Th17-cells in vitro. Patients and Methods/Material and Methods: Data of clinical and neuropsychological status (Beck's scale) of 45 relapsing-remitting MS patients and 20 healthy controls were included. The concentration biogenic amines in the serum were measured by ELISA. Circulating Th17- cells were determined by flow cytometry (CD4CD26CD161CD196). The levels of interleukin-17 (IL-17) and interferon-gamma (IFN-gamma) were studied by ELISA in supernatants of peripheral blood mononuclear cells (PBMCs) stimulated with microbeads coated with anti-CD3 and anti-CD28 antibodies in the absence and in the presence of different concentrations of biogenic amines (10⁻⁴ M, 10⁻⁵ M,10⁻⁶ M). Result(s): The levels of biogenic amines were comparable in all groups. The percentages of Th17-cells and production of IL-17 and IFN-gamma by PBMCs were higher in patients with depression compared to patients without depression or to the control group (p<0.05). Biogenic amines reduced IL-17 and IFN-gamma production in all groups (p<0.05). Conclusion(s): Depression can increase Th17-immune response in multiple sclerosis.

Melnikov, M. V., et al. (2016). "[The influence of catecholamines on Th17-cells in multiple sclerosis]." Zhurnal Nevrologii i Psikhiatrii Imeni S.S. Korsakova **116**(10 Pt 2): 16-20.

AIM: To investigate the possible association between clinical characteristics of multiple sclerosis (MS), quantitative and qualitative characteristics of Th17, dopamine and norepinephrine concentrations in the serum in patients with multiple sclerosis (MS).

MATERIAL AND METHODS: A comprehensive neurological and immunological examination of 43 patients with relapsing-remitting-MS (RR-MS) was performed. All patients were subjected to a standard neurological examination with assessment of the EDSS score. Dopamine and norepinephrine concentrations in serum were measured by enzyme-linked immunosorbent assay (ELISA). Percentage of Th17-cells was determined by flow cytometry. The functional activity of Th17- and Th1-cells was assessed by the production of interleukin-17 (IL-17) and interferon-gamma (IFN-gamma), respectively, by peripheral blood mononuclear cells (PBMC) stimulated with microbeads coated with anti-CD3 and anti-CD28-antibodies.

RESULTS: The percent Th17-cells and cytokine production was significantly higher in MS patients with the exacerbation of disease than in the control group or remission, while the dopamine level was lower. Norepinephrine levels in MS patients in the acute stage and remission were comparable, but nevertheless, reliably lower than in the control group.

CONCLUSION: The results suggest the inhibitory effect of catecholamines on Th17 cells.

Melo, R. C. N., et al. (2007). "Histological approaches for high-quality imaging of zooplanktonic organisms." Micron (Oxford, England : 1993) **38**(7): 714-721.

The investigation of the internal organization of zooplankton communities provides important information on the plankton biology with special interest for the study of ecological processes. Zooplanktoners can play a structural function as indicators for ecosystem health or stress, but their study using histological techniques is still limited. Here we report that the internal structure of zooplanktonic organisms can be facilely observed by a histological approach that combines optimal fixation and processing with a plastic resin (glycol methacrylate) embedding, resulting in increased tissue resolution. Using copepods, organisms that can dominate zooplankton assemblages, as models, collected from a tropical ecosystem (Paraibuna river, Brazil), we showed fine histological details of their muscular, nervous and digestive systems, structure of appendages and cell features. Critical advantages of this approach are that it permits optimal preservation and adequate handling of the organisms (embedded in agar after fixation) for further histological processing and investigation. This is important because it prevents both mechanically induced artifacts and loss of these diminutive organisms during the

different steps of processing. Moreover, embedding in plastic resin showed a superior imaging of copepod internal structures compared to paraffin embedding. The use of glycol methacrylate is advantageous over paraffin/paraplast embedding by avoiding heat damage, tissue retraction and allowing faster embedding procedure and better tissue resolution. The value of histological approaches in enabling high-quality imaging of the internal structure of copepods is particularly important because these organisms can be used as indicators of environmental changes.

Mendoza, A., et al. (1999). "Energy dispersive X-ray fluorescence analysis of marine pollution indicators." Journal of Radioanalytical and Nuclear Chemistry **240**(2): 459-465.

The present work shows a methodology for the application of EDXRF with a X-ray tube, in the analysis of elements in the following matrices: microalgae, marine algae, marine sediments and corals. Various methods were applied: one using a relative external standard, a fundamental parameters method, an absolute method based on elemental sensitivity, a method which used X-ray fluorescence excitation measured in the back side of the sample for low contents heavy elements determination and a TRXRF method. The thin layer samples were prepared using a plastic resin. The analyzed samples of marine algae, marine sediments and corals belong to a marine ecosystem from the North of Havana City, the most affected area by natural metereological phenomena and human impact.

Mendoza, L. M. R. and P. R. Jones (2015). "Characterisation of microplastics and toxic chemicals extracted from microplastic samples from the North Pacific Gyre." Environmental Chemistry **12**(5): 611-617.

Initial studies of floating plastic debris in the oceans dealt with macroscopic particles. This research found microscale plastic present as well. Chemical analysis of sorbed materials revealed toxic materials associated with the microparticles. Seawater and plastic fragment samples were collected in September 2007 in the North Pacific Central Gyre. Polycyclic aromatic hydrocarbons and polychlorinated biphenyls (PCBs) were detected by mass spectrometry in extracts from the plastic fragments. Net concentrations of PCBs ranged from 1 to 223 ng g-1 plastic. The most common synthetic polymers were found to be polypropylene and polyethylene. Microscopic plastic fibres and particles were also discovered in the seawater samples and examined by scanning electron microscopy. Analysis of filtered seawater samples also revealed toxic materials in concentrations lower than found on the plastic particles.

Menezes, R., et al. (2019). "Ingestion of macroplastic debris by the common dolphinfish (Coryphaena hippurus) in the Western Equatorial Atlantic." Marine Pollution Bulletin **141**: 161-163.

We report the occurrence of macroplastic debris in the stomach of a common dolphinfish (Coryphaena hippurus) caught in the Western Equatorial Atlantic. On the deck, we noticed that the fish was remarkably undernourished and decided to remove its stomach for laboratory analysis. A large part of a plastic bowl and a tuna pectoral fin were the only items recorded in the fish stomach. The plastic measured 99.57 cm² and weighed 12.77 g, likely blocking the digestive tract and reducing food intake by the fish, as supported by signs of starvation. This is the record of the largest plastic debris ingested by a dolphinfish to date. As the source of the plastic container was probably a tuna fishing boat, we suggest strengthening environmental education programs to enhance the awareness of fishermen and mitigate the impacts of plastic pollution on the pelagic ecosystem and associated organisms, such as C. hippurus.

Meng, G., et al. (2005). "Present situation and restoration of agriculture ecological environment in

Western Mountain of China." Research of Agricultural Modernization **26**(3): 182-185.

The western mountain region is an important area of eco-environmental protection and construction in China. It is an important ecological barrier for the Yangtze River and the major water supplying area to the eastern region. However, a series of ecological environmental problems have emerged. The main problems of the agricultural eco-environment includes the denudation of virgin forests; the weakening of ecological function; desertification and soil erosion due to unreasonable resource exploitation and construction; pesticide and fertilizer residues; non-degradable plastic; pollution from municipal and industrial solid wastes; acid rain; and livestock manure. Serious ecological and environmental problems have hindered social and economic development in the region. Ecological agriculture is a means of encouraging economic development and protecting the ecological environment in the western mountain region. This paper, on the basis of latest survey data, analyses the background, current situation and features of eco-agriculture in this region.

Meng, X., et al. (2010). "Direct fluorescence detection of point mutations in human genomic DNA using microbead-based ligase chain reaction." Talanta **80**(5): 1725-1729.

This report has described a convenient genotyping method capable of detecting point mutations directly in human genomic DNA based on the combination of ligase chain reaction (LCR) and microbead-enrichment technique. LCR primers, including a biotin-labeled common primer and two fluorescence-labeled allele-specific primers, are designed for two alleles of a mutated site. When genomic DNA carries the mutated site, the common primer and allele-specific primer are ligated to form exponential amplified biotin-labeled fluorescence ligation products. These ligated products are enriched by streptavidin-coated microbeads, and genotypes are identified conveniently according to the fluorescence color of microbeads using fluorescent microscopy. Due to amplification of LCR process and enrichment of microbeads, the detection limit of the proposed method is as low as 10(-15)mol/L templates. The method provides a convenient and simple strategy to detect point mutation directly in human genome. We have confirmed the efficiency of this approach with the identification of beta-globin gene point mutation, which results in the reduced production of globin in an inherited hemoglobin disorder thalassemia disease.

Meng, Y., et al. (2020). "Advances and challenges of microplastic pollution in freshwater ecosystems: A UK perspective." Environmental Pollution **256**: 113445.

Microplastics have been increasingly documented in freshwater ecosystems in recent years, and growing concerns have been raised about their potential environmental health risks. To assess the current state of knowledge, with a focus on the UK, a literature review of existing freshwater microplastics studies was conducted. Sampling and analytical methodologies currently used to detect, characterise and quantify microplastics were assessed and microplastic types, sources, occurrence, transport and fate, and microplastic-biota interactions in the UK's freshwater environments were examined. Just 32% of published microplastics studies in the UK have focused on freshwater environments. These papers cover microplastic contamination of sediments, water and biota via a range of methods, rendering comparisons difficult. However, secondary microplastics are the most common type, and there are point (e.g. effluent) and diffuse (non-point, e.g. sludge) sources. Microplastic transport over a range of spatial scales and with different residence times will be influenced by particle characteristics, external forces (e.g. flow regimes), physical site characteristics (e.g. bottom topography), the degree of biofouling, and anthropogenic activity (e.g. dam release), however, there is a lack of data on this. It is predicted that impacts on biota will mirror that of the marine environment. There are many important gaps in current knowledge; field data on the transport of microplastics from diffuse sources are less available, especially in England. We provide recommendations for future research to further our understanding of microplastics in the environment and their impacts on freshwater biota in the UK.

