabled the determination of the point where particle rearrangement stops.

Mahmoud, W., et al. (2010). "Emerging applications of fluorescent nanocrystals quantum dots for micrometastases detection." Proteomics **10**(4): 700-716.

The occurrence of metastases is one of the main causes of death in many cancers and the main cause of death for breast cancer patients. Micrometastases of disseminated tumour cells and circulating tumour cells are present in more than 30% of breast cancer patients without any clinical or even histopathological signs of metastasis. Low abundance of these cell types in clinical diagnostic material dictates the necessity of their enrichment prior to reliable detection. Current micrometastases detection techniques are based on immunocytochemical and molecular methods suffering from low efficiency of tumour cells enrichment and observer-dependent interpretation. The use of highly fluorescent semiconductor nanocrystals, also known as "quantum dots" and nanocrystal-encoded microbeads tagged with a wide panel of antibodies against specific tumour markers offers unique possibilities for ultrasensitive micrometastases detection in patients' serum and tissues. The nanoparticle-based diagnostics provides an opportunity for highly sensitive parallel quantification of specific proteins in a rapid and low-cost method, thereby providing a link between the primary tumour and the micrometastases for early diagnosis. © 2010 WILEY-VCH Verlag GmbH & Co. KGaA.

Mahon, A. M., et al. (2017). "Microplastics in Sewage Sludge: Effects of Treatment." Environmental Science & Technology **51**(2): 11-11.

Waste water treatment plants (WWTPs) are receptors for the cumulative loading of microplastics (MPs) derived from industry, landfill, domestic wastewater and stormwater. The partitioning of MPs through the settlement processes of wastewater treatment results in the majority becoming entrained in the sewage sludge. This study characterized MPs in sludge samples from seven WWTPs in Ireland which use anaerobic digestion (AD), thermal drying (TD), or lime stabilization (LS) treatment processes. Abundances ranged from 4196 to 15-385 particles kg-1 (dry weight). Results of a general linear mixed model (GLMM) showed significantly higher abundances of MPs in smaller size classes in the LS samples, suggesting that the treatment process of LS shears MP particles. In contrast, lower abundances of MPs found in the AD

samples suggests that this process may reduce MP abundances. Surface morphologies examined using scanning electron microscopy (SEM) showed characteristics of melting and blistering of TD MPs and shredding and flaking of LS MPs. This study highlights the potential for sewage sludge treatment processes to affect the risk of MP pollution prior to land spreading and may have implications for legislation governing the application of biosolids to agricultural land. Mahon, H. K. and D. M. Dauer (2005). "Organic coatings and ontogenetic particle selection in Streblospio benedicti Webster (Spionidae: Polychaeta)." Journal of Experimental Marine Biology and Ecology **323**(1): 84-92.

Surface deposit feeders select food particles based upon characteristics including size, texture, specific gravity, and organic coatings. Spionid polychaetes feed at the sediment-water interface using a pair of ciliated palps and switch between surface deposit feeding and suspension feeding primarily as a function of water flow. Juveniles and adults of some spionid species have different stable isotopic carbon signals, indicating the ingestion of different food sources and potentially the ability to differentiate organic cues ontogenetically. In the present study, the feeding responses of juvenile and adult Streblospio benedicti Webster to seven organic coatings bound to glass microbeads were tested using five amino acids and two carbohydrates. Coated versus uncoated particles were presented in equal proportions based upon surface area. Juveniles and adults were highly selective for all seven types of organically coated beads - 87.1% of all beads ingested were organically coated beads. For two of the organic coatings, there were ontogenetic differences; juveniles were more selective of threonine and adults were more selective of proline. These differences may result in ontogenetic diet shifts that allow maximization of energy and/or essential nutrients during critical early life- history stages. Particle selection in tentaculate surface deposit feeders is generally thought to occur primarily during particle contact and transport to the mouth, and is typically characterized as a passive process. Active particle selection at the site of the everted pharynx was observed and quantified for S. benedicti. Organically coated particles represented 50% of the ambient experimental treatment, 64.4% of the particles transported along the palp after contact, and 81.8% of the particles ingested after pharyngeal rejection behavior. Of the beads reaching the pharynx, 26.9% were rejected by ciliary sorting on the pharynx before ingestion, and 81.8% of the rejected beads at the site of the pharynx were uncoated. Our study demonstrates that microphagous feeders that generally handle food particles in bulk are capable of significant levels of active selection for organically coated particles.

Mahony, J., et al. (2007). "Development of a respiratory virus panel test for detection of twenty human respiratory viruses by use of multiplex PCR and a fluid microbead-based assay." Journal of Clinical Microbiology **45**(9): 2965-2970.

Virology laboratories historically have used direct fluorescent-antibody assay (DFA) and culture to detect six or seven respiratory viruses. Following the discovery of five new human respiratory viruses since 2000, there is an increasing need for diagnostic tests to detect these emerging viruses. We have developed a new test that can detect 20 different respiratory virus

types/subtypes in a single 5-h test. The assay employs multiplex PCR using 14 virus-specific primer pairs, followed by a multiplexed target-specific primer extension (TSPE) reaction using 21 primers for specific respiratory virus types and subtypes. TSPE products were sorted and identified by using a fluid microsphere-based array (Universal Array; TmBioscience Corporation, Toronto, Canada) and the Luminex x-MAP system. The assay detected influenza A and B viruses; influenza A virus subtypes H1, H3, and H5 (including subtype H5N1 of the Asian lineage); parainfluenza virus types 1, 2, 3, and 4; respiratory syncytial virus types A and B; adenovirus; metapneumovirus; rhinovirus; enterovirus; and coronaviruses OC43, 229E, severe acute respiratory syndrome coronavirus, NL63, and HKU1. In a prospective evaluation using 294 nasopharyngeal swab specimens, DFA/culture detected 119 positives and the respiratory virus panel (RVP) test detected 112 positives, for a sensitivity of 97%. The RVP test detected an additional 61 positive specimens that either were not detected by DFA/culture or were positive for viruses not tested for by DFA/culture. After resolution of discordant results by using a second unique PCR assay and by using a combined reference standard of positivity, the RVP test detected 180 of 183 true positives, for a sensitivity of 98.5%, whereas DFA and culture detected only 126 of 183 true positives, for a sensitivity of 68.8%. The RVP test should improve the capabilities of hospital and public health laboratories for diagnosing viral respiratory tract infections and should assist public health agencies in identifying etiologic agents in respiratory tract infection outbreaks.

Mahou, R., et al. (2011). "Alginate-PEG hybrid microspheres for biomedical applications." European Cells and Materials **4)**: 6.

INTRODUCTION: Hydrogel microspheres with sodium alginate (Na-alg) as major component are among the most suitable materials for cell immobilization. Ionotropic gelation of Na-alg in presence of divalent cations yields such hydrogels. However, they suffer from mechanical stability deficiency, limited durability, and permeability drawbacks. Frequently used reinforcement with polycations requires multi-step processes and can have a negative impact on the biocompatibility. Our approach combines ionotropic gelation of Na-alg and covalent cross-linking of PEG derivatives in one step and yields alginate-PEG hybrid microspheres (Alg-PEG-M) convertible into PEG beads (PEG-M) [1]. METHOD(S): Alg-PEG-M and PEG-M were prepared at 37degreeC under physiological conditions using a coaxial airflow droplet generator (Fig.1). (Figure presented) RESULTS AND DISSCUSSION: The precursor quality and concentration govern the mechanical resistance. Dissolution of Ca-alg slightly raises the mechanical resistance to compression (Fig.2). The permeability can be tailored by adequate choice of the arm length of PEG-VS. The MWCO was tuneable in a range of 70 to 150 kg/mol. (Figure presented) Cell toxicity of Alg-PEG-M assessed for EC219 rat endothelial cells, ECp23 murine endothelial cells, and RAW264.7 murine macrophages did not reveal cytotoxic effects (examples in Fig.3). (Figure presented) The immune response upon intraperitoneal implantation into mice was comparable to the control and pure Ca-alg microbeads (Fig.4). Encapsulated human islets continued insulin secretion upon stimulation. CONCLUSION(S): Combining ionotropic gelation and chemical cross-linking in a one-step process yields Alg-PEG-M with well-controllable physical properties. Significant toxic effects were observed neither in vivo nor in vitro.

Mai, L., et al. (2018). "Polycyclic aromatic hydrocarbons affiliated with microplastics in surface waters of Bohai and Huanghai Seas, China." Environmental Pollution **241**: 834-840.

Microplastics (MPs) sized between 0.33 and 5 mm were collected using Manta trawls from ten surface seawater sites in Bohai and Huanghai Seas, China. A total of 1024 (Bohai Sea) and 132 (Huanghai Sea) microplastic pieces were classified, including polystyrene foams, polyethylene

films and lines, and other plastic pellets, with concentrations of MPs ranging from 3 to 162 particles per 100 m 3 (0.012–2.96 mg m −3). A pretreatment of MPs with 30% H 2 O 2 in water did not significantly lower polycyclic aromatic hydrocarbon (PAH) concentrations on MPs compared to no H 2 O 2 pretreatment. Measurements of PAHs carried on the collected MPs indicated that the concentrations of the sum of 16 PAHs were in the range of 3400−119,000 ng g −1 . The sources of PAHs in Bohai and Huanghai Seas were highly similar, with petroleum and gasoline probably as the dominant sources. The present study shows the relative importance of MPs in regards to chemical transport in the marine environment. The combination of high concentrations of PAHs affiliated with MPs and the increasing magnitude of plastic pollution in the world's oceans demonstrates the considerable importance of MPs to the fate of PAHs in marine environments. Mai, L., et al. (2019). "Riverine Microplastic Pollution in the Pearl River Delta, China: Are Modeled Estimates Accurate?" Environmental Science & Technology **53**(20): 11810.
Plastic pollution has caused increasing global concern. Currently, model estimates of the riverine plastic inputs to the global oceans based on the concept of Mismanaged Plastic Waste (MPW) varied substantially, and no field measurements of riverine inputs were available. We conducted sampling at the eight major river outlets of the Pearl River Delta, South China with rapid economic growth and urbanization to provide field measured data for fine-tuning modeling results. Floating microplastics (MPs) were collected with a Manta net (mesh size of 0.33 mm) five times during 2018. Microplastic particles (0.3–5.0 mm) widely occurred in all sampling sites. The number and mass concentrations of MPs were in the ranges of 0.005–0.7 particles m–3 and 0.004–1.28 mg m–3 and were positively correlated with water discharges. The annual riverine input of MPs from the Pearl River Delta was estimated at 39 billion particles or 66 tons, which converts to 2400–3800 tons of plastic debris based on calculations described in Text S2. These values were substantially below the MPW-based model estimates (91,000–170,000 tons). The large difference between measured and modeling results may have derived from the large uncertainty in the MPW values assigned to the world's countries/regions.

Mai, T. D., et al. (2015). "Magneto-immunocapture with on-bead fluorescent labeling of amyloid-beta peptides: towards a microfluidized-bed-based operation." Analyst **140**(17): 5891-5900.
A new sample treatment approach for sensitive determination of three amyloid-beta peptides (Abeta 1-42, Abeta 1-40 and Abeta 1-38) with capillary electrophoresis coupled with laser induced fluorescent detection is reported herein. These Abeta peptides are considered an important family of biomarkers in the cerebrospinal fluid (CSF) for early diagnosis of Alzheimer's disease (AD). Due to their extremely low abundance in CSF (down to sub nM ranges), batch-wise preconcentration via magneto-immunocapture with enrichment factors up to 100 was implemented. The Abeta peptides were first captured onto magnetic micro-beads. Then, on-beads fluorescent labeling of the captured Abeta peptides were carried out to avoid the unwanted presence of extra fluorescent dye in the eluent as in the case of in-solution labeling. Finally thermal elution was performed and eluted labeled peptides were analyzed off line with CE-LIF. The Abeta-capturing efficiencies of different commercially available antibodies grafted

onto magnetic beads were tested. Abeta peptides in CSF samples collected from AD's patients and healthy persons (used as controls) were measured and evaluated. As a proof of concept, the developed strategy was adapted into a miniaturized fluidized bed configuration that has the potential for coupling with a microchip separation system.

Maity, S., et al. (2020). "Cytogenotoxic potential of a hazardous material, polystyrene microparticles on Allium cepa L." Journal of Hazardous Materials **385**: 121560.

Plastic pollution represents a global concern for the biodiversity conservation, ecosystem and public health. The polystyrene is one of the dominant pollutants in both terrestrial and aquatic ecosystem. This work measured the hazardous nature of 100nm micropolystyrene (MPS) using 25, 50, 100, 200, and 400mg/L concentrations in terms of oxidative stress, morphotoxicity and cytogenotoxicity in Allium cepa. The results were compared with the positive control (PC) (400mg/L chlorpyrifos). MPS significantly (p<0.05) reduced the root length while induced the production of hydroxyl, superoxide radicals with a concomitant increase in DPPH scavenging activity and lipid peroxidation as compared to the negative control. The significant decrease in mitotic index with respect to the negative control (MI: 23.855+/-5.336 %; lowest MI: 3.88+/-1.042 %) showed the cytotoxic nature of MPS. Genotoxicity was assessed by various chromosomal and nuclear aberrations. The highest 3.029+/-0.403 % (PC: 3.09+/-0.535 %) chromosomal abnormality index and 2.31+/-0.338 % (PC: 1.178+/-0.095 %) nuclear abnormality index were observed. MPS down-regulated the expression of plant CDKA encoding gene: cdc2, an important cell cycle regulator. The overall results indicated that MPS could induce cytogenotoxicity through the exacerbation of ROS production and inhibition of cdc2.

Majewsky, M., et al. (2016). "Determination of microplastic polyethylene (PE) and polypropylene (PP) in environmental samples using thermal analysis (TGA-DSC)." Science of the Total Environment **568**: 507-511.

Microplastics are increasingly detected in the environment and the consequences on water resources and ecosystems are not clear to date. The present study provides a cost-effective and straightforward method to determine the mass concentrations of polymer types using thermal analysis. Characteristic endothermic phase transition temperatures were determined for seven plastic polymer types using TGA-DSC. Based on that, extracts from wastewater samples were analyzed. Results showed that among the studied polymers, only PE and PP could be clearly identified, while the phase transition signals of the other polymers largely overlap each other. Subsequently, calibration curves were run for PE and PP for qualitative measurements. 240 and 1540 mg/m³ of solid material (12micro m to 1mm) was extracted from two wastewater effluent samples of a municipal WWTP of which 34% (81 mg/m³) and 17% (257 mg/m³) could be assigned to PE, while PP was not detected in any of the samples. The presented application of TGA-DSC provides a complementary or alternative method to FT-IR analyses for the determination of PE and PP in environmental samples. Copyright © 2016 Elsevier B.V.

Mak, C., et al. (2019). "Acute toxic effects of polyethylene microplastic on adult zebrafish." Ecotoxicology and Environmental Safety **182**(109442).

To identify the physical effects, behavioral changes, and gene expression profiles of the phase 1 detoxification-related gene (cyp 1a) and oogenesis-related gene (vtg 1) induced by microplastics, high-density polyethylene microplastics of various sizes were used because of their dominance in coastal areas and effluent samples in Hong Kong. Adult zebrafish were used as the model organism to identify the upper and lower boundaries of microplastics ingestion and were

exposed to individual polyethylene microplastics in five size ranges (10-22 micro m, 45-53 micro m, 90-106 micro m, 212-250 micro m, and 500-600 micro m) at a concentration of 2 mg/L for 96 h. To study behavioral changes and targeted gene expression profiles via real-time PCR (qPCR), a mixture of microplastics in three size ranges at effluent-related (11 particles/L), moderate (110 particles/L), and high concentrations (1,100 particles/L) were applied for 96 h. The zebrafish behavior was recorded by a video camera and by two observers (interrater reliability, >85%). The results implied that the upper and lower size boundaries for microplastic ingestion were 558.4+or-26.2 micro m (yellow) and 19.7+or-3.1 micro m (red), respectively. In addition, 61+or-10% of fish in medium concentration treatments and 61+or-10% of fish in high concentration treatments were found with the microplastic ingestion and remaining in their intestine. In addition, 28+or-10% of fish in high concentration treatments were found with microplastic retaining in their gills (No. of fishes=18 in each treatment). The presence of microplastics, which occupied 89+or-6% of intestine area, reduced the voids inside the intestine for feed. The expression of cyp1a in the intestine (medium concentration) and vtg1 in the liver (medium and high concentration) showed significant up-regulation, and abnormal behavior (i.e., seizures and tail bent downward) was observed (medium and high concentration). In summary, the effects on the aryl hydrocarbon receptor (AHR) pathway, disruption of the oogenesis process, and neurotoxicity could be caused by acute exposure of adult zebrafish to microplastics.

Makar, R. S., et al. (2011). "Analysis of cutoffs for screening sensitized blood donors for HLA alloantibodies using a cytometric microbead assay." Transfusion **51**(1): 166-174.

BACKGROUND: Cytometric-based microbead assays for HLA alloantibodies may be effective tools for transfusion-related acute lung injury (TRALI) risk reduction. However, the optimal cutoff for donor screening is unclear.

STUDY DESIGN AND METHODS: To optimize the screening test cutoff in sensitized donors, sera were screened with a cytometric microbead assay. Confirmatory testing was performed on samples with a normalized background (NBG) ratio of 2.4 or more.

RESULTS: Sera with a NBG of 2.4 to 9.9 had positive predictive values (PPVs) of 78.2% (95% confidence interval [CI], 67.8%-86.0%) and 71.1% (95% CI, 56.5%-82.4%) for Class I and II antibodies, respectively. Sera with a NBG of 10 or more had PPVs of 98.9% (95% CI, 93.3%-100%) and 99.1 (95% CIs, 94.7%-100%) for Class I and II, respectively. The percent panel-reactive antibody (PRA) of confirmed HLA alloantibodies from sera with a NBG of 2.4 to 9.9 was 29.3+/-17% (mean+/-standard deviation) for Class I and 22.3+/-16.7% for Class II, but for antibodies from sera with a NBG of 10 or more the PRAs were 65.3+/-24.0 and 64.1+/-25.2% for Class I and II, respectively (p<0.00001). Serial dilution studies comparing the screening test with antiglobulin-enhanced lymphocytotoxicity suggested that NBG correlated with antibody titer. In our center, deferral for prior pregnancy or transfusion would result in loss of 28.8% of apheresis platelet (PLT) donors. Using the screening test at a cutoff of 2.4 or more or 10 or more would reduce the fraction of donors lost to 12.7 or 8.0%, respectively.

CONCLUSIONS: A screening cutoff of 10 or more predicts HLA alloimmunization in sensitized donors and is associated with higher PRAs and titers. Implementation of this cutoff may reduce TRALI risk while limiting unnecessary deferral of PLT donors.

Maker, A. V., et al. (2016). "Hepatectomy After Yttrium-90 (Y90) Radioembolization-Induced Liver Fibrosis." Journal of Gastrointestinal Surgery **20**(4): 869-870.

An obese 55-year-old woman with nonalcoholic fatty liver disease presented 7 years after resection of a T3N1 ileal carcinoid tumor with an elevated chromogranin A, multifocal metastatic disease to the liver, and carcinoid syndrome. She underwent right hepatic artery yttrium-90 (Y90) radioembolization, followed a month later by selective Y90 treatment to segment IV. She then presented to our clinic 10 months later, remaining symptomatic with flushing, diarrhea, anxiety, myalgia, pain, and persistent night sweats despite Sandostatin administration. At least 11 tumors were identified in the right lobe of the liver and three in segment IV on liver-specific imaging. These lesions were stable over a year with no new lesions. At exploration, there was marked hypertrophy of the left lateral segment due to the yttrium-90 treatment of segments IV-VIII, corresponding with preoperative volumetrics predicting a functional liver remnant (FLR) of 40% after extended right hepatectomy. The right lobe and segment IV were fibrotic, hard, and visibly damaged. The gland had a thick, fibrotic capsule, and the parenchyma was dense, inflexible, and difficult to dissect, consistent with the previously reported morbidity of these operations. Extended right hepatectomy was performed. Final pathology demonstrated 15 foci of metastatic well-differentiated neuroendocrine carcinoma that were negative for necrosis, as was expected given her continued symptoms despite radioembolization. Numerous amorphous spheres, frequently in clusters, were present in segments IV-VIII in vessels and approximating tumors consistent with prior Y90 radioembolization. The patient had an uneventful post-operative recovery and remains symptom free on follow-up. Treatment options for metastatic tumors to the liver have increased in recent years and currently include radioembolization in selected patients. Surgical cytoreduction and complete metastasectomy continue to offer improvement in symptoms, quality of life, and survival in patients with neuroendocrine liver metastases; however, hepatectomy after radioembolization is unique and carries increased morbidity/mortality, likely due to Y90-induced liver fibrosis. We demonstrate images of fibrotic yttrium-90 radiation-affected liver and histological sections of radioembolic microbeads in blood vessels and distributed around resected tumors.

Makri, C., et al. (2019). "Use and assessment of "e-plastics" as recycled aggregates in cement mortar." Journal of Hazardous Materials **379**: 120776.

In this study we investigated the physical and mechanical properties of cement mortars, partially replaced with plastic (recycled plastic aggregate, RPA) recovered from WEEE (namely, "e-plastics"). The plastic housing of 14 LCD screens was sampled and, subsequently, compositionally and elementally analysed. Acrylonitrile-butadiene-styrene (ABS), being the most commonly found polymer in WEEE, was used as aggregate in the cement mortar. The replacement percentages (RPs) used were 2.5%, 5%, 7.5%, 10% and 12.5%, while the water to cement (w/c) ratio was maintained constant at 0.5 in all tests. The basic properties (e.g. compressive strength (CS), modulus of elasticity (MoE), density (rho), porosity (PHI) and water absorption (WA)) of the created specimens were investigated. The obtained results, for all RPs, (especially those of 7.5% and 10%) exhibited an increase in the CS of the specimens by 15.4% and 7.8%, respectively, with the MoE decreased in both cases by 18.1% and 23.8%, respectively. The rest of the examined specimens' physical properties measured (rho, PHI, and WA) indicated, also, greater strength but lower ductility than the reference (standard) specimen. Concluding, the use of recovered plastics from WEEE as recycled aggregates (RAs) in cement could potentially be proved a useful downcycling alternative for waste plastics.

Maksym, G. N., et al. (2000). "Mechanical properties of cultured human airway smooth muscle cells from 0.05 to 0.4 Hz." Journal of Applied Physiology **89**(4): 1619-1632.

We investigated the rheological properties of living human airway smooth muscle cells in culture and monitored the changes in rheological properties induced by exogenous stimuli. We

oscillated small magnetic microbeads bound specifically to integrin receptors and computed the storage modulus (G') and loss modulus (G") from the applied torque and the resulting rotational motion of the beads as determined from their remanent magnetic field. Under baseline conditions, G' increased weakly with frequency, whereas G" was independent of the frequency. The cell was predominantly elastic, with the ratio of G" to G' (defined as eta) being approximately 0. 35 at all frequencies. G' and G" increased together after contractile activation and decreased together after deactivation, whereas eta remained unaltered in each case. Thus elastic and dissipative stresses were coupled during changes in contractile activation. G' and G" decreased with disruption of the actin fibers by cytochalasin D, but eta increased. These results imply that the mechanisms for frictional energy loss and elastic energy storage in the living cell are coupled and reside within the cytoskeleton.

Malafaia, G., et al. (2020). "Developmental toxicity in zebrafish exposed to polyethylene microplastics under static and semi-static aquatic systems." Science of the Total Environment **700**: 134867.

Different studies have reported the ecotoxicological effects of polyethylene microplastics (PE MPs) on aquatic organisms; however, little is known about their toxicity in the early life stages of aquatic vertebrates living in freshwater ecosystems. Thus, the aim of the current study is to evaluate the toxicity of PE MPs throughout the development of Danio rerio after their static and semi-static exposure to different concentrations of these pollutants (6.2, 12.5, 25, 50 and 100mg/L) - models were monitored at different time-periods, namely: 24, 48, 72, 96, 120 and 144h. Based on the collected data, small PE MP concentrations have harmful effects on D. rerio embryos and larvae; the magnitude and characteristics of these effects depend on the adopted exposure system, which can be static or semi-static. PE MPs had negative effect on embryos' hatching rate in both exposure systems. However, the early hatching observed during the exposure through the static system could explain the lower larval survival rate after egg hatching. Nevertheless, PE MPs induced significant changes in various morphometric parameters. The present study is the first to assess the addressed topic; therefore, it is recommended to carry out future investigations to broaden the knowledge about PE MP toxicity.

Malci, S., et al. (2005). "Selective adsorption, pre-concentration and matrix elimination for the determination of Pb(II), Cd(II), Hg(II) and Cr(III) using 1,5,9,13- tetrathiacyclohexadecane-3,11-diol anchored poly (p-chloromethylstyrene- ethyleneglycoldimethacrylate) microbeads." Analytica Chimica Acta **550**(1-2): 24-32.

Poly(p-chloromethylstyrene-ethyleneglycoldimethacrylate) polymeric microbeads, poly(p-CMS-EGDMA), were synthesized and 1,5,9,13- tetrathiacyclohexadecane-3,11-diol (S4HD) was attached chemically onto the polymeric microbeads. Characterization of all microbeads was done by Fourier transform-infrared spectrometry (FT-IR) and elemental analyzer. The amount of attached 1,5,9,13-tetrathiacyclohexadecane-3,11-diol to the polymer was found to be 2.23 mmol g⁻¹ polymers. The ligand attached microbeads, poly(p-CMS-EGDMA-S4HD), were used to examine the adsorption capacity of Pb(II), Cd(II), Hg(II) and Cr(II) ions for recovery, pre-concentration and the matrix elimination by changing the pH and the initial metal ion concentrations and also adsorption kinetics of the studied metal ions was determined. Pre-concentration factors for the studied toxic metal ions were found to be more than 500-fold and recovery was between 92 and 106%. In the drinking, lake, tap and sea-water samples from water lands, ultra-trace toxic metal ion concentrations were determined easily by using ligand modified microbeads after pre-concentration because of the high pre-concentration factor and easily matrix elimination using ligand modified microbeads. Reference sea-water material was used for the validation of the method and it was found that recovery, pre-concentration and the matrix elimination were performed perfectly. For the desorption of the toxic metal ions, 3 M HCl containing 0.8 M thiourea was used and desorption ratio was obtained more than 96%. © 2005 Elsevier B.V. All rights reserved.

Malinich, T. D., et al. (2018). "No evidence of microplastic impacts on consumption or growth of larval Pimephales promelas." Environmental Toxicology and Chemistry **37**(11): 2912-2918.

Microplastics are an abundant pollutant in aquatic systems, but little is known regarding their effects on larval fish. We conducted foraging and growth experiments to observe how increasing densities of microplastics (polyethylene microspheres) impact the foraging and growth of Pimephales promelas larvae. We found minimal impacts on larval consumption of Artemia nauplii in the consumption study, as well as little impact on total length after 30 d of the growth experiment.

Mallakpour, S. and V. Behranvand (2017). "Recycled pet/MWCNT-ZnO quantum dot nanocomposites: adsorption of Cd(II) ion, morphology, thermal and electrical conductivity properties." Chemical Engineering Journal **313**: 873-881.

This paper investigates the possibility of utilizing recycled PET bottle waste as matrix of novel composites. The effect of various MWCNT-ZnO quantum dot (QD) loadings (1, 2 and 4 by weight) on the morphology, thermal, electrical conductivity properties and water treatment of PET was studied. Results showed that the incorporation of MWCNT-ZnO QDs into the PET matrix causes that the pure polymer undergoes transition from electrically insulated to conductive at room temperature. Enhancement in thermal stability was obtained by the 4 wt% MWCNT-ZnO loading. Our results also show that rPET/MWCNT-ZnO QD composites can be used as absorbents for easy, convenient, and efficient removal of Cd(II) ions from aqueous solution. Actually, plastic waste was used and changed it to a valuable composite with potential of heavy metal adsorption as well as high electrical conductivity.

Mallappa, M. K., et al. (2015). "Calcium Alginate-Neusilin US2 Nanocomposite Microbeads for Oral Sustained Drug Delivery of Poor Water Soluble Drug Aceclofenac Sodium." Journal of Drug Delivery **2015**: 826981.

The aim of the present study was to formulate and investigate the calcium alginate- (CA-) Neusilin US2 nanocomposite microbeads containing preconcentrate of aceclofenac sodium (ACF-Na) liquid microemulsion (L-ME) for enhancement of oral bioavailability. The preconcentrate L-ME is prepared by using Labrafac PG, Labrasol, and Span 80 as oil, surfactant, and cosurfactant, respectively. The solid CA nanocomposite microbeads of L-ME prepared by microemulsification internal gelation technique using sodium alginate (SA) gelling agent, Neusilin US2 as adsorbent, and calcium chloride as crosslinking agent. L-ME has good thermodynamic stability; globule size was found to be 32.4 nm with polydispersity index 0.219

and -6.32 mV zeta potential. No significant interactions of excipients, drug in the formulations observed by FT-IR, DSC and XPRD. The concentration of SA and Neusilin US2 influences the flow properties, mean particle size, mechanical strength, drug entrapment efficiency, and percentage of drug release. All the formulations show minimum drug release in simulated gastric fluid (SGF) pH 1.2 for initial 2 h, maximum drug release in pH 6.8 phosphate buffer solution (PBS) at 6 h, followed by sustaining in simulated intestinal fluid (SIF) of pH 7.4 up to 12 h. The interaction of SA with Neusilin US2 creates a thick thixotropic gel network structure which acts as barrier to control the release of drug in the alkaline pH environment. Neusilin US2 is a novel filler used to convert L-ME into solid nanocomposite microbeads to enhance dissolution rate of poor water soluble drugs sustaining the drug release for prolonged period of time.