Meng, Y. and H. S. Ramaswamy (2007). "Effect of system variables on heat transfer to canned particulate non-Newtonian fluids during end-over-end rotation." Food and Bioproducts Processing **85**(1): 34-41.
Apparent heat transfer coefficients h_{ap} and U_a were evaluated to quantify the heat transfer process with particulates in high viscosity non-Newtonian fluids in end-over-end thermal processing. An orthogonal array L16 experiment was used to examine the significances of system factors on h_{ap} and U_a values with plastic particles in CMC aqueous solutions. The variance analysis showed that rotation speed, liquid viscosity, retort temperature, particle material and particle concentration were significant factors (P<0.05) for h_{ap} and U_a. The effects of can size was also significant for h_{ap}. A central composite rotatable design (CCRD) experiment and two full factorial experiments were carried out to study the effects of those significant factors on h_{ap} and U_a values. Results showed that with the decrease of liquid viscosity and the increase of rotation speed, particle density and retort temperature, h_{ap} and U_a values increased. With the increase of can size h_{ap} values decreased. With the particle concentration increasing h_{ap} and U_a values firstly increased and then decreased with further increase in particle concentration.

Menges, G. and W. Hoffmanns (1974). "Possibilities and limits of recycling of plastic waste materials. [German]." Muell Abfall **6**(4): 114-118.
The methods presented indicate that economic recycling of plastic wastes is perfectly feasible. Pyrolysis and separation procedures for mixed plastic wastes are still in the developmental phase. As long as these procedures cannot be used on a large technical scale, further processing and use of plastic wastes is justified both for avoiding environmental stresses and for saving on new raw materials. Finally, investigations and the possibilities of further use of unseparated and unreduced plastic wastes are discussed.

Menke, D., et al. (2003). "Don't ban PVC: incinerate and recycle it instead!" Waste Management & Research **21**(2): 172-177.
Plastics are making a growing contribution to sustainable development. For example, over an expected lifetime of 50 years, the use of window frames and insulating materials made of plastic in buildings save many times the energy required to manufacture them. Plastics for packaging purposes provide protection against damage and dirt contamination, thereby saving considerable amounts of material and energy. Choosing appropriate disposal strategies for plastic waste also helps to protect the environment (Mark 2000).

Menon, T. V. and C. I. Sajeeth (2013). "Formulation and evaluation of sustained release sodium alginate microbeads of carvedilol." International Journal of PharmTech Research **5**(2): 746-753.
The main aim of the study is to formulate Carvedilol loaded microbeads of sodium alginate using gelatine and pectin as release modifiers by ionotropic gelation method. The microbeads were prepared by varying the concentration of sodium alginate, gelatin and pectin. The drug-polymer compatibility was studied by FTIR studies. The prepared microbeads were evaluated for swelling ratio, particle size, drug entrapment, Scanning electron microscopy (SEM), bio adhesion study

and invitro release study. Particle size distribution of both placebo and drug loaded formulations were measured by an optical microscope and particle size of optimized beads was determined by SEM. No significant drug-polymer interactions were observed in FT-IR studies. In-vitro drug release profile of Carvedilol micro beads was examined in pH 1.2 N Hydrochloric acid for first 2 hours followed by phosphate buffer pH 7.4 for remaining time. The in vitro wash-off test indicated that the sodium alginate micro beads had good mucoadhesive properties. The formulated beads had shown higher entrapment efficiency, drug loading, low particle size and moisture content. The formulation F3 released Carvedilol for longer duration (24 hours) and showed better mucoadhesion.

Meo, S. A., et al. (2018). "Men's Health in Industries: Plastic Plant Pollution and Prevalence of Pre-diabetes and Type 2 Diabetes Mellitus." American Journal of Mens Health **12**(6): 2167-2172.

Plastic production is prominently increasing and its pollution is an emerging environmental global health concern. This study aimed to investigate the occurrence of pre-diabetes and type 2 diabetes mellitus (T2DM) among nonsmoking plastic industry workers. Three hundred and forty volunteers male plastic industry workers were interviewed after medical history and examination; finally, 278 nonsmoking plastic industry workers were selected. The mean age for the participants was 38.03 +/- 10.86 years and body mass index was 25.52 +/- 3.15 (kg/m)². The plastic industry workers had been exposed to plastic plant pollution for 8 hr daily, 6 days in a week. Subjects with glycated hemoglobin (HbA1c) less than 5.7% were considered non-diabetics; HbA1c 5.7%-6.4% were pre-diabetics; and subjects with HbA1c greater than 6.4% were considered diabetics. In plastic industry workers, the prevalence of pre-diabetes was 176 (63.30%) and T2DM was 66 (23.74%); however, 36 (12.95%) plastic plant workers were normal. The prevalence of pre-diabetes and T2DM among plastic industry workers was significantly increased with duration of working exposure in plastic industry (p = .0001). Exposure to plastic plant pollution is associated with the prevalence of pre-diabetes and T2DM among plastic industry workers. The prevalence was associated with the duration of working exposure in plastic industry. The occupational and environmental health executives must take priority steps to minimize the plastic plant pollution from plastic industries to reduce the occurrence of pre-diabetes and T2DM among the plastic industrial workers and save the men's health in industries.

Merchant, M. S., et al. (2015). "Genetically engineered NY-ESO-1-specific T cells in HLA-A2+ patients with synovial sarcoma." Cancer Research. Conference: 106th Annual Meeting of the American Association for Cancer Research, AACR **75**(15 SUPPL. 1).

NY-ESO-1 is expressed in ~70% of synovial sarcomas and not expressed in vital tissues. We report interim results of NCT01343043 evaluating safety and activity of autologous T cells engineered to express an HLA-A2+ restricted, affinity-enhanced T cell receptor (TCR) targeting NY-ESO-1. HLA-A2+ patients with unresectable, metastatic, or recurrent synovial sarcoma were eligible if tumors expressed NY-ESO-1 by IHC. Lymphocytes were activated using anti-CD3/28 microbeads, genetically modified with a lentivector, then cryopreserved. Subjects received fludarabine 30mg/m²/d (D-6 to -2) and cyclophosphamide 1800mg/m²/d (D-3,-2), and infusion of engineered T cells. Systemic IL-2 was not administered. Nine subjects have received NY-ESO-1 cell infusions. Median transduced T cell dose was 3.4 x 10⁹ cells (range 0.4-14.4), 60x10⁶ cells/kg (range 5.7-165.5), and median transduction efficiency was 45.8%. Toxicity likely attributable to the T cells included fever, and grade 1-2 cytokine release syndrome. No autoimmune toxicity has been observed. Circulating engineered NY-ESO-1 cells were detected in all patients, peaking 3-21 days

post-infusion. Persistence has been evaluated beyond 3 months in 4 subjects, all of whom had detectable NY-ESO-1 cells at 4 mos, 6 mos+, 12 mos+ and 12 mos+. We identified persisting NY-ESO-1 T cells using dextamer and/or anti-vbeta13.1 mAbs, and observed that a high fraction of CD4+ and CD8+ NY-ESO-1 TCR expressing T cells were CD45RA+CCR7+CD95+, consistent with a stem cell memory phenotype. Persisting cells also demonstrate a polyfunctional (IFN-gamma and TNF-alpha) and cytotoxic (CD107a and granzyme B) signature without overexpression of exhaustion markers (PD-1, LAG-3, and TIM-3). Of 8 patients whose follow-up is sufficient to assess response, 4 experienced objective responses (1CR x 9 mos, 1PR x 9 mos, 2PR x 6 mos). Tumor shrinkage could not be attributed to chemotherapy alone as progressive decreases in tumor size were observed over several months following completion of the lymphodepleting regimen. All PR patients (2 upon signs of progression and 1 still responding to therapy) ultimately underwent resection for residual disease and two remain without evidence of disease. Adoptive immunotherapy with NY-ESO-1 engineered T cells shows promising results in synovial sarcoma with acceptable toxicity. High dose IL-2 is not required for therapeutic benefit with this regimen.

Meseck, S. L., et al. (2016). "Ocean Acidification Affects Hemocyte Physiology in the Tanner Crab (Chionoecetes bairdi)." PLoS ONE **11**(2).

We used flow cytometry to determine if there would be a difference in hematology, selected immune functions, and hemocyte pH (pHi), under two different, future ocean acidification scenarios (pH = 7.50, 7.80) compared to current conditions (pH = 8.09) for Chionoecetes bairdi, Tanner crab. Hemocytes were analyzed after adult Tanner crabs were held for two years under continuous exposure to acidified ocean water. Total counts of hemocytes did not vary among control and experimental treatments; however, there were significantly greater number of dead, circulating hemocytes in crabs held at the lowest pH treatment. Phagocytosis of fluorescent microbeads by hemocytes was greatest at the lowest pH treatment. These results suggest that hemocytes were dying, likely by apoptosis, at a rate faster than upregulated phagocytosis was able to remove moribund cells from circulation at the lowest pH. Crab hemolymph pH (pHe) averaged 8.09 and did not vary among pH treatments. There was no significant difference in internal pH (pHi) within hyalinocytes among pH treatments and the mean pHi (7.26) was lower than the mean pHe. In contrast, there were significant differences among treatments in pHi of the semi-granular+granular cells. Control crabs had the highest mean semi-granular+granular pHi compared to the lowest pH treatment. As physiological hemocyte functions changed from ambient conditions, interactions with the number of eggs in the second clutch, percentage of viable eggs, and calcium concentration in the adult crab shell was observed. This suggested that the energetic costs of responding to ocean acidification and maintaining defense mechanisms in Tanner crab may divert energy from other physiological processes, such as reproduction.

Messier, E. M., et al. (2013). "N-acetylcysteine protects murine alveolar type II cells from cigarette smoke injury in a nuclear erythroid 2-related factor-2-independent manner." American Journal of Respiratory Cell & Molecular Biology **48**(5): 559-567.

Emphysema is caused by the cigarette smoke (CS)-induced destruction of alveolar wall septa, and CS is the main risk factor for chronic obstructive pulmonary disease (COPD). To study the mechanisms of response to this insult, we focused on oxidant-induced lung injury and the potential role of nuclear erythroid 2-related factor-2 (Nrf2), which is a key regulator of the antioxidant defense system. We studied the protective role of N-acetylcysteine (NAC) against the injury of alveolar type II (ATII) cells induced by CS in vivo and in vitro. ATII cells were isolated and purified using magnetic MicroBeads (Miltenyi Biotec, Auburn, CA) from Nrf2(-/-) mice and wild-type mice. We analyzed pulmonary injury, inflammation, glutathione (GSH) concentrations, the expression of glutathione cysteine ligase catalytic subunit mRNA, glutathione cysteine ligase modifier subunit mRNA, and glutathione reductase mRNA, and Nrf2, heme oxygenase-1, and nicotinamide adenine dinucleotide phosphate-reduced:quinone oxireductase levels by Western blotting, TUNEL assay, and immunocytofluorescence for 4-hydroxynonenal as a marker of oxidative stress. We found that CS induced greater injury in ATII cells obtained from Nrf2(-/-) mice than from wild-type mice. Furthermore, NAC attenuated the injuries by CS in ATII cells obtained from wild-type mice both in vivo and in vitro. Moreover, NAC decreased the injury of ATII cells obtained from Nrf2(-/-) mice. Our results suggest that Nrf2-GSH signaling is important for the protective activity of NAC. In addition, in ATII cells deficient in Nrf2, this compound can provide partial protection through its reactive oxygen species-scavenging activities. Targeting the antioxidant system regulated by Nrf2 may provide an effective strategy against lung injury in COPD.

Messinetti, S., et al. (2018). "Effects of polystyrene microplastics on early stages of two marine invertebrates with different feeding strategies." Environmental Pollution **237**: 1080-1087.

Nowadays, microplastics represent one of the main threats to marine ecosystems, being able to affect organisms at different stages of their life cycle and at different levels of the food web. Although the presence of plastic debris has been reported in different habitats and the ability to ingest it has been confirmed for different taxa, few studies have been performed to elucidate the effects on survival and development of marine animals. Thus, we explored the effects of different environmental concentrations of polystyrene microbeads on the early stages of two invertebrate species widespread in the Mediterranean shallow waters: the pelagic planktotrophic pluteus larvae of the sea urchin Paracentrotus lividus and the filter-feeding sessile juveniles of the ascidian Ciona robusta. We evaluated the effects on larvae and juvenile development and determined the efficiency of bead ingestion. The feeding stages of both species proved to be extremely efficient in ingesting microplastics. In the presence of microbeads, the metamorphosis of ascidian juveniles was slowed down and development of plutei altered. These results prompted the necessity to monitor the populations of coastal invertebrates since microplastics affect sensitive stages of life cycle and may have consequences on generation recruitment.

Metzner, C., et al. (2007). "Simple model of cytoskeletal fluctuations." Physical Review E. Statistical, Nonlinear, & Soft Matter Physics **76**(2 Pt 1): 021925.

The spontaneous motion of microbeads bound to the cytoskeleton of living cells is not an ordinary random walk. Unlike Brownian motion, the mean-square displacement undergoes a transition from subdiffusive to superdiffusive behavior with time. This transition is associated with characteristic changes of the turning angle distribution. Recent experimental data demonstrated that force fluctuations measured in an elastic hydrogel matrix beneath the cell correlate with the bead motion [C. Raupach, Phys. Rev. E 76, 011918 (2007)]. These data indicate that the bead trajectory is driven by motor forces originating from the actomyosin network and that cytoskeletal remodeling processes with short- and long-time dynamics are mainly responsible for the non-Brownian behavior. We show that the essential statistical properties of the spontaneous bead motion can be reproduced by a particle diffusing in a potential well with a slowly drifting minimum position. Based on this simple model, which can be solved analytically, we develop a biologically plausible numerical model of a tensed and continuously remodeling actomyosin network that accounts quantitatively for the measured data.

Meyer, W. and N. H. Zschemisch (2002). "[Skin layer thickness at the ear of the domesticated pig , with special reference to the use of the ear integument for human dermatological research]." Berliner und Munchener Tierarztliche Wochenschrift **115**(11-12): 401-406.

Based on a shrinkage-free methodical approach (special plastic resin embedding, frozen section technique) and histological routine staining, the thickness of the different skin layers was measured from 15 regions of the outer and the inner side of the porcine auricle. Mean thickness values were for the str. corneum: 19 microns outside/20 microns inside, vital epidermis without ridges: 52 microns outside/56 microns inside, dermis: 1175 microns outside/1112 microns inside, hypodermis: 1024 microns outside/741 microns inside, perichondrium: 295 microns outside/220 microns inside. When both sides of the auricle were compared, it became obvious that the outer side generally had a thicker dermis (1140-1290 microns) and hypodermis (780-1150 microns), whereas the inner side had a thicker vital epidermis (50-60 microns) and deeper epidermal ridges (145-165 microns). The results are discussed with regard to corresponding findings from the human skin, and one region of the outer side of the porcine auricle is recommended as suitable for human dermatological research.

Mi, L., et al. (2019). "Occurrence and spatial distribution of phthalate esters in sediments of the Bohai and Yellow seas." Science of the Total Environment **653**: 792-800.

Phthalate esters (PEs) are a class of synthetic chemicals that have been widely used as plasticizers in industrial products and households. The occurrence of PEs in the marine environment has been a concern for many years because of their adverse impacts on marine organisms and human health. In this study, six major PEs, i.e. diethyl phthalate (DEP), di-isobutyl phthalate (DiBP), di-n-butyl phthalate (DnBP), benzylbutyl phthalate (BBP), dicyclohexyl phthalate (DCHP) and di-(2-ethylhexyl) phthalate (DEHP), were analyzed in sediment samples collected in the Bohai and Yellow seas. The sum concentrations of the six PEs ranged from 1.4 to 24.6ng/g and the average was 9.1ng/g. The highest concentrations of PEs in the sediment samples were those of DEHP with a median concentration of 3.77ng/g, followed by DiBP (median, 1.60ng/g), DnBP (0.91ng/g), DEP (0.32ng/g), BBP (0.03ng/g) and DCHP (0.01ng/g). Generally, concentrations of PEs in the Bohai Sea are higher than those in the Yellow Sea. The varying spatial distributions of the individual PEs can be the result of discharge sources, regional ocean circulation patterns, and mud areas in the Bohai and Yellow seas. Significant positive correlations were found between total organic carbon content and the concentrations of DiBP, DnBP, and DEHP. It is estimated that the inventories of the 6PEs were 20.73tons in the Bohai Sea and 65.87tons in the Yellow Sea. Both riverine discharge and atmospheric deposition are major input sources for the PE sedimentation, while massive plastic litter and microplastics sinking to the ocean floor can directly release PEs into sediment. This study provides an appropriate data set for the assessment of the risk of PEs to the marine ecosystem.

Miandad, R., et al. (2016). "Catalytic pyrolysis of plastic waste: A review." Process Safety & Environmental Protection: Transactions of the Institution of Chemical Engineers Part B **102**(Part B): 822-838.

This paper reviews the progress and challenges of the catalytic pyrolysis of plastic waste along with future perspectives in comparison to thermal pyrolysis. The factors affecting the catalytic pyrolysis process such as the temperature, retention time, feedstock composition and the use of catalyst were evaluated in detail to improve the process of catalytic pyrolysis. Pyrolysis can be carried out via thermal or catalytic routes. Thermal pyrolysis produces low quality liquid oil and

requires both a high temperature and retention time. In order to overcome these issues, catalytic pyrolysis of plastic waste has emerged with the use of a catalyst. It has the potential to convert 70-80% of plastic waste into liquid oil that has similar characteristics to conventional diesel fuel; such as the high heating value (HHV) of 38-45.86 MJ/kg, a density of 0.77-0.84g/cm3, a viscosity of 1.74-2.5 mm2/s, a kinematic viscosity of 1.1-2.27 cSt, a pour point of (-9) to (-67) ;IC, a boiling point of 68-352 °C, and a flash point of 26.1-48 °C. Thus the liquid oil from catalytic pyrolysis is of higher quality and can be used in several energy-related applications such as electricity generation, transport fuel and heating source. Moreover, process by-products such as char has the potential to be used as an adsorbent material for the removal of heavy metals, pollutants and odor from wastewater and polluted air, while the produced gases have the potential to be used as energy carriers. Despite all the potential advantages of the catalytic pyrolysis, some limitations such as high parasitic energy demand, catalyst costs and less reuse of catalyst are still remaining. The recommended solutions for these challenges include exploration of cheaper catalysts, catalyst regeneration and overall process optimization. [ABSTRACT FROM AUTHOR]

Miandad, R., et al. (2018). "Untapped conversion of plastic waste char into carbon-metal LDOs for the adsorption of Congo red." Journal of Colloid and Interface Science **511**: 402-410.

A low-cost novel carbon-metal double layered oxides (C/MnCuAl-LDOs) nano-adsorbent was synthesized by co-precipitation, for the adsorption of Congo red (CR), using modified carbon derived from pyrolysis of polystyrene (PS) plastic waste. The synthesized C/MnCuAl-LDOs has a crystalline structure with a high surface area of 60.43 m²/g and pore size of 99.85 A. Adsorption of CR using all prepared adsorbents from aqueous solution under equilibrium and kinetic conditions were evaluated against different values of the pH (4-10), initial CR concentrations (25-250 mg/g), contact time (0-310 min) and temperature (30-50 degrees C). The obtained results revealed that C/MnCuAl-LDOs showed maximum adsorption capacity for CR among all the used adsorbents. The optimum equilibrium time was 180 min, whereas acidic medium (pH 4.5) favored the maximum adsorption of CR up to 317.2 mg/g on C/MnCuAl-LDOs. The adsorption kinetics followed the pseudo-second-order model, whereas Freundlich adsorption isotherm fitted best to obtained data in comparison to Langmuir adsorption isotherm. The results suggested that C/MnCuAl-LDOs is an efficient material for the removal of organic pollutants from the wastewater.

Miao, L., et al. (2019). "Effects of Nanoplastics on Freshwater Biofilm Microbial Metabolic Functions as Determined by BIOLOG ECO Microplates." International Journal of Environmental Research & Public Health [Electronic Resource] **16**(23): 21.

Nanoplastic (NP) contamination is becoming a pervasive issue as NPs, originating from microplastic particles, pose potentially harmful environmental impacts on aquatic ecosystems. The environmental hazards of NPs on microorganisms have been well documented in recent studies; however, little is known about their ecotoxicity effects on freshwater biofilms, which serve as important primary producers and decomposers and are highly connected with other ecosystem components. We investigated the effects of NPs on the microbial metabolic functions

of freshwater biofilms in terms of carbon source utilization ability. Biofilm samples were collected, cultivated in a hydrodynamic flume for six weeks, and then exposed in polystyrene (PS) beads (100 nm in size) with different NP concentrations (1, 5, and 10 mg/L). BIOLOG ECO microplates were used to quantify carbon source utilization characteristics. The data were analyzed using average well-color development (AWCD), functional diversity indices, and principle component analysis (PCA).

Miao, L., et al. (2019). "Acute effects of nanoplastics and microplastics on periphytic biofilms depending on particle size, concentration and surface modification." Environmental Pollution **255**(Pt 2): 113300.