Mallikarjuna Rao, K., et al. (2015). "Formulation and IN-VITRO characterization of gastro retentive microbeads of terbutaline sulphate." International Journal of Advances in Pharmaceutical Research **6**(9): 264-274.

To develop and evaluate Terbutaline sulphate (TBS) floating micro beads using polymers like HPMC K15 M and Eudragit RL100. TBS is a beta2 stimulant drug which is having a very short half life of less than 4 hours hence requires frequent administration. Therefore the possible way by which this can be overcome is by formulating gastro retentive system a controlled release formulation (CRF). Floating Micro beads of TBS were prepared by iontropic gelation method by using individual polymers like HPMC K15M and Eudragit RL100. The prepared TBS floating micro beads were then subjected to FTIR, SEM, particle size & % yield, drug content, entrapment efficiency, in vitro dissolution studies, release kinetics. The FTIR Spectra's shown that, there was no interaction between polymers and TBS. The TBS floating micro beads was spherical in nature, which was confirmed by SEM. A maximum of 95.2% drug entrapment efficiency was obtained with HPMC K15M, and 83.22% with Eudragit RL100 formulations. The in-vitro performance of TBS floating micro beads showed controlled release depends on the polymer concentration. The co-efficient of determination indicated that the release data was best fitted with zero order kinetics and it follows Case II transport drug release mechanism.

Mallory, M. L., et al. (2006). "Marine Plastic Debris in Northern Fulmars from Davis Strait, Nunavut, Canada." Marine Pollution Bulletin **52**(7): 800.

Marine plastic debris in northern fulmars from Davis Strait, Nunavut, Canada is presented. Waste marine plastic debris on the ocean surface, bottom and coastlines is a worldwide, marine pollution problem that affects a wide range of wildlife species. The debris can be divided into industrial plastics, typically small pellets that are the precursors to plastic manufacturing, and user plastics, the molded, manufactured items made from industrial plastics. Wildlife ingests these plastic particles, presumably mistaking them for prey species. Once swallowed, the particles can lead to reduced digestive efficiency, blockages or ulcerations of the digestive tract, and increased contaminant loads due to plastic digestion. Ingestion of plastic is a potential problem for marine birds, and especially for procellariids, because they have the highest incidence of plastic ingestion among sea birds, and do not regurgitate indigestibles like other species.

Malsch, R., et al. (1997). "Measurement of fluorescent-labeled LMM-heparin in biological fluids using protamine-linked microbeads." Seminars in Thrombosis & Hemostasis **23**(1): 23-30.

A quantitative assay for fluorescent heparin in a purified system and in plasma was developed (Piazolo et al: Semin Thromb Hemostas 20:227-235, 1994). The protamine microbeads (1.6 microns) showed a broad size distribution and a large standard variation in low concentrations.

Our aim was to optimize these protamine microbeads for the measurement of fluorescent heparin. The following results were obtained: Paramagnetic protamine microbeads of different average diameters (0.8, 1.6, 2.8, and 4.5 microns) were synthesized by cyclocarbodiimide and tosyl activation. These microbeads bind heparin and are assayed using flow cytometry. The protamine concentration on the surface of the beads ranged between 2.0 and 61 mg/mL. The protamine microbeads bound fluorescent heparin and were analyzed by flow cytometry. The protamine microbeads bound LMM-heparin-tyramine-FITC dose dependently in saline solution, plasma, and blood. There are substantial differences between the microbeads of different origins with regard to the amount of protamine bound, the sensitivity of the detection, and the reliability for the determination of heparins in plasma and blood. The minimal sensitivity of the final method was 0.001 U/mL LMMH-tyramine-FITC in saline solution and in plasma. Human blood cells were not bound to protamine microbeads. The half-maximal binding of LMMH-tyramine-FITC of the different protamine-coated microbeads ranged from 1.7 to 8.0 micrograms/mL in saline solution, 2.3 to 8.7 micrograms/mL in plasma, and 3.1 to 6.4 micrograms/mL in blood. We conclude that all protamine microbeads can be used to quantify the concentration of LMMH-tyramine. Protamine Dynabeads M-450 (diameter 4.5 microns) have advantages over other microbeads because of their more homogeneous size distribution, a higher selectivity, and they can be measured together with leukocytes. They are currently used to develop a competitive binding assay for heparin in plasma.

Malviya, G., et al. (2013). "Assessment of the in-vivo biodistribution of NK cells induced by therapeutic antibodies in a mouse tumor model." Journal of Labelled Compounds and Radiopharmaceuticals **1)**: S386.

Objectives: Deregulation of the epidermal growth factor receptors (EGFR) signalling pathway is a recognized mechanism of carcinogenesis. Recent studies demonstrated that tumours have an effective way to suppress the immune system, that there is increasing attention for new treatment strategies that activate immune cells and tumour infiltration and that NK cell infiltration could be an early biomarker to study this process and to monitor treatment response. To gain further insight into the immune response in the tumour in vivo, and to investigate potential alterations of NK biodistribution in response to treatment, we developed a non-invasive method to assess NK cell trafficking. For this purpose, we ex-vivo radiolabeled murine NK cells with ¹¹¹In-oxine. Method(s): Transgenic SCID mice were used to isolate NK cells. These mice were generated to express human CD16 on murine NK cells. The CD16a receptor, present in human macrophages and NK cells, is responsible for recognizing the Fc domain of therapeutic IgG1 antibodies and mediate Fc related immune effectors functions. The purity and viability of the isolated NK cells was confirmed by FACS analysis. NK cells were radiolabeled with ¹¹¹In-oxine to be injected into SCID mice. Different labelling buffers and incubation times were evaluated to optimize the best labelling conditions. We also evaluated the functionality of the radiolabeled NK cell by 51Crrelease assay. Result(s): NK cells were successfully isolated from mouse spleens using anti-CD49b micro-beads and expanded in in-vitro culture. However, ex-vivo expansion of NK cells in the presence of IL-15 for 1 week resulted in the activation of NK cells and induction of cell proliferation, which also changed the expression of different cell receptors. We therefore labelled freshly purified NK cells immediately after isolation, without expansion. We optimized the conditions for NK cell labelling by titrating the amount of radioactivity and found that approximately 11 kBq of ¹¹¹In-oxine per million mouse NK cells is the maximum dose for labelling without affecting cell viability. Moreover, PBS (pH 7.4) and 20 min incubation period were selected as a method of choice that provides the highest labelling efficiency. There was no statistically

significant difference found in the functional activity of unlabelled and ¹¹¹In-oxine labelled NK cells. Biodistribution studies in SCID mice demonstrated that ¹¹¹In-oxine labelled NK cells mainly accumulate in the spleen, and to a lesser extend in the liver. Lung uptake of labelled NK cells is low, suggesting that little damage to the cells. In contrast, ¹¹¹In-oxine released from labelled NK cells, is mainly excreted from the body via the kidneys into the urine. Conclusion(s): Our results demonstrate that labelling murine NK cells is feasible with 111In without affecting their antigen expression, viability and functionality. ¹¹¹In-oxine labelled NK cells mainly target spleen, while released ¹¹¹In-oxine excreted via the kidneys into urine. Experiments are in progress to evaluate the possible alterations of NK cell biodistribution in A549 human lung tumour bearing mice before and after treatment, with different anti- EGFR antibodies.

Malviya, G., et al. (2016). "Isolation and (111)In-Oxine Labeling of Murine NK Cells for Assessment of Cell Trafficking in Orthotopic Lung Tumor Model." Molecular Pharmaceutics **13**(4): 1329-1338.

A noninvasive in vivo imaging method for NK cell trafficking is essential to gain further understanding of the pathogenesis of NK cell mediated immune response to the novel cancer treatment strategies, and to discover the homing sites and physiological distribution of NK cells. Although human NK cells can be labeled for in vivo imaging, little is known about the murine NK cell labeling and its application in animal models. This study describes the isolation and ex vivo radiolabeling of murine NK cells for the evaluation of cell trafficking in an orthotopic model of human lung cancer in mice. Scid-Tg(FCGR3A)Blt transgenic SCID mice were used to isolate NK cells from mouse splenocytes using the CD49b (DX5) MicroBeads positive selection method. The purity and viability of the isolated NK cells were confirmed by FACS analysis. Different labeling buffers and incubation times were evaluated to optimize (111)In-oxine labeling conditions. Functionality of the radiolabeled NK cell was assessed by (51)Cr-release assay. We evaluated physiological distribution of (111)In-oxine labeled murine NK cells in normal SCID mice and biodistribution in irradiated and nonirradiated SCID mice with orthotopic A549 human lung tumor lesions. Imaging findings were confirmed by histology.

Malviya, S., et al. (2013). "Formulation and evaluation of floating microbeads of ciprofloxacin HCl by emulsion gelation method." Der Pharmacia Lettre **5**(2): 63-68.

The objective of this investigation is to develop a multi-unit gastro retentive sustained release dosage form of a water soluble drug, Ciprofloxacin, from a completely aqueous environment avoiding the use of any organic solvent. A new emulsion gelation technique is used to prepare emulsion gel beads using sodium alginate as the polymer. The gel beads containing is prepare by gently mixing or homogenizing oil and water phase containing sodium alginate which is then extruded in to calcium chloride solution. The effects of factors like concentration of oil, curing time, drug: polymer ratio, alginate: pectin ratio and curing agent on drug entrapment efficiency, floating lag time, morphology and drug release are study. Minimizing the curing time of beads leaded to enhanced drug entrapment efficiency. The use of sodium alginate and combinations of sodium alginate and pectin are used to study the effect on the sustaining property of the formed beads. It is found that sodium alginate was not sufficient to sustain the drug release at gastric pH. Instead of it, appropriate combination of alginate and pectin could provide the sustain release of drug. The results show that these beads can entrap even a water soluble drug as Ciprofloxacin in sufficient amount and also can successfully deliver the drug in stomach for a prolong duration of time.

Mancuso, M., et al. (2019). "First record of microplastics ingestion by European hake MERLUCCIUS

MERLUCCIUS from the Tyrrhenian Sicilian coast (Central Mediterranean Sea)." Journal of Fish Biology **94**(3): 517-519.

A sample of 67 European hake Merluccius merluccius were examined to highlight the ingestion of microplastics in the Tyrrhenian Sea. In all samples, 31 black fibres were found in the stomach contents corresponding to 46.3% of the specimens. The data presented here could be important for the implementation of the EU Marine Strategy Framework Directive in Mediterranean waters.

Manfra, L., et al. (2017). "Comparative ecotoxicity of polystyrene nanoparticles in natural seawater and reconstituted seawater using the rotifer Brachionus plicatilis." Ecotoxicology and Environmental Safety **145**: 557-563.

The impact of nanoplastics using model polystyrene nanoparticles (PS NPs), anionic (PS-COOH) and cationic (PS-NH₂), has been investigated on the marine rotifer Brachionus plicatilis, a major component of marine zooplanktonic species. The role of different surface charges in affecting PS NP behaviour and toxicity has been considered in high ionic strength media. To this aim, the selected media were standardized reconstituted seawater (RSW) and natural sea water (NSW), the latter resembling more natural exposure scenarios. Hatched rotifer larvae were exposed for 24 h and 48 h to both PS NPs in the range of 0.5-50 micro g/ml using PS NP suspensions made in RSW and NSW. No effects on lethality upon exposure to anionic NPs were observed despite a clear gut retention was evident in all exposed rotifers. On the contrary, cationic NPs caused lethality to rotifer larvae but LC₅₀ values resulted lower in rotifers exposed in RSW (LC₅₀=2.75+or-0.67 micro g/ml) compared to those exposed in NSW (LC₅₀=6.62+or-0.87 micro g/ml). PS NPs showed similar pattern of aggregation in both high ionic strength media (RSW and NSW) but while anionic NPs resulted in large microscale aggregates (Z-average 1109+or-128 nm and 998+or-67 nm respectively), cationic NP aggregates were still in nano-size forms (93.99+or-11.22 nm and 108.3+or-12.79 nm). Both PDI and Z-potential of PS NPs slightly differed in the two media suggesting a role of their different surface charges in affecting their behaviour and stability. Our findings confirm the role of surface charges in nanoplastic behaviour in salt water media and provide a first evidence of a different toxicity in rotifers using artificial media (RSW) compared to natural one (NSW). Such evidence poses the question on how to select the best medium in standardized ecotoxicity assays in order to properly assess their hazard to marine life in natural environmental scenarios.

Manfroi, S. and P. Pagliaro (2012). "Patients and donors blood group genotyping for an efficient blood therapy." Vox Sanguinis **1)**: 220.

Background: In the Transfusion Service of our Hospital in a few months the Rare Blood Bank will be started on a molecular biology approach. This is a new project of Blood Regional Centre of Emilia-Romagna (Italy) and is based (i) on a first instance, on the identification of rare blood group donors using high throughput automated genotyping; and then (ii) by collecting and cryopreserving rare phenotype blood units. Furthermore, genotyping will be applied also to chronically transfused, alloimmunized and autoimmune hemolytic anemia patients for better red blood cell recover. Aim(s): The aim of this work is to evaluate accuracy, reliability and flexibility of BLOODchip IDCore+ (Progenika-Grifols) on patients and donor samples. Method(s): We performed genotyping on DNA samples of 39 adult and pediatric patients affected by hemoglobinopathies (five of them alloimmunized) and 42 regular blood donors. DNA was extracted from buffy coat samples. RBC genotyping was performed with BLOODchip IDCore+ (Progenika-Grifols) using XMAP Luminex technology. The products of a multiplex PCR, using biotinylated dCTP, are hybridated onto 100 sets of colored microbeads: each set exhibits a unique fluorescence signature of red and infrared dye and is conjugated with specific SNPs oligonucleotides. After a labeling phase with streptavidin-conjugated phycoerytrin, the fluorescence samples is detected by Luminex laser and results analyzed by BIDS software. The software interprets phycoerytrin and beads fluorescence, produces genotype results and converts them into predicted phenotypes for RBC tested. The IDCore+ kit can identify polymorphisms of 33 RBC antigens of RhCE, Kell (K, Kp, Js), Duffy, Kidd, MNSs, Diego, Dombrock, Colton and Cartwright systems.32/39 patient samples were also typed with HEA BeadChip (Bioarray Solutions, USA) and divergent results were solved by PCRSSP (Innotrain, Germany). Donors samples genotyping was performed with BLOODchip IDCore+ and results compared with serological typing (Sanquin). Result(s): In all samples we obtained a complete genotyping with zero 'no calls' or 'not valid' (repetition rate = 0%). For all tests internal and external control were valid. In patient group genotyped with alternative test (BeadChip) concordance was 100% in all shared antigens: RhCe (C, c, E, e), Kell (K, Kp, Js), Kidd, Duffy, MNSs, Diego, Dombrock, Colton. Compared with serological typing, we found divergent RhCE and Kell typing respectively in 9/39 and 3/39 patient samples. PCR-SSP confirmed RhCE genotyping results of both methods. BLOODchip genotyping did not find discrepancies in all donors samples between genomic and serological RhCE, Kell (K, Kp), Kidd, Duffy, MNSs antigen typing. Further we identified:- a r's variant associated to weak C expression, VS+V+ expression in five African Black patients,- Fy(a-b-)phenotype [FY*B (FYB-33)] in seven African black patients. Summary/conclusions: A reliable high throughput automated system is essential for implementing RBC genotyping in routine blood bank testing. BLOODchip IDCore+ genotyping is a robust system (wide range of DNA concentration, low contamination), ease to use, fast (<5 h for overall procedure) and flexible (up to 48 sample per run). Further, BIDS software assists during every work steps, from generating worklist to SNP genotype and predicting phenotype in final report.

Manganelli, V., et al. (2010). "Increased HMGB1 expression and release by mononuclear cells following surgical/anesthesia trauma." Critical Care (London, England) **14**(6): R197.

INTRODUCTION: High mobility group box 1 (HMGB1) is a key mediator of inflammation that is actively secreted by macrophages and/or passively released from damaged cells. The proinflammatory role of HMGB1 has been demonstrated in both animal models and humans, since the severity of inflammatory response is strictly related to serum HMGB1 levels in patients suffering from traumatic insult, including operative trauma. This study was undertaken to investigate HMGB1 production kinetics in patients undergoing major elective surgery and to address how circulating mononuclear cells are implicated in this setting. Moreover, we explored the possible relationship between HMGB1 and the proinflammatory cytokine interleukin-6 (IL-6).

METHODS: Forty-seven subjects, American Society of Anesthesiologists physical status I and II, scheduled for major abdominal procedures, were enrolled. After intravenous medication with midazolam (0.025 mg/Kg), all patients received a standard general anesthesia protocol, by thiopentone sodium (5 mg/Kg) and fentanyl (1.4 mug/Kg), plus injected Vecuronium (0.08 mg/Kg). Venous peripheral blood was drawn from patients at three different times, t(0): before surgery, t(1): immediately after surgical procedure; t(2): at 24 hours following intervention. Monocytes were purified by incubation with anti-CD14-coated microbeads, followed by sorting with a magnetic device. Cellular localization of HMGB1 was investigated by flow cytometry assay; HMGB1 release in the serum by Western blot. Serum samples were tested for IL-6 levels by ELISA. A one-way repeated-measures analysis ANOVA was performed to assess differences in HMGB1 concentration over time, in monocytes and serum.

RESULTS: We show that: a) cellular expression of HMGB1 in monocytes at t(1) was significantly higher as compared to t(0); b) at t(2), a significant increase of HMGB1 levels was found in the sera of patients. Such an increase was concomitant to a significant down-regulation of cellular HMGB1, suggesting that the release of HMGB1 might partially derive from mononuclear cells; c) treatment of monocytes with HMGB1 induced in vitro the release of IL-6; d) at t(2), high amounts of circulating IL-6 were detected as compared to t(0).

CONCLUSIONS: This study demonstrates for the first time that surgical/anesthesia trauma is able to induce an early intracellular upregulation of HMGB1 in monocytes of surgical patients, suggesting that HMGB1 derives, at least partially, from monocytes.

Mangare, C., et al. (2019). "Robust Identification of Suitable T-Cell Subsets for Personalized CMV-Specific T-Cell Immunotherapy Using CD45RA and CD62L Microbeads." International Journal of Molecular Sciences **20**(6): 20.

Viral infections and reactivations remain a serious obstacle to successful hematopoietic stem cell transplantation (HSCT). When antiviral drug treatment fails, adoptive virus-specific T-cell transfer provides an effective alternative. Assuming that naive T cells (T_N) are mainly responsible for GvHD, methods were developed to generate naive T-cell-depleted products while preserving immune memory against viral infections. We compared two major strategies to deplete potentially alloreactive T cells: CD45RA and CD62L depletion and analyzed phenotype and functionality of the resulting CD45RA⁻/CD62L⁻ naive T-cell-depleted as well as CD45RA+/CD62L+ naive T-cell-enriched fractions in the CMV pp65 and IE1 antigen model. CD45RA depletion resulted in loss of terminally differentiated effector memory T cells re-expressing CD45RA (T_{EMRA}), and CD62L depletion in loss of central memory T cells (T_{CM}). Based on these differences in target cell-dependent and target cell-independent assays, antigen-specific T-cell responses in CD62L-depleted fraction were consistently 3-5 fold higher than those in CD45RA-depleted fraction. Interestingly, we also observed high donor variability in the CD45RA-depleted fraction, resulting in a substantial loss of immune memory. Accordingly, we identified donors with expected response (DER) and unexpected response (DUR). Taken together, our results showed that a naive T-cell depletion method should be chosen individually, based on the immunophenotypic composition of the T-cell populations present.

Mani, A., et al. (2015). "Data mining strategies to improve multiplex microbead immunoassay tolerance in a mouse model of infectious diseases." PLoS ONE [Electronic Resource] **10**(1): e0116262.

Multiplex methodologies, especially those with high-throughput capabilities generate large volumes of data. Accumulation of such data (e.g., genomics, proteomics, metabolomics etc.) is fast becoming more common and thus requires the development and implementation of effective data mining strategies designed for biological and clinical applications. Multiplex microbead immunoassay (MMIA), on xMAP or MagPix platform (Luminex), which is amenable to automation, offers a major advantage over conventional methods such as Western blot or ELISA, for increasing the efficiencies in serodiagnosis of infectious diseases. MMIA allows detection of antibodies and/or antigens efficiently for a wide range of infectious agents simultaneously in host blood samples, in one reaction vessel. In the process, MMIA generates large volumes of data. In this report we demonstrate the application of data mining tools on how the inherent large volume data can improve the assay tolerance (measured in terms of sensitivity and specificity) by analysis of experimental data accumulated over a span of two years. The combination of prior knowledge with machine learning tools provides an efficient approach to improve the diagnostic power of the assay in a continuous basis. Furthermore, this study provides an in-depth knowledge base to study pathological trends of infectious agents in

mouse colonies on a multivariate scale. Data mining techniques using serodetection of infections in mice, developed in this study, can be used as a general model for more complex applications in epidemiology and clinical translational research.

Mani, M., et al. (2010). "An experimental investigation on a DI diesel engine using waste plastic oil with exhaust gas recirculation." Fuel **89**(8): 1826-1832.

Abstract: Environmental degradation and depleting oil reserves are matters of great concern around the globe. Developing countries like India depend heavily on oil import of about 125Mt per annum (7:1 diesel/gasoline). Diesel being the main transport fuel in India, finding a suitable alternative to diesel is an urgent need. In this context, waste plastic solid is currently receiving renewed interest. Waste plastic oil is suitable for compression ignition engines and more attention is focused in India because of its potential to generate large-scale employment and relatively low environmental degradation. The present investigation was to study the effect of cooled exhaust gas recirculation (EGR) on four stroke, single cylinder, direct injection (DI) diesel engine using 100% waste plastic oil. Experimental results showed higher oxides of nitrogen emissions when fueled with waste plastic oil without EGR. NO x emissions were reduced when the engine was operated with cooled EGR. The EGR level was optimized as 20% based on significant reduction in NO x emissions, minimum possible smoke, CO, HC emissions and comparable brake thermal efficiency. Smoke emissions of waste plastic oil were higher at all loads. Combustion parameters were found to be comparable with and without EGR. Compression ignition engines run on waste plastic oil are found to emit higher oxides of nitrogen. [Copyright &y& Elsevier]

Mani, T., et al. (2019). "Repeated detection of polystyrene microbeads in the Lower Rhine River." Environmental Pollution **245**: 634-641.

Microplastics are emerging pollutants in water bodies worldwide. The environmental entry areas must be studied to localise their sources and develop preventative and remedial solutions. Rivers are major contributors to the marine microplastics load. Here, we focus on a specific type of plastic microbead (diameter 286-954mum, predominantly opaque, white-beige) that was repeatedly identified in substantial numbers between kilometres 677 and 944 of the Rhine River, one of Europe's main waterways. Specifically, we aimed (i) to confirm the reported abrupt increase in microbead concentrations between the cities of Leverkusen and Duisburg and (ii) to assess the concentration gradient of these particles along this stretch at higher resolution. Furthermore, we set out (iii) to narrow down the putative entry stretch from 81.3km, as reported in an earlier study, to less than 20km according to our research design, and (iv) to identify the chemical composition of the particles and possibly reveal their original purpose. Surface water filtration (mesh: 300mum, n=9) at regular intervals along the focal river stretch indicated the concentration of these spherules increased from 0.05 to 8.3 particles m⁻³ over 20km. This spot sampling approach was supported by nine suspended solid samples taken between 2014 and 2017, encompassing the river stretch between Leverkusen and Duisburg. Ninety-five percent of microbeads analysed (202/212) were chemically identified as crosslinked polystyrene-divinylbenzene (PS-DVB, 146/212) or polystyrene (PS, 56/212) via Raman or Fourier-transform infrared spectroscopy. Based on

interpretation of polymer composition, surface structure, shape, size and colour, the PS(-DVB) microbeads are likely to be used ion-exchange resins, which are commonly applied in water softening and various industrial purification processes. The reported beads contribute considerably to the surface microplastic load of the Rhine River and their potential riverine entry area was geographically narrowed down.

Mani, T. and P. Burkhardt-Holm (2019). "Seasonal microplastics variation in nival and pluvial stretches of the Rhine River - From the Swiss catchment towards the North Sea." Science of the Total Environment: 135579.

Rivers are pivotal carriers of microplastic (MP) towards the oceans. Investigative data on MP pollution in rivers at specific timepoints is continuously compiled. However, such snapshot data can only roughly indicate the long-term extent of contamination and particle fluxes; modelling studies informed by this limited data are prone to large uncertainties. The present study sought to narrow this knowledge gap by examining the differences in MP concentrations, loads and compositions at three nival tributaries and the Rhine River in Basel, Switzerland, as well as two downstream pluvial Lower Rhine River locations in Germany over four seasons throughout 2016-2017. MP concentrations (>0.3 mm) correlated positively with average water discharge and catchment size of the evaluated stream locations and MP concentrations were significantly higher at the downstream pluvial than upstream nival sites. There was no coherent pattern in MP concentration fluctuations between seasons across the six sites investigated, and no correlation with recent precipitation. These findings suggest that temporal variations in MP fluxes towards the North Sea through the year are dominated by the different discharge regimes along the river course. This study also corroborates theoretical models that predict the highest MP loads move downstream the Rhine River during the European winter months.

Mani, T., et al. (2019). "Using castor oil to separate microplastics from four different environmental matrices." Analytical Methods **11**(13): 1788-1794.

The detection of environmental microplastics (MP) is limited by the need to rigorously separate polymers from the surrounding sample matrix. Searching for an affordable, low-risk and quick separation method, we developed a protocol to separate microplastics (size range: 0.3-1 mm; virgin polymers: PP, PS, PMMA and PET-G) from suspended surface solids (marine and fluvial) as well as soil and sediment using castor oil. We demonstrate effective separation of the four polymers in a spike-recovery experiment. The mean+or-SD MP spike-recovery rate was 99+or-4% with an average matrix reduction of 95+or-4% (dry weight, n=16). The protocol was validated by separating non-spiked environmental Rhine River suspended solids samples recovering 74+or-13% of MP. There PS comprised 76% of the non-retrieved MP and additional H₂O₂ digestion was needed to sufficiently reduce the highly abundant natural matrix. This castor oil lipophilicity-based protocol (i) achieves high MP recovery rates as a function of its environmental matrix reduction ability and (ii) provides environmentally friendly, non-hazardous and resource-efficient separation of MP from four different, typically investigated environmental compartments using one and the same method. Based on the Rhine River sample validation, the protocol is a potent replacement for traditional density separation techniques. Samples with high biogenic concentrations may require additional digestion.

Mani, T., et al. (2015). "Microplastics profile along the Rhine River." Scientific Reports **5**: 17988.

Microplastics result from fragmentation of plastic debris or are released to the environment as pre-production pellets or components of consumer and industrial products. In the oceans, they contribute to the 'great garbage patches'. They are ingested by many organisms, from protozoa

to baleen whales, and pose a threat to the aquatic fauna. Although as much as 80% of marine debris originates from land, little attention was given to the role of rivers as debris pathways to the sea. Worldwide, not a single great river has yet been studied for the surface microplastics load over its length. We report the abundance and composition of microplastics at the surface of the Rhine, one of the largest European rivers. Measurements were made at 11 locations over a stretch of 820 km. Microplastics were found in all samples, with 892,777 particles km (-2) on average. In the Rhine-Ruhr metropolitan area, a peak concentration of 3.9 million particles km (-2) was measured. Microplastics concentrations were diverse along and across the river, reflecting various sources and sinks such as waste water treatment plants, tributaries and weirs. Measures should be implemented to avoid and reduce the pollution with anthropogenic litter in aquatic ecosystems.

Mani, T., et al. (2019). "Microplastic Pollution in Benthic Midstream Sediments of the Rhine River." Environmental Science & Technology **53**(10): 6053-6062.

Rivers are major transport vectors for microplastics (MP) toward the sea. However, there is evidence that MP can temporarily or permanently be inhibited from migrating downstream by retention in sediments or ingestion by organisms. MP concentrations, compositions, and fate within the different compartments of the fluvial environment are poorly understood. Here, benthic, midstream sediments of two undammed, open-flowing stretches were investigated in the Rhine River, one of the world's busiest inland waterways. Twenty-five samples were collected at ten sites via riverbed access through a diving bell or dredging. We performed the first comprehensive analysis of riverbed sediment aliquots that avoids visual selection bias using state-of-the art automated micro-Fourier-transform infrared spectroscopy (muFTIR) imaging. MP numbers ranged between 0.26 +/- 0.01 and 11.07 +/- 0.6 x 10³ MP kg⁻¹ while MP particles <75 mum accounted for a mean numerical proportion +/- SD of 96 +/- 6%. MP concentrations decreased with sediment depth. Eighteen polymers were identified in the size range of 11-500 mum; the acrylates/polyurethane/varnish (APV) cluster was found at all sites (mean numerical proportion, 70 +/- 19%), possibly indicating particulate pollution from ship antifouling paint. Overall, polymers denser than freshwater (>1 g cm⁻³) dominated (85 +/- 18%), which contrasts the large proportions of low-density polymers previously reported in near-surface compartments of the Rhine.