Microplastics (MPs) can disintegrate into smaller sized microplastics and even nanoplastics (NPs). The toxicity of nanoplastics and microplastics on freshwater organisms have been well explored recently, however, very little is known about the potential impacts of NPs on freshwater biofilms, which are essential for primary production and nutrient cycling in aquatic ecosystems. In this study, we studied the acute effects (3h of exposure) of polystyrene beads (PS, with diameter range from 100nm to 9mum) on five biological endpoints targeting community and ecosystem-level processes in biofilms: chlorophyll a, photosynthetic yield, and three extracellular enzyme activities. The results showed that the large size PS beads (500nm, 1mum, and 9mum) exhibited negligible effects on the determined biological endpoints in biofilms within the range of concentrations (5-100mg/L) in this study. However, high concentration of PS beads (100nm, 100mg/L) significantly decreased the content of chlorophyll a, and the functional enzyme activities of beta-glucosidase and leucine aminopeptidase, suggesting negative effects on the carbon and nitrogen cycling of freshwater biofilms. Moreover, the influences of PS NPs (100nm) on biofilms strongly depended on the surface modification of PS particles, with the positively charged PS NPs (amide-modified) exhibiting the highest toxicity to biofilms. The excess generation of reactive oxygen species (ROS) in this study indicated oxidative stress induced by PS NPs, which might lead to the observed nano-toxic effects on biofilms. In response, the antioxidant activity of biofilm was enhanced as indicated by the increased total antioxidant capacity (T-AOC). Overall, our findings highlight nanoplastics have potential to disrupt the basic ecological functions of biofilms in aquatic environments.

Miceli, A., et al. (2008). "Influence of greenhouse Volume/Area ratio on soil solarization efficiency." Acta Horticulturae **801**(Vol 1): 211-218.

Soil temperature under plastic cover is a function of incoming radiation and thermal characteristics of the mulching material and the soil, but it could be also affected by greenhouse characteristics (structure, cover, volume:area ratio). The aim of this research was to evaluate the effects of different greenhouse unitary volumes and different plastic mulching on soil temperature and soil solarization efficiency. The experiment was carried out in non-heated greenhouses covered with low density transparent polyethylene (PE), located at the experimental field of AAT Department of Palermo University, Italy. Four volume:area (V/A) ratios were tested: 1.5, 2.0, 2.5 and 3.0. Individual plots were covered with transparent or black PE film from the end of July till the end of August (30 days) in 2003, 2004 and 2005. Results showed a good efficiency of soil solarization under closed greenhouse and confirmed other studies. Maximum soil temperatures were increased solarizing under greenhouse with V/A 2.5 ratio. Plots mulched with transparent PE film reached higher soil temperatures than those mulched with black PE. Nevertheless, black PE mulching under high V/A ratio greenhouses allowed to keep soil temperature over threshold values lethal for soilborne pathogens and seeds. Black PE film could be used and left on the soil even after solarization as crop mulching, saving money for mulching replacement and reducing plastic waste.

Miceli-Richard, C., et al. (2016). "Overlap between differentially methylated DNA regions in blood B lymphocytes and genetic at-risk loci in primary Sjogren's syndrome." Annals of the Rheumatic Diseases **75**(5): 933-940.

BACKGROUND: Beyond genetics, epigenetics alterations and especially those related to DNA methylation, play key roles in the pathogenesis of autoimmune diseases such as primary Sjogren's syndrome (pSS) and systemic lupus erythematosus. This study aimed to assess the role of methylation deregulation in pSS pathogeny through a genome-wide methylation approach.

PATIENTS AND METHODS: 26 female patients with pSS and 22 age-matched controls were included in this study. CD4+ T cells and CD19+ B cells were isolated from peripheral blood mononuclear cells by magnetic microbeads and their genome-wide DNA methylation profiles were analysed using Infinium Human Methylation 450 K BeadChips. Probes with a median DNA methylation difference of at least 7% and $p<0.01$ between patients and controls were considered significantly differentially methylated.

RESULTS: Methylation alterations were mainly present in B cells compared with T cells. In B cells, an enrichment of genes with differentially methylated probes in genetic at-risk loci was observed, suggesting involvement of both genetic and epigenetic abnormalities in the same genes. Methylation alterations in B cells were more frequent in some specific pathways including Interferon Regulated Genes, mainly among patients who were autoantibody positive. Moreover, genes with differentially methylated probes were over-represented in B cells from patients with active disease.

CONCLUSIONS: This study demonstrated more important deregulation of DNA methylation patterns in B cells compared with T cells, emphasising the importance of B cells in the pathogenesis of the disease. Overlap between genes with differentially methylated probes in B lymphocytes and genetic at-risk loci is a new finding highlighting their importance in pSS.

Michael, D. (2003). Biopolymers from crops: their potential to improve the environment. Horsham, Solutions for a better environment
Australian Society of Agronomy Inc , Victorian Institute for Dryland Agriculture**:** 0-4 2 ref.

Development of a bio-plastics industry in Australia has the potential to benefit the environment and Australian agriculture by creating new markets for existing and new crops and increased competition at the farm-gate. Bio-plastics might also benefit the Australian plastics industry a lot more than it currently thinks it would! The worldwide interest in renewable resources, reduced greenhouse gas emissions and more efficient and effective management of waste has created renewed interest in bio-plastics. The immediate problem for Australia is that the bio-plastics industry does not exist here. But the raw materials, plant breeding expertise, molecular scientists and biochemists are here to develop one. And there are over 2000 synthetic plastic resin converters operating here. A systematic and coordinated industry development programme, with significant investments in resin plants and strategic research is required.

Michel, J., et al. (2017). "Effect of titanium disks, micro beads and nanoparticles on the expression of metallothioneins and bactericidal activity in human monocyte-derived macrophages." European Journal of Immunology **47 (Supplement 2)**: 137.

Introduction: Titanium is widely used as implant material in a great variety of medical applications. Macrophages are crucial regulators of the foreign body response and related inflammation. Metallothioneins (MT) are responsible for the trace metal homeostasis, heavy metal detoxification, and downregulation of inflammatory response during the bacterial clearance. However the effect of titanium on the MT expression and function in human

macrophages was no addressed to date. Objective(s): Our study aimed to investigate whether titanium disks with polished or porous surfaces, micro-and nanoparticles induce the expression of MT family, and to examine how overexpression of MTs affects intracellular zinc homeostasis, bacterial killing and phagocytic capacity of macrophages. Material(s) and Method(s): Primary human CD14+ monocytes were isolated from buffy coats of healthy blood donors, cultured with titanium disks, or exposed to titanium micro-or nanoparticles. Three subtypes of macrophages were generated: M0 (no cytokines), M1 (IFNgamma stimulated) and M2 (IL-4 stimulated). RT-PCR was used to quantify mRNA levels of MTs. The level of intracellular zinc was determined with FluoZinTM-3 by flow cytometry. The intracellular bacterial killing was analysed with a gentamicin protection assay. Phagocytic activity was quantified by flow cytometry using fluorescent beads. Result(s): MT-1F, MT-1G and MT-1X were induced on mRNA level in M0, M1 and M2 propagated on the titanium disks (polished and porous), or exposed to titanium micro beads. Exposure of macrophages to titanium nanoparticles did not induce MT overexpression. Despite strong upregulation of MT expression, the intracellular zinc levels remain stable in macrophages cultured on titanium disks. Propagation of M1 on titanium disks enhanced MT related bactericidal activity. In contrast, titanium nanoparticles, that were unable to induce MT expression, impaired the bactericidal capacity in M1. Phagocytic capacity of M1 was not affected by titanium disks or particles. Bacterial infection induced secretion of IL-1beta and TNFalpha in M1 independently on titanium; in M0 and M2 the release of IL-1beta and TNFalpha was enhanced by titanium nanoparticles. Conclusion(s): Our data suggests that the upregulation of MTs by titanium disks have a compensatory effect on the intracellular zinc homeostasis and also by micro beads supports intracellular bacterial clearance under inflammatory conditions without enhancing the inflammatory response.

Michels, J., et al. (1885). "Rapid aggregation of biofilm-covered microplastics with marine biogenic particles." Proceedings of the Royal Society of London Series B: Biological Sciences **285**(1885): 29.

Ocean plastic pollution has resulted in a substantial accumulation of microplastics in the marine environment. Today, this plastic litter is ubiquitous in the oceans, including even remote habitats such as deep-sea sediments and polar sea ice, and it is believed to pose a threat to ecosystem health. However, the concentration of microplastics in the surface layer of the oceans is considerably lower than expected, given the ongoing replenishment of microplastics and the tendency of many plastic types to float. It has been hypothesized that microplastics leave the upper ocean by aggregation and subsequent sedimentation. We tested this hypothesis by investigating the interactions of microplastics with marine biogenic particles collected in the southwestern Baltic Sea. Our laboratory experiments revealed a large potential of microplastics to rapidly coagulate with biogenic particles, which substantiates this hypothesis. Together with the biogenic particles, the microplastics efficiently formed pronounced aggregates within a few days. The aggregation of microplastics and biogenic particles was significantly accelerated by microbial biofilms that had formed on the plastic surfaces. We assume that the demonstrated aggregation behaviour facilitates the export of microplastics from the surface layer of the oceans and plays an important role in the redistribution of microplastics in the oceans.

Michielssen, M. R., et al. (2016). "Fate of microplastics and other small anthropogenic litter (SAL) in wastewater treatment plants depends on unit processes employed." Environmental Science: Water Research & Technology **2**(6): 1064-1073.

The accumulation of microplastics (plastic particles less than 5 mm) and similarly sized small anthropogenic litter (SAL; e.g., cellulosic products manufactured from natural material) in aquatic ecosystems is a growing concern. These particles can serve as vectors of chemical toxins and microbial pathogens and thus, as organisms consume them, may lead to biomagnification of these contaminants. As collection points in managed water systems, wastewater treatment plants (WWTPs) provide an opportunity to develop and implement novel technologies to manage SAL pollution. Here, we assessed the efficiency of different unit processes at three WWTPs in removing SAL. Samples were collected from WWTPs that employ either secondary treatment (activated sludge) or tertiary treatment (granular sand filtration) as a final step, as well as a pilot membrane bioreactor system that finishes treatment with microfiltration. SAL from 20 micro m to 4.75 mm was quantified and categorized by shape. The WWTP with secondary treatment removed 95.6% of SAL, discharging 5.9 SAL per L in the final effluent; the plant with tertiary treatment removed 97.2% of SAL, discharging 2.6 SAL per L; the membrane bioreactor plant removed 99.4% of SAL, discharging 0.5 SAL per L. The majority of SAL in effluent from all plants was comprised of thin fibers (e.g., textile fibers). While the WWTP with tertiary granular sand filtration and the membrane bioreactor exhibited greater overall removal of SAL, fibers represented a larger percentage of SAL in effluent from these plants (79 and 83%, respectively) than the plant with activated sludge as a final step (44% fibers). This study suggests that retrofitting existing secondary WWTPs with granular sand filtration or membrane filtration would result in the highest possible removal of SAL - though treatment facilities would continue to serve as pathways of SAL pollution to the environment. Further, the fate of the 95-99% of SAL that is retained or leaves WWTPs through means other than effluent (e.g., sludge) must be resolved to effectively address this problem.