Manimekalai, T. K., et al. (2015). "Kinetic, equilibrium and thermodynamic studies of synthetic dye removal using plastic waste activated carbon prepared by CO<inf>2</inf> activation." International Journal of ChemTech Research **8**(6): 225-240.

Activated carbon prepared by CO<inf>2</inf> activation of pyrolysed chars of waste plastic materials used as a high-efficiency adsorbent for the removal of a reactive dye from textile industrial effluents. Characterizations of the synthesized plastic waste activated carbon (PWAC) were analyzed using SEM, XRD and FTIR analysis. The effects of temperature, initial concentration, and contact time were systematically investigated. The equilibrium adsorption data fitted the Langmuir isotherm well and the monolayer adsorption capacity was 68.21 mg/g. Moreover, kinetics of adsorption exhibit followed the pseudo-second-order kinetic model. Thermodynamic parameters such as Gibbs free energy, enthalpy and entropy were determined. It was found that reactive dye adsorption was spontaneous, exothermic and physisorption process. Copyright © 2015, Sphinx Knowledge House. All rights reserved.

Manjann, K. M., et al. (2012). "Formulation and evaluation of dexibuprofen alginate-clay composite microbeads for oral controlled drug delivery." Asian Journal of Pharmaceutical Sciences **7**(1): 28-29.

The objective of the present research work to formulate solid microemulsion microbeads containing dexibuprofen with sodium alginate (SA)and hydrated aluminium silicate (HAS) solid matrix by micro-emulsification ionotropic gelation technique using calcium chloride as cross-linking agent. The effects of different variables such as drug-polymer ratios, concentration of cross-linking agent, clay (HAS) were evaluated on mean particle size, drug content, drug entrapment efficiency and drug release potential The shape and surface characteristics were determined by scanning electron microscopy (SEM), SA-HAS composite microbeads shows smoother surface and were found to be uniform size, spherical shape. No significant drug-polymer interactions were observed in FT-IR and DSC studies. While increasing in the concentrations of SA and HAS increased size distribution, flow properties, mean particle size, and drug entrapment efficiency. While increasing cross-linking agent significantly decreases the mean particle sizes of microbeads and found to be in the range 734 +/- 1.14 to 661 +/- 0.87. The concentration of HAS influences the mechanical strength and percentage of drug entrapment efficiency of SA microbeads and obtained in the range of 67.60 +/- 0.68 to 98.80 +/- 0.87 (w/v). In-vitro drug release profile of microbeads was examined in pH 1.2 for initial 2 h, pH 6.8 up to 6 h and pH 7.4 at end of 12 h. The mechanism of drug release from microbeads depends on swelling and erosion process resulting alginate microbeads was diffusion controlled followed by First order kinetics and whereas alginate/clay composite microbeads approaching to near Zero-order kinetics.

Manjanna, K. M., et al. (2010). "Calcium alginate cross-linked polymeric microbeads for oral sustained drug delivery in arthritis." Drug Discoveries & Therapeutics **4**(2): 109-122.

After the successful optimization and development of a drug entity, design of dosage form then plays an important role. Hence, research continuously keeps on searching for ways to deliver drugs over an extended period of time. With aceclofenac, a novel NSAID used in the treatment of rheumatoid arthritis, frequency of administration may cause certain GI-adverse effects. The objective of the present research work was to develop a microparticulate oral sustained release dosage form, to reduce dosing frequency, to eliminate the dose related adverse effects and to ultimately improve compliance in the pharmacotherapy of arthritis. The microbeads were prepared by an ionotropic external gelation technique, by using sodium alginate as the hydrophilic carrier and calcium chloride as the cross-linking agent. The shape and surface characteristics were determined by scanning electron microscopy (SEM). Particle size distribution was determined by an optical microscope. The physical state of the drug in the formulation was determined by differential scanning calorimetry (DSC). While increasing the concentration of sodium alginate dispersion increased flow properties, mean particle size, swelling ratio and drug entrapment efficiency. The mean particle sizes of drug-loaded microbeads were found to be in the range 596.45 +/- 1.04 to 880.10 +/- 0.13 mum. The drug entrapment efficiency was obtained in the range of 63.24-98.90% (w/v). The release of drug from the microbeads at pH 1.2 is negligible. Under neutral conditions, the beads will swell and the drug release depends on swelling and the erosion process resulting in an optimum level of drug released in a sustained manner which exhibits zero-order kinetics.

Manjanna, K. M., et al. (2009). "Natural polysaccharide hydrogel dexibuprofen microbeads for oral sustained drug delivery." Journal of Pharmacy Research **2**(7): 1271-1278.

The successful optimization and development of drug entity, design of dosage form then plays important role. Hence, research continuously keeps on searching for ways to deliver drugs over an extended period of time. Dexibuprofen a novel NSAID used in the treatment of rheumatoid arthritis which has a short half-life approximately 3.5 h and dosing frequency 2-3 times daily, causes certain side effects like abdominal pain, gastritis, constipation, etc. In the present study, spherical microbeads are able to prolong the release of dexibuprofen were prepared by ionotropic gelation method, using sodium alginate in combination with guar gum, chitosan and pectin natural polysaccharide hydrogels as drug release modifiers in various proportions to overcome the drug related adverse effects, improve drug bioavailability in different GI tract conditions. All investigated properties showed satisfactory results. While increase in concentration of sodium alginate and other polymer dispersion increased sphericity, size distribution, flow properties and mean diameter of microbeads No significant drugpolymer interactions were observed in FT-IR studies. Drug entrapment efficiencies were obtained in the range of 70.4% to 95.2%. Increase in concentration of calcium chloride significantly affects the mean diameter but no appreciable change in morphology and release behavior. The shape and surface characteristics were determined by scanning electron microscopy (SEM) using gold sputter technique. The mean particle size was determined by an optical microscope. The physical state of the drug in the formulation was determined by differential scanning calorimetry (DSC). In-vitro drug release profile of dexibuprofen from microbeads was examined in simulated gastric fluid (SGF pH1.2) and simulated intestinal fluid (SIF pH 7.2). Microbeads coated with chitosan and guar gum aqueous polymer dispersion shows optimum level of sustained release and exhibited zero-order kinetics followed by super case-II transport.

Manjanna, K. M., et al. (2009). "Formulation of oral sustained release aceclofenac sodium microbeads." International Journal of PharmTech Research **1**(3): 940-952.

The objective of the present study was microencapsulate the Aceclofenac sodium (NSAIDs) by ionotropic gelation technique by using sodium alginate as hydrophilic carrier in various proportions and examines the influences of various process parameters like drug: polymer ratio, concentration of calcium chloride, stirring speed and cross-linking time on physicochemical properties of drug loaded microbeads. This system was able to prolong the drug release, minimizing the drug related adverse effects and improve bioavailability in different GI-tract conditions. Formulated drug loaded microbeads were investigated for physicochemical properties and drug release potential. All investigated properties showed satisfactory results. While increasing in the concentration of sodium alginate, calcium chloride and cross-linking time increased sphericity, size distribution, flow properties, mean particle size, swelling ratio and drug entrapment efficiency. No significant effect of drug polymer interactions were observed in FT-IR studies. The drug entrapment efficiency obtained in the range of 63.24-98.90% Particle size of drug loaded formulations were measured by an optical microscope. The mean particle size of drug-loaded microbeads were found to be in the range 596.45+/-1.04 to 880.10+/-0.13. Increase in the stirring rate and cross-linking time tremendous decrease in mean particle size. The shape and surface characteristics were determined by scanning electron microscopy (SEM) using gold sputter technique. The physical state of the drug in the formulation was determined by differential scanning calorometry(DSC). In-vitro drug release profile of aceclofenac sodium from microbeads was examined in simulated gastric fluid pH1.2 for initial 2h, mixed phosphate buffer pH6.8 upto 6h and simulated intestinal pH 7.2 at end of 24h studies. The release of drug from the microbeads was pH dependent, showed negligible drug release in pH1.2. Under neutral conditions the beads will swell and the drug release depend on the swelling and erosion process resulting optimum level of drug released in a sustained manner and exhibited zero-order kinetics followed by super case-II transport.

Mann, T. (2018). "SHARING COLLECTIVE POWER." Earth Island Journal **33**(3): 11-13.

The article presents the views of women working with Earth Island Institute's (EII) network of

projects on their leadership styles and the power of women in the environmental movement. Plastic Pollution Coalition co-founder and director Dianna Cohen says women are great multi-taskers by necessity. Dana Frasz, the fonder and director of Food Shift, says women need to take the lead as they care about the planet.

Manojlovic, V., et al. (2006). "Immobilization of cells by electrostatic droplet generation: a model system for potential application in medicine." International Journal of Nanomedicine **1**(2): 163-171.

The process of electrostatic extrusion as a method for cell immobilization was investigated that could be used for potential applications in medicine. An attempt was made to assess the effects of cell addition and polymer concentration on the overall entrapment procedure, ie, on each stage of immobilization: polymer-cell suspension rheological characteristics, electrostatic extrusion process, and the process ofgelation. The findings should contribute to a better understanding of polymer-cell interactions, which could be crucial in possible medical treatments. Alginate-yeast was used as a model system for carrier-cells. The electrostatic extrusion was considered as a complex two-phase flow system and the effects of cell and alginate concentrations on the resulting microbead size and uniformity were assessed. Under investigated conditions, microbeads 50-600 microm in diameter were produced and the increase in both alginate and cell concentrations resulted in larger microbeads with higher standard deviations in size. We attempted to rationalize the findings by rheological characterization of the cell-alginate suspensions. Rheological characterization revealed non-Newtonian, pseudoplastic behavior of cell-alginate suspensions with higher viscosities at higher alginate concentrations. However, the presence of cells even at high concentrations (5x10(8) and 1x10(9) cells/mL) did not significantly affect the rheological properties of Na-alginate solution. Lastly, we investigated the kinetics of alginate gelation with respect to the quantity of Ca2+ ions and cell presence. The gelation kinetics were examined under conditions of limited supply with Ca2+ ions, which can be essential for immobilization of highly sensitive mammalian cells that require minimal exposure to CaCl2 solution. The molar ratio of G units to Ca2+ ions of 3.8:1 provided complete crosslinking, while the increase in alginate concentration resulted in prolonged gelation times but higher strength of the resulting gel. The cell presence decreased the rate of network formation as well as the strength of the obtained Ca-alginate hydrogel.

Manojlovic, V., et al. (2008). "Application of Electrostatic Extrusion - Flavour Encapsulation and Controlled Release." Sensors **8**(3): 1488-1496.

The subject of this study was the development of flavour alginate formulationsaimed for thermally processed foods. Ethyl vanilline was used as the model flavourcompound. Electrostatic extrusion was applied for the encapsulation of ethyl vanilline inalginate gel microbeads. The obtained microbeads with approx. 10 % w/w of ethylvanilline encapsulated in about 2 % w/w alginate were uniformly sized spheres of about450 mum. Chemical characterization by H-NMR spectroscopy revealed that the alginateused in this study had a high content (67 %) of guluronic residues and was rich in GG diadblocks (FGG = 55%) and thus presented a high-quality immobilisation matrix. The thermalbehaviour of alginate beads encapsulating ethyl vanilline was investigated bythermogravimetric (TG) and differential scanning calorimetry measurements (TG-DSC)under heating conditions which mimicked usual food processing to provide informationabout thermal decomposition of alginate matrix and kinetics of aroma release. Two wellresolved weight losses were observed. The first one was in the 50-150 degreeC temperaturerange with the maximum at approx. 112 degreeC, corresponding to the dehydration of thepolymer network. The second loss in the 220-325 degreeC temperature range, with a maximumat ~ 247 degreeC corresponded to the release of vanilline. The obtained results indicate that up to230 degreeC most of the vanilline remained intacta, while prolonged heating at elevatedtemperatures led to the entire loss of the aroma compound.

Manoochehrabadi, T., et al. (2016). "Effects of speed and time of centrifugation and time of freezing on the amount of produced microparticles from concentrates platelet. [Persian]." Koomesh **17**(3): 686-691.

Introduction: The main method of separating platelet microparticles (PMP) is based on the centrifugation speed and time. Due to the high cost of determining the number of PMP via micro-particles (micro bead) and also the necessity of using an expensive device such as a flow cytometer, it seems that Bradford method would be rather an inexpensive, fast and efficient way to determine the concentration of PMP. Therefore, in this study the effect of different factors, such as speed and time of centrifugation and time of freezing on the concentration of PMP in the platelet concentrates bags was studied. Material(s) and Method(s): We studied two different speeds of centrifugation for separating PRP. In the first protocol for preparation of PRP, the platelet bags were centrifuged at 1500g for 15min and in the second protocol; they were centrifuged at 5000g for the same duration. To evaluate the effect of time, microparticles were separated in 16000g for 20 and 2 min. To determine the concentration of PMP, Bradford method was used. To evaluation the effect of freezing, the PRP was prepared at 300g for 20 min, and then it was freezed in -80c for five days. Flow cytometery analysis was performed for microparticles identification. Result(s): PMP concentrates with the 1500g centrifugation speed showed higher concentration (P <0.05). There was not any significant difference in concentrations of PMPs in relation to the time of centrifugation (2 and 20 min) (P <0.05). Freezing the platelet bags led to higher PMP concentration in compare to the first day of experiment. Flow cytometry analysis showed that microparticles had platelet marker CD41, which represented their origin. Conclusion(s): The result of this study showed that the reduction of centrifugation speed could produce higher levels of the microparticles. In addition, the time of separation in the final stage had no significant effect on PMP isolation. Freezing could lead to higher PMP concentration. Manoussakis, M. N., et al. (2014). "Impaired clearance of early apoptotic cells mediated by inhibitory IgG antibodies in patients with primary Sjogren's syndrome." PLoS ONE [Electronic Resource] **9**(11): e112100.

OBJECTIVES: Deficient efferocytosis (i.e. phagocytic clearance of apoptotic cells) has been frequently reported in systemic lupus erythematosus (SLE). Todate, patients with primary Sjogren's syndrome (SS) have not been assessed for phagocytosis of apoptotic cells (ApoCell-phagocytosis) and of particulate targets (microbeads, MB-phagocytosis).

DESIGN: ApoCell-phagocytosis and MB-phagocytosis were comparatively assessed by flow cytometry in peripheral blood specimens and monocyte-derived macrophage (MDM) preparations from healthy blood donors (HBD) and consecutive SS, SLE and rheumatoid arthritis (RA) patients. Cross-admixture ApoCell-phagocytosis experiments were also performed using phagocytes from HBD or patients, and apoptotic cells pretreated with whole sera or purified serum IgG derived from patients or HBD.

RESULTS: Compared to HBD, approximately half of SS and SLE patients studied (but not RA) manifested significantly reduced ApoCell-phagocytosis (p<0.001) and MB-phagocytosis (p<0.003) by blood-borne phagocytes that correlated inversely with disease activity (p<=0.004). In cross-admixture assays, healthy monocytes showed significantly reduced ApoCell-phagocytosis

when fed with apoptotic cells that were pretreated with sera or purified serum IgG preparations from SS and SLE patients (p<0.0001, compared to those from HBD or RA). Such aberrant effect of the SS and SLE sera and IgG preparations correlated linearly with their content of IgG antibodies against apoptotic cells (p<=0.0001). Phagocytic dysfunction maybe also present in certain SS and SLE patients, as supported by deficient capacity of MDM for ApoCell-phagocytosis and MB-phagocytosis under patients' serum-free conditions.
CONCLUSION: Similarly to SLE, efferocytosis is frequently impaired in SS and is primarily due to the presence of inhibitory IgG anti-ApoCell antibodies and secondarily to phagocytes' dysfunction.

Manuel, J., et al. (2015). "An educational intervention programme on hazards of plastic waste and its disposal among adults: A rural community based study." Nitte University Journal of Health Science **5**(2): 16-18.

Introduction: Plastic is everywhere in today's lifestyle. It is used for packaging, protecting, serving, and even disposing of all kinds of consumer goods. Improper plastic disposal has become a leading problem in both developed and developing countries. As plastic is non-biodegradable in nature, it remains in environment for several years and disposing plastic wastes at landfill are unsafe and has led to various health problems. So researcher felt it is vital that adults should possess knowledge on hazards of plastic wastes and its disposal. Method(s): In this study cross sectional descriptive survey was used. Adults were selected through probability simple random sampling. The data was collected using a pretested structured questionnaire. The structured-teaching programme was administered at the end of the pre-test. The post-test was carried out after 7 days, using the same tool as the pre-test. The data was analysed using SPSS version 16 and the results expressed as proportions. Result(s): A total of 100 adults were included in the study. Analysis of data revealed pre-test knowledge score was 42.52%.Considering the level of knowledge of adults, a structured teaching programme was administered. The post-test knowledge score was 80.48%. Hence comparison in pre-test knowledge score and post-test percentage of hazards of plastic waste and its disposal was approximately 37.96%. A significant association between source of information and post-test knowledge was found. Conclusion(s): A significant number of adults had inadequate knowledge. So researcher felt that awareness programmes regarding hazards of plastic waste and its disposal should be emphasized.

Mao, Y., et al. (2018). "Phytoplankton response to polystyrene microplastics: Perspective from an entire growth period." Chemosphere **208**: 59-68.

Microplastics are widely identified in aquatic environments, but their impacts on phytoplankton have not been extensively studied. Here, the responses of Chlorella pyrenoidosa under polystyrene (PS) microplastics exposure were studied across its whole growth period, with microplastic sizes of 0.1 and 1.0mum and 3 concentration gradients each, which covered (10 and 50mg/L) and exceeded (100mg/L) its environmental concentrations, respectively. PS microplastics caused dose-dependent adverse effects on Chlorella pyrenoidosa growth from the lag to the earlier logarithmic phases, but exhibited slight difference in the maximal inhibition ratio (approximately 38%) with respect to the two microplastic sizes. In addition to the reduced photosynthetic activity of Chlorella pyrenoidosa, unclear pyrenoids, distorted thylakoids and damaged cell membrane were observed, attributing to the physical damage and oxidative stress caused by microplastics. However, from the end of the logarithmic to the stationary phase, Chlorella pyrenoidosa could reduce the adverse effects of microplastics jointly through cell wall thickening, algae homo-aggregation and algae-microplastics hetero-aggregation, hence triggering an increase of algal photosynthetic activity and its growth, and cell structures turned to normal. Our study confirmed that PS microplastics can impair but then enhance algae growth, which will be helpful in understanding the ecological risks of microplastics.

Mao, Y., et al. (2019). "Nanoplastics display strong stability in aqueous environments: Insights from aggregation behaviour and theoretical calculations." Environmental Pollution **258**: 113760.

Nanoplastics are inevitably released into aquatic environments due to their extensive use and the continuous fragmentation of plastics. Therefore, it is imperative to understand the aggregation behaviours that determine the transport and fate of nanoplastics in aquatic environments. In this study, the effects of various metal cations, pH, aging and extracellular polymeric substances (EPS) on the aggregation of polystyrene nanoplastics (nano-PS) in aqueous solutions were systematically evaluated based on aggregation kinetics experiments and Derjaguin-Landau-Verwey-Overbeek (DLVO) theoretical calculation. The concentration, valence and hydration ability of metal cations jointly affected the aggregation of nano-PS. The critical coagulation concentration (CCC) of nano-PS was significantly higher than the ionic strengths in aquatic environments, indicating that the aggregation rate of nano-PS is relatively low in aquatic environments. The results of the aggregation kinetics experiments were consistent with DLVO theory, which showed that the energy barrier of nano-PS was dependent on electrostatic repulsion forces and van der Waals forces, and increased with pH. Nano-PS was artificially aged by UV-H₂O₂, which reduced the hydrophobic nature of the particle surfaces, consequently enhancing the stability of the nanoplastics. EPS (excreted from Chlorella pyrenoidosa) decreased the aggregation rates of nano-PS due to steric effects, which was confirmed by the extend DLVO model. Our results highlight the high stability of nano-PS in aquatic environments, which could help facilitate the evaluation of their environmental impact.

Maquet, L., et al. (2014). "Organization of microbeads in Leidenfrost drops." Soft Matter **10**(23): 4061-4066.

We investigated the organization of micrometric hydrophilic beads (glass or basalt) immersed in Leidenfrost drops. Starting from a large volume of water compared to the volume of the beads, while the liquid evaporates, we observed that the grains are eventually trapped at the interface of the droplet and accumulate. At a moment, the grains entirely cover the droplet. We measured the surface area at this moment as a function of the total mass of particles inserted in the droplet. We concluded that the grains form a monolayer around the droplet assuming (i) that the packing of the beads at the surface is a random close packing and (ii) that the initial surface of the drop is larger than the maximum surface that the beads can cover. Regarding the evaporation dynamics, the beads are found to reduce the evaporation rate of the drop. The slowdown of the evaporation is interpreted as being the consequence of the dewetting of the particles located at the droplet interface which makes the effective surface of evaporation smaller. As a matter of fact, contact angles of the beads with the water deduced from the evaporation rates are consistent with contact angles of beads directly measured at a flat air-water interface of water in a container.

Maragos, C. M. (2000). Novel assays and sensor platforms for the detection of aflatoxins. (Advances in Experimental Medicine and Biology Volume 504). Dordrecht, Mycotoxins and food safety Kluwer Academic Publishers**:** 85-93 40 ref.

The importance of the aflatoxins from food safety and economic standpoints has continued to drive the development of new analytical methods for these mycotoxins. Currently, the widely used methods for measurement of aflatoxins fall into two groups, the established chromatographic methods and traditional enzyme-linked immunosorbent assays (ELISAs).

Recently substantial progress has been made in the application of new technologies to the monitoring of aflatoxins. In particular, several research groups have developed biosensors for detection of the toxins as well as presumptive tests for fungal infection. Biosensors have been developed in a variety of formats including surface plasmon resonance, fibre optic probes, and microbead-based assays. The sensitivity and selectivity of the biosensors and of the presumptive tests has reached the level to where the application of these techniques to the screening of foods warrants further investigation.

Maragos, C. M. (2002). "Novel assays and sensor platforms for the detection of aflatoxins." Advances in Experimental Medicine & Biology **504**: 85-93.

[References: 40]

Maragos, C. M. (2009). "Biosensors for mycotoxin analysis: Recent developments and future prospects." World Mycotoxin Journal **2**(2): 221-238.

The toxicity and prevalence of mycotoxins in commodities and foods has necessitated the development of rapid methods in order to ensure the protection of human food and animal feed supplies. Testing for mycotoxins can be accomplished by many techniques that range from determinative tests in which the presence of the toxin is confirmed, to presumptive tests in which the presence of the toxin is inferred from the presence of markers. This review focuses on tests that fall into a third category, namely indirect assays, where the presence of the toxin is established by it's interaction with an intermediary. Such intermediaries include biological materials that bind mycotoxins, such as antibodies, as well as synthetic materials such as polymers and man-made peptides. The diversity of assays within this category is extraordinary and includes assays based upon traditional microwell formats, microbeads, membranes, electrodes, wave-guides, and solution-phase assays. The microbead format includes platforms as diverse as flow injection immunoassays, tandem column immunoassays, and immunoaffinity columns. The membrane-based formats include flow-through as well as lateral-flow assays. The electrode-based formats incorporate miniaturised immunoassays with electrochemical endpoints. The wave-guide-based devices include formats such as surface plasmon resonance, and fluorescence array biosensors, and the solution phase formats include homogeneous assays such as fluorescence polarisation immunoassay. The breadth of technologies brought to bear upon solving the need for rapid, accurate, detection of mycotoxins is impressive and includes technologies currently available commercially and those which appear poised to enter the marketplace.

Maran, J. P., et al. (2012). "Development of model for mechanical properties of tapioca starch based edible films." Industrial Crops and Products **42**: 159-168.

Eco-efficient products are the new generation of bio-based products prepared with sustainable

materials, which agree with ecological and economic requirements including environmentally acceptable disposal of post-user waste. Increasing environmental concerns associated with handling of plastic waste has emphasized the importance of developing biodegradable edible films from starch. The objective of this study is to develop models and study the individual and interactive effects of the process variables on the mechanical properties of tapioca starch-based edible films using Box-Behnken design. Box-Behnken design with four factors at three levels was employed to evaluate the individual and interactive effects of process parameters (tapioca starch 1-3 g; glycerol 0.5-1.0 ml; agar 0.5-1.0 g; and span 80: 0.1-0.5 ml) on the tensile strength, elongation, Young's modulus, puncture force, and puncture deformation respectively. The results were analyzed using Pareto analysis of variance (ANOVA). For each response, second order polynomial regression models were developed and it showed good fit of the experimental data with high coefficient of determination (R²) and a close agreement between experimental and predicted values was found. The response surface and contour plots were constructed for representing the relationship between the process parameters and the responses.

Marayati, R., et al. (2015). "New circulating biomarker for patients with metastatic pancreatic ductal adenocarcinoma." Annals of Surgical Oncology **1)**: S21.

Introduction: Pancreatic ductal adenocarcinoma (PDAC) is a highly aggressive disease characterized by early invasion and metastasis, for which there are limited diagnostic tools and minimal effective therapies. Circulating tumor cell (CTC) burden has been shown to be prognostic in patients with metastatic disease. We aimed to identify novel biomarkers of CTCs that have potential clinical use for patients with metastatic PDAC (mPDAC). Method(s): Microarray data was analyzed from 154 primary and 30 metastatic PDAC patients. After IRB approval, CTCs and hematopoietic cells were isolated from blood samples from a prospective cohort of 20 PDAC and 4 non-PDAC patients using density gradient centrifugation followed by CD45 microbead selection. Quantitative real-time PCR was used for gene expression validation. Overall survival (OS) was assessed using the log-rank test. Result(s): We identified 67 genes differentially overexpressed in mPDAC tumors compared to primary PDAC and normal tissues. Expression of these genes was evaluated in a panel of 11 pancreatic cancer cell lines and in blood samples from 3 non-PDAC patients. We found that connexin 31 (GJB3), a gap junction protein, was undetectable in blood samples from non-PDAC patients but had high expression in all pancreatic cancer cell lines. We then validated GJB3 expression in blood samples from 20 PDAC patients including 5 patients with localized, 7 with locally advanced, and 8 with metastatic PDAC, as well as 3 non-cancer patients and 1 patient with a cancer other than PDAC. GJB3 expression was higher in samples from patients with mPDAC compared to patients with localized PDAC (p=0.016). In an analysis of 131 patients with resected PDAC tumors, patients with high tumor expression of GJB3 had a shorter median OS (15 mos vs. 24 mos, p=0.031). Conclusion(s): Our results suggest that GJB3 is associated with metastasis as patients with higher GJB3 expression have a worse outcome. GJB3 is found selectively in blood samples from patients with mPDAC and thus is a potential circulating biomarker for mPDAC Further analysis in a larger cohort of patients will be done to establish the use of GJB3 as a prognostic circulating biomarker.

Marcato, S. M. and G. J. M. M. d. Lima (2005). "Feed restriction as an alternative to reduce environmental impact of pig waste." Revista Brasileira de Zootecnia **34**(3): 855-863.

The objective of this study was to evaluate the effect of feed restriction on faecal mineral content of finishing pigs (n=48) with initial weight of 41.92+or-0.27 kg assigned to an

experimental randomized block design. Treatments were: T1=ad libitum feeding; T2=95% T1 feed intake; and T3=90% T1 feed intake and 16 replicates. The animals were kept for 21 days adaptation period in collective pens and metabolism cages. Urine and faecal collections were performed for two days using 20 g of coloured plastic particles as faecal markers. There was a reduction of 8.54% in the daily feed consumption in the diet in T3 animals, causing a decrease of 9.65% in faecal mineral content when compared with ad libitum consumption (T1). All macrominerals, except for magnesium, decreased in the faeces while feed restriction increased. Calcium and potassium in the faeces represented ~29% of the excreted mineral matter of the animals and both significantly decreased during feed restriction. For all microminerals, the relationship between the excreted amount and consumed amount were equal or >86.60%, indicating that the animals had a low retention efficiency of these nutrients. It is concluded that feed restriction in the finishing phase of pigs cause a reduction in the amount of dry matter and almost all minerals excreted. Therefore, the use of this practice can contribute to reduce pollution problems of pig manure.

Marcinkowski, U., et al. (2015). "Evaluation of polycaprolactone as a new sorbent coating for determination of polar organic compounds in water samples using membrane-SPME." Analytical and bioanalytical chemistry **407**(4): 1205-1215.

Issue Title: A different way of looking at vibrational hyperspectral data/Micellar extraction for the analysis of Alzheimer's disease brain proteome/Quantification of polyolefin microplastics in personal-care products/Removal of Triton X-100 by microdialysis Commercially available solid-phase microextraction fibers used for isolation of polar analytes are based on the adsorption phenomenon. In consequence, typical limitations bonded with analytes displacement and matrix effects are very frequent. In the present study, alternative solution is described. Polycaprolactone (PCL) was used for the first time as sorbent to isolate polar organic compounds from water samples using the membrane-solid-phase microextraction (M-SPME) technique. In this technique, due to protective role of the mechanically and thermally stable polydimethylsiloxane (PDMS) membrane, internal polar coating might be melted during extraction and desorption of analytes. In consequence sorbents with low melting points like a PCL might be utilized. Based on chromatographic retention data, triazines were selected as a model compounds for evaluation of the sorptive properties of the polycaprolactone. Applying the screening plan and central composite design, statistically significant parameters influencing extraction efficiency were determined and optimized. The analysis of variance confirmed the significant influence of temperature, salt content, and pH of samples on the extraction efficiency. Besides the new PCL/PDMS fiber, a commercial fiber coated with divinylbenzene/polydimethylsiloxane (DVB/PDMS) was used for comparative studies. The results obtained showed that PCL is an interesting sorbent which can be successfully applied for isolation of polar organics from aqueous matrices at a broad range of analytes concentration. The determined detection limits of procedure based on the novel fiber enable its application at the concentration levels of triazines recommended by the US EPA standards. The practical applicability of the developed fiber has been confirmed by the results based on the analysis of real samples.

Mardyani, S. (2011). Nanoparticles for Cancer Detection and Therapy: Towards Diagnostic Applications of Quantum Dots and Rational Design of Drug Delivery Vehicles.

This thesis describes observations, techniques and strategies, which contribute towards the development of nanoparticle based detection and treatment of cancer. Quantum dots and biorecognition molecules were studied towards applications in detection and microgels were

used in the rational design of a targeted drug delivery vehicle. The fluorescence intensity of quantum dots was examined in buffers commonly used in molecular biology. The fluorescence intensity of ZnS-capped CdSe quantum dots (QDs) was found to vary significantly, depending on the amount of ZnS capping on the QDs or the concentration, pH and type of buffer the QDs were in. Since fluorescence cannot reliably be used to quantify QDs, an alternative quantification method was developed, which does not rely on their fluorescence. This method employs phage display to identify nanoparticle-specific bacteriophage which were then applied in an assay to quantify QDs in environments where absorbance or fluorescence spectroscopy are ineffective. Biorecognition molecules, which can direct nanoparticles to a molecular target, were also identified through phage display. Phage display on whole cells was used to identify a peptide, which was conjugated with QDs to stain HeLa (cervical cancer) cells. A high-throughput phage display screening strategy was also developed, which could enable the simultaneous identification of multiple biorecognition molecules from a single library. QD-encoded microbead barcodes were conjugated to protein targets and then used to screen a phage display library. The beads and the binding phage were then separated using flow cytometry and fluorescence assisted cell sorting. Finally, biorecognition molecules were combined with nanoparticles to create drug delivery vehicles, which were designed to protect, deliver and then release chemotherapeutic drugs through an intracellular pH trigger. PolyNIPAAm and chitosan hydrogels, under 200 nm in diameter, were loaded with chemotherapeutic drugs, conjugated to transferrin and tested in vitro on HeLa cells. These projects demonstrate the great potential in this growing field as well as some of the many challenges that have yet to be overcome.

Margiotta, S. (2007). "Technical characterization of eco-compatible plastic films for soil solarization: four years of experiments." Rivista di Ingegneria Agraria **38**(4): 1-10.

Soil solarization relies on solar radiation being converted to heat for the killing of soilborne pathogens. On one hand, this technique can be considered as an environmentally-friendly way to manage soilborne pests, as an alternative of methyl bromide phased-out in 2005, than using chemicals. On the other hand, high employment of traditional plastic sheets in agriculture causes the production of enormous quantities of waste, whose inappropriate management might have negative effects on the environment. In order to determine a reduction of the charge of plastic waste and to facilitate the waste disposal, one of the most interesting approaches, from an environmental point of view, lies in the location of innovatory plastic films such as co-extruded ultrathin films, which are able to reduce the plastic quantity to be managed, and biodegradable laminates, which after a first usage, will spontaneously start up a degradation process that avoids their collection and their consequent disposal. Beside the ecological proprieties of these innovative films, it is necessary to study their technical and agronomical behavior in order to determine their efficiency and the possibility to be used in place of the traditional plastic films. This paper represents a review of the research carrier out by the Technical Economics Department of the University of Basilicata (Italy) in the last years (1999, 2000, 2002 and 2003) on the technical performances of some innovative plastic films used for soil solarization.

Margovsky, A., et al. (1998). "Small vessel ischaemia induced by microbead embolization in the sheep hind limb." Australian and New Zealand Journal of Surgery **68**(8): 592-598.

Background: Peripheral ischaemia may be caused by small vessel disease but there has been no satisfactory experimental model for studying this condition. We have developed a model in which microbeads are embolized to the distal vascular bed of a sheep. This model induces ischaemia proportional to the volume of microbead infusion and allows the pathophysiology and therapy of small vessel occlusion to be studied. Method(s): Gradual reduction of femoral artery blood flow by 50% and 75% in unilateral hind limbs of eight sheep was achieved by slow introduction of latex microbeads (mean size = 400 mum) into the peripheral vascular bed. The other hind limb served as a control. Measurements of blood flow, subcutaneous temperature and arterial and venous blood gases were recorded in both hind limbs after each level of flow reduction. Angiography confirmed small vessel occlusion. Muscle samples were analysed for ultrastructural changes by transmission microscopy. Result(s): A linear correlation was found between the amount of microbeads infused and the reduction in the blood flow. Significant subcutaneous temperature and venous pO<inf>2</inf> changes were observed in the embolized limb at both 50% and 25% flow levels compared to baseline (P < 0.05; ANOVA). Angiography demonstrated abrupt cut-off images of the small vessels. Transmission microscopy showed graded levels of muscle cell damage from ischaemia. Conclusion(s): Latex microbead embolization induces reproducible controlled small artery occlusion. The degree of outflow obstruction and the extent of ischaemia can be varied by delivering measured quantities of microbeads. This model should be useful for studying the pathophysiology of ischaemia and for assessing the efficacy of treatment, especially the use of pharmacological agents.

Maria, M. S., et al. (2015). "Development of a microfluidic device for cell concentration and blood cell-plasma separation." Biomedical Microdevices **17**(6): 115.

This work presents design, fabrication and test of a microfluidic device which employs Fahraeus-Lindqvist and Zweifach-Fung effects for cell concentration and blood cell-plasma separation. The device design comprises a straight main channel with a series of branched channels placed symmetrically on both sides of the main channel. The design implements constrictions before each junction (branching point) in order to direct cells that would have migrated closer to the wall (naturally or after liquid extraction at a junction) towards the centre of the main channel. Theoretical and numerical analysis are performed for design of the microchannel network to ensure that a minimum flow rate ratio (of 2.5:1, main channel-to-side channels) is maintained at each junction and predict flow rate at the plasma outlet. The dimensions and location of the constrictions were determined using numerical simulations. The effect of presence of constrictions before the junctions was demonstrated by comparing the performances of the device with and without constrictions. To demonstrate the performance of the device, initial experiments were performed with polystyrene microbeads (10 and 15 mum size) and droplets. Finally, the device was used for concentration of HL60 cells and separation of plasma and cells in diluted blood samples. The cell concentration and blood-plasma purification efficiency was quantified using Haemocytometer and Fluorescence-Activated Cell Sorter (FACS). A seven-fold cell concentration was obtained with HL60 cells and a purification efficiency of 70 % and plasma recovery of 80 % was observed for diluted (1:20) blood sample. FACS was used to identify cell lysis and the cell viability was checked using Trypan Blue test which showed that more than 99 % cells are alive indicating the suitability of the device for practical use. The proposed device has potential to be used as a sample preparation module in lab on chip based diagnostic platforms.

Mariano, E. d. F. and C. H. Targino (2012). "Plastic ingestion by Masked booby, Sula dactylatra Lesson, 1831, on Biological Reserve of Rocas Atoll, RN, Brazil." Biotemas **25**(4): 285-288.

Plastic particles are one of the most common pollutants in the marine environment and it is reaching regions with low human population density. These particles are frequently ingested by many marine organisms, causing digestive problems, which may lead to the weakening and death of the animal. In a research on the feeding of 631-masked boobies, Sula dactylatra from

the Biological Reserve of Atol das Rocas, plastic particles were found in stomach contents of four adults. The artifacts found were made of transperant plastic, a piece of label of a mineral water bottle, two pieces of black plastic and a small hard and red piece. The flow of fishing and tourism boats on the Atol das Rocas Biological Reserve may be the source of origin of the plastic parts in both the stomach contents and those found on the islands of the reserve, which suggests that anthropogenic behaviour has already reached isolated areas which should have a high degree of biodiversity protection. Several measures can be taken to avoid deleterious events in the marine biota, but there is great difficulty in avoiding waste dumping from fishing and tourism ships/boats, in addition to that, there are many materials from the mainland, which requires an increase in awareness and supervision.

Marie Kampmann, E., et al. (2019). "Quality Assessment and Circularity Potential of Recovery Systems for Household Plastic Waste." Journal of Industrial Ecology **23**(1): 156-168.

Plastic recycling is promoted in the transition toward a circular economy and a closed plastic loop, typically using mass-based recycling targets. Plastic from household waste (HHW) is contaminated and heterogeneous, and recycled plastic from HHW often has a limited application range, due to reduced quality. To correctly assess the ability to close plastic loops via recycling, both plastic quantities and qualities need to be evaluated. This study defines a circularity potential representing the ability of a recovery system to close material loops assuming steady-state market conditions. Based on an average plastic waste composition including impurities, 84 recovery scenarios representing a wide range of sorting schemes, source-separation efficiencies, and material recovery facility (MRF) configurations and performances were assessed. The qualities of the recovered fractions were assessed based on contamination and the circularity potential calculated for each scenario in a European context. Across all scenarios, 17% to 100% of the generated plastic mass could be recovered, with higher source-separation and MRF efficiencies leading to higher recovery. Including quality, however, at best 55% of the generated plastic was suitable for recycling due to contamination. Source-separation, a high number of target fractions, and efficient MRF recovery were found to be critical. The circularity potential illustrated that less than 42% of the plastic loop can be closed with current technology and raw material demands. Hence, Europe is still far from able to close the plastic loop. When transitioning toward a circular economy, the focus should be on limiting impurities and losses through product design, technology improvement, and more targeted plastic waste management.

Markic, A., et al. (2019). "Plastic ingestion by marine fish in the wild." Critical Reviews in Environmental Science and Technology.

Marine plastic pollution has become a prominent environmental issue in the recent years. Plastic ingestion is of special concern, as its magnitude and consequences for marine organisms and potentially humans are still largely unknown. We reviewed 93 papers on plastic ingestion by wild marine fish published since 1972. Plastic ingestion was detected in 323 (65%) of 494 examined fish species, and in 262 (67%) of 391 examined commercial fish species. These proportions are likely greater, as a detailed analysis of the sampling effort and analytical methods used in the reviewed studies suggests an underestimation of plastic ingestion in some assessments. A significant positive relationship ($R = +0.845$, $p = 0.004$) was found between the sample size up to $N = 10$ and the detection of plastic ingestion. We also found significant differences in detection and frequency of occurrence (FO, %) of plastic ingestion among the three main types of analytical methods: naked-eye, microscopic analysis and chemical digestion. The chemical digestion method, which is also the most robust laboratory method, had the

greatest detection (86%) and the highest FO (37.6 +/- 0.6%). To avoid the underestimation of plastic ingestion in future work, we provided recommendations for sample sizes and laboratory analysis. Copyright © 2019, © 2019 Taylor & Francis Group, LLC.

Markic, A., et al. (2018). "Double trouble in the South Pacific subtropical gyre: increased plastic ingestion by fish in the oceanic accumulation zone." Marine Pollution Bulletin **136**: 547-564.

Fish are an important food source for South Pacific (SP) island countries, yet there is little information on contamination of commercial marine fish species by plastic. The aim of our study was to perform a broad-scale assessment of plastic ingestion by fish common in the diet of SP inhabitants. We examined 932 specimens from 34 commercial fish species across four SP locations, and some of the prey they ingested, for the presence of marine plastics. Plastic was found in 33 species, with an average ingestion rate (IR) of 24.3+or-1.4% and plastic load of 2.4+or-0.2 particles per fish. Rapa Nui fish exhibited the greatest IR (50.0%), significantly greater than in other three locations. Rapa Nui is located within the SP subtropical gyre, where the concentration of marine plastics is high and food is limited. Plastic was also found in prey, which confirms the trophic transfer of microplastics.

Markovetz, M. R., et al. (2019). "Establishing the mucus flake burden as a biomarker of CF disease severity." Pediatric Pulmonology **54 (Supplement 2)**: 161.

Rationale: Dehydration of the airway surface layer is a hallmark of cystic fibrosis (CF) airway disease. We have recently demonstrated that mucins (the key gel-forming polymeric component of mucus) are elevated in bronchoalveolar lavage fluid (BALF) in preschool-aged CF patients (Esther CR Jr, et al. Sci Transl Med. 2019;11:486), and that roughly half of the mucins present in BALF are present in nonswelling gels termed mucus flakes. However, the relationship between flake formation and CF disease severity has not been established. Method(s): BALF was collected from 25 children with CF (age 10.9 +/-4.6 years, % FEV<inf>1</inf> predicted 78.9 +/-13.5%) as part of routine treatment (UNC-CF). Mucin and DNA concentrations of each sample were measured by refractometry and PicoGreen assay respectively. Flake rheology was measured by microbead rheology, and the coverage area of flakes (proxy for the amount of sample that flakes occupy) was measured by tilling fluorescence microscopy. Results from this cohort group were compared to samples from healthy adults as well as previously collected data from preschool children with CF (AREST CF) undergoing bronchoscopy when clinically stable (Esther, et al). Result(s): Both mucin and DNA concentrations were increased in BALF from school-aged children with CF (UNC-CF) relative to preschool children with CF (AREST CF), with mucin and DNA concentrations higher in both groups relative to healthy adults. Although the fraction of mucins present in mucus flakes was not different between preschool and school-aged CF groups (though increased relative to healthy adults), the total flake coverage area was higher in the UNC-CF relative to both AREST CF and healthy adults. Furthermore, within the school-aged group both flake coverage area and rheology of flakes (viscosity) were inversely proportional with % FEV<inf>1</inf> predicted. Our data also shows that infection further elevates the mucin concentration, flake coverage, and rheology of flakes within the UNC-CF group. Conclusion(s): Mucus flakes are present at higher concentrations in children with CF and become more abundant and rheologically thicker with disease progression, as measured by age or worsening pulmonary function. Mucus flakes are therefore a candidate biomarker of CF disease severity and a therapeutic target. Rheologic and imaging methods can be used to assess mucus flake abundance and biophysical properties in young children.

Markovetz, M. R., et al. (2017). "Evaluating mucus-based biomarkers of CF airway disease." Pediatric

Pulmonology **52 (Supplement 47)**: 258.

The AREST CF project represents a unique opportunity to document the early onset of airway disease in cystic fibrosis. In this ongoing study, bronchoalveolar lavage (BAL) samples are collected from pediatric patients at regular intervals over the first 6 years of life. The goal of our analysis is to investigate changes in the rheological properties of mucus brought on by CF airway disease. We have previously shown that CF sputum is characterized by significantly increased mucin concentration (1) resulting in modified biophysical properties such as viscoelasticity and osmotic pressure (2, 3). Due to the dilute nature of BAL samples, determining the native concentration of mucus along the airways from BAL samples has proven impossible. While small flecks of concentrated, viscoelastic mucus are present in pediatric CF BALs, these samples also contain highly diluted mucus that is rheologically identical to saline. By combining sophisticated microbead rheological measurements of BAL samples with advanced data analytics, we are able to determine a diversity of rheological microenvironments. Specifically, we embed 1 micron diameter tracer particles into the sample volume and analyze their diffusive fluctuations. Analytically, we convert each particle's position series into a local rheological characterization (4), reflecting motilities from a range of diluted to pure mucus samples. We compare our results to young-adolescent CF patients and to normal BALs, finding that the samples collected from the pediatric AREST participants display a rheology that lies between that of healthy adults and adult CF patients. We further show that pre-school aged CF patients already have mucus that is consistent with high concentration pathology, and that mucus from CF patients has a fundamentally altered molecular structure compared to normal adults over a wide range of mucus concentrations. Finally, we evaluate the relative efficacy of mucolytic treatments with dithiothreitol (DTT) and lambda DNase in restoring pathologically altered mucus to normal.

Marques, G. A. and J. A. S. Tenorio (2000). "Use of froth flotation to separate PVC/PET mixtures." Waste Management **20**(4): 265-269.

Recycling is an important activity in the minimization of waste that results from human activities. The idea re-using this waste has increased during the last decades due to environmental, economics and social factors. In the United States, 75 billion pounds of plastic are produced every year. Unfortunately, the majority of this plastic ends up in landfills where its decomposition process can take anywhere from 10 to 30 years. The United States currently recycles about 5% of its post-consumer plastic waste; however, as much as 55% could be recycled if economically viable methods can be developed to collect and process waste streams that contain at least 50% thermoplastic materials. Froth flotation is the cheapest and most extensively used process for the separation of chemically similar minerals, and to concentrate ores for economical smelting. Flotation has a reduced cost compared to other separation operations. In this work, froth flotation was used to treat PVC and PET mixtures. The parameters studied are reagents, pH, conditioning time and particle size. The results show a yield of 99.3% pure PVC separated from PET. (C) 2000 Elsevier Science Ltd.

Marques-Santos, L. F., et al. (2018). "Cationic polystyrene nanoparticle and the sea urchin immune system: biocorona formation, cell toxicity, and multixenobiotic resistance phenotype." Nanotoxicology **12**(8): 847-867.

In order to assess the impact of nanoplastics on marine species, polystyrene nanoparticles (PS NPs) have been largely used as model particles. Here we studied the effects of 50 nm amino-modified PS-NH2 on Mediterranean sea urchin Paracentrotus lividus immune system cells (coelomocytes) in the presence of celomic fluid (CF) and at different NP concentrations (1, 5, 10, and 25 μg mL-1) and experimental conditions (absence or presence of EDTA). PS-NH2 acquired a protein corona once incubated with CF, dominated by the toposome precursor protein (TPP). In short-term cultures, a significant concentration- and time-dependent decrease in lysosomal membrane stability and apoptotic-like nuclear alterations were observed in phagocytes upon exposure to PS-NH2 (10 and 25 μg mL-1) in CF but they resulted abolished in the presence of EDTA confirming the role of TPP in triggering PS-NH2-coelomocytes interaction and toxicity. PS-NH2 did not alter MXR phenotype but the observed dose-dependent decrease in calcein accumulation suggests the ability of PS-NH2 to affect pump's efflux activity. Overall results encourage additional studies on positively charged nanoplastics, since the observed effects on sea urchin coelomocytes as well as the TPP corona formation might represent a first step for addressing their impact on sensitive marine species.

Marra, F., et al. (2017). "Virtualization of fluid-dynamics in micro-air assisted extruders for food microfluidic based encapsulation. (Special Issue: Responsible research and innovation in the food value chain.)." Journal of Food Engineering **213**: 89-98.

Microfluidic technique represents an interesting technological solution for the production of alginate microbeads in pharmaceutical, food and cosmetics industry. Given the characteristic small size of microfluidic devices and the extremely complex dynamics which are at the base of transport phenomena involved in this process, a purely experimental approach is not able to provide all significant data to design cheap but trustable devices. In this work, a virtual approach - based on computational fluid dynamics analysis - has been proposed to analyze the behavior of a micro air-assisted extruder and to provide mechanistic insight into the particle formation dynamics. The particle formation was characterized by a complex periodic dynamics, during which elongations and instabilities brought to merging of liquid droplets, of different main size, into bigger drops. Jet instabilities dominating the drops break-up dynamics were greatly influenced by geometric parameters: the fluid-dynamic analysis showed that small misalignment can dramatically change the jet breakup dynamics, introducing a completely different framework. The analysis proposed in this work represents a powerful tool for the design of simple and cheap microfluidic devices, capable of mass production of small (around 300 micro m of diameter) and regular alginate microbeads, at least for matrix encapsulation.

Marrari, M. and R. J. Duquesnoy (2010). "Detection of donor-specific HLA antibodies before and after removal of a rejected kidney transplant." Transplant Immunology **22**(3-4): 105-109.

UNLABELLED: Serum analysis of patients considered for retransplantation has a potential limitation that the rejected allograft may absorb HLA antibodies. We have determined how the highly sensitive micro bead-based Luminex antibody-binding assay with single antigens can detect donor-specific HLA antibodies (DSA) in patients before and after surgical removal of a rejected allograft. This analysis was done for 65 allograft nephrectomy (allonx) cases contributed by 16 laboratories worldwide. In the HLA-A,B and -DRB1 mismatch categories the incidence of DSA reactivity pre-allonx and post-allonx was 64% vs 87% (p=0.0033) and 57% vs 86% (p=0.001), respectively. The frequencies of individual reactive antigens were also lower before allonx: for HLA-A,B antigens: 49% vs 75% (p<0.0001) and DRB1 antigens: 48% vs 79% (p=0.0001). On the other hand, no significant differences were seen between the pre-allonx and post-allonx frequencies of DSA to DRB3/4/5 (65% vs 78%, p=0.22) and DQ mismatches (76% vs 87%, p=0.18).

CONCLUSION: although the sensitive Luminex antibody assay can detect anti-donor antibodies in the presence of a rejected transplant, it is apparent that the antibody specificity pattern is often incomplete especially against the HLA-A, -B and DR mismatches. This understanding seems relevant to the determination of acceptable mismatches for patients considered for

retransplantation.

Marsic-Lucic, J., et al. (2018). "Levels of trace metals on microplastic particles in beach sediments of the island of Vis, Adriatic Sea, Croatia." Marine Pollution Bulletin **137**: 231-236.

The aim of this study was to determine the levels of trace metals (Cd, Cr, Cu, Fe, Mn, Ni, Pb and Zn) in plastic pellets collected from two sandy beaches on the island of Vis, Croatia. A total of 92 pellets in a sediment volume of 3965mL were collected at the investigated sampling sites. Concentrations of pellets in sediment samples ranged from 6 to 36particlesdm⁻³ of wet sediment. Mean particle weight of the collected beached pellets ranged from 17mg to 31mg. Trace metal concentrations in plastic pellets were greater than the concentrations reported for seawater in the investigated area, which indicates that plastic pellets sorb metals from the marine environment. The adsorbed trace metals may enter the food chain due to incidental ingestion of microplastic particles by marine animals, which presents a potential human health risk due to consumption of seafood.

Martellini, T., et al. (2018). "A snapshot of microplastics in the coastal areas of the Mediterranean Sea." TrAC - Trends in Analytical Chemistry **109**: 173-179.

The Mediterranean Sea is affected by one of the most significant plastic pollution worldwide. This review critically evaluates the most recent literature on the presence of microplastics in sediments, suggested to be long term sinks and have a high potential to accumulate this kind of marine debris. A picture of microplastic levels in coastal environments is given, evidencing information gaps and considering also estuary, lagoons and areas influenced by the contribution of rivers. A wide range of contamination levels has been found, with the highest in lagoon and estuary environments. The lack of homogeneity in the methods of study and the need to harmonize the latter and the expression of the results in addition to the need to obtain data on the contributions of the main tributaries of the Mediterranean and on lagoons, are other important considerations taken. Copyright © 2018 Elsevier B.V.

Martin, C., et al. (2019). "Seasonality of marine plastic abundance in central Red Sea pelagic waters." Science of the Total Environment **688**: 536-541.

The Red Sea holds one of the lowest concentrations of floating plastic worldwide and no evident congregation zones were identified so far, despite peculiar oceanographic features that candidate the basin as an accumulation area for floating debris. However, the Red Sea exhibits a complex pattern of surface currents, which changes according to the monsoon season, possibly affecting the abundance of plastic throughout the year. To explore the effect of seasonality on plastic concentration in surface waters, we conducted a fortnightly time series sampling, using a neuston net, for 21months at a pelagic station in the central Red Sea, where the major seasonal overturn of the Red Sea surface circulation occurs. The estimated average abundance (+/-SE) was 58,563+/-19,272itemsKm⁻² (73.5+/-40.75gKm⁻²), highly variable according to season, lower during the summer monsoon. Indeed, the winter monsoon pushes oceanic surface waters inside the Red Sea, transporting alongside floating plastic items, whilst surface currents exit the basin during the summer monsoon, depleting central Red Sea waters from floating plastic. Composition of plastic items also changes through time. Particularly, the higher proportion of films and foams during summer months suggests that the main source of plastic at the sampling station from June to September is a short-range transport, while during winter months, the higher contribution of small fragments indicates that, from October to May, plastic is also transported to the central Red Sea through surface currents for long distances, possibly coming all the way from the Indian Ocean.

Martin, C., et al. (2019). "Adhesion to coral surface as a potential sink for marine microplastics." Environmental Pollution **Part 2. 255 (no pagination)**(113281).

Only 1% of plastic entering the ocean is found floating on its surface, with high loads in ocean accumulation zones and semi-enclosed seas, except for the Red Sea, which supports one of the lowest floating plastic loads worldwide. Given the extension of reefs in the Red Sea, we hypothesize a major role of scleractinian corals as sinks, through suspension-feeding, and assessed microplastic removal rates by three Red Sea coral species. Experimental evidence showed removal rates ranging from 0.25 x 10⁻³ to 14.8 x 10⁻³ microplastic particles polyp⁻¹ hour⁻¹, among species. However, this was only 2.2 +/- 0.6% of the total removal rate, with passive removal through adhesion to the coral surface being 40 times higher than active removal through suspension-feeding. These results point at adhesion of plastic to coral reef structures as a major sink for microplastics suspended in the water column after sinking, helping explain low concentrations in Red Sea surface waters. Corals remove microplastics from the water mainly through a passive mechanism of surface adhesion, which is a removal process 40 times more efficient than retention after ingestion. Martin, C. and M. Dubois (2000). "Solarization as a practical integrated soil disinfestation system in salad crop of Roussillon (southern France)." Acta Horticulturae **532**: 243-246.

A long term demonstration project on solarization as a viable alternative for soil disinfestation is discussed. A special registered prototype of a plastic-laying machine for open fields was developed and a channel for the collection of plastic waste was tested. Cost comparisons were made for three methods for taking the plastic from the grower's field to the conditioning unit and up to a recycling unit. The results indicate an increasing potential for solarization in open fields and greenhouses, on rotations including a salad crop with cucurbits, early potatoes and artichokes in Roussillon (southern France).

Martin, E. D., et al. (1982). "Attitude in the histologic diagnosis of small-bowel disease. [French]." Acta Endoscopica **12**(4): 295-305.

Peroral biopsy is an essential diagnostic tool in diffuse mucosal small bowel disease. Enteroscopy allows a macroscopic examination, the orientation of specimens, and especially a quick retrieval of biopsies at several levels. A comparison between human and animal biopsies, obtained through aspiration-section tubes or by biopsy foreceps, reveals that the orientation of the specimens and the risks of artefacts are more important in endoscopic biopsies. For these cases, systematic serial sectioning is recommended. Rapid inclusion in plastic resin allows the use of thin sections, without retraction, which is useful in the detection of minor cytologic changes and in quantitative studies such as intraepithelial lymphocyte-counts or villous morphometry.

Martin, I. (2007). "Plastics scrap: Europe struggling with supply." Recycling International(8): 92-97.

This article focuses on issues facing the plastic scrap industry in Europe. It explains that plastic scrap consumers in Europe are finding it hard to maintain their regular supplies. This is because about 60% of the European Union's polyethylene film scrap is being exported to China. Another factor that contributed to the decline in the supply of scrap plastics is the development of efficient equipment that produce less scrap and many producers are recycling their plastic products. It explains that transportation plastic scraps via oceans is less costly than transporting them via land. For this reason, many plastic scrap collectors tend to export to China than supply

Europe's scrap plastic consumers.

Martin, I. (2010). "Market 'weaker than expected' in 2010." Recycling International(9): 33-33.
The article reports that the plastics scrap market has been weaker than expected in 2010, according to delegates at the 2010 Bureau of International Recycling (BIR) Convention. The weak market can be attributed to the wait-and-see policy adopted by buyers, according to Jacques Musa of Veolia Propreté France Recycling. It relates the amount of plastic scrap imported by China in the first five months of 2010. Some of the events in China that affect the demand for plastic scrap include tighter customs controls and stricter environmental obligations.

Martin, J., et al. (2017). "The Deposition and Accumulation of Microplastics in Marine Sediments and Bottom Water from the Irish Continental Shelf." Scientific Reports **7**(1): 10772.
Microplastics are widely dispersed throughout the marine environment. An understanding of the distribution and accumulation of this form of pollution is crucial for gauging environmental risk. Presented here is the first record of plastic contamination, in the 5 mm-250 mum size range, of Irish continental shelf sediments. Sixty-two microplastics were recovered from 10 of 11 stations using box cores. 97% of recovered microplastics were found to reside shallower than 2.5 cm sediment depth, with the area of highest microplastic concentration being the water-sediment interface and top 0.5 cm of sediments (66%). Microplastics were not found deeper than 3.5 +/- 0.5 cm. These findings demonstrate that microplastic contamination is ubiquitous within superficial sediments and bottom water along the western Irish continental shelf.