Miel, R. (2009). "Legally, recycling's road is a bumpy one." Waste & Recycling News **15**(14): 16-11NULL.
The article informs that post-consumer recycling stream of the plastics industry is facing some challenges. Elizabeth Bedard, director of the Association of Postconsumer Plastic Recyclers' rigid plastics recycling program, said that poor infrastructure for collecting and reusing plastics hampers the ability for businesses to make a real business case for recycling. The U.S. Federal Trade Commission cracks down on companies that make false environmental claims about their products

Mifune, J., et al. (2009). "Production of Functionalized Biopolyester Granules by Recombinant Lactococcus lactis." Applied and environmental microbiology **75**(14): 4668-4675.
Many bacteria are naturally capable of accumulating biopolyesters composed of 3-hydroxy fatty acids as intracellular inclusions, which serve as storage granules. Recently, these inclusions have been considered as nano-/microbeads with surface-attached proteins, which can be engineered to display various protein-based functions that are suitable for biotechnological and biomedical applications. In this study, the food-grade, generally-regarded-as-safe gram-positive organism Lactococcus lactis was engineered to recombinantly produce the biopolyester poly(3-hydroxybutyrate) and the respective intracellular inclusions. The codon-optimized polyhydroxybutyrate biosynthesis operon phaCAB from Cupriavidus necator was expressed using the nisin-controlled gene expression system. Recombinant L. lactis accumulated up to 6% (wt/wt) poly(3-hydroxybutyrate) of cellular dry weight. Poly(3-hydroxybutyrate) granules were isolated and analyzed with respect to bound proteins using biochemical methods and with respect to shape/size using transmission electron microscopy. The immunoglobulin G (IgG) binding ZZ domain of Staphylococcus aureus protein A was chosen as an exemplary functionality to be displayed at the granule surface by fusing it to the N terminus of the granule-associated poly(3-hydroxybutyrate) synthase. The presence of the fusion protein at the surface of isolated granules was confirmed by peptide fingerprinting using matrix-assisted laser desorption ionization-time of flight (mass spectrometry). The functionality of the ZZ domain-displaying

granules was demonstrated by enzyme-linked immunosorbent assay and IgG affinity purification. In both assays, the ZZ beads from recombinant L. lactis performed at least equally to ZZ beads from Escherichia coli. Overall, in this study it was shown that recombinant L. lactis can be used to manufacture endotoxin-free poly(3-hydroxybutyrate) beads with surface functionalities that are suitable for biomedical applications.

Miller, B. B., et al. (2002). "Trace Element Emissions from Co-combustion of Secondary Fuels with Coal: A Comparison of Bench-Scale Experimental Data with Predictions of a Thermodynamic Equilibrium Model." Energy & Fuels **16**(4): 956-963.

Trace element emissions from the co-combustion of coal with biomass and waste secondary fuels have been measured, under conditions relevant to commercial fluidized bed combustors, using a novel, bench-scale, suspension-firing reactor. Experiments have been conducted using two coals (one Polish, one Colombian), four biomass fuels (wood-bark, straw, pulp sludge, and paper sludge), and three waste fuels (agricultural waste, sewage sludge and plastic waste). Concentrations of eighteen trace elements have been measured in these raw fuels and a variety of combustion and co-combustion ashes, using inductively coupled plasma-mass spectrometry (ICP-MS) and inductively coupled plasma-atomic emission spectroscopy (ICP-AES), plus an atomic absorption based mercury determination devise. The influence of chlorine and sulfur on trace element release from combustion has been tested also, in the case of wood-bark, by injecting first HCl and then SO2 into the reactor during combustion. Experimental data have been compared with the predictions of a thermodynamic equilibrium model throughout this study. The Metallurgical and Thermochemical Databank (MTDATA) Gibbs free energy minimization software has been used to predict the speciation of individual trace elements. The trace elements have been ranked according to their average retention in combustion ashes, the most volatile being Hg and Se, followed by Cd, Tl, Pb, and As. Potentially problematic trace element emissions have been noted in certain cases, e.g., Cu and Zn from wood-bark, As and Pb from Polish coal, and Cd and Hg from sewage sludge. The injection of HCl served to decrease the retention by ash of the elements Cd, Cu, Zn, Mn, and Ba, while injection of SO2 increased the retention by ash of As and Hg, but decreased that of Cd.

Miller, C. (1992). "Polyethylene terephthalate." Waste Age **23**(9): 73-76.

This is the fourth in a series of profiles--brief, factual listings of the solid waste management characteristics of materials in the waste stream. These profiles highlight a product, explain how it fits into integrated waste management systems, and provide current data on recycling and markets for the product. Polyethylene terephthalate (PET) is a plastic resin used primarily to make soft drink bottles. Peanut butter, salad dressing, and other household and consumer products are also packaged in PET bottles. Other forms of PET packaging include trays, sheeting for cups and food trays, etc.

Miller, C. (2006). "Polyethylene Terephthalate." Waste Age **37**(4): 84-84.

The article provides information on polyethylene Terephthalate (PET), a plastic resin used to make bottles for soft drinks and other consumer products. The PET bottle was patented in 1973 and after four years, the first PET bottle was recycled. PET is one of the most highly valued plastic recyclables because it is expensive to produce. Because PET has replaced heavier steel and glass containers, PET use has reduced the size of the waste stream. Various PET packaging municipal solid waste facts are also presented.

Miller, C. (2007). "Polyethylene Terephthalate." Waste Age **38**(11): 51-51.

The article provides information on polyethylene terephthalate (PET) and looks at how it has helped reduce the size of the waste stream. PET is a plastic resin used to make bottles for soft drinks and other household and consumer products. PET is a relatively new packaging resin. The PET bottle was patented in 1973. Four years later, the first PET bottle was recycled. Soft drink bottles remain the biggest user of PET resin. PET use has reduced the size of the waste stream because PET has replaced heavier steel and glass containers.

Miller, C. (2009). "Polyethylene Terephthalate." Waste Age **40**(6): 102-102.
The article offers information on polyethylene terephthalate (PET). It is a plastic resin used to make bottles for soft drinks and other household and consumer products. It as patented in 1973 and after four years, the first PET bottle was recycled. The use of PET has reduced the size of waste stream since PET has replaced heavier steel and glass containers.

Miller, C. (2012). "Polyethylene Terephthalate." Waste Age **43**(11): 46-46.
The article focuses on polyethylene terephthalate (PET), a plastic resin which is used to make bottles for food, beverages, and other consumer products.

Miller, C. (2019). "My 2020 Vision." Waste360: N.PAG-N.PAG.
Markets remain daunting as we continue to deal with the fallout from China's decision to ban mixed paper and mixed plastic imports. The good news is that while China is banning imports of mixed recycled plastics, it is not banning imports of recycled plastic resin and pellets. Food waste recovery legislation aimed at restaurants, groceries and other large food waste generators will be popular at the state and local level. [Extracted from the article]

Miller, M., et al. (2018). "Marine debris trends: 30 years of change on Ventura County and Channel Island beaches." Western North American Naturalist **78**(3): 328-340.
The persistence of plastics in marine ecosystems and the physical hazards marine debris pose to wildlife have become issues of global concern. The Santa Barbara Channel is home to a number of important marine and coastal ecosystems, including the 5 islands of Channel Islands National Park, and has a variety of factors that influence marine debris accumulation. We examined the spatial variation of marine debris density and composition across the Santa Barbara Channel by quantifying marine debris on beaches of Santa Rosa and Santa Cruz Islands and the Ventura County mainland. Debris from surveyed beaches was cataloged, weighed, and measured to compare differences in island and mainland marine debris abundance, density, and composition. Derelict fishing gear accounted for a higher proportion of marine debris on island beaches compared to mainland beaches, and marine debris items on island beaches were significantly heavier compared to debris items on mainland beaches. The majority of debris on mainland beaches comprised smaller plastic fragments and single-use plastic items, and debris accumulation rates varied by season and location. Microplastics (plastic fibers and particles <5 mm) were found in the sand of all island and mainland beaches; however, density of microplastics did not appear to correlate with density of visually observable debris items (>25 mm) that were collected during marine debris cleanups. We compared our data from 2015 and

2016 with historical surveys performed from 1989 to 1994 to examine the temporal variation of marine debris on Santa Rosa Island. We found that there has been a significant increase in the amount of derelict fishing gear found on Santa Rosa Island over the past 27 years, which mirrors expansion of the California spiny lobster (Panulirus interruptus) fishery. This study highlights the importance of marine debris monitoring, as local changes in policy, fisheries, and consumer culture are reflected in accumulations of marine debris found on the California mainland and the uninhabited Channel Islands. Monitoring marine debris can provide insight into anthropogenic impacts and is a useful mechanism in monitoring the health of coastal and marine ecosystems.Alternate abstract:La presencia de plástico en los ecosistemas marinos, así como la amenaza que los desechos marinos significan para la vida silvestre se han convertido rápidamente en un problema global. El canal de Santa Barbara es hogar de un gran número de ecosistemas marinos y costeros, los cuales incluyen a las cinco islas que forman parte del parque nacional "Channel Islands," el cual consta de una gran variedad de factores que influyen en la acumulación de dichos desechos. Cuantificamos los desechos marinos de las playas en las islas Santa Rosa y Santa Cruz, así como en la costa del condado de Ventura para examinar la variación espacial en la densidad y composición de desechos marinos a lo largo del canal de Santa Barbara. Los desechos obtenidos en dichas playas fueron catalogados, pesados y medidos con el fin de comparar la diferencia en abundancia, densidad y composición de los desechos entre las playas de las islas y del condado. Notamos que los desechos en las playas de las islas tienden a ser más pesados y a contar con una mayor cantidad de equipo de pesca abandonado que las playas del condado, las cuales contaban con plásticos más pequeños y desechables, y cuya acumulación varía mucho dependiendo de la estación y la localización de la playa. Encontramos micro plásticos (fibras de plástico y partículas <5 mm) en la arena de todas las playas que fueron estudiadas, sin embargo, la densidad de plástico no parece estar correlacionada con la densidad de objetos más grandes (>25 mm) que fueron recolectados en días de recolección de desechos marinos en las playas de nuestro estudio. También comparamos nuestros resultados con encuestas científicas realizadas entre 1989 y 1994 para examinar la variación temporal de desechos en la isla de Santa Rosa y encontramos que ha habido un incremento significativ en la cantidad de equipo de pesca abandonado que ha sido encontrado en los últimos 27 años en ésta isla, lo cual refleja el rápido crecimiento de la industria pesquera enfocada en las langostas de California. Éste estudio hace hincapié en la importancia del monitoreo de desechos marinos, ya que los cambios en la industria pesquera, implementación o cambios en leyes y la cultura del consumidor son reflejadas en la acumulación de dichos desechos en la costa de California y hasta en las islas "Channel Islands," que son inhabitadas, también, dicho monitoreo puede brindar información en impactos antropogénicos, y ayudar a supervisar la salud de los ecosistemas tanto costeros como marinos.