Martin, K. and A. Turner (2019). "Mobilization and bioaccessibility of cadmium in coastal sediment contaminated by microplastics." Marine Pollution Bulletin **146**: 940-944.
Cadmium has had a number of historical applications in plastics but is now highly regulated. In this study, plastics containing pigmented or recycled Cd at concentrations up to 16,300mugg⁻¹ were processed into microplastic-sized fragments and added to clean estuarine sediment. Plastic-sediment mixtures (mass ratio=1:100) were subsequently exposed to fluids simulating the digestive conditions encountered in marine deposit-feeding invertebrates prepared from a protein and a bile acid surfactant in seawater and the mobilization of Cd measured as a function of time. Kinetic profiles over a six-hour period were complex, with some fitted using a diffusion model and others exhibiting evidence of Cd interactions between the plastic and sediment surface. The maximum concentration of Cd released from plastic-sediment mixtures was about 0.8mugg⁻¹ and orders of magnitude greater than Cd mobilization from sediment alone. It is predicted that large communities of deposit-feeders could mobilize significant quantities of Cd from historical microplastics.

Martin, V. M., et al. (1998). "Immunomagnetic enrichment of disseminated epithelial tumor cells from peripheral blood by MACS." Experimental Hematology **26**(3): 252-264.
Disseminated epithelial tumor cells have been detected in the bone marrow and blood of cancer patients by means of immunocytochemical or immunofluorescent staining of cytocentrifuge slides, multiparameter flow cytometry, and reverse transcriptase-polymerase chain reaction. However, it is hardly possible using such methods to detect tumor cells at a frequency below 10(-6). To increase the sensitivity of these detection techniques we have developed a new technology for the enrichment of disseminated epithelial tumor cells from hematopoietic cell samples by high-gradient magnetic cell sorting (MACS). Cells are permeabilized and fixed and

carcinoma cells are magnetically labeled specifically with an anti-cytokeratin 8 monoclonal antibody (mAb) directly conjugated to superparamagnetic microbeads. Magnetically labeled cells are enriched on high-gradient magnetic columns. Tumor cells are detected in the enriched cell fraction by flow cytometry, fluorescence microscopy, or immunocytochemisty. In this study we demonstrated the method using a model system in which five to 5,000 cells from a breast cancer cell line were seeded into blood cell samples from a healthy donor containing 1.2 x 10(8) leukocytes. Tumor cells were 10,477+/-4242 (n=25)-fold magnetically enriched, and 57.7%+/-16.9% (n=33) of the initially seeded tumor cells were recovered. Applying the method to 20-40 mL blood samples from patients with advanced carcinomas of the breast, prostate, colon, rectum, or lung, we were able to detect between one and 6.8 x 10(4) cytokeratin-expressing tumor cells in 21 of 34 patients. This corresponds to frequencies of tumor cells between 6.8 x 10(-9) and 1.1 x 10(-3) among nucleated cells in the original sample. Enriched tumor cells were further analyzed for expression of tissue-specific and prognostic markers such as breast mucin glycoproteins, erbB2, and CD44v6 for additional characterization and to confirm their tumor origin. The technique described could become a valuable tool for the quantification and molecular characterization of metastatic carcinoma cells in hematopoietic tissue, and may ultimately prove useful in the diagnosis, prognosis, and monitoring of patients with carcinoma.

Martinelli Filho, J. E. and R. C. P. Monteiro (2019). "Widespread microplastics distribution at an Amazon macrotidal sandy beach." Marine Pollution Bulletin **145**: 219-223.

Microplastics (MPs) are widespread and cause many impacts, yet their distribution and abundance are unknown for the Amazon coast. We estimated the abundance and distribution of microplastics at a sandy beach on the northern Brazilian coast during April 2014. Sand was collected and analyzed at three depth strata (0-20, 20-40 and 40-60 cm). MPs (250-500, 501-5000 mum) from each depth were sieved and retrieved by flotation when necessary. We found 492.5 +/- 556.4 particles m⁻³, with fibers comprising up to 95%. The abundance decreased with depth (61.5, 25 and 13.5% from the surface to 40-60 cm) and the deposition zone showed higher densities compared to the erosion zone. Although present in low to moderate abundance, MPs were widespread on the beach. The Amazon coast is an important area for fisheries and traditional communities, and further studies of its potential as a source or sink of MPs are needed. Copyright © 2019 Elsevier Ltd

Martinez, H. R., et al. (2009). "Stem-cell transplantation into the frontal motor cortex in amyotrophic lateral sclerosis patients." Cytotherapy **11**(1): 26-34.

BACKGROUND AIMS: Amyotrophic lateral sclerosis (ALS) is characterized by the selective death of motor neurons. CD133(+) stem cells are known to have the capacity to differentiate into neural lineages. Stem cells may provide an alternative treatment for ALS and other neurodegenerative diseases.

METHODS: Five men and five women (aged 38-62 years) with confirmed ALS were included in this study. Our institutional ethics and research committees approved the protocol. After informed consent was obtained, patients underwent Hidrogen-Magnetic Resonance Imaging (H-MRI) spectroscopy and were given scores according to an ALS functional rating scale, Medical Research Council power muscle scale and daily living activities. Bone marrow was stimulated with 300 microg filgrastim subcutaneously daily for 3 days. Peripheral blood mononuclear cells were obtained after admission by leukapheresis. The cell suspension was conjugated with anti-human CD133 superparamagnetic microbeads, and linked cells were isolated in a magnetic field. The isolated cells (2.5-7.5x10(5)) were resuspended in 300 microL of the patient's cerebrospinal fluid, and

implanted in motor cortexes using a Hamilton syringe. Ten patients with confirmed ALS without transplantation were used as a control group. Patients were followed up for a period of 1 year.
RESULTS: The autologous transplantation of CD133(+) stem cells into the frontal motor cortex is a safe and well-tolerated procedure in ALS patients. The survival of treated patients was statistically higher (P=0.01) than untreated control patients.
CONCLUSIONS: Stem-cell transplantation in the motor cortex delays ALS progression and improves quality of life.

Martínez-Gómez, C., et al. (2017). "The adverse effects of virgin microplastics on the fertilization and larval development of sea urchins." Marine Environmental Research **130**: 69.
A study investigating the adverse effects of virgin and experimentally aged polysterene (PS) and high density polyethylene (HDPE) materials and their leachates on the pelagic fertilization and larval development of the sea urchin Paracentrotus lividus. Commercial synthetic polymers of polystyrene (PS) microspheres and HPDE fluff were used as proxies for microplastics in marine systems. About twenty mature sea urchin adults were sampled in March and April (reproductive period of the species) from the reference site Cala Reona (Murcia, SE Spain) and transported immediately to the laboratory. Physicochemical parameters were recorded in all test chambers before and after each bioassay and adjusted when necessary to maintain optimum test conditions. Sea urchin eggs were mixed (stirring gently) with PS microspheres for 10 mm in four test solutions and nominal concentrations. The sea urchin embryotoxicity test (SET) was performed following the methodology described by Duran and Beiras (2010) and Beiras et al. Statistical analyses were carried out using SPSS v.11.0 (IBM SPSS software/www.spsss.com). The study concluded that toxic effects on fertilization (ANOVA, post hoc Dunnett test; p- value <0.05) were observed after the exposure of the sea urchin eggs to virgin PS microspheres.

Martinez-Lera, S., et al. (2013). "Design and first experimental results of a bubbling fluidized bed for air gasification of plastic waste." Journal of Material Cycles and Waste Management **15**(3): 370-380.
Plastic wastes have an especially high potential for use as alternative fuels, considering their high heating value and their large and stable availability. They could be used in electricity production based on gasification technologies, wherein electricity is produced in engines by means of the conversion of plastic wastes into a valuable gas. However, there are still some technical barriers to overcome before this technology can access the commercial stage, and further scientific research is needed to gain deeper understanding of the process and to be able to control and optimize it. This research presents the design and first experimental results of a bubbling fluidized bed gasifier conceived for the gasification of actual plastic residues. The experimental tests revealed that the selection and design of the reactor were adequate and proved some of the advantages of using plastic as a fuel, related in part to the absence of ashes and char. A valuable syngas over 5 MJ/m super(3) was generated, which contained a considerable fraction of methane as well as hydrogen and carbon monoxide as main combustible gases. The highest efficiency was achieved when the equivalence ratio was increased to 0.35, reaching 61 % in terms of cold gas efficiency and 66 % carbon conversion.

Martins, A. and L. Guilhermino (2018). "Transgenerational effects and recovery of microplastics exposure in model populations of the freshwater cladoceran Daphnia magna Straus." Science of the Total Environment **631**(632): 421-428.
The environmental contamination by microplastics is a global challenge to ecosystem and human health, and the knowledge on the long-term effects of such particles is limited. Thus, the effects of microplastics and post-exposure recovery were investigated over 4 generations

(F₀, F₁, F₂, F₃) using Daphnia magna as model. Effect criteria were parental mortality, growth, several reproductive parameters, and population growth rate. Microplastics exposure (0.1 mg/l of pristine polymer microspheres 1-5 micro m diameter) caused parental mortality (10-100%), and significantly (p<=0.05) decreased growth, reproduction, and population growth rate leading to the extinction of the microplastics-exposed model population in the F₁ generation. Females descending from those exposed to microplastics in F₀ and exposed to clean medium presented some recovery but up to the F₃ generation they still had significantly (p<=0.05) reduced growth, reproduction, and population growth rate. Overall, these results indicate that D. magna recovery from chronic exposure to microplastics may take several generations, and that the continuous exposure over generations to microplastics may cause population extinction. These findings have implications to aquatic ecosystem functioning and services, and raise concern on the long-term animal and human exposure to microplastics through diverse routes.

Martins, I., et al. (2019). "MODELPlastics workshop - Modelling Ocean Plastic Litter in a Changing Climate: Gaps and future directions." Marine Pollution Bulletin **146**: 22-25.

Here we summarize the overarching issues that emerged from a workshop held to discuss scientific challenges and future directions on the use of numerical models to predict the amount, distribution and effects of plastic pollution on marine ecosystems. The need for multi-disciplinary approaches, standardized protocols for plastic quantification and analyses, using realistic contaminant concentrations in laboratorial experiments and targeting early-life stages of marine organisms were pointed out as needs to improve data accuracy.

Martins, J. and P. Sobral (2011). "Plastic marine debris on the Portuguese coastline: a matter of size?" Marine Pollution Bulletin **62**(12): 2649-2653.

Plastic debris is a worldwide threat to marine environments and Portugal is not immune to it. Though never quantified, items of all sizes can be found in the Portuguese coastline; therefore the objective of this work is the identification of main size classes in stranded plastic debris. Beaches sediment was sampled and in the laboratory plastic items were sorted in 11 classes from <1 to >10mm, counted and weighted. Plastic size ranged from 50 mum to 20 cm and microplastics (<5mm) were the majority (72%). Most plastic fits in the smaller size classes, due to expected high residence time in the sea enhancing degradation processes, which increase surface exposure and potentially persistent organic pollutants (POP) adsorption. These results point out the important contribution of microplastics to marine debris pollution, its risks, and the need to set a higher focus on this size class.

Martynenko, I. V., et al. (2019). "Magneto-Fluorescent Microbeads for Bacteria Detection Constructed from Superparamagnetic Fe₃O₄ Nanoparticles and AIS/ZnS Quantum Dots." Analytical Chemistry **91**(20): 12661-12669.

The efficient and sensitive detection of pathogenic microorganisms in aqueous environments, such as water used in medical applications, drinking water, and cooling water of industrial plants, requires simple and fast methods suitable for multiplexed detection such as flow cytometry (FCM) with optically encoded carrier beads. For this purpose, we combine fluorescent Cd-free Ag-In-S ternary quantum dots (t-QDs) with fluorescence lifetimes (LTs) of several hundred nanoseconds and superparamagnetic Fe₃O₄ nanoparticles (SPIONs) with mesoporous CaCO₃ microbeads to a magneto-fluorescent bead platform that can be surface-functionalized with bioligands, such as antibodies. This inorganic

bead platform enables immuno-magnetic separation, target enrichment, and target quantification with optical readout. The beads can be detected with steady-state and time-resolved fluorescence microscopy and flow cytometry (FCM). Moreover, they are suited for readout by time gated emission. In the following, the preparation of these magneto-fluorescent CaCO₃ beads, their spectroscopic and analytic characterization, and their conjugation with bacteria-specific antibodies are presented as well as proof-of-concept measurements with Legionella pneumophila including cell cultivation and plating experiments for bacteria quantification. Additionally, the possibility to discriminate between the long-lived emission of the LT-encoded capture and carrier CaCO₃ beads and the short-lived emission of the dye-stained bacteria with time-resolved fluorescence techniques and single wavelength excitation is demonstrated.

Maruyama, H., et al. (2008). "On-chip pH measurement using functionalized gel-microbeads positioned by optical tweezers." Lab on a Chip **8**(2): 346-351.

This paper demonstrates local pH measurement in a microchip using a pH-sensing gel-microbead. To achieve this, the gel-microbead made of a hydrophilic photo-crosslinkable resin was functionalized with the pH indicator bromothymol blue (BTB). The primary constituent of this photo-crosslinkable resin is poly(ethylene glycol). Gel-microbeads impregnated with BTB were obtained by stirring the mixture solution, which was composed of the resin, BTB, and an electrolyte solution. The gel-microbead is polymerized by UV illumination. The polymerized gel-microbead can be manipulated by optical tweezers and made to adhere to a glass surface. The local pH was measured from the color of the gel-microbead impregnated with BTB by calibrated color information in the YCrCb color space. We succeeded in measuring the local pH value using the pH-sensing gel-microbead by manipulating and positioning it at the desired point in the microchip.

Marx, G., et al. (2008). "Heat denaturation of fibrinogen to develop a biomedical matrix." Journal of Biomedical Materials Research. Part B, Applied Biomaterials **84**(1): 49-57.

Native and heat denatured fibrinogen are the basis for various matrices used to establish hemostasis as well as for constructing biomedical devices. For example, fibrin microbeads (FMB) prepared by a heated (approximately 70 degrees C) oil emulsion process were reported to be attractive to mesenchymal-type cells, such as fibroblasts, endothelial and smooth muscle cells, and useful for isolating mesenchymal stem cells from bone marrow. Here, we examined the solution properties of fibrinogen subjected to heat (47-60 degrees C). Fibrinogen exhibited maximal stability of pH(max stab) = 6.8. At physiologically relevant concentrations, Ca(II) stabilized and Zn(II) destabilized fibrinogen against heat denaturation. Scanning electron micrographs (SEM) of precipitated, heat denatured, fibrinogen showed globular structures (approximately 400 nm diameter), composed of aggregates of >3000 fibrinogen monomers. Monoclonal antibodies (MAb) to various regions of fibrinogen, as well as two polyclonal antibody (Ab) to haptotactic peptides (Haptides) equivalent to or near the C-termini of beta and gamma-chains (beta(463-483) and gamma(372-391/411)), were used to monitor epitopic changes of fibrinogen bound to and heated on plastic ELISA plates. The pattern of altered Ab binding indicated that fibrinogen heat denaturation on plastic exposed the C-terminal epitope gamma(397-411) as well as Haptide epitopes (beta(463-483) and gamma(372-391)). Immuno-staining of FMB prepared by a heated (below 75 degrees C) oil emulsion process, also presented many exposed Haptide epitopes, which probably helped to attract cells. Our results indicated that moderately heat-denatured fibrinogen, in the form of FMB, could be used for cell culturing and biomedical applications.

Masarik, M., et al. (2011). "Isolation of metallothionein from cells derived from aggressive form of high-grade prostate carcinoma using paramagnetic antibody-modified microbeads off-line coupled with electrochemical and electrophoretic analysis." Electrophoresis **32**(24): 3576-3588.

Prostate cancer with altered zinc(II) cell metabolism is the second most frequently diagnosed cancer in developed countries. The alterations of zinc(II) metabolism can influence metabolism of other metal ions and can also be associated with the expression and translation of metal-binding proteins including metallothioneins. The aim of this article was to optimize immunoseparation protocol based on paramagnetic beads conjugated with protein G for the isolation of metallothionein. Isolated metallothionein was determined by differential pulse voltammetry Brdicka reaction and SDS-PAGE. Optimal conditions: antigen-binding time - 60 min, temperature - 70degreeC, and buffer composition and pH - acetate buffer, pH 4.3, were determined. Under the optimized conditions, lysates from 22Rv1 prostate cancer cells treated with various concentrations of cadmium(II) and copper(II) ions were analyzed. We observed strong correlation in all experimental groups and all lysate types ($r>0.83$ at $p<0.041$) between metallothionein concentration related to viability and concentration of copper(II) ions and cadmium(II) ions in medium. Moreover, the results were compared with standard sample preparation as heat treatment and SDS-PAGE analysis.

Masia, P., et al. (2019). "Microplastics in special protected areas for migratory birds in the Bay of Biscay." Marine Pollution Bulletin **146**: 993-1001.

Plastic pollution is a major ecological catastrophe that endangers vulnerable species. Small plastic fragments and filaments enter the food web in the ocean threatening marine species health. Here microplastics between 0.5 and 5 mm were quantified from eight beaches of southwest Bay of Biscay (Spain) within Natura-2000 Special Protection Areas for birds. Sand samples were taken using a randomized quadrat-based protocol. Between 145 and 382 particles per kg of dry sand were found, which is relatively high in comparison with other European beaches. Microfibers were more abundant than microplastics. PERMANOVA revealed a significant effect of the beach location (inside versus outside the estuary). Open beaches contained a higher microplastic density than sheltered ones suggesting that many beached microplastics come from the ocean. Birds are at risk in the studied protected spaces as revealed from high concentrations of fibres in depositions of European shag and gulls.

Mason, S. A. (2019). "Plastics, Plastics Everywhere." American Scientist **107**(5): 284-287.

Mason highlights the ubiquity of microplastics in our rivers and drinking water. In 1967, there was a "great future in plastics." Since then plastics production has exploded, and in 2017 the world produced nearly 450 million metric tons of these lightweight materials used in everything from automobiles to food packaging to personal care products. Nearly two-thirds is discarded, whereas almost 10 percent is recycled and 12 percent is incinerated. As much as 15 percent ends up in our waterways each year.

Mason, S. A., et al. (2016). "Microplastic pollution is widely detected in US municipal wastewater treatment plant effluent." Environmental Pollution **218**: 1045-1054.

Municipal wastewater effluent has been proposed as one pathway for microplastics to enter the aquatic environment. Here we present a broad study of municipal wastewater treatment plant effluent as a pathway for microplastic pollution to enter receiving waters. A total of 90 samples were analyzed from 17 different facilities across the United States. Averaging all facilities and sampling dates, 0.05 +/- 0.024 microparticles were found per liter of effluent. Though a small

value on a per liter basis, even minor municipal wastewater treatment facilities process millions of liters of wastewater each day, yielding daily discharges that ranged from ~50,000 up to nearly 15 million particles. Averaging across the 17 facilities tested, our results indicate that wastewater treatment facilities are releasing over 4 million microparticles per facility per day. Fibers and fragments were found to be the most common type of particle within the effluent; however, some fibers may be derived from non-plastic sources. Considerable inter- and intra-facility variation in discharge concentrations, as well as the relative proportions of particle types, was observed. Statistical analysis suggested facilities serving larger populations discharged more particles.

Mason, S. A., et al. (2016). "Pelagic plastic pollution within the surface waters of Lake Michigan, USA." Journal of Great Lakes Research **42**(4): 753-759.

During the summer of 2013, a total of 59 surface water samples were collected across Lake Michigan making it the best surveyed for pelagic plastics of all the Laurentian Great Lakes. Consistent with other studies within the Great Lakes, Mantra-trawl samples were dominated by particles less than 1 mm in size. Enumeration of collected plastics under a microscope found fragments to be the most common anthropogenic particle type, followed by fibers, with more minor contributions from pellets, films and foams. The majority of these pelagic plastic particles were found to be polyethylene, with polypropylene being the second most common polymeric type, which is consistent with manufacturing trends and beach survey results. The pelagic plastic was found to be fairly evenly distributed across the entire Lake Michigan surface, despite the formation of a seasonal gyre at the southern end of the lake. We found that an average plastic abundance of ~17,000 particles/km², which when multiplied by the total surface area, gives on the order of 1 billion plastic particles floating on the surface of Lake Michigan. As the majority of these particles are extremely small, less than 1 mm in size, which allows for easy ingestion, these results highlight the need for additional studies with regard to the possible impacts upon aquatic organisms.

Mason, S. A., et al. (2018). "Synthetic Polymer Contamination in Bottled Water." Frontiers of Chemistry **6**: 407.

Eleven globally sourced brands of bottled water, purchased in 19 locations in nine different countries, were tested for microplastic contamination using Nile Red tagging. Of the 259 total bottles processed, 93% showed some sign of microplastic contamination. After accounting for possible background (lab) contamination, an average of 10.4 microplastic particles >100 um in size per liter of bottled water processed were found. Fragments were the most common morphology (66%) followed by fibers. Half of these particles were confirmed to be polymeric in nature using FTIR spectroscopy with polypropylene being the most common polymer type (54%), which matches a common plastic used for the manufacture of bottle caps. A small fraction of particles (4%) showed the presence of industrial lubricants. While spectroscopic analysis of particles smaller than 100 um was not possible, the adsorption of the Nile Red dye indicates that these particles are most probably plastic. Including these smaller particles (6.5-100 um), an average of 325 microplastic particles per liter of bottled water was found. Microplastic contamination range of 0 to over 10,000 microplastic particles per liter with 95% of particles being between 6.5 and 100 um in size. Data suggests the contamination is at least partially coming from the packaging and/or the bottling process itself. Given the prevalence of the consumption of bottled water across the globe, the results of this study support the need for further studies on the impacts of micro- and nano- plastics on human health.

Masoudipour, N., et al. (2016). "Cyanide removal efficiency of photocatalytic nanoparticles stabilized on glass microbeads under sun irradiation." Journal of Water and Wastewater/Ab va Fazilab **27**(6): e42-Pe49.

This paper investigates cyanide photodestruction (at pH 9) using the S, N-TiO₂ photocatalyst synthesized by the sol-gel method and stabilized on glass microbeads. The main raw materials were thiourea, as a source of N and S, and tetra butyl ortho titanate. The effects of S and N doses, visible light (a 400W light), sunlight, irradiation time, and different initial cyanide concentrations (50, 100, 200, and 300 ppm) were studied on cyanide photodestruction. Cyanide concentration was measured by the titration method and the photocatalyst film was characterized by X-ray diffraction (XRD), UV-Vis diffuse reflection spectroscopy (DRS), Scanning Electron Microscopy (SEM), and Energy dispersive X-ray (EDX) analysis. XRD patterns and SEM images were used to determine the nanoparticle size of the photocatalyst on glass microbeads. EDX and DRS analyses confirmed the presence of S and N as well as the activity of the photocatalyst in the visible region, respectively. The S, N-TiO₂ film with 0.25 g Thiuourea proved to be the best cyanide photodestruction agent in the visible light. Based on the results obtained, S, N-TiO₂/glass microbead was capable of destroying cyanide (50 ppm) by up to 94% in the visible light and by approximately 100% in the sunlight. The results also indicated that S, N-Tio₂/scoria stone was capable of destroying cyanide by 85% in the visible light and by 94% in the sunlight within 4 h. The reaction kinetic for all cyanide concentrations and two photocatalyst substrates were described by a first order equation. Finally, it was concluded that the S, N-TiO₂ stabilized on glass microbeads could be effectively used as a new method for treating wastewater containing free cyanide under the sunlight.

Masoudipour, N., et al. (2018). "Photo-catalytic inactivation of E. coli using stabilized Ag/S, N-TiO₂ nanoparticles by fixed bed photo-reactor under visible light and sunlight." Desalination and Water Treatment **110**: 109-116.

Silver (Ag), sulfur (S), and nitrogen (N)-codoped titanium dioxide (TiO₂) photo-catalysts were prepared by sol-gel method. The main compounds were tetrabutyl orthotitanate, 250 mg of thiourea, and 0.7, 1.4, and 2.8 mg of silver nitrate as the suppliers of sulfur, nitrogen, and silver, respectively. These photo-catalysts were stabilized on glass microbeads. The structural properties of synthesized photo-catalysts were investigated by X-ray diffraction, scanning electron microscopy, and energy dispersive X-ray. The optical activity of the photo-catalysts was evaluated by UV/Vis diffuse reflectance spectroscopy. Finally, the feasibility of inactivation of Escherichia coli, an index of water contamination, was investigated by the stabilized photo-catalyst in a fixed bed photo-reactor under visible light and sunlight. We observed that Ag (0.14 mg)/S, N-TiO₂ caused 99.6% removal of E. coli at 1.5x10⁸ CFU/mL initial concentration under visible light, but this photo-catalyst caused approximately 97% removal of E. coli under sunlight. These findings would help to better use the fixed bed reactor filled with stabilized photo-catalysts such as Ag/S, N-TiO₂, as a multipurpose and efficient technique to disinfect waters highly contaminated with E. coli.

Massos, A. and A. Turner (2017). "Cadmium, lead and bromine in beached microplastics." Environmental Pollution **227**: 139-145.

Samples of microplastic (n = 924) from two beaches in south west England have been analysed by field-portable-x-ray fluorescence (FP-XRF) spectrometry, configured in a low-density mode and with a small-spot facility, for the heavy metals, Cd and Pb, and the halogen, Br. Primary plastics in the form of pre-production pellets were the principal type of microplastic (>70%) on

both beaches, with secondary, irregularly-shaped fragments representing the remainder of samples. Cadmium and Pb were detected in 6.9% and 7.5% of all microplastics, respectively, with concentrations of either metal that exceeded 10³ mug g⁻¹ usually encountered in red and yellow pellets or fragments. Respective correlations of Cd and Pb with Se and Cr were attributed to the presence of the coloured, inorganic pigments, cadmium sulphoselenide and lead chromate. Bromine, detected in 10.4% of microplastics and up to concentrations of about 13,000 mug g⁻¹, was mainly encountered in neutrally-coloured pellets. Its strong correlation with Sb, whose oxides are effective fire suppressant synergists, suggests the presence of a variety of brominated flame retardants arising from the recycling of plastics originally used in casings for heat-generating electrical equipment. The maximum bioaccessible concentrations of Cd and Pb, evaluated using a physiological extraction based on the chemical characteristics of the proventriculus-gizzard of the northern fulmar, were about 50 mug g⁻¹ and 8 mug g⁻¹, respectively. These concentrations exceed those estimated for the diet of local seabirds by factors of about 50 and 4, respectively.

Masuya, T., et al. (2014). "Site-specific chemical labeling of mitochondrial respiratory complex i through ligand-directed tosylate chemistry." Biochemistry **53**(14): 2307-2317.

The site-specific chemical modification of NADH-quinone oxidoreductase (complex I) by various functional probes such as fluorophores and microbeads, without affecting the enzyme activity, may allow single-molecule analyses of putative dynamic conformational changes in the enzyme. In an attempt to address this challenge, we performed site-specific alkynylation of complex I in bovine heart submitochondrial particles by means of a ligand-directed tosylate (LDT) chemistry strategy with synthetic acetogenin ligand 1, which has an alkynylated tosylate in the tail moiety, as a high-affinity ligand against the enzyme. The terminal alkyne was chosen as the tag to be incorporated into the enzyme because this functional group can serve as a "footing" for subsequent diverse chemical modifications via so-called click chemistry (i.e., azide-alkyne [3+2] cycloaddition in water). To identify the position alkynylated by ligand 1, fluorescent tetramethylrhodamine was covalently attached to the incorporated alkyne by click chemistry after the solubilization of complex I. Detailed proteomic analyses revealed that alkynylation occurred at Asp160 in the 49 kDa subunit, which may be located in the inner part of the putative quinone-binding cavity. The alkynylation was completely suppressed in the presence of an excess of other inhibitors such as bullatacin and quinazoline. While the reaction yield of the alkynylation step via LDT chemistry was estimated to be ~50%, the alkynylation unfortunately resulted in the almost complete inhibition of enzyme activity. Nevertheless, the results of this study demonstrate that complex I can be site-specifically alkynylated through LDT chemistry, providing a clue about the diverse chemical modifications of the enzyme in combination with click chemistry. © 2014 American Chemical Society.

Mata, M. F., et al. (2019). "A modified CD34+ hematopoietic stem and progenitor cell isolation strategy from cryopreserved human umbilical cord blood." Transfusion **59**(12): 3560-3569.

BACKGROUND: Umbilical cord blood (UCB) is a source of hematopoietic stem cells for transplantation, offering an alternative for patients unable to find a matched adult donor. UCB is also a versatile source of hematopoietic stem and progenitor cells (hCD34 + HSPCs) for research into hematologic diseases, in vitro expansion, ex vivo gene therapy, and adoptive immunotherapy. For these studies, there is a need to isolate hCD34 + HSPCs from cryopreserved units, and protocols developed for isolation from fresh cord blood are unsuitable.

STUDY DESIGN: This study describes a modified method for isolating hCD34 + HSPCs from cryopreserved

UCB. It uses the Plasmatherm system for thawing, followed by CD34 microbead magnetic-activated cell sorting isolation with a cell separation kit (Whole Blood Columns, Miltenyi Biotec). hCD34 + HSPC phenotypes and functionality were assessed in vitro and hematologic reconstitution determined in vivo in immunodeficient mice.

RESULTS: Total nucleated cell recovery after thawing and washing was 44.7 +/- 11.7%. Recovery of hCD34 + HSPCs after application of thawed cells to Whole Blood Columns was 77.5 +/- 22.6%. When assessed in two independent laboratories, the hCD34+ cell purities were 71.7 +/- 10.7% and 87.8 +/- 2.4%. Transplantation of the enriched hCD34 + HSPCs into NSG mice revealed the presence of repopulating hematopoietic stem cells (estimated frequency of 0.07%) and multilineage engraftment.

CONCLUSION: This provides a simplified protocol for isolating high-purity human CD34 + HSPCs from banked UCB adaptable to current Good Manufacturing Practice. This protocol reduces the number of steps and associated risks and thus total production costs. Importantly, the isolated CD34 + HSPCs possess in vivo repopulating activity in immunodeficient mice, making them a suitable starting population for ex vivo culture and gene editing.

Mataji, A., et al. (2020). "Distribution and Characterization of Microplastics in Surface Waters and the Southern Caspian Sea Coasts Sediments." Archives of Environmental Contamination & Toxicology **78**(1): 86-93.

The Caspian Sea is the largest enclosed aquatic ecosystem in the world. The combinations of the toxic pollutants with microplastics endanger the Caspian Sea ecosystem. In this work, the distribution of microplastics was studied in surface waters and southern Caspian Sea coasts sediments. The samples were collected from eight stations, including the Tonakabon, Chalos, Nowshahr, Noor, Mahmood Abad, Babolsar, Sari, and Neka coasts. The average concentrations of microplastics in the coastal waters and sediments were 34,490 particles per km2 and 210 particles per kg, respectively. Isolated microplastics were characterized using ATR-FTIR and energy dispersive X-ray (EDS) techniques. The samples exhibited a strong carbon peak in the EDS spectra, which was screened as microplastic particles. The microplastics were mainly fragments and foams and identified as polyethylene, polypropylene, and polystyrene by means of ATR-FTIR spectra. This is the first study to determine the distribution of microplastics in southern Caspian coastal regions. [ABSTRACT FROM AUTHOR]

Mateos-Cardenas, A., et al. (2019). "Polyethylene microplastics adhere to Lemna minor (L.), yet have no effects on plant growth or feeding by Gammarus duebeni (Lillj.)." Science of the Total Environment **689**: 413-421.

Microplastics (1-1000 micro m) are ubiquitous in the marine, freshwater and terrestrial environments. These microsized plastics are considered freshwater pollutants of emerging concern, although the impacts on organisms and ecosystems are not yet clear. In particular, effects of microplastics on freshwater aquatic plants and the fate of microplastics in the freshwater trophic chain remain largely unexplored. Here we demonstrate that 10-45 micro m polyethylene (PE) microplastics can strongly adsorb to all surfaces of the duckweed species Lemna minor. Despite adsorbance of up to 7 PE microplastics per mm², seven day

exposure experiments showed that photosynthetic efficiency and plant growth are not affected by microplastics. Rather, dense surface coverage suggests L. minor as a potential vector for the trophic transfer of microplastics. Here we show that the freshwater amphipod Gammarus duebeni can ingest 10-45 micro m PE microplastics by feeding on contaminated L. minor. In this study, ingestion of microplastics had no apparent impact on amphipod mortality or mobility after 24 or 48 h exposure. Yet, the feeding study showed that the fate of microplastics in the environment may be complex, involving both plant adsorbance and trophic transfer.

Materic, D., et al. (2020). "Micro- and nanoplastics in Alpine snow - a new method for chemical identification and (semi)quantification in the nanogram range." Environmental Science & Technology **17**: 17.

We present a new method for chemical characterisation of micro- and nanoplastics based on thermal desorption - proton transfer reaction - mass spectrometry. The detection limit for polystyrene (PS) obtained is <1 ng of the compound present in a sample, which results in 100 times better sensitivity than previously reported by other methods. This allows us to use small volumes of samples (1 mL) and to carry out experiments without a preconcentration step. Unique features in the high-resolution mass spectrum of different plastic polymers make this approach suitable for fingerprinting, even when the samples contain mixtures of other organic compounds. Accordingly, we got a positive fingerprint of PS when just 10 ng of the polymer was present within dissolved organic matter of snow. Multiple types of microplastics (PET, PVC, and PPC), were identified in a snow-pit from the Austrian Alps, however, only PET was detected in the nanometer range for both snow-pit and surface-snow samples. This is in accordance with other publications showing that the dominant form of airborne microplastics are PET fibres. The presence of nanoplastics in high-altitude snow indicate airborne transport of plastic pollution with environmental and health consequences yet to be understood.

Matern, D. (2008). "Newborn screening for lysosomal storage disorders." Acta Paediatrica **97**(457): 33-37.

UNLABELLED: Newborn screening is a public health programme aimed at identifying treatable conditions in pre-symptomatic newborns to avoid premature mortality, morbidity and disabilities. With the advent of successful treatment options for an increasing number of lysosomal storage disorders (LSDs), such as enzyme replacement or bone marrow transplantation, inclusion of these disorders into newborn screening programmes seems reasonable. However, the success of these programmes depends on the availability of testing methods that are suitable for population screening, have high sensitivity and a low false-positive rate. In recent years, two methods have been proposed for newborn screening of LSDs, which enable assessment of more than one LSD from a single blood spot sample. One applies tandem mass spectrometry, the other microbead array technology. Now, prospective studies are needed to determine the most effective approach to newborn screening that will identify those patients who require treatment.

CONCLUSION: With the advent of high-throughput assays for the detection of LSDs, newborn screening for these disorders may soon become a reality. However, careful prospective studies are required to optimize this process before it is used on a larger scale. [References: 32]

Mathalon, A. and P. Hill (2014). "Microplastic fibers in the intertidal ecosystem surrounding Halifax Harbor, Nova Scotia." Marine Pollution Bulletin **81**(1): 69-79.

Humans continue to increase the use and disposal of plastics by producing over 240 million tonnes per year, polluting the oceans with persistent waste. The majority of plastic in the oceans are microplastics (<5 mm). In this study, the contamination of microplastic fibers was quantified in sediments from the intertidal zones of one exposed beach and two protected beaches along Nova Scotia's Eastern Shore. From the two protected beaches, polychaete worm fecal casts and live blue mussels (Mytilus edulis) were analyzed for microplastic content. Store-bought mussels from an aquaculture site were also analyzed. The average microplastic abundance observed from 10 g sediment subsamples was between 20 and 80 fibers, with higher concentrations at the high tide line from the exposed beach and at the low tide line from the protected beaches. Microplastic concentrations from polychaete fecal casts resembled concentrations quantified from low tide sediments. In two separate mussel analyses, significantly more microplastics were enumerated in farmed mussels compared to wild ones.

Mathiasson, A., et al. (1988). "Hydrolytic treatment of plastics waste contaminated with paper." Resources, Conservation and Recycling **2**(1): 57-67.

This paper summarizes the results of an experimental study of the effect of a hydrolytic treatment of the plastics fraction of municipal solid waste or industrial waste of similar composition prior to conventional processing (injection moulding). During such treatment the contaminating paper component can be expected to undergo significant embrittlement resulting in disintegration of the cellulose fibres when subjected to the shear forces acting in normal plastics processing machinery. This leads to improved flow properties of the melt and also improves the homogeneity and processibility of the waste material. The results obtained show that the method can be applied to plastics waste containing as much as 40% paper. The hydrolytic treatment can be carried out with organic or inorganic acids of reasonable strength at concentrations of well below 1%. While the modulus and strength of the final products are largely unaffected by the hydrolytic treatment, the impact strength and breaking elongation increase significantly. The stiffness of the final product increases with paper content. Thus, plastics waste containing paper can be used in several applications such as artificial wood. © 1988.

Mathies, H. (1975). "Sources of error in measurement and interpretation of rheumatic factor reactions. [German]." Allergie und Immunologie **21**(1): 77-79.

The results of determination of the rheumatic factor may be influenced by all the media involved in the demonstration reactions. The statistical data concerning the reliability of various methods are considerably influenced by the selection of the clinical material. It is also known that very different anti gammaglobulins react with aggregated gammaglobulin. The frequently underestimated factor affecting the reliability of the test methods is the difficulty of preparing constant gammaglobulin preparations and of obtaining plastic particles of constant size. The most difficult problem is that of the inhibitors, of which the most important are the gammaglobulin aggregates which are inevitably produced during every manipulation of serum (inactivation, fractionation, etc.).

Mathuriya, A. S. and J. V. Yakhmi (2019). Polyhydroxyalkanoates: Biodegradable plastics and their applications. Handbook of Ecomaterials. **4:** 2873-2900.

Human civilization has experienced several ages such as stone, bronze, iron, and steel, and now it is a plastic age. Due to multifaceted properties of plastic, it is one of the most widely available and overused item in the world today and became a necessary evil. When disposed, it does not decompose and pollutes the land or air nearby when burned in the open air. Plastic pollution is affecting the global economy. Polyhydroxyalkanoates (PHAs) have been drawing much attention as biodegradable substitutes for conventional nondegradable plastics. PHAs are synthesized by numerous bacteria as carbon and energy storage capsules and are good candidates as biodegradable plastic material. Because of their versatility and wide range of properties, biodegradable PHAs are being used in various areas of modern benefits.With the currently increased interest level and the extensive research being carried out in this area, PHAs are potentially emerging as environmentally friendly materials of the next generation with a wide range of applicability. This chapter deals with the recent advances in applicability of PHAs. © Springer Nature Switzerland AG 2019. All Rights Reserved.

Mato, Y., et al. (2001). "Plastic resin pellets as a transport medium for toxic chemicals in the marine environment." Environmental Science & Technology **35**(2): 318-324.

Plastic resin pellets (small granules 0.1-0.5 centimeters in diameter) are widely distributed in the ocean all over the world. They are an industrial raw material for the plastic industry and are unintentionally released to the environment both during manufacturing and transport. They are sometimes ingested by seabirds and other marine organisms, and their adverse effects on organisms are a concern. In the present study, PCBs, DDE, and nonylphenols (NP) were detected in polypropylene (PP) resin pellets collected from four Japanese coasts. Concentrations of PCBs (4-117 ng/g), DDE (0.16-3.1 ng/g), and NP (0.13-16 microg/g) varied among the sampling sites. These concentrations were comparable to those for suspended particles and bottom sediments collected from the same area as the pellets. Field adsorption experiments using PP virgin pellets demonstrated significant and steady increase in PCBs and DDE concentrations throughout the six-day experiment, indicating that the source of PCBs and DDE is ambient seawater and that adsorption to pellet surfaces is the mechanism of enrichment. The major source of NP in the marine PP resin pellets was thought to be plastic additives and/or their degradation products. Comparison of PCBs and DDE concentrations in mari

Matsuguma, Y., et al. (2017). "Microplastics in Sediment Cores from Asia and Africa as Indicators of Temporal Trends in Plastic Pollution." Archives of Environmental Contamination & Toxicology **73**(2): 230-239.

Microplastics (<5 mm) were extracted from sediment cores collected in Japan, Thailand, Malaysia, and South Africa by density separation after hydrogen peroxide treatment to remove biofilms were and identified using FTIR. Carbonyl and vinyl indices were used to avoid counting biopolymers as plastics. Microplastics composed of variety of polymers, including polyethylene (PE), polypropylene (PP), polystyrene (PS), polyethyleneterphthalates (PET), polyethylene-polypropylene copolymer (PEP), and polyacrylates (PAK), were identified in the sediment. We measured microplastics between 315 µm and 5 mm, most of which were in the range 315 µm-1 mm. The abundance of microplastics in surface sediment varied from 100 pieces/kg-dry sediment in a core collected in the Gulf of Thailand to 1900 pieces/kg-dry sediment in a core collected in a canal in Tokyo Bay. A far higher stock of PE and PP composed microplastics in sediment compared with surface water samples collected in a canal in Tokyo Bay suggests that sediment is an important sink for microplastics. In dated sediment cores from Japan, microplastic pollution started in 1950s, and their abundance increased markedly toward the surface layer (i.e., 2000s). In all sediment cores from Japan, Thailand, Malaysia, and South Africa, the abundance of microplastics increased toward the surface, suggesting the global occurrence of and an increase in microplastic pollution over time. Matsuhashi, M. (2013). "Advances in granulocyte test methodologies." Vox Sanguinis **2)**: 36.

Antibodies against human neutrophil antigens (HNA) are involved in the pathogenesis of immune neutropenia, such as neonatal alloimmune neutropenia (NAN), refractoriness to granulocyte transfusions, and transfusion reactions, such as febrile non-hemolytic transfusion reactions, and transfusion-related acute lung injury (TRALI). The HNA systems are assigned to five antigen groups, namely HNA-1 to 5. HNA-1, -2, and -3a alloantibodies have been implicated in the pathogenesis of TRALI, and especially HNA-3a alloantibody has been found in the severe cases requiring artificial ventilation or with fatal reactions. Besides alloantibodies to HNA-1, -2 and -3, those against HNA- 4a and HNA-5a have been implicated in NAN. The identification of the causative antibodies is essential for the diagnosis as well as for the prevention of these disorders. The detection of HNA antibodies has been mainly dependent on cell-based assays so far. Among them, the granulocyte agglutination test (GAT), the granulocyte immunofluorescence test (GIFT) and the monoclonal antibody immobilization of granulocyte antigens (MAIGA) are the most commonly applied. According to the ISBT Working Party on Granulocyte Immunobiology, the combination of GAT and GIFT is presently the best means of HNA antibody detection. GIFT is usually more sensitive than GAT, however, HNA-3a antibodies associated with severe cases of TRALI are better detectable by GAT. In GAT and GIFT, the presence of HLA antibodies with broad specificities may affect the detection of HNA antibodies. On the other hand, the MAIGA assay allows the differentiation between HNA and HLA antibodies. These classical methods, however, require fresh neutrophils from HNA-typed donors. Also, these assays are time-consuming, which makes them not appropriate for the large-scale antibody screening. In our lab, we modified the mixed-passive hemagglutination (MPHA) assay, the method largely applied in Japan for platelet antigen/antibody detection, for the detection of HNA antibodies. Recently, alternative assays have been developed, including ELISA with recombinant HNA (rHNA), and immunofluorescence tests with transfectant cells of HNA (HNA-1, -2, -4, and -5). More recently, the molecular basis of HNA-3 antigen has been elucidated, and stable cell lines expressing HNA-3 antigens became available. These cell lines seem to have low background, and do not express detectable levels of HLA antigens, which make the identification of HNA antibodies easier. Additionally, kits that use Luminex microbeads coated with HNA antigen are being developed. These kits, however, do not include HNA-3 antigens. These new technologies significantly help improving the detection and identification of HNA antibodies, and allow the large scale screening of HNA antibodies, contributing for the reduction of the risk of the pathological conditions associated with HNA antibodies, especially TRALI. However, these new technologies significantly increase the cost of the tests. Presently, although many assays have been developed, the standard HNA antisera are not necessarily available in every lab, which makes their validation difficult to be conducted. Thus, the collaborative study among the various labs, by exchanging the available antisera, and comparing the test results, is essential for the improvement of this field.

Matsukami, H., et al. (2020). "Liquid chromatography-electrospray ionization-tandem mass spectrometry for the determination of short-chain chlorinated paraffins in mixed plastic wastes." Chemosphere **244 (no pagination)**(125531).

Wastes containing short-chain chlorinated paraffins (SCCPs) at concentrations above the Basel Convention low persistent organic pollutant content (LPC) values must be destroyed or irreversibly transformed in an environmentally-sound manner. Here, we developed a novel

liquid chromatography-electrospray ionization-tandem mass spectrometry (LC-ESI-MSMS) method for determining the concentrations of SCCPs in mixed plastic wastes. Major SCCP homologues were identified with good separation and peak width by using a low-hydrophobicity cyano-propyl column and a mobile phase consisting of water and methanol containing ammonium acetate. Precursor ion peaks corresponding to the formation of stable SCCP homologue-adducts were observed, followed by two intense product ion peaks corresponding to separation of the adduct into acetate and the homologue. The formulation of a novel calibration standard with known SCCP homologue percentage composition supported the development of our novel mass spectrometric technique. The results obtained with the LC-ESI-MSMS system were quantitatively and qualitatively comparable with those obtained with a high-resolution mass spectrometry (HRMS) coupled to gas chromatography (GC) system. Homologue concentrations determined by LC-ESI-MSMS were significantly correlated with those determined by GC-HRMS in samples of commercial chlorinated paraffin mixture and mixed plastic waste, respectively. As a complementary technique to the highly accurate, but less versatile GC-HRMS approaches, the SCCP analysis by LC-ESI-MSMS is a practical way to identify mixed plastic wastes containing SCCPs at concentrations higher than the Basel Convention's LPC value. Matta, R., et al. (2019). "Minimally Invasive Delivery of Microbeads with Encapsulated, Viable and Quiescent Neural Stem Cells to the Adult Subventricular Zone." Scientific Reports **9**(1): 17798.

Stem cell therapies demonstrate promising results as treatment for neurological disease and injury, owing to their innate ability to enhance endogenous neural tissue repair and promote functional recovery. However, delivery of undifferentiated and viable neuronal stem cells requires an engineered delivery system that promotes integration of transplanted cells into the inflamed and cytotoxic region of damaged tissue. Within the brain, endothelial cells (EC) of the subventricular zone play a critical role in neural stem cell (NSC) maintenance, quiescence and survival. Therefore, here, we describe the use of polyethylene glycol microbeads for the coincident delivery of EC and NSC as a means of enhancing appropriate NSC quiescence and survival during transplantation into the mouse brain. We demonstrate that EC and NSC co-encapsulation maintained NSC quiescence, enhanced NSC viability, and facilitated NSC extravasation in vitro, as compared to NSC encapsulated alone. In addition, co-encapsulated cells delivered to an in vivo non-injury model reduced inflammatory response compared to freely injected NSC. These results suggest the strong potential of a biomimetic engineered niche for NSC delivery into the brain following neurological injury.

Mattam, J. and A. Krishna Sailaja (2016). "Preparation and evaluation of sulfasalazine loaded sodium alginate microbeads for sustained delivery." Asian Journal of Pharmaceutical and Clinical Research **9**(Supplement 2): 72-76.

Objective: The main objective of the work was to prepare and evaluate sulfasalazine loaded sodium alginate microbeads for sustained delivery for the treatment of inflammatory bowel disease and rheumatoid arthritis. Sulfasalazine has crystalluria, thrombocytopenia, and megaloblastic anemia as side effects, so to reduce side effect microbeads were prepared. Method(s): The sulfasalazine microbeads were prepared by inotropic gelation method by optimizing process parameters such as concentration of calcium chloride, agitation speed, and time of agitation. The concentration of polymer sodium alginate was varied. Result(s): Among the five formulations, the best formulation was considered by comparing process parameters such as the entrapment efficiency, drug content, in vitro drug release studies, scanning electron microscope analysis, and zeta potential. Conclusion(s): On comparison, B3 formulation was

considered as best formulation with a mean particle size ranging from 40.9 to 244 micro m, drug content of 94.7%, entrapment efficiency of 87.7%, and the drug release was found to be 97.1% for 12 hrs and followed zero order kinetics and non-Fickian diffusional pathway, with a zeta potential value of -56.8 mV indicating higher stability. Mattie, P. A., et al. (1994). "Development of a radiopaque, autopolymerizing dental acrylic resin." Journal of Prosthodontics **3**(4): 213-218.

PURPOSE: Current prosthetic acrylic resins are radiolucent and cannot be imaged using standard radiographic techniques. If accidentally impacted or ingested, delays in localizing or removing the foreign body may be life-threatening. The purpose of this study was to evaluate the influence of an experimental radiopaque additive, triphenyl bismuth (TPB), on polymethyl methacrylate resins formulated for dental use. We also investigated methods to improve TPB-containing resin microbeads and optimize processing variables for specimen fabrication in autopolymerizing resin systems.

MATERIALS AND METHODS: Selfcured samples of experimental resins were prepared containing 0% to 27% TPB and were tested according to American National Standards Institute/American Dental Association and International Organization for Standardization performance standards. A control group and two commercial provisional crown and bridge resins were used for comparison.

RESULTS: The standard of radiopacity (> or = aluminum radiopacity) is met at TPB levels of > or = 14.5%. The control resin had a greater transverse deflection compared with the TPB-resin groups, but deflection was within standard limits for all resins. Polishability, color stability, and solubility were unaffected by TPB, whereas sorption decreased, although not significantly, at higher TPB levels. Translucency decreased at 27% TPB, and specimens containing 0% to 20% TPB were transparent. A tendency to entrain air bubbles, because of the hydrophobicity of TPB, resulted in increased susceptibility to brittle failure at the higher TPB levels. Solubility slightly exceeded American Dental Association standards for all TPB-resins and the control. All other performance standards were acceptable for resins containing 0% to 20% TPB.

CONCLUSIONS: At concentrations that provide a diagnostic level of radiopacity, TPB does not significantly alter required performance and processing properties. Thus, TPB is capable of commercially acceptable performance as a radiopacifying additive for dental acrylics.

Mattsson, K., et al. (2015). "Altered behavior, physiology, and metabolism in fish exposed to polystyrene nanoparticles." Environmental Science & Technology **49**(1): 553-561.

The use of nanoparticles in consumer products, for example, cosmetics, sunscreens, and electrical devices, has increased tremendously over the past decade despite insufficient knowledge about their effects on human health and ecosystem function. Moreover, the amount of plastic waste products that enter natural ecosystems, such as oceans and lakes, is increasing, and degradation of the disposed plastics produces smaller particles toward the nano scale. Therefore, it is of utmost importance to gain knowledge about how plastic nanoparticles enter and affect living organisms. Here we have administered 24 and 27 nm polystyrene nanoparticles to fish through an aquatic food chain, from algae through Daphnia, and studied the effects on behavior and metabolism. We found severe effects on feeding and shoaling behavior as well as metabolism of the fish; hence, we conclude that polystyrene nanoparticles have severe effects on both behavior and metabolism in fish and that commonly used nanosized particles may have considerable effects on natural systems and ecosystem services derived from them.

Mattsson, K., et al. (2015). "Nano-plastics in the aquatic environment." Environmental Sciences: Processes and Impacts **17**(10): 1712-1721.

The amount of plastics released to the environment in modern days has increased substantially since the development of modern plastics in the early 1900s. As a result, concerns have been raised by the public about the impact of plastics on nature and on, specifically, aquatic wildlife. Lately, much attention has been paid to macro- and micro-sized plastics and their impact on aquatic organisms. However, micro-sized plastics degrade subsequently into nano-sizes whereas nano-sized particles may be released directly into nature. Such particles have a different impact on aquatic organisms than larger pieces of plastic due to their small size, high surface curvature, and large surface area. This review describes the possible sources of nano-sized plastic, its distribution and behavior in nature, the impact of nano-sized plastic on the well-being of aquatic organisms, and the difference of impact between nano- and micro-sized particles. We also identify research areas which urgently need more attention and suggest experimental methods to obtain useful data. Copyright © 2015 The Royal Society of Chemistry.

Mattsson, K., et al. (2017). "Brain damage and behavioural disorders in fish induced by plastic nanoparticles delivered through the food chain." Scientific Reports **7**(1).

The tremendous increases in production of plastic materials has led to an accumulation of plastic pollution worldwide. Many studies have addressed the physical effects of large-sized plastics on organisms, whereas few have focused on plastic nanoparticles, despite their distinct chemical, physical and mechanical properties. Hence our understanding of their effects on ecosystem function, behaviour and metabolism of organisms remains elusive. Here we demonstrate that plastic nanoparticles reduce survival of aquatic zooplankton and penetrate the blood-to-brain barrier in fish and cause behavioural disorders. Hence, for the first time, we uncover direct interactions between plastic nanoparticles and brain tissue, which is the likely mechanism behind the observed behavioural disorders in the top consumer. In a broader perspective, our findings demonstrate that plastic nanoparticles are transferred up through a food chain, enter the brain of the top consumer and affect its behaviour, thereby severely disrupting the function of natural ecosystems.

Maury, S., et al. (2010). "CD4+CD25+Regulatory T-Cell Depletion Improves the Graft-Versus-Tumor Effect of Donor Lymphocytes After Allogeneic Hematopoietic Stem Cell Transplantation." Human Gene Therapy **21**(6): 767.

Donor T-cells play a pivotal role in the graft-versus-tumor (GVT) effect after allogeneic hematopoietic stem cell transplantation (HSCT). Regulatory T-cells (Treg) may reduce alloreactivity, the major component of the GVT effect. In the setting of donor lymphocyte infusion (DLI) after HSCT, We postulated that Treg depletion could improve alloreactivity and likewise the GVT effect of donor T-cells. The safety and efficacy of Treg-depleted DLI (d-DLI) were studied in 17 adult patients with malignancy relapse after HSCT. d-DLI were prepared from donor leukaphereses using anti-CD25 magnetic microbeads. Six out of the 17 patients developed graft-versus-host disease after d-DLI and experienced a partial (n = 3) or complete (n = 3) long-term remission of their malignancy. In the whole cohort, GVHD induction through Treg depletion was associated with improved survival. Compared with unmanipulated DLI, the alloreactivity and efficacy of d-DLI appear improved.

Mavropoulos, A., et al. (2010). "Phoshorylation of P38 mapk is detectable in NKT cells of patients with autoimmune hepatitis in whom it mirrors disease activity." Journal of Hepatology **1)**: S428.

Background: Recent experimental and clinical studies demonstrate the importance of the p38

mitogen activated protein kinase (MAPK) pathway in the pathogenesis of autoimmune diseases, through the induction of pro-inflammatory cytokines. Activation of p38 MAPK has been reported in a murine model of autoimmune hepatitis (AIH) but whether p38 MAPK is activated in patients with AIH is not known. Aim(s): To investigate p38 MAPK pathway activation in patients with AIH tested at diagnosis and during drug-induced remission. Method(s): Peripheral blood mononuclear cells (PBMC) from 20 AIH patients tested at diagnosis or at the time of immunosuppressive-induced remission and 20 demographically-matched healthy controls were obtained by Ficoll-Hypaque density gradient-based centrifugation. CD56⁺ cells were isolated by magnetic microbeads, and stained for CD3, CD3⁺CD56⁺ being the phenotype of natural killer T cells (NKT). p38 phosphorylation levels at 0', 30', 60', 120' and 240' after stimulation with either phorbol 12-myristate 13-acetate (PMA) (50ng/ml) and ionomycin (1muM) or with the physiological agonist combination of IL-12 (20ng/ml) and IL-18 (25 ng/ml) were determined by flow cytometric intracellular kinase detection using p38 phospho-specific conjugated antibodies. Result(s): The frequency of phospho-p38 MAPK positive NKT cells is significantly higher in undivided AIH patients than in healthy controls at baseline (18.44+/-2.97% vs 7.9+/-1%, p<0.01) and following a 30-minute PMA/ionophore stimulation (51.14+/-5.17% vs 31 +/-3.4%, p < 0.01). Stimulation with IL-12 and IL-18 led to a more pronounced and longer-lasting NKT cell p38 phosphorylation in patients with AIH than in healthy controls at 120' (28.51 +/-5% vs 12.3+/-1.7%) and 240' (29.88+/-5.5% vs 10.9+/-1.8%) (p<0.05 for all). Within the AIH patient group, baseline phospho-p38 MAPK positive NKT cells were more frequent at diagnosis (25.33+/-3.59%) than in remission (8.62+/-2.18%, p < 0.05). This pattern was also observed after exposure to PMA/ionophore (62.03+/-4.48% vs 38.6+/-6.92%, p < 0.01) or to IL-12 plus IL-18 (39.56+/-6.5% vs 14.05+/-2.75% at 120'; 43.54+/-6.4% vs 11.75+/-2.77.% at 240') (p<0.01). Conclusion(s): Our data demonstrate that the p38 MAPK pathway is activated in the NKT cells of patients with AIH and that the magnitude of this activation mirrors disease activity. It is likely that p38 MAPK activation is involved in generating the inflammatory milieu characterising AIH.

Maximenko, N., et al. (2018). "Numerical simulations of debris drift from the Great Japan Tsunami of 2011 and their verification with observational reports." Marine Pollution Bulletin **132C**: 5.

A suite of five ocean models is used to simulate the movement of floating debris generated by the Great Japan Tsunami of 2011. This debris was subject to differential wind and wave-induced motion relative to the ambient current (often termed “windage”) which is a function of the shape, size, and buoyancy of the individual debris items. Model solutions suggest that during the eastward drift across the North Pacific the debris became “stratified” by the wind so that objects with different windages took different paths: high windage items reached North America in large numbers the first year, medium windage items recirculated southwest toward Hawaii and Asia, and low windage items collected in the Subtropical Gyre, primarily in the so-called “garbage patch” area located northeast of Hawaii and known for high concentrations of microplastics. Numerous boats lost during the tsunami were later observed at sea and/or found on the west coast of North America: these observations are used to determine optimal windage values for scaling the model solutions. The initial number of boats set adrift during the tsunami is estimated at about 1000, while about 100 boats are projected to still float in year 2018 with an e-folding decay of 2 to 8 years.

Mayank, D., et al. (2017). "Clay soil stabilization using plastic (polythene) waste as admixture." International Journal for Research in Applied Science and Engineering Technology **5**(9): 352-357.