Miller, M. E., et al. (2017). "Recovering microplastics from marine samples: A review of current practices." Marine Pollution Bulletin **123**(1-2): 6-18.

An important component of microplastic research is development of reproducible methods for microplastic recovery and characterization. Presented is a review of the literature comparing microplastic separation and identification methodologies from seawater, sediment and marine organisms. The efficiency of methods was examined, including processing time, recovery rates, and potential destruction of microplastics. Visual examination and acid digestion were the most common separation methods for seawater samples and organisms, while density flotation was the primary method for sediment. Few studies reported recovery rates, or investigated the physical or chemical impact on plastics. This knowledge gap may lead to misidentification of plastic or unreliable pollution estimates. Further investigation of the impact chemical

treatments have on plastic is warranted. Factors, i.e. biomass loading, recovery rates, and chemical compatibility, must be considered to allow for appropriate methodology. Standardizing this will contribute to efficient sample processing, and allow for direct comparison of microplastic contamination across environments. Copyright © 2017

Miller, R. Z., et al. (2017). "Mountains to the sea: River study of plastic and non-plastic microfiber pollution in the northeast USA." Marine Pollution Bulletin **124**(1): 245-251.

Aquatic environments are sinks for anthropogenic contamination, whether chemical or solid pollutants. Microfibers shed from clothing and other textiles contribute to this problem. These can be plastic or non-plastic origin. Our aim was to investigate the presence and distribution of both types of anthropogenic microfibers along the length of the Hudson River, USA. Surface grab samples were collected and filtered through a 0.45mum filter paper. Abundance of fibers was determined after subtraction of potential contamination. 233 microfibers were recorded in 142 samples, averaging 0.98microfibersL⁻¹. Subsequent micro-FTIR showed half of the fibers were plastic while the other half were non-plastic, but of anthropogenic origin. There was no relationship between fiber abundance, wastewater treatment plant location or population density. Extrapolating from this data, and using available hydrographic data, 34.4% of the Hudson River's watershed drainage area contributes an average 300 million anthropogenic microfibers into the Atlantic Ocean per day.

Miller, S., et al. (2019). "Electroosmotic flow driven microfluidic device for bacteria isolation using magnetic microbeads." Scientific Reports **9**(1): 14228.

The presence of bacterial pathogens in water can lead to severe complications such as infection and food poisoning. This research proposes a point-of-care electroosmotic flow driven microfluidic device for rapid isolation and detection of E. coli in buffered solution (phosphate buffered saline solution). Fluorescent E. coli bound to magnetic microbeads were driven through the microfluidic device using both constant forward flow and periodic flow switching at concentrations ranging from 2 x 10⁵ to 4 x 10⁷ bacteria/mL. A calibration curve of fluorescent intensity as a function of bacteria concentration was created using both constant and switching flow, showing an increase in captured fluorescent pixel count as concentration increases. In addition, the use of the flow switching resulted in a significant increase in the capture efficiency of E. coli, with capture efficiencies up to 83% +/- 8% as compared to the constant flow capture efficiencies (up to 39% +/- 11%), with a sample size of 3 micro L. These results demonstrate the improved performance associated with the use of the electroosmotic flow switching system in a point-of-care bacterial detection assay.

Min, J. H., et al. (2014). "Isolation of DNA using magnetic nanoparticles coated with dimercaptosuccinic acid." Analytical Biochemistry **447**: 114-118.

Lately, the isolation of DNA using magnetic nanoparticles has received increased attention owing to their facile manipulation and low costs. Although methods involving their magnetic separation have been extensively studied, there is currently a need for an efficient technique to isolate DNA for highly sensitive diagnostic applications. We describe herein a method to isolate and purify DNA using biofunctionalized superparamagnetic nanoparticles synthesized by a modified polyol method to obtain the desired monodispersity, followed by surface modification with meso-2,3-dimercaptosuccinic acid (DMSA) containing carboxyl groups for DNA absorption. The DMSA-coated magnetic nanoparticles (DMSA-MNPs) were used for the isolation of DNA, with a maximum yield of 86.16%. In particular, we found that the isolation of DNA using small quantities of DMSA-MNPs was much more efficient than that using commercial microbeads

(NucliSENS-easyMAG, BioMerieux). Moreover, the DMSA-MNPs were successfully employed in the isolation of genomic DNA from human blood. In addition, the resulting DNA-nanoparticle complex was directly subjected to PCR amplification without prior elution, which could eventually lead to simple, rapid, sensitive and integrated diagnostic systems.

Minamoto, K., et al. (2002). "Skin problems among fiber-glass reinforced plastics factory workers in Japan." Industrial Health **40**(1): 42-50.

Two surveys, one in winter the other in summer time, examined the skin problems of the entire manual workers (N=148) from 11 small-to-medium sized fiber-glass reinforced plastics (FRP) factories located in Kyushu, Japan. The workers were exposed to unsaturated polyester resin, including styrene and auxiliary agents such as cobalt naphthenate, hardeners such as methyl ethyl ketone peroxides, glass fiber and dust including shortened glass fiber and plastic particles. Eighty-seven workers (58.8%) reported having skin problems (mainly itching or dermatitis) since they started to work in FRP manufacturing and 25 workers had consulted a physician because of their skin problems; one worker was forced to take sick leave because of his severe dermatitis. History of allergic diseases and shorter occupational period (duration of employment) in a FRP factory were associated with greater probability of having a history of work-related skin symptoms. Workers in factories where dust-generating and lamination sites were located in different buildings were significantly less likely to have a history of skin problems than those in factories where the two sites were located in the same building. Of the 67 workers examined in both seasons closed to double the prevalence of dermatitis was found in summer (23.3%) than winter (13.4%).

Minhas, N. A. (1996). "RECYCLING IN THE FAR EAST - A STUDY OF COTTON WASTE." Recycling Textile & Plastic Waste: 121-126.

The article discusses a case study on cotton waste recycling as the textile industry believes that cotton will become scarcer and more expensive due to population growth and occasional crop failures. In India and China, acute shortage of cotton supplies has occurred of which the actual shortfall was about 1.5 million bales. Using the locally-made machine, it resulted to excessive fiber damage to the material being processed. Experience tells that cotton waste recovered on local Willey and wasteopeners is good enough for subsequent processing. It was illustrated that waste processing offers great opportunities for textile processors in Asia using locally-made machinery and that the recycled fibers may be used wholly or as blends.

Miniati, A., et al. (2014). "Stimulated human melanocytes express and release interleukin-8, which is inhibited by luteolin: relevance to early vitiligo." Clinical & Experimental Dermatology **39**(1): 54-57.

Vitiligo is a disorder of depigmentation, for which the pathogenesis is as yet unclear. Interleukin (IL)-8 (CXCL8) is a key inflammatory chemokine. We investigated the regulation of IL-8 production in human melanocytes, and the IL-8 serum levels and skin gene expression in patients with vitiligo and in controls. Cultured melanocytes were stimulated for 24 h with tumour necrosis factor (TNF) 100 ng/mL and IL-1beta 10 ng/mL, with or without pretreatment with luteolin 50 mumol/L for 30 min, and IL-8 release was measured by ELISA. Serum cytokines were measured by a microbead array. Skin biopsies were taken from healthy subjects (n = 14) as well as from marginal lesional and nonlesional skin from patients with vitiligo (n = 15). IL-8 gene expression was evaluated by quantitative real time PCR. Both TNF and IL-1beta stimulated significant IL-8 release (P < 0.01) from melanocytes, whereas pretreatment with luteolin significantly inhibited this effect (P < 0.01). IL-8 gene expression was significantly increased in vitiligo compared with control skin (P < 0.05). IL-8 may be involved in vitiligo inflammation.

Inhibition by luteolin of IL-8 release could be useful for vitiligo therapy.

Mintenig, S. M., et al. (2018). "Closing the gap between small and smaller: towards a framework to analyse nano- and microplastics in aqueous environmental samples." Environmental Science: Nano **5**(7): 1640-1649.

Measuring concentrations and sizes of micro- and nanoplastics in the environment is essential to assess the risks plastic particles could pose. Microplastics have been detected globally in a variety of aquatic ecosystems. The determination of nanoplastics, however, is lagging behind due to higher methodological challenges. Here, we propose a framework that can consistently determine a broad spectrum of plastic particle sizes in aquatic environmental samples. Analytical evidence is provided as proof of principle. FTIR microscopy is applied to detect microplastics. Nanoplastics are studied using field-flow-fractionation and pyrolysis GC-MS that gives information on the particle sizes and polymer types. Pyrolysis GC-MS is shown to be promising for the detection of nanoplastics in environmental samples as a mass of approximately 100 ng is required to identify polystyrene. Pre-concentrating nanoplastics by crossflow ultrafiltration enables polystyrene to be identified when the original concentration in an aqueous sample is >20 micro g L⁻¹. Finally, we present an approach to estimate polymer masses based on the two-dimensional microplastic shapes recorded during the analysis with FTIR microscopy. Our suite of techniques demonstrates that analysis of the entire size spectrum of plastic debris is feasible.

Mintenig, S. M., et al. (2017). "Identification of microplastic in effluents of waste water treatment plants using focal plane array-based micro-Fourier-transform infrared imaging." Water Research **108**: 365-372.

The global presence of microplastic (MP) in aquatic ecosystems has been shown by various studies. However, neither MP concentrations nor their sources or sinks are completely known. Waste water treatment plants (WWTPs) are considered as significant point sources discharging MP to the environment. This study investigated MP in the effluents of 12 WWTPs in Lower Saxony, Germany. Samples were purified by a plastic-preserving enzymatic-oxidative procedure and subsequent density separation using a zinc chloride solution. For analysis, attenuated total reflection Fourier-transform infrared spectroscopy (ATR-FT-IR) and focal plane array (FPA)-based transmission micro-FT-IR imaging were applied. This allowed the identification of polymers of all MP down to a size of 20 mu m. In all effluents MP was found with quantities ranging from 0 to 5 101 m-3 MP > 500 mu m and 1 101 to 9 103 m-3 MP < 500 mu m. By far, polyethylene was the most frequent polymer type in both size classes. Quantities of synthetic fibres ranged from 9 101 to 1 103 m-3 and were predominantly made of polyester. Considering the annual effluxes of tested WWTPs, total discharges of 9 107 to 4 109 MP particles and fibres per WWTP could be expected. Interestingly, one tertiary WWTP had an additionally installed post-filtration that reduced the total MP discharge by 97%. Furthermore, the sewage sludge of six WWTPs was examined and the existence of MP, predominantly polyethylene, revealed. Our findings suggest that WWTPs could be a sink but also a source of MP and thus can be considered to play an important role for environmental MP pollution.