The object of the present paper is to investigate the strength characteristics of clay soil of

western Rajasthan stabilized by readily available material of plastic (polythene) waste. Standard proctor test, California bearing test, Direct shear tests were conducted for assessing the suitability of clay soil mixed with polythene strips. This is also a way to reuse of polybag waste with reinforcing the clay soil. It will help in plastic waste removal and management. These materials cannot be disposed of properly and their disposal is not economical. These wastes impose hazardous effect on environment and human health.

Mayanskiy, N. A. (2011). "Laborator y markers for differential diagnosis of bacterial and viral infections in children with fever." Clinical Chemistry and Laboratory Medicine **1)**: S122.

Discrimination between viral and bacterial infections in pediatric febrile patients is often a puzzle, and correct solution is a prerequisite to adequate patient care. Verification of diagnosis and substantiation of treatment rely on a clinical evaluation in conjunction with laboratory tests. Available panel of the laboratory markers that are used for screening in febrile diseases does not always give sufficiently clear results. This warrants a search for additional markers and their effective combinations. Febrile infections are accompanied by alteration in cytokine production. By means of a Bio-plex microbead suspension array system we measured serum concentrations of a wide cytokine panel and found that the patients with bacterial and viral infections, as well as healthy children, all have distinct cytokine profiles. Triggering acute inflammation in febrile infections, cytokines mediate changes of homeostasis that are reflected by modifications of the laboratory variables such as white blood count with differential, C-reactive protein, procalcitonin, etc. One of the inflammatory cytokines, IL-6, has been validated as a diagnostic marker for neonatal sepsis, and IL-6 immunoassay is now available in an automated analyzer format. The cytokine production alteration during acute inflammatory response, particularly elevation of IL-6 concentration, modifies iron metabolism stimulating synthesis of hepcidin. Being a key regulator of the iron metabolism, hepcidin diminishes the availability of iron for erythropoiesis. This functional lack of iron affects hemoglobin synthesis that is promptly reflected by reduction of the hemoglobin content in reticulocytes. A test for reticulocyte hemoglobin equivalent that is available on several hematological analyzers could be an early and easy marker of infection. Inflammation and cytokines influence also neutrophil granulocytes, inducing elevation of the neutrophil counts as well as modifying their function. The latter is mirrored by change of granularity and cellular biosynthesis/nucleic acid content in the neutrophils that could be measured by an automated hematological analyzer. It is worthwhile to speculate that a combination of several laboratory parameters will possess higher discriminative ability for bacterial and viral infection than a single marker alone. Elaboration of the infection "laboratory fingerprint" will promote development of more accurate diagnostic tools that will help physicians to make important clinical decisions.

Mazurais, D., et al. (2015). "Evaluation of the impact of polyethylene microbeads ingestion in European sea bass (Dicentrarchus labrax) larvae." Marine Environmental Research **112**: 78-85.

Microplastics are present in marine habitats worldwide and may be ingested by low trophic organisms such as fish larvae, with uncertain physiological consequences. The present study aims at assessing the impact of polyethylene (PE 10-45 mu M) microbeads ingestion in European sea bass (Dicentrarchus labrax) larvae. Fish were fed an inert diet including 0, 104 and 105 fluorescent microbeads per gram from 7 until 43 days post-hatching (dph). Microbeads were detected in the gastrointestinal tract in all fish fed diet incorporating PE. Our data revealed an efficient elimination of PE beads from the gut since no fluorescent was observed in the larvae after 48 h depuration. While the mortality rate increased significantly with the amount of microbeads scored per larvae at 14 and 20 dph, only ingestion of the highest concentration slightly impacted mortality rates. Larval growth and inflammatory response through Interleukine-1-beta (IL-1 beta) gene expression were not found to be affected while cytochrome-P450-1A1 (cyp1a1) expression level was significantly positively correlated with the number of microbeads scored per larva at 20 dph. Overall, these results suggest that ingestion of PE microbeads had limited impact on sea bass larvae possibly due to their high potential of egestion.

Mbedzi, R., et al. (2020). "Functional response quantifies microplastic uptake by a widespread African fish species." Science of the Total Environment **700**: 134522.

Ecological impacts of microplastic remain poorly understood, despite their ubiquity across all habitat types globally. Microplastic concentrations vary significantly across spatiotemporal gradients, however we lack quantitative methodologies to predict species-level responses to differential environmental concentrations. In the present study, we expose a key species, the banded tilapia Tilapia sparrmanii Smith, 1940, to different concentrations of microplastic particles. We apply and develop the functional response approach for quantifications of microplastic uptake by the fish across different environmental densities. Tilapia consumed microplastic even when relatively rare in their environment, and consumption rates related negatively to concentrations supplied, conducive with a saturating Type II (i.e., inversely-density-dependent) functional response. Attack rate (i.e., search efficiency), handling time and maximum feeding rate estimates towards microplastic were estimated, providing key information on feeding behaviour in relation to exposure concentrations. We propose the utility of functional response approaches for predictive quantifications of microplastic uptake rates. In turn, this can better-link laboratory exposure studies to environmental concentrations which are known to cause ecological impact, and provide a means of comparing uptakes among species and across environmental contexts.

McAloose, D. and A. L. Newton (2009). "Wildlife cancer and plastic pollution." Nature Reviews Cancer **9**(11): 842.

McCarney, K. M., et al. (2010). "Identification of common fungal pathogens in a single sample." Clinical Microbiology and Infection **2)**: S718.

Objectives: The objective was to develop a highly sensitive and specific single test for the direct detection of Aspergillus and Candida species within clinical specimens. Method(s): Surface enhanced resonance Raman scattering (SERRS) allows more analytes to be detected at lower concentration than fluorescence. Multiplex assays were developed to detect a broad range of pathogenic fungal species, present in clinical samples, in low copy number. Genus specific polymerase chain reaction (PCR) primers and species specific probes were designed to detect multiple targets from spiked serum/whole blood samples. Each probe has a unique spectrum allowing identification of multiple targets in a mixture. One primer from each set was modified with biotin to capture amplified DNA on microbeads. The specific probes were hybridised to the PCR products and captured on microbeads. The probe is released from the microbeads and analysed by SERRS for rapid detection of multiple pathogenic fungal targets. Result(s): The assay was tested successfully against blind panels and is capable of detecting most clinically relevant species of Candida and Aspergillus. It is designed to differentiate azole resistant species and can detect multiple aetiologies in one specimen. The detection limit is 2-3 copies input per reaction and can reproducibly detect 101 organisms within a simulated clinical specimen. Conclusion(s): In this preliminary study, the assay successfully identifies the most common fungal pathogens with high efficiency and demonstrates sensitivity down to 2-3 PCR input copies. This assay is ready to go into pre-clinical testing with the addition of software designed to automate the analysis and the detection range will be increased to cover additional fungal agents. This is the first clinical application developed using D3 Technologies' powerful detection platform. The flexibility of this technology will enable ready adaptation to other clinical applications.

McCarthy, B. J. (1996). "THE ECO MOVEMENT." Recycling Textile & Plastic Waste: 155-159.

The article focuses on the start of the Eco-movement in responding to the environmental damages caused by the textile industry. As the publication of environmental reports increased, so is the public's awareness about the impact of the industry on the environment. The public's awareness had increased after the publication of Rachel Carson's article on the impact of pesticides on the environment and this time marks the beginning of the Eco-movement. With the media coverage in Germany on dioxin levels found on textiles in contact with the skin and in Great Britain on cot deaths to added flame retardants, consumers are becoming environmentally aware. As a result, the textile sector will continue to face increasing pressures and costs related to environmental issues.

McCassie, J., et al. (1992). Current methods for determining biodegradation of polymerical materials, ACS, BOOKS & JOURNALS DIVISION, WASHINGTON, DC (USA).

The Maritime Pollution Treaty will prohibit the ocean dumping of plastic waste by the U.S. Navy and all other marine commerce activities by 1994. This treaty was enacted to protect marine life from the hazards of ingestion and entanglement due to jettisoned plastic materials. In the paper, the authors give and update on the development of standardized methodologies to characterize the biodegradation of polymeric films. For the accelerated marine and soil systems biodegradation is defines as weight loss per surface area. In the automated respirometry system biodegradation is defined as mineralization.

McCormick, A., et al. (2014). "Microplastic is an Abundant and Distinct Microbial Habitat in an Urban River." Environmental Science & Technology **48**(20): 11863-11871.

Recent research has documented microplastic particles (< 5 mm in diameter) in ocean habitats worldwide and in the Laurentian Great Lakes. Microplastic interacts with biota, including microorganisms, in these habitats, raising concerns about its ecological effects. Rivers may transport microplastic to marine habitats and the Great Lakes, but data on microplastic in rivers is limited. In a highly urbanized river in Chicago, Illinois, USA, we measured concentrations of microplastic that met or exceeded those measured in oceans and the Great Lakes, and we demonstrated that wastewater treatment plant effluent was a point source of microplastic. Results from high-throughput sequencing showed that bacterial assemblages colonizing microplastic within the river were less diverse and were significantly different in taxonomic composition compared to those from the water column and suspended organic matter. Several taxa that include plastic decomposing organisms and pathogens were more abundant on microplastic. These results demonstrate that microplastic in rivers are a distinct microbial habitat and may be a novel vector for the downstream transport of unique bacterial assemblages. In addition, this study suggests that urban rivers are an overlooked and potentially significant component of the global microplastic life cycle. [ABSTRACT FROM AUTHOR]

McCormick, A. R., et al. (2016). "Microplastic in surface waters of urban rivers: concentration, sources, and associated bacterial assemblages." Ecosphere **7**(11).

The ecological dynamics of microplastic (<5 mm) are well documented in marine ecosystems, but the sources, abundance, and ecological role of microplastic in rivers are unknown and likely to be substantial. Microplastic fibers (e.g., synthetic fabrics) and pellets (e.g., abrasives in personal care products) are abundant in wastewater treatment plant (WWTP) effluent, and can serve as a point source of microplastic in rivers. The buoyancy, hydrophobic surface, and long transport distance of microplastic make it a novel substrate for the selection and dispersal of unique microbial assemblages. We measured microplastic concentration and bacterial assemblage composition on microplastic and natural surfaces upstream and downstream of WWTP effluent sites at nine rivers in Illinois, United States. Microplastic concentration was higher downstream of WWTP effluent outfall sites in all but two rivers. Pellets, fibers, and fragments were the dominant microplastic types, and polymers were identified as polypropylene, polyethylene, and polystyrene. Mean microplastic flux was 1,338,757 pieces per day, although the flux was highly variable among nine sites (min=15,520 per day, max=4,721,709 per day). High-throughput sequencing of 16S rRNA genes showed bacterial assemblage composition was significantly different among microplastic, seston, and water column substrates. Microplastic bacterial assemblages had lower taxon richness, diversity, and evenness than those on other substrates, and microplastic selected for taxa that may degrade plastic polymers (e.g., Pseudomonas) and those representing common human intestinal pathogens (e.g., Arcobacter). Effluent from WWTPs in rivers is an important component of the global plastic "life cycle," and microplastic serves as a novel substrate that selects and transports distinct bacterial assemblages in urban rivers. Rates of microplastic deposition, consumption by stream biota, and the metabolic capacity of microplastic biofilms in rivers are unknown and merit further research.

McDevitt, J. P., et al. (2017). "Addressing the Issue of Microplastics in the Wake of the Microbead-Free Waters Act?A New Standard Can Facilitate Improved Policy." Environmental Science & Technology **51**(12): 6611-6617.

The United States Microbead-Free Waters Act was signed into law in December 2015. It is a bipartisan agreement that will eliminate one preventable source of microplastic pollution in the United States. Still, the bill is criticized for being too limited in scope, and also for discouraging the development of biodegradable alternatives that ultimately are needed to solve the bigger issue of plastics in the environment. Due to a lack of an acknowledged, appropriate standard for environmentally safe microplastics, the bill banned all plastic microbeads in selected cosmetic products. Here, we review the history of the legislation and how it relates to the issue of microplastic pollution in general, and we suggest a framework for a standard (which we call "Ecocyclable") that includes relative requirements related to toxicity, bioaccumulation, and degradation/assimilation into the natural carbon cycle. We suggest that such a standard will facilitate future regulation and legislation to reduce pollution while also encouraging innovation of sustainable technologies. [ABSTRACT FROM AUTHOR]

McDonald, B. F., et al. (2015). "In-vitro characterisation of a novel celecoxib microbead formulation for the treatment and prevention of colorectal cancer." Journal of Pharmacy & Pharmacology **67**(5): 685-695.

OBJECTIVES: Colorectal cancer (CRC) is a life-threatening disease that can develop as a consequence of a sustained chronic inflammatory pathology of the colon. Although not devoid of side effects, the anti-inflammatory drug celecoxib (CLX) has been shown to exert protective effects in CRC therapy. The purpose of this study was to develop and characterise a novel CLX microbead formulation suitable for use in the treatment and prevention of CRC, which has the potential to minimise the side effects associated with CLX.

METHODS: The study involved the assessment of the effectiveness of CLX formulations in an in-vitro cell model (HT29 cells) and a comparison of these effects to that of the marketed CLX product, Celebrex. Liquid CLX formulations were developed as precursors to microbead formulations. The effect of liquid CLX formulations on HT29 cell viability (MTT and flow cytometry apoptotic assays) and motility (scratch wound assay) were assessed and compared with the effect of Celebrex. A correlation between the in-vitro dissolution performance of the formulations and the effect in the cell model was also explored. Liquid CLX formulations were translated into an optimised CLX microbead formulation, and a colonic targeted sustained release coat (Surelease) was applied to the beads with the aim of producing a formulation for a future in-vivo study to compare the effect of the coated CLX microbeads versus Celebrex in the attenuation of CRC tumours and inflammation in a CRC murine model. The production of CLX microbeads was scaled-up using vibrating-jet encapsulation technology to allow for the development of an optimised dissolution profile to enable colonic release.

KEY FINDINGS: In-vitro cell viability and motility were shown to be significantly reduced after treatment with CLX liquid formulations relative to the control, whereas the results for treatment with Celebrex were comparable with the control. Dissolution experiments and correlation analysis demonstrated that the formulations that showed a greater extent of drug release had reduced cell viability and motility. The CLX liquid formulations were translated into colon-targeted CLX microbeads suitable for use in a future in-vivo mouse study.

CONCLUSIONS: These results represent a significant step forward in the chemopreventative treatment of CRC using CLX, as the microbead formulation developed suggests the possibility of presenting CLX in a format that has the potential to minimise gastrointestinal and cardiovascular side effects.

McDonald, N. (2019). "Biological Recycling Of Biodegradable Plastics: To meet demand for organics recovery and reduced plastic waste, biodegradable plastics will be an increasing part of the future. Biological recycling infrastructure must be ready to respond." BioCycle **60**(7): 32-36.

The article offers information on importance of biological recycling of biodegradable plastics to meet demand for organics recovery and reduced plastic waste. Topics discussed include information on aerobic composting (AC) in which fungi and aerobic bacteria consume the biopolymers; combination of anaerobic digestion (AD) with existing or new AC facilities which increases percent recovery and recycling of the organics and biopolymers; and informaton on thermoplastic starch.

McDonough, K., et al. (2017). "Assessing the biodegradability of microparticles disposed down the drain." Chemosphere **175**: 452-458.

Microparticles made from naturally occurring materials or biodegradable plastics such as poly(3-hydroxy butyrate)-co-(3-hydroxy valerate), PHBV, are being evaluated as alternatives to microplastics in personal care product applications but limited data is available on their ultimate biodegradability (mineralization) in down the drain environmental compartments. An OECD 301B Ready Biodegradation Test was used to quantify ultimate biodegradability of microparticles made of PHBV foam, jojoba wax, beeswax, rice bran wax, stearyl stearate, blueberry seeds and walnut shells. PHBV polymer was ready biodegradable reaching 65.4+or-4.1% evolved CO₂ in 5 d and 90.5+or-3.1% evolved CO₂ in 80 d. PHBV foam microparticles (125-500 micro m) were mineralized extensively with >66% CO₂ evolution in 28 d and >82% CO₂ evolution in 80 d. PHBV foam microparticles were mineralized at a similar rate and extent as microparticles made of jojoba wax, beeswax, rice bran wax, and stearyl stearate which reached 84.8+or-4.8, 84.9+or-2.2, 82.7+or-4.7, and 86.4+or-3.2% CO₂ evolution respectively in 80 d. Blueberry seeds and walnut shells mineralized more slowly only reaching 39.3+or-6.9 and 5.1+or-2.8% CO₂ evolution in 80 d respectively.

McEachern, K., et al. (2019). "Microplastics in Tampa Bay, Florida: Abundance and variability in estuarine waters and sediments." Marine Pollution Bulletin **148**: 97-106.

This study provides the first measurement of microplastic abundance and distribution in surface waters and sediments in Tampa Bay, FL. Microplastic concentrations in discrete water samples ranged from 0.25 to 7.0 particles/L with an average of 0.94 (+/-0.52) particles/L. Samples taken with a 330 mum plankton net had 1.2-18.1 particles/m³ with an average of 4.5 (+/-2.3) particles/m³. Discrete samples were 200 times higher than net samples, suggesting substantial losses or undersampling with the net. For both discrete and plankton tow samples, there were no significant differences in concentrations between stations or regions. Intense rainfall events in the summer always preceded samples with substantially higher counts. Most (>75%) microplastics were fibers. Using an average value of 1 particle/L, Tampa Bay contains ~4 billion microplastic particles. Surface sediments had an average of 280 (+/-290) particles/kg, ranging from 30 to 790 particles/kg. Highest concentrations of microplastics were found in sediments close to industrial sources; lowest values in Middle and Lower Tampa Bay are consistent with shorter residence times. Copyright © 2019

McGoran, A. R., et al. (2017). "Presence of microplastic in the digestive tracts of European flounder, Platichthys flesus, and European smelt, Osmerus eperlanus, from the River Thames." Environmental Pollution **220**(Part A): 744-751.

Like many urban catchments, the River Thames in London is contaminated with plastics. This pollutant is recorded on the river banks, in the benthic environment and in the water column. The present study was conducted to assess the extent of microplastic ingestion in two River Thames fish species, the European flounder (Platichthys flesus) and European smelt (Osmerus eperlanus). Samples were collected from two sites in Kent, England; Erith and Isle of Grain/Sheppey, near Sheerness, with the latter being more estuarine. The results revealed that up to 75% of sampled European flounder had plastic fibres in the gut compared with only 20% of smelt. This difference may be related to their diverse feeding behaviours: European flounder are benthic feeders whilst European smelt are pelagic predators. The fibres were predominantly red or black polyamides and other fibres included acrylic, nylon, polyethylene and polyethylene terephthalate and there was no difference in occurrence between the sites sampled.

McGowan, B. H. (2014). The effects of applied hydrostatic pressure on osteogenic differentiation of mouse mesenchymal stem cells in an in vitro 3D culture.

Changes in the mechanical loading on the skeleton have been shown to influence bone density. In bone disorders, such as disuse osteoporosis, the reduction of loading on bone leads to reduced bone mineral density and thus increased risk of fracture. Previous studies have suggested this may be caused by a change in the mechanical environment, specifically hydrostatic pressures, of the bone cells, resulting in a change in cellular activity. However, the pressure parameters and mechanisms involved in the promotion/suppression of osteogenesis in 3D in vitro culture of bone cells are not well understood. This doctoral thesis sought to investigate the role cyclic pressure frequency has on the osteogenic differentiation of mesenchymal stem cells (MSC) in a 3D alginate microbead in vitro culture. Specifically, the objective of this research was to test the hypothesis that the osteogenic differentiation of MSCs in 3D was enhanced by cyclic pressure applied at a critical threshold frequency. To test this hypothesis an alginate scaffold and 3D culture conditions were first developed and then used to assess the effects of cyclic pressure at different frequencies on MSC differentiation. To develop a 3D culture system the effects of RGD modification on mouse MSC survival and differentiation in alginate microbeads were first examined. MSCs were encapsulated in unmodified or RGD-modified alginate and cell proliferation and the expression of several osteogenic markers were monitored over a 28 day culture. While RGD modification did facilitate cell adhesion, it did not affect MSC viability or proliferation. However, RGD did promote the development of mature osteoblasts and was therefore used in the remaining experiments. Both an increased matrix stiffness and low seeding density were found to enhance the osteogenic differentiation of MSCs in 3D, most likely through a change in integrin binding and nutrient supply, respectively. The addition of cyclic pressure (5-35 kPa for 1 h/day) also resulted in increased osteogenesis of MSCs in 3D, but only when applied at 0.5 Hz and not 0.1 Hz. In summary, we have demonstrated that RGD, a high matrix stiffness, and low seeding density can promote the early upregulation of osteogenic markers and maturation of osteoblasts. Additionally, the results of the present study provide evidence that the promotion of the osteogenesis of MSCs in 3D by cyclic pressure is affected by frequency and that a threshold likely exists around 0.5 Hz. The current findings will help progress the field of bone cell mechanobiology and can be used in the treatment of bone degenerative diseases.

McIntyre, A., et al. (1997). "Effect of bran, ispaghula, and inert plastic particles on gastric emptying and small bowel transit in humans: the role of physical factors." Gut **40**(2): 223-227.

BACKGROUND: Coarse bran is known to accelerate transit through the whole gut and to increase stool weight. This effect is much reduced by grinding the bran, suggesting that particle size influences gut motor patterns.

AIMS: To compare the effect of 15 g coarse bran with 15 g inert plastic particles and 7 g of ispaghula on the gastric emptying and small bowel transit of a rice pudding test meal.

SUBJECTS: 13 healthy volunteers.

METHODS: Transit of 99mTc labelled rice studied by gamma-scintigraphy measuring gastric emptying and colonic arrival over 10 hours. Small bowel transit was estimated from the difference between time to 50% gastric emptying and 50% colonic arrival.

RESULTS: Bran delayed gastric emptying by 22 (SEM 8) minutes compared with control values of 88 (SEM 6) minutes $p < 0.05$. Ispaghula and plastic particles had no significant effect. Small bowel transit was accelerated compared with control values of 322 (SEM 29) minutes, decreasing by 95 (29) minutes and 62 (22) minutes after bran and plastic particles respectively. Ispaghula again showed no significant effect.

CONCLUSION: Coarse bran delays gastric emptying and accelerates small bowel transit. The marked acceleration of small bowel transit also seen with inert plastic particles may be due to increased

upper gut secretions after stimulation of enteric nerves.

McKeage, K. and L. J. Scott (2003). "SLI-381 (Adderall XR)." CNS Drugs **17**(9): 669-675.
SLI-381 is an extended-release formulation of short-acting Adderall, a racemic mixture of dextro- and levo-isomers of amphetamine salts. Drug-containing microbeads within the SLI-381 capsule give a double-pulsed delivery, similar to that achieved by two equal doses of the short-acting formulation administered 4 hours apart. In an intent-to-treat analysis of a 3-week, double-blind study in 563 children with attention-deficit hyperactivity disorder (ADHD), SLI-381 10, 20 or 30mg once daily improved mean morning and afternoon behaviour scores compared with baseline significantly more than placebo ($p < 0.001$ for all comparisons), as assessed by the Connors Global Index Scale for teachers (CGIS-T). Following treatment, CGIS-T scores were similar to those reported in children without ADHD. In the same study, a dose-response relationship was observed, and increasing the dosage of SLI-381 by 10mg at weekly intervals, to a maximum of 30mg once daily, resulted in further improvements in the scores of the CGIS-T. After early morning administration of SLI-381 in this double-blind study, late-afternoon scores of the CGIS for parents were similar to morning scores. SLI-381 was generally well tolerated in randomised trials in children with ADHD for up to 24 months. Overall, adverse events were mild to moderate in intensity.

McKee, M. D., et al. (2011). "Osteopontin and wound healing in bone." Cells Tissues Organs **194**(2-4): 313-319.
Bone wound healing after surgical drilling/cutting initially involves a typical inflammatory response with a leukocyte-rich cell infiltrate whose professional phagocytes (neutrophils and macrophages) clear the wound site of various bacterial (if present), particulate, and insoluble components arising from the original wounding event. As part of this process, in a surgical model of bone repair in rats, osteopontin (OPN) secreted by macrophages - with its known mineral-binding properties arising from abundant calcium-binding phosphorylations and overall net negative charge - binds to the newly exposed mineralized surfaces of particulate bone debris and the osseous wound margins created by the drilling, as shown by high-resolution immunogold labeling and transmission electron microscopy. For bone debris powder, OPN serves as an opsonin for clearance by macrophage phagocytosis, as demonstrated in vitro by phagocytosis assays using cultured J774.A1 murine macrophages and OPN-coated microbeads. Macrophage-secreted OPN binding to the bone wound margins contributes to cement line (plane) formation with subsequent OPN additions to the cement line coming from osteoblast lineage cells arriving at this site to effect bone repair upon further osteoblast differentiation, and extracellular matrix deposition and mineralization. Such interfacial OPN is thought to contribute to the cell adhesion, cell signaling, and matrix mineralization events required to effectively integrate the new bone into the preexisting bone at the margins of the drill site. McLaughlin, A. (2018). "Branding the world's first plastic-free supermarket aisle." Design Week (Online Edition): 1-1.
The article focuses on logo and campaign for Plastic Free Aisle, an initiative launched in collaboration with environmental charity "A Plastic Planet" and Dutch's "Ekoplaza" to prevent plastic pollution. Topics discussed include inclusion of more than 700 food items and other goods with recyclable packaging in the aisle which bear the "plastic free" mark; comments of founding partner Ben Parker along with information on the second "Plastic Free Aisle".

McLaughlin, J. S. (2008). "THE KINGDOM FUNGI, FOOD CHAINS & PLASTIC POLLUTION." The American Biology Teacher **70**(4): 201.

In class, we identify plastic bags, nets, ropes, bottles, motor-oil jugs, diapers, toys, razors, toothbrushes, cigarette lighters and more, swirling endlessly in what was once pristine seascape. Even more alarming, we speculate about what it means to the food chain that microscopic pieces of plastic are drifting like fish food throughout the water, mimicking plankton, the food supply of most aquatic life.

McLaughlin, T., et al. (2018). "p58^{IPK} Is an Endogenous Neuroprotectant for Retinal Ganglion Cells." Frontiers in aging neuroscience **10**: 267.

p58^{IPK} is an endoplasmic reticulum (ER)-resident chaperone playing a critical role in facilitating protein folding and protein homeostasis. Previously, we have demonstrated that p58^{IPK} is expressed broadly in retinal neurons including retinal ganglion cells (RGCs) and loss of p58^{IPK} results in age-related RGC degeneration. In the present study, we investigate the role of p58^{IPK} in neuroprotection by in vitro and in vivo studies using primary RGC culture and two well-established disease-relevant RGC injury models: retinal ischemia/reperfusion (I/R) and microbead-induced ocular hypertension. Our results demonstrate that in both in vivo models, p58^{IPK -/-} mice exhibit significantly increased RGC loss compared to wild type (WT) mice. In vitro, p58^{IPK}-deficient RGCs show reduced viability and are more susceptible to cell death induced by the ER stress inducer tunicamycin (TM). Overexpression of p58^{IPK} by adeno-associated virus (AAV) significantly diminishes TM-induced cell death in both WT and p58^{IPK -/-} RGCs. Interestingly, we find that loss of p58^{IPK} leads to reduced mRNA expression, but not the protein level, of mesencephalic astrocyte-derived neurotrophic factor (MANF), a neurotrophic factor that resides in the ER. Treatment with recombinant MANF protein protects R28 retinal neural cells and mouse retinal explants from TM-induced cell death. Taken together, our study suggests that p58^{IPK} functions as an endogenous neuroprotectant for RGCs. The mechanisms underlying p58^{IPK}'s neuroprotective action and the potential interactions between p58^{IPK} and MANF warrant future investigation.

McMullen, C. (2017). "Why Restaurants are Going Straw-less in Seattle by 2018." Waste360: 1-1.

The article reports on steps taken by Seattle, Washington in banning plastic disposable straws for minimizing plastic disposals and their impact on ocean life, the environment and the health of human life. It mentions that the marketplace good, compostable items that are compostable straws and compostable cutlery that meet performance standards and can be composted at our local compost facilities.

McNeish, R. E., et al. (2018). "Microplastic in riverine fish is connected to species traits." Scientific Reports **8**(1): 11639.

Microplastic is a contaminant of concern worldwide. Rivers are implicated as major pathways of microplastic transport to marine and lake ecosystems, and microplastic ingestion by freshwater biota is a risk associated with microplastic contamination, but there is little research on microplastic ecology within freshwater ecosystems. Microplastic uptake by fish is likely affected by environmental microplastic abundance and aspects of fish ecology, but these relationships have rarely been addressed. We measured the abundance and composition of microplastic in fish and surface waters from 3 major tributaries of Lake Michigan, USA. Microplastic was detected in fish and surface waters from all 3 sites, but there was no correlation between microplastic concentrations in fish and surface waters. Rather, there was a significant effect of

functional feeding group on microplastic concentration in fish. Neogobius melanostomus (round goby, a zoobenthivore) had the highest concentration of gut microplastic (19 particles fish⁻¹) compared to 10 other fish taxa measured, and had a positive linear relationship between body size and number of microplastic particles. Surface water microplastic concentrations were lowest in the most northern, forested watershed, and highest in the most southern, agriculturally dominated watershed.

McNicholas, G. and M. Cotton (2019). "Stakeholder perceptions of marine plastic waste management in the United Kingdom." Ecological Economics **163**: 77-87.

Plastic pollution is a significant threat to the marine environment. The problem has become subject to increasing scientific scrutiny, media campaigning and growing public awareness. This has stimulated policy-makers to introduce changes aiming to reduce plastic consumption and production. However, in order to arrive at socially acceptable policy and behaviour change solutions, we need to better understand the diverse array of stakeholder perspectives on ocean plastic pollution, economic policy and consumption responsibilities. We employ a Q-methodological study to research key stakeholder viewpoints from ENGO, government agency, plastic manufacturer, retailer, research and citizen representatives in the UK. We find four emergent types of perspectives surrounding this topic, labelled: (a) socio-cultural visibility and responsibility, (b) dragons of inaction - disempowerment and defeatism, (c) value-action gap, (d) refuting retailer responsibility. We also identify a clear consensus that current and proposed government policy is not radical enough - the focus needs to move beyond single-product taxes and levies on disposal items (e.g. bags, coffee cups), to a deeper reflection about public awareness raising and education, defining waste responsibilities more clearly, and working to change the habits and unsustainable practices of consumers in the face of public apathy and a resistant retail environment.

McWilliam, L. J., et al. (1991). "Spinous injury caused by a sea urchin." Journal of Clinical Pathology **44**(5): 428.

A bather on holiday in Kenya injured a finger on a spiny marine creature living on the sea bed. A skin biopsy specimen from the injured finger contained several black spines about 0.5 mm in diameter and up to 1.5 cm in length. Spines removed from the specimen were embedded in plastic resin to facilitate transverse sectioning. Light microscopical examination using crossed polarisers showed an ornate symmetrical structure brightly illuminated against a dark background. These features are characteristic of sea urchin (Echinoderm) spines which are composed of ornately formed calcite crystals covered by an epithelium. The spines of sea mice, on the other hand, are chitinous in nature; they are also much finer and lack the ornate symmetry of sea urchin spines.

Md Amin, R., et al. (2020). "Microplastic ingestion by zooplankton in Terengganu coastal waters, southern South China Sea." Marine Pollution Bulletin **150**: 110616.

This study investigates the presence of microplastics in surface seawater and zooplankton at five different locations off the Terengganu coast in Malaysia, southern South China Sea. A total of 983 microplastic particles, with an average abundance of 3.3 particles L⁻¹ were found in surface seawater. An average of one plastic particle was detected in 130 individuals from 6 groups of zooplankton. These groups include fish larvae, cyclopoid, shrimps, polychaete, calanoid and chaetognath where they ingested 0.14, 0.13, 0.01, 0.007, 0.005 and 0.003 particle per individual, respectively. Microplastics in the form of fragments are the most common type of ingested microplastics that ranged between 0.02mm (cyclopoid) - 1.68mm (shrimp and zoea).

Contrastingly, fibers, which are identified as polyamide are the main type of microplastics that dominate in seawater.

Meallem, I. and Y. Garb (2008). "The Exposure of Bedouin Women to Waste Related Hazards." Women & Environments International Magazine(76/77): 44-48.

The article investigates the exposure of Bedouin women to waste related hazards in Negev, Israel. As Bedouin adopted more sedentary and westernized lifestyles, however, the nature of their consumption changed, generating volumes and kinds of waste that require organized disposal. In addition to waste burning as an informal method of disposal, cooking and heating fires often use scavenged wood and plastic waste is often used as an ignition aid.

Mederake, L. and D. Knoblauch (2019). "Shaping EU Plastic Policies: The Role of Public Health vs. Environmental Arguments." International Journal of Environmental Research & Public Health [Electronic Resource] **16**(20): 16.

Few other environmental problems have received as much public attention and criticism in recent years as plastic pollution. Accordingly, in recent years, a number of plastic policies have been adopted at the national and supranational level in the EU and worldwide. In the U.S., health risks were repeatedly raised in the decision-making process of these policies and scholars have pointed out the crucial role of these arguments for the adoption of plastic policies. Hence, this article uses a structuring qualitative content analysis to investigate the parliamentary debates of two recently adopted plastic policies in the EU-namely the EU Plastics Strategy and the Single-Use Plastics Directive-and to assess the relevance of public health and environmental arguments for the EU debate. The analysis reveals broad support for plastics regulation among Members of the European Parliament, who most often use environmental arguments to corroborate their support for the policies in question. In contrast, health concerns do not seem to be crucial for the adoption of plastic policies in the EU.

Medinger, M., et al. (2011). "Increased Dkk3 protein expression in platelets and megakaryocytes of patients with myeloproliferative neoplasms." Thrombosis & Haemostasis **105**(1): 72-80.

Dickkopf-3 (Dkk3) has been proposed as tumour suppressor gene and a marker for tumour blood vessels. We analysed the expression and function of Dkk3 in platelets and megakaryocytes from healthy controls and patients with BCR-ABL1-negative myeloproliferative neoplasms (MPN). Dkk3 protein and gene expression in platelets was compared with endothelial and other blood cell populations by ELISA, real-time PCR, and immunofluorescence. Moreover, megakaryocytes were isolated from bone marrow aspirates by CD61 microbeads. Immunohistochemical studies of Dkk3 expression were performed in essential thrombocythemia (ET), polycythemia vera (PV), primary myelofibrosis (PMF) and control reactive bone marrow cases (each n=10). Compared to all other blood cell populations platelets showed the highest concentration of Dkk3 protein (150 +/- 19 ng/mg total protein). A strong DKK3 gene and protein expression was also observed in isolated megakaryocytes. Dkk3 co-localised with VEGF in alpha-granules of platelets and was released similar to VEGF upon stimulation. Addition of recombinant Dkk3 had no influence on blood coagulation (aPTT, INR) and platelet aggregation. Significantly more Dkk3+ megakaryocytes/mm2 could be found in bone marrow biopsies from patients with MPN (ET 40 +/- 10, PV 31 +/- 4, PMF 22 +/- 3) than in controls (15 +/- 3). The mean proportion of Dkk3+ megakaryocytes was increased in MPN as well (ET 83% +/- 15%; PV 84% +/- 12%; PMF 77% +/- 8%) compared to controls (53% +/- 11%). Dkk3+ megakaryocytes correlated with microvessel density in PV and PMF. We conclude that Dkk3 might be involved in the pathogenesis of MPN.

Medoro, G., et al. (2003). "A Lab-on-a-Chip for Cell Detection and Manipulation." IEEE Sensors Journal **3**(3): 317-325.

This paper presents a lab-on-a-chip for electronic manipulation and detection of microorganisms based on the use of closed dielectrophoretic (DEP) cages combined with impedance sensing. A printed circuit board (PCB) prototype has been used to trap, concentrate, and quantify polystyrene micro-beads in agreement with CAD simulations. The experiment was successfully repeated with S. cerevisiae. The results prove the effectiveness of the approach for particle manipulation and detection without the need for external optical components nor chemical labeling. With the proposed approach, particle concentration may be increased on-chip of more than three orders of magnitude, correspondingly boosting the detection sensitivity.

Meenu, S. and B. Rajeshwari (2011). "Market potential of developed consumer products of bonded material using plastic wastes." Asian Journal of Home Science **6**(2): 107-111.

One of the biggest challenges with plastic waste is that it is extremely hard to dispose of and persist in the environment for longer period. While the problem of plastics disposal has to be recognized and accepted globally, India's particular situation could be worsened by its poor drainage infrastructure in the cities, and fewer resources to spare for post disaster rectification. The study was carried out at Udaipur city of Rajasthan on Development of Bonded fabric using plastic waste for developing consumer products and assessment of their market potential. Finding of the study revealed that developed bonded fabrics of 200-300 GSM was suitable for the development of those consumer products requiring more thickness, stiffness and bursting strength. On the other hand, the developed bonded fabrics of 100-200 GSM was found more suitable for developing consumer products of general use on account of less stiffness and other related properties. Majority of the respondents appreciated developed value added consumer products. Thus, it can be concluded that the developed value added consumer products by the use of polythene bags for developing bonded fabrics were found highly acceptable in terms of acceptability and further this will also be helpful in reducing the environmental pollution in a fruitful manner.

Megri, A. C., et al. (1998). "Using plastic waste as thermal insulation for the slab-on-grade floor and basement of a building." Building and Environment **33**(2-3): 97-104.

Experimental and theoretical studies were performed to investigate the possibility of substituting traditional insulation materials with a rigid manufactured polyethylene packing waste. This procedure is of economic interest and contributes to the protection of the environment, since the disposal of plastic waste consumes energy and results in emissions of pollutants to air, water and soil. The first part involved the measurement of the thermal characteristics of the plastic waste using a non-isothermal procedure, based on the transient state of temperature. Two methods were employed: the heat wire method and the ring sensor method. In the second part, a comparative study was carried out for different building configurations using the traditional insulation or the rigid manufactured polyethylene packing waste. The effect of the water table on a building with a rectangular slab-on-grade foundation or with a basement was studied. An analytic method and a commercial software, which uses the finite difference method in two and three dimensions, were used for the comparison. For all configurations, the quantitative values of the heat loss through the ground from the building floor demonstrate the effective performance of the rigid polyethylene packing waste insulation and substantiate the pertinence of its use.

Mehdinia, A., et al. (2019). "Identification of microplastics in the sediments of southern coasts of the Caspian Sea, north of Iran." Environmental Pollution **258**: 113738.

Microplastic (MPs) pollution in the aquatic and terrestrial environments has caught many attentions in the scientific literatures. Currently, no information is available about MPs pollution in Caspian Sea, the largest lake in the world. This study indicates the first report on the MPs pollution in the sediments of the southern Caspian coastal zones, northern Iran. Density separation method was conducted on 17 surficial sediments. The combination of observation techniques including SEM-EDS analysis, polarized light microscopy and Raman micro-spectroscopy were used to identify MPs. The abundance and size of microplastics in the samples ranged between 25 and 330 items/kg and 250-500 mum, respectively. Fibers constituted the most common MPs shape and polystyrene (PS) and polyethylene (PE) were major polymer types in the samples. The distribution of MPs in the study area reflected a patchy and irregular spatial pattern implying that the higher MPs concentration are near mouth of permanent rivers and in the regions with higher level of the fishing and tourism activities. The results showed the wide occurrence of MPs in the sediments of the world's largest lake which extend the knowledge on MPs pollution in the marine system. We also recommend further research on microplastics in different compartments of Caspian Sea to inform policy discussions and the development of appropriate management responses.

Mehendale, S. S., et al. (1998). "Studies on impact of environmental plastic pollution hazard to the health of dairy cows (new emerging problem)." Journal of Bombay Veterinary College **6**(1): 21-23.

Severe rumen overloading with plastic material was diagnosed in 22 cows in early lactation and 2 pregnant cows in late lactation from the Mumbai region, India between January 1995 and May 1997. Rumenotomy was performed treated under field conditions in all cows. Plastic material (strings, carrier bags) weighing 19 to 68 kg was removed from the rumen of affected cows. Of 22 cows in early lactation, 17 resumed normal milk production after surgery, 3 reduced production level and 2 died. Of 2 pregnant animals, one aborted and the other had normal parturition.

Mehrjouei, M., et al. (2014). "Treatment of pyrolysis wastewater using heterogeneous advanced oxidation processes." Environmental Progress & Sustainable Energy **33**(1): 178-183.

In this study, treatment of a real wastewater sample produced in a thermal pyrolysis plant for plastic waste disposal was performed using a practical design of multiphase falling film reactor. The reduction in the level of chemical oxygen demand (COD) as well as color removal of this type of wastewater was evaluated by means of three different heterogeneous advanced oxidation processes (TiO_2/UVA/O_2, TiO_2/O_3, and TiO_2/UVA/O_3). In addition, the effect of acidification of this type of wastewater as well as the influence of the content of phosphate anions existing in the wastewater for biological treatment purposes on several treatment aspects were investigated and discussed in detail. The COD level of pyrolysis wastewater was decreased by about 32 and 38% after 1 h of treatment using the catalytic ozonation and photocatalytic ozonation approaches, respectively, while the decrease in the COD of this wastewater was negligible during the photocatalytic oxidation. The wastewater color was completely removed after 40 min of treatment using both ozone-based oxidation systems, while the photocatalytic oxidation led to a slight decrease in color extinction by about 10% after 1 h of treatment. © 2013 American Institute of Chemical Engineers Environ Prog, 33: 178-183, 2014 [ABSTRACT FROM AUTHOR]

Meier, R. P., et al. (2017). "Microencapsulation of Hepatocytes and Mesenchymal Stem Cells for Therapeutic Applications." Methods in Molecular Biology **1506**: 259-271.

Encapsulated hepatocyte transplantation and encapsulated mesenchymal stem cell transplantation are newly developed potential treatments for acute and chronic liver diseases, respectively. Cells are microencapsulated in biocompatible semipermeable alginate-based hydrogels. Microspheres protect cells against antibodies and immune cells, while allowing nutrients, small/medium size proteins and drugs to diffuse inside and outside the polymer matrix. Microencapsulated cells are assessed in vitro and designed for experimental transplantation and for future clinical applications.Here, we describe the protocol for microencapsulation of hepatocytes and mesenchymal stem cells within hybrid poly(ethylene glycol)-alginate hydrogels.

Meimaridou, A. (2013). "Microsphere-based binding assays for organic pollutants." Microsphere based binding assays for organic pollutants **139**.

This thesis describes the application of microsphere-based multiplex platforms and extraction procedures for the detection of various persistent organic pollutants (POPs) in foods, particularly in fish products. Chapter 1 provides a general introduction to the topic. Chapter 2 describes a spectrally encoded microbead-based flow cytometric immunoassay for detection of polycyclic hydrocarbons in foods, while Chapter 3 discusses multiplex screening of POPs in fish using spectrally-encoded microspheres. Chapter 4 describes the use of multiplex immunoassay for POPs detection in tilapia and Chapter 5 present a comparison between multiplex flow cytometric and biosensor platforms for detection of thyroid hormone disruption. Chapter 6 offers concluding discussions and recommendations.

Meimaridou, A., et al. (2010). "Color encoded microbeads-based flow cytometric immunoassay for polycyclic aromatic hydrocarbons in food." Analytica Chimica Acta **672**(1/2): 9-14.

Food contamination caused by chemical hazards such as persistent organic pollutants (POPs) is a worldwide public health concern and requires continuous monitoring. The chromatography-based analysis methods for POPs are accurate and quite sensitive but they are time-consuming, laborious and expensive. Thus, there is a need for validated simplified screening tools, which are inexpensive, rapid, have automation potential and can detect multiple POPs simultaneously. In this study we developed a flow cytometry-based immunoassay (FCIA) using a color-encoded microbeads technology to detect benzo[a]pyrene (BaP) and other polycyclic aromatic hydrocarbons (PAHs) in buffer and food extracts as a starting point for the future development of rapid multiplex assays including other POPs in food, such as polychlorinated biphenyls (PCBs) and polybrominated diphenyl ethers (PBDEs). A highly sensitive assay for BaP was obtained with an IC₅₀ of 0.3 micro g L⁻¹ using a monoclonal antibody (Mab22F12) against BaP, similar to the IC₅₀ of a previously described enzyme-linked immunosorbent assay (ELISA) using the same Mab. Moreover, the FCIA was 8 times more sensitive for BaP compared to a surface plasmon resonance (SPR)-based biosensor immunoassay (BIA) using the same reagents. The selectivity of the FCIAs was tested, with two Mabs against BaP for 25 other PAHs, including two hydroxyl PAH metabolites. Apart from BaP, the FCIAs can detect PAHs such as indenol[1,2,3-cd]pyrene (IP), benz[a]anthracene (BaA), and chrysene (CHR) which are also appointed by the European Food Safety Authority

(EFSA) as suitable indicators of PAH contamination in food. The FCIAs results were in agreement with those obtained with gas chromatography-mass spectrometry (GC-MS) for the detection of PAHs in real food samples of smoked carp and wheat flour and has great potential for the future routine application of this assay in a simplex or multiplex format in combination with simplified extraction procedure which are under development.

Meimaridou, A., et al. (2011). "Multiplex screening of persistent organic pollutants in fish using spectrally encoded microspheres." Analytical Chemistry **83**(22): 8696-8702.

Persistent organic pollutants (POPs) are environmental and food-related contaminants of global public health concern and known to be carcinogenic and endocrine disruptors. Their monitoring is essential, and an easy-to-use, rapid, and affordable multianalyte screening method with simplified sample preparation can be a valuable tool prior to instrumental analysis. For this purpose, a flow cytometric immunoassay (FCIA), based on a spectrally encoded microbeads technology, was developed for the multiplex detection of polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), and polybrominated diphenyl ethers (BDEs) in buffer and fish extracts. The sensitivities of the assays in the three-plex FCIA format were similar to the individual FCIAs for the marker compounds benzo[a]pyrene (BaP), 3,3',4,4'-tetrachlorobiphenyl (PCB77), and 2,2',4,4'-tetrabromodiphenyl ether (BDE47) in buffer with IC₅₀ values of 0.4, 20, and 2 micro g L⁻¹, respectively. Apart from the three markers, we could detect at least 14 other POPs. Extracts of fish with different fat content, prepared with a simplified extraction and cleanup procedure, had an insignificant influence on the overall three-plex FCIA performance, with the exception of some impact on the PAHs detection. The performance of the three-plex FCIA, in combination with the simple extraction procedure, is adequate for regulatory control in accordance with the required limits.

Mekhalef Benhafssa, A., et al. (2018). "Continuous operation of a fluidized-bed disk-type electrostatic separator for micronized plastic waste." Waste Management **79**: 763-769.

The objective of this work is to highlight the peculiarities of the continuous operating regime of a new tribo-aero-electrostatic separator for the recycling of plastics contained in micronized waste electrical and electronic equipment. The experiments were carried out with an ABS/PS mixture. The particles are charged by triboelectric effect in a fluidized bed in the presence of an electric field created between two disk electrodes connected to high voltage supplies of opposite polarities. The installation described in this paper has several control variables: the high voltage, the mass of the mixture initially introduced into the fluidized bed, the flow of fluidizing air and the rotation speed of the disk electrodes. The influence of each control variable of the machine on the efficiency of the separation was studied by simultaneously and continuously measuring the mass and the electrical charge of the collected products. The quality of the products obtained and the high hourly rates recommend this type of installation for industrial use.

Meldgaard, M., et al. (2012). "A novel multiplex analysis of filaggrin polymorphisms: a universally applicable method for genotyping." Clinica Chimica Acta **413**(19-20): 1488-1492.

BACKGROUND: The filaggrin protein is expressed as profilaggrin mainly in stratum granulosum cells of the epidermis. The profilaggrin gene codes for 10-12 filaggrin repeats. The filaggrin protein is important for skin barrier function. Filaggrin deficiency due to functional null-polymorphisms affects 8-10% of the people in Northern Europe and is a strong risk factor for several diseases. Here, we describe a novel method for efficient, multiplexed genotyping of variations in the profilaggrin gene.

METHODS: Five known techniques were combined: i) allele-specific PCR, ii) PCR with tagged primers, iii) asymmetric PCR, iv) multiplex PCR, and v) hybridization of single-stranded PCR products to spectrally coded microbeads carrying tag sequences as capture probes. Asymmetry of PCR was accomplished by having the tagged and allele-specific forward primers present in limiting concentrations. Asymmetry ensured that the later PCR cycles generated only single-stranded reverse-strand products. This greatly improved the assay sensitivity and allowed for simple optimization.

RESULTS: The specificity of the tags was verified with single PCR in wildtype and homozygous samples. Only the PCR products with the appropriate anti-tag hybridized to the corresponding beads, demonstrating the specificity of the signal. The hybridization signal is strongly dependent on single-stranded PCR products. After 46 PCR cycles, double-stranded products are clearly present, but only the single-stranded products generated in later cycles hybridize to the beads and elicit the strong signals that allow for unambiguous genotyping.

CONCLUSIONS: We have tested 17,000 samples for three filaggrin polymorphisms using this method, with a call rate exceeding 99% and a reagent cost of US $ 0.75 per sample. The method is universally applicable for multiplex genotyping of e.g. hereditary hemochromatosis, lactose intolerance, or cystic fibrosis.

Meldgaard, M., et al. (2012). "A novel multiplex analysis of filaggrin polymorphisms. An universally applicable method for genotyping." Clinical Chemistry **1)**: A85.

Background: Filaggrin is a protein located in the epidermis with a repetitive filaggrin gene located in the epidermal differentiation complex on chromosome 1q21 and the protein is important for skin barrier function. Deficiency due to functional null-polymorphisms affects 8-10% of the population in Northern Europe and cause ichthyosis vulgaris, and is a strong risk factor for atopic dermatitis, asthma, rhinitis, and food allergies. We describe a method for genotyping of three common variations in the filaggrin gene. The method is versatile and universally applicable for multiplexed genotyping. Method(s): Five known techniques are combined i) allele-specific PCR, ii) PCR with tagged primers, iii) asymmetric PCR, iv) multiplexed PCR, and v) hybridization of single-stranded PCR products to spectrally coded microbeads carrying tag-sequences as individual capture-probes. Asymmetric PCR is accomplished as the tagged and allele-specific forward primers of the three individual PCR's are present in limiting concentrations relative to the corresponding reverse primers. Asymmetry ensures that the later PCR cycles generate only single-stranded reverse strand products. This leads to highly improved assay sensitivity and allows for easy assay optimization Results: Specificity of the tags was verified by single PCR with wildtype and homozygote samples. Only PCR-products with the appropriate anti-tag hybridized to the corresponding beads, indicating a specific signal. The hybridization signal strongly dependent upon single-stranded PCR products resulting from the depletion of forward primers. After 40-48 PCR cycles double-stranded PCR products are clearly present, but only the single-stranded PCR products generated in later cycles hybridize and elicit the strong signals that allow for unambiguous genotyping. Conclusion(s): We have tested > 17,000 samples for three filaggrin polymorphisms using this method with a call-rate exceeding 99.0% and at reagent cost of only 0.75 US $ per sample. The method is universally applicable for multiplexed genotyping, and may be adapted for genotyping of for instance hereditary hemochromatosis, lactose intolerance, or cystic fibrosis.

Melero, M., et al. (2015). "Fluorescent microbead-based immunoassay for anti-Erysipelothrix rhusiopathiae antibody detection in cetaceans." Diseases of Aquatic Organisms **117**(3): 237-243.

A fluorescent microbead-based immunoassay (FMIA) for detection of anti-Erysipelothrix

rhusiopathiae antibodies in pigs was adapted for use in cetaceans. The FMIA was validated and adjusted using serum samples from 10 vaccinated captive bottlenose dolphins Tursiops truncatus collected between 1 and 13 mo after immunization. The technique was then used to analyze specimens from 15 free-ranging cetaceans stranded alive on the Valencian Mediterranean coast between 2006 and 2014: 11 striped dolphins Stenella coeruleoalba, 3 Risso's dolphins Grampus griseus and 1 bottlenose dolphin Tursiops truncatus. One of these wild animals was confirmed to have died from E. rhusiopathiae septicemia, but no anti-E. rhusiopathiae antibodies were detected in its serum, pericardial fluid or milk samples. Another free-ranging individual, which lacked any signs or lesions that might be indicative of E. rhusiopathiae infection, showed high fluorescence intensity similar to that measured in captive dolphins at 6-13 mo after vaccination. These results suggest that this animal underwent an E. rhusiopathiae infection several months before stranding. The findings in the present study suggest that FMIA can be useful for detecting anti-E. rhusiopathiae antibodies in cetaceans, and its application to free-ranging animals is particularly interesting because of the great value of these specimens. Furthermore, the FMIA can be multiplexed to allow the determination of up to 100 analytes per sample in a single well, thereby reducing the cost, time and sample volume needed.

Melief, J., et al. (2012). "Phenotyping primary human microglia: tight regulation of LPS responsiveness." GLIA **60**(10): 1506-1517.

Much is still unknown about mechanisms underlying the phenotypical and functional versatility of human microglia. Therefore, we developed a rapid procedure to isolate pure microglia from postmortem human brain tissue and studied their immediate ex vivo phenotype and responses to key inflammatory mediators. Microglia were isolated, along with macrophages from the choroid plexus by tissue dissociation, density gradient separation, and selection with magnetic microbeads. By flow cytometry, microglia were identified by a CD11b(+) CD45(dim) phenotype and a smaller size compared with CD11b(+) CD45(high) macrophages. Interestingly, white matter microglia from donors with peripheral inflammation displayed elevated CD45 levels and increased size and granularity, but were still distinct from macrophages. The phenotype of isolated microglia was further specified by absent surface expression of CD14, CD200 receptor, and mannose receptor (MR, CD206), all of which were markedly expressed by macrophages. Microglia stimulated immediately after isolation with LPS and IFNgamma failed to upregulate TNFalpha or CCR7. Notably, responsiveness to LPS and IFNgamma was clearly instigated in microglia after overnight preculture, which coincided with a strong upregulation of CD14. Culture of microglia with IL-4 resulted in the induction of HLA-DR and CCL18 but not MR, whereas culture with dexamethasone did induce MR, in addition to CD163 and CCL18. In conclusion, this study demonstrates phenotypic changes of microglia associated with peripheral inflammation, and reveals tight regulation of responses to LPS and IFNgamma as well as distinct microglial responses to IL-4 and glucocorticoids. These findings are of high relevance to studies on human microglia functioning in health and disease.

Meliton, A. Y., et al. (2014). "Pathologic cyclic stretch induces caspase-dependent apoptosis-independent microparticle formation by pulmonary endothelium." American Journal of Respiratory and Critical Care Medicine. Conference: American Thoracic Society International Conference, ATS **189**(MeetingAbstracts).

Introduction: Microparticles (MP) release from vascular endothelium has been implicated as an important mediators and markers of endothelial injury. Increased MP formation was also been described recently in the lungs of acute respiratory distress patients. MP also possess biological

activities and may exacerbate existing pathological conditions by promoting inflammatory processes. In this study, we investigated the role of pathologic mechanical stretch in MP release from human pulmonary arterial endothelial cells (HPAEC). We also examined combined effects of cyclic stretch (CS) and agonist stimulation on MP formation and investigated the mechanisms involved in increased MP production by pathologic magnitudes of cyclic stretch. Method(s): Monolayers of HPAEC were subjected to static culture (no CS) or 5% CS or 18% CS for 6 hr or 24 hr +/- thrombin or LPS. Conditioned media were collected, and MP isolation was done by differential centrifugation followed by FACS analysis using Annexin V and in comparison with fluorescent microbeads. TUNNEL assay was done to determine cells viability after cyclic stretched. Result(s): MP released after 24 hr of pathologic 18% CS showed significant increased of Annexin V compared to no CS and physiologic 5% CS. Pronounced activation of MP production caused by 18% CS was not further affected by HPAEC co-treatment with thrombin or LPS. Pretreatment of HPAEC with Rho kinase inhibitor Y-27632 or calpain inhibitor calpeptin did not alter CS-induced MP production. This effect was suppressed by pan-caspase inhibitor Z-VAD. Conclusion(s): This study demonstrates that 18% CS, but not 5% CS is a potent activator of MP production by pulmonary endothelium. We also showed that Rho kinase mechanism was not involved in CS-induced MP production by HPAEC. In contrast, CS-induced MP production was suppressed by pan-caspase inhibitor ZVAD. These data may suggest that caspase activation may trigger Rho-independent mechanisms of MP production, which may be dictated by cell type and cyclic stretched stimulation.

Melli, L., et al. (2010). "Development of electrochemical and optical immunobiosensors for diagnosis of chagas disease." Biocell **1)**: 58.

Access to appropriate diagnostic tools is an essential component in the evaluation and improvement of global health. Most diagnostic tools currently available have been developed to be implemented in laboratories highly or moderately equipped; so, largely inadequate for meeting health needs in remote or impoverished settings with no or limited infrastructure. To solve this problem, point-of-care (POC) diagnostic platforms based on immunobiosensors emerge as an alternative. Immunobiosensors are detection systems that transduce a biological signal based on the antibody-antigen recognition into a measurable signal through physical, chemical, optical or electronic transducers. In this work, we have developed optical and electrochemical immunobiosensors for the diagnosis of Chagas disease. Recombinant antigens Ag1, Ag13, Ag36, SAPA and TSSA were purified as GST fusion proteins by affinity chromatography and immobilized on carboxi-modified magnetic beads. Functionalized micro-beads were incubated with sera from infected and non-infected patients and the immune complexes were detected using rabbit anti-human IgM/G Cy5 or peroxidase conjugate antibodies. Our results indicate that the immunobiosensors here developed can be use for the diagnosis of Chagas disease and reveal the potential of such biosensors for the development of POC diagnostic platforms for multiple infectious diseases.

Melnikov, M., et al. (2017). "The influence of depression on Th17-immune response in multiple sclerosis." Journal of the Neurological Sciences **381 (Supplement 1)**: 653.

Background: Multiple sclerosis (MS) is a chronic inflammatory demyelinating disease of the central nervous system with autoimmune mechanism of development. Depression can influence on MS course modulating immune cells activity and cytokine production. Objective(s): To study the relationship between clinical and neuropsychological impairment, concentration of biogenic amines (serotonin, dopamine, norepinephrine, epinephrine) in the serum, quantitative characteristics of Th17-cells, and to clarify the influence of biogenic amines on the function of