Mintenig, S. M., et al. (2019). "Low numbers of microplastics detected in drinking water from ground water sources." Science of the Total Environment **648**: 631-635.

Microplastic particles have been detected in various natural habitats and the digestive tracts of several species. These particles have also been reported in commercially available seafood, salt or bottled water starting discussions on potential implications for human health. To be able to assess the related risks, exposure concentrations and pathways need to be known. Here, we analysed ground water and drinking water for the presence of microplastics (>20mum) using FTIR imaging. Samples were taken at different positions within the drinking water supply chain. Determined concentrations ranged from 0 to 7microplasticsm⁻³ raw water or drinking water with an overall mean of 0.7microplasticsm⁻³. These particles were identified as polyethylene, polyamide, polyester, polyvinylchloride or epoxy resin and between 50 and 150mum in size. Plastic is a resistant and durable material, still, the abrasion of plastic equipment used during water purification or transport is a likely explanation for the plastic particles detected in water samples.

Miraj, S. S., et al. (2019). "Plastic microbeads: small yet mighty concerning." International Journal of Environmental Health Research: 1-17.

The net use of plastic has increased and this augmentation in plastic usage results in ever-growing accumulation of plastic waste in our ecosystems. Regrettably, a portion of this waste is the microplastics including microbeads, which are tiny plastic particles <5 mm in diameter. Microbeads are used in our personal care products. Although, legislative ban of microbeads in some developed countries has proven effective, but many countries do not take any legal action. Hence, microbead-containing products are openly sold in international market and entered into the food chain and disturb it. In human beings and animals, plastic when ingested causes internal bleeding, abrasion, ulcers and blockage of the digestive tract. The present review highlighted the bioaccumulation of microbeads via the food chain and its adverse effect on environment health. Moreover, different scientific views and suggestions for eradication of the problem and present scenario of the use of microbeads in some Asian countries have also been discussed.

Miranda, D. d. A. and G. F. d. Carvalho-Souza (2016). "Are we eating plastic-ingesting fish?" Marine Pollution Bulletin **103**(1/2): 109-114.

Yes, we are eating plastic-ingesting fish. A baseline assessment of plastic pellet ingestion by two species of important edible fish caught along the eastern coast of Brazil is described. The rate of plastic ingestion by king mackerel (Scomberomorus cavalla) was quite high (62.5%), followed by the Brazilian sharpnose shark (Rhizoprionodon lalandii, 33%). From 2 to 6 plastic resin pellets were encountered in the stomachs of each fish, with sizes of from 1 to 5 mm, and with colors ranging from clear to white and yellowish. Ecological and health-related implications are discussed and the potential for transferring these materials through the food-chain are addressed. Further research will be needed of other species harvested for human consumption.

Miranda, M. N., et al. (2019). "Microplastics in the environment: A DPSIR analysis with focus on the responses." Science of the Total Environment: 134968.

This review organizes key information about microplastic pollution through a DPSIR (driving forces, pressures, states, impacts and responses) analysis, namely the current knowledge on the sources of microplastics in the environment, the abundance, mobility and fate of microplastics distributed across the different environmental compartments, as well as their socio-economic and environmental impacts. The available or developing upstream and downstream responses to the microplastic pollution are also reviewed as part of the DPSIR analysis. These include the regulatory and policy instruments, environmental education campaigns, product design, the development of biodegradable plastics, environmental cleanups, waste management, drinking water and wastewater treatment plants, and other treatment technologies and processes. Whenever possible, the current trends and discerning gaps in the research conducted so far by the scientific community are identified, giving some clues to what is going to be the future

research on this topic and into new lines of research.

Miranda, T., et al. (2019). "Neurotoxicity, Behavior, and Lethal Effects of Cadmium, Microplastics, and Their Mixtures on Pomatoschistus microps Juveniles from Two Wild Populations Exposed under Laboratory Conditions-Implications to Environmental and Human Risk Assessment." International Journal of Environmental Research & Public Health [Electronic Resource] **16**(16): 10.

Microplastics (MPs) were found to modulate the toxicity of other pollutants but the knowledge on the topic is still limited. The goals of this study were to investigate the short-term toxicity of cadmium (Cd) to wild Pomatochistus microps juveniles, the potential modulation of acute Cd toxicity by 1-5 micro m polyethylene MPs in this species, and possible differences of sensitivity to Cd and MPs-Cd mixtures between juveniles from two distinct wild populations. Juveniles were collected in the estuaries of Minho (M-est) and Lima (L-est) Rivers (NW Portugal). One 96 h bioassay with M-est juveniles and another one with L-est juveniles were carried out in laboratory conditions. Each bioassay had 12 treatments: control, 5 Cd concentrations, 1 MPs concentration, and 5 MPs-Cd mixtures. No significant differences in Cd-induced mortality between juveniles from distinct estuaries or between juveniles exposed to Cd alone and those exposed to MPs-Cd mixtures were found. The total 96h LC₁₀ and LC₅₀ of Cd alone were 2 mg/L (95% CI: 0-4 mg/L) and 8 mg/L (95% CI: 2-17 mg/L), respectively. Cd alone significantly decreased the post-exposure predatory performance (PEPP) of M-est (>=6 mg/L) and L-est juveniles (>=3 mg/L), and acetylcholinesterase (AChE) activity of M-est juveniles (13 mg/L). MPs alone (0.14 mg/L) significantly reduced the PEPP and AChE activity of L-est juveniles but not of M-est juveniles. MPs-Cd mixtures (3-13 mg/L of Cd + 0.14 mg/L of MPs) significantly inhibited the PEPP of juveniles from both estuaries and AChE of L-est estuary juveniles but not of M-est juveniles. Evidences of toxicological interactions, namely antagonism, between MPs and Cd were found. Overall, the results indicate that MPs modulated the sub-lethal toxic effects of Cd in wild P. microps juveniles, especially neurotoxicity. Moreover, the environmental conditions of the natural habitats to which juveniles were exposed during pre-developmental phases influence the sub-lethal toxicity of Cd, MPs, and their mixtures. The implications to environmental and human risk assessment are discussed and further research is needed.

Mirdamadi, E. S., et al. (2020). "Liver Tissue Engineering as an Emerging Alternative for Liver Disease Treatment." Tissue Engineering Part B Reviews **17**: 17.

Chronic liver diseases affect thousands of lives throughout the world every year. The shortage of liver donors for transplantation has been the main driving force to employ alternative methods such as liver tissue engineering (LTE) in fabricating a three-dimensional transplantable liver tissue or enhancing cell delivery techniques alleviating the need for liver donors. LTE consists of three components, cells, ECM (extracellular matrix), and signaling molecules, which we discuss the first and second. The three most common cell sources used in LTE are human and animal primary hepatocytes, and stem cells for different applications. Two major categories of ECM are used to mimic the microenvironment of these cells, named scaffolds and microbeads. Scaffolds have been made by numerous methods with a wide range of synthetic and natural biomaterials. Cell encapsulation has also been utilized by many polymeric biomaterials. To investigate their functions, many properties have been discussed in the literature, such as biochemical, geometrical, and mechanical properties, in both of these categories. Overall, LTE shows excellent potential in assisting hepatic disorders. However, some challenges exist that prevent the practical use of it clinically, making LTE an ongoing research subject in the scientific society. Impact Statement This article is a comprehensive review of almost every step of liver tissue engineering (LTE) that a researcher should consider in this field. Thus, it provides knowledge and trusted references for further investigation. The main facets of LTE, cells and extracellular matrix, are reviewed and classified with precision to direct researchers to a state of the art strategy for achieving meaningful results and improvements, and, therefore, inclination toward clinical use with the aim of efficient treatment for liver diseases.

Mishima, Y., et al. (2019). "The necessary for long-term follow-up of mutated genes and clonal evolutions in multiple myeloma combined with cfDNA assay." Blood. Conference: 61st Annual Meeting of the American Society of Hematology, ASH **134**(Supplement 1).

Introduction)Somatic mutations in multiple myeloma (MM) are strongly related to the clinical outcome and clonal evolution over the clinical course, and are a major problem. From a clinical viewpoint, although numerous novel drugs have been utilized, achieving long-lasting and complete remission remains difficult. Recent studies have elucidated the mutated genes using next-generation sequencing, and have examined how clonal change can be acquired in myeloma. In this study, we traced the transition of the somatic mutations of bone marrow tumor cells in patients with MM over a long-term follow-up. Furthermore, we compared the somatic mutations found in serum cell-free DNA (cfDNA) and mutated genes obtained from bone marrow myeloma cells. Material and Methods)Patients diagnosed with multiple myeloma who provided written informed consent to participate in the study were enrolled. Patients were treated by immuno-chemotherapy with or without radiation between 2000 and 2017 at our institute. Bone marrow aspiration and biopsy were performed at the time of diagnosis and upon disease progression. Around the time of bone marrow aspiration, serum was obtained from a peripheral blood sample for cfDNA analysis. Myeloma cells were separated from bone marrow samples with MicroBeads of CD138 antibody and genomic DNA was extracted. The peripheral blood samples derived from myeloma patients. The cfDNA was extracted from the serum using Sa Maxwell RSC cfDNA Plasma kit. Using genomic DNA derived from cfDNA and bone marrow, multiplex polymerase chain reaction (PCR) was performed, and a sequence library was then constructed with an Ion Custom Amplicon panel. The panel for the sequence library was designed using an Ion AmpliSeq Designer^{TM}. 126 targeted genes were selected. The genomes were sequenced using the Ion Proton^{TM} System. This protocol was approved by the institutional review board and the Genomic Review Board of the Japanese Foundation for Cancer Research. Result)We followed 7 patients' long term-clinical course and the transition of mutations (8.5 year average). The expression of myeloma driver genes, such as RAS, BRAF, and MYC, were not critical. We did, however, detect a relationship between an increase in the dominant mutated gene, such as TP53, DIS3, FAM46C, KDM6B, and EGR1 and poor prognosis in patients with myeloma. Next, we calculated the cfDNA concentrations from 34 cases. The cfDNA concentrations were significantly higher than 10 control cases (average 62.0 ng/mL (0-200 ng/mL) and 8.18 ng/mL (4.3-14.1 ng/mL), P=0.0046). The 2.5 year-progression free survival (PFS) during the first treatment of MM were tend to be poorer in the group with cfDNA>50 ng/mL (72.9%) than the group with cfDNA<50 ng/mL(25.9%), however there are no statistical significance (P = 0.15).We calculated concordance rate of derived mutations from bone marrow MM cells and cfDNA in 7 cases. The somatic mutations found in serum cell-free DNA (cfDNA) and bone marrow MM cells were determined the correlation coefficients. However, there are few difference expression pattern in each source. In cfDNA assay, CREEP, EGR1, HDAC4, HDAC6, and JMJD1C were highly expressed as 57.1% (4/7) - 85.7% (6/7), and these results were almost the same as those for bone marrow MM cells. On the other hand, KDM1A (85.7%), PI3KCD (71.4%), and KDM3B (57.1%) were highly detected in cfDNA, although those were not frequently expressed in bone marrow. Discussion)Our data demonstrate the importance of the long-term follow-up of somatic mutations during the clinical course of myeloma. Serum cfDNA is a useful alternative source for detecting somatic mutations in MM patients during long-term follow-up.

Mishra, P., et al. (2019). "Distinctive impact of polystyrene nano-spherules as an emergent pollutant toward the environment." Environmental Science & Pollution Research **26**(2): 1537-1547.

The increasing load of nanoplastic pollution in the environment has become a major concern toward human and environmental safety. The current investigation mainly focused on assessing the toxic behavior of nanoplastics (polystyrene nano-spheres (PNS)) toward blood cells and marine crustacean. The study also investigated the temporal stability of PNS under different water matrices and its size-dependent sedimentation behavior in the sea water dispersion. The nano-dispersion showed mean particle size of 561.4 +/- 0.80 and 613.7 +/- 0.11 nm for PNS 1 and 781.4 +/- 0.80 and 913.7 +/- 0.11 nm for PNS 2 in lake and seawater, respectively after 48-h incubation, which is ~ 8-fold increase from its original size. The LC50 value against Artemia salina and lymphocytes were found to be 4.82 and 8.79 mug/mL, and 75 mug/mL, respectively for PNS 1 and PNS 2. The genotoxic study reveals that around 50% of lymphocytes were affected by both PNS at 50 mug/mL concentration, whereas the cytotoxic studies on RBC and lymphocytes showed 50% toxicity only at 100 mug/mL concentration. The genotoxic study displayed numerous tri- and multi-nucleated cells. The biochemical profile of A. salina exposed to lethal concentration demonstrated a significant decrease in the total protein, reduced glutathione, and catalase activity and increase in lipid peroxidation activity as a result of PNS permeation to tissues. In conclusion, the present study demonstrated that the polystyrene nano-spheres are emerging pollutant in the environment and are hazardous to humans.

Mishra, S. K., et al. (2008). "Passage-delaying microbeads for controlled delivery of loratadine." Pda Journal of Pharmaceutical Science & Technology **62**(6): 421-428.

A passage-delaying, multiple unit, controlled release system of loratadine was designed to increase residence time in the stomach involving minimum contact with the gastric mucosa. Oil-entrapped floating microbeads prepared using the emulsion gelation method were optimized by a 2(3) factorial design and a polymer ratio of 1.5:0.5 (casein:sodium alginate) by weight, and 15% w/v of oil (mineral oil/castor oil) and 1 M calcium chloride solution were selected as the optimized processing conditions for the desired buoyancy and physical stability. In vitro drug release in acid phthalate buffer, pH 3.12, demonstrated a sustained release for 8 h that best fitted the peppas model with n < 0.45. The ethylcellulose coating of the passage-delaying microbeads optimized by a 2(2) factorial design resulted in a controlled release formulation of loratadine that provided zero-order release for 8 h.

Misiewicz-Krzeminska, I., et al. (2018). "Expression of proteins in CD138+ plasma cells predicts prognosis in newly diagnosed multiple myeloma patients treated with VRD regimen." HemaSphere **2 (Supplement 2)**: 727-728.

Background: The development of precision medicine requires powerful biomarkers mainly based on the mechanism of drug action to predict and improve response to treatment. Although genomic technologies have significantly increased the numbers of potential biomarkers in MM, most of them have not been subsequently validated at protein level. The low protein concentration obtained after CD138+ selection has limited the quantification of proteins in MM so far. We have recently reported the usefulness of a new technique based on capillary nanoimmunoassay (CNIA) for protein expression quantification from purified CD138+ plasma cells (PC). Aim(s): To investigate the prognostic impact of the expression of proteins involved in

the anti-myeloma mechanism of bortezomib (V), lenalidomide (R) and dexamethasone (D), together with the expression of cyclin D1 and D2 in a large cohort of CD138+ PC samples from MM patients treated with VRD. Method(s): Bone marrow aspirates from 213 newly diagnosed MM patients treated according to the Spanish clinical trial VRD-GEM followed by ASCT conditioned with Mel-200 vs BuMel, were included in the study. Plasma cells were purified by anti-CD138 magnetic microbeads using the AutoMACs separation system (purity was above 85%) and next, were stored in RLT+ buffer at -800C. Proteins were extracted by a method previously reported by our group. Total protein quantification and protein expression were analyzed by the CNIA methodology (ProteinSimple, WESTM system). Progression free survival (PFS) and overall survival (OS) were calculated for each protein. Survival curves were plotted by means of the Kaplan-Meier method and statistical significance was tested using the log-rank test. The Cutoff Finder software was used to obtain the optimal cutoff. Result(s): After the analysis of total protein content, 194 MM samples of 213 (91%) fulfilled the quantity and quality requirements. Among the 10 proteins analyzed the expression of aiolos, cereblon, ikaros, gankyrin, proteasome activator subunit 1 (PSME1), glucocorticoid receptor (GR), exportin 1 (XPO1) and interferon regulatory factor 4 (IRF4) were detected in about 90% of MM samples. On the contrary, cyclin D1 and cyclin D2 proteins were detected in only 43% and 25% of MM samples, respectively. Regard-ing cytogenetic risk, IRF4, PSME1 GR and XPO1 proteins were significantly upregulated in low risk MM patients, while cyclin D2 was upregulated in high risk MM ($p<0.05$). At the time of study, the median follow-up for survivors was 25.5 months (range, 14.1-42.1). Kaplan-Meier survival analyses showed that high levels of ikaros and gankyrin were associated with shorter PFS ($p < 0.01$ and $p < 0.05$, respectively), while high level of cereblon was associated with longer PFS ($p < 0.05$). Regarding OS, high protein levels of aiolos, cereblon, GR and XPO1 were associated with better prognosis (see table below). Interestingly, patients with high cyclin D2 protein levels had a significantly shorter PFS and OS ($p < 0.0001$), while those with high level of cyclin D1 exhibited longer OS ($p < 0.05$). Summary/Conclusion: The expression level of proteins involved in the mechanism of action of bortezomib, lenalidomide and dexamethasone, discriminate prognosis in MM patients. High level of cyclin D2 protein identified MM patients with poor outcome. The quantification of protein expression by CNIA platform can be a useful tool for biomarker identification in the era of precision medicine. (Figure Presented).

Mistri, M., et al. (2017). "Small plastic debris in sediments from the Central Adriatic Sea: Types, occurrence and distribution." Marine Pollution Bulletin **124**(1): 435-440.

This is the first survey to investigate the occurrence and extent of microplastic contamination in sediments collected along a coast-open sea 140km-long transect in the Central Adriatic Sea. Plastic debris extracted from 64 samples of sediments were counted, weighted and identified by Fourier-transform infrared spectroscopy (FT-IR). Several types of plastic particles were observed in 100% of the stations. Plastic particles ranged from 1 to 30mm in length. The primary shape types by number were filaments (69.3%), followed by fragments (16.4%), and film (14.3%). Microplastics (1-5mm) accounted for 65.1% of debris, mesoplastics (5-20mm) made up 30.3% of total amount, while macro debris (>20mm) accounted for 4.6% of total plastics collected. Identification through FT-IR spectroscopy evidenced the presence of 6 polymer types: the majority of plastic debris were nylon, polyethylene and ethylene vinyl alcohol copolymer. Our data are a baseline for microplastic research in the Adriatic Sea.

Mitchell, G. F., et al. (1990). "Further studies on variable resistance of 129/J and C57BL/6 mice to infection with Schistosoma japonicum and Schistosoma mansoni." Parasite Immunology **12**(6): 559-567.

Two mouse strains maintained in the Walter and Eliza Hall Institute (WEHI) are variably resistant to infection with S. japonicum and S. mansoni in that worms cannot be found in the liver and portal system in a high proportion (WEHI 129/J mice) or low proportion (C57BL/6 mice) some weeks after exposure to cercariae. Resistance can be as high as 100% in WEHI 129/J mice and is usually around 20% in C57BL/6 mice. The proportion of resistant mice closely parallels the proportion of mice that demonstrate a shunting of microbeads, injected into a mesenteric vein, from liver to lungs. This applies to F₁ X WEHI 129/J backcross mice in which the data suggest oligogenic genetic effects although no evidence for a participation of MHC-linked genes in the phenomenon has emerged. 129/J mice derived from the Jackson Laboratory do not show a shunting of beads from the portal system to the lungs but their progeny bred at WEHI do. Germ-free WEHI 129/J mice resemble conventionally-maintained, SPF-derived WEHI 129/J mice in their variable resistance to schistosome infection. It is suggested that nutritional factors such as hypervitaminosis A superimposed on a genetic predisposition may contribute to the hepato-portal system peculiarities in WEHI 129/J and C57BL/6 mice.

Mitchell, K., et al. (2019). "Selenium in buoyant marine debris biofilm." Marine Pollution Bulletin **149 (no pagination)**(110562).

Marine debris is widespread in all the world's oceans. Currently little is understood about how marine debris affects the chemistry of the surface oceans, particularly trace elements that can adsorb to the surface of marine debris, especially plastic debris, or be taken up by biofilms and algae growing on the surface of marine debris. Selenium (Se) is a micronutrient that is essential to all living organisms. Average seawater Se concentrations in the modern ocean are <1 nM. Here we measure the concentration of Se in surface water and one deep water sample and the concentration of Se found in algae/biofilms growing on the surface of macro-debris collected in October of 2012. Concentrations of Se in biofilm varied more according to the type of biofilm rather than the type of plastic. However, further Se measurements are needed for more conclusive results. Copyright © 2019

Mitchell, M. S., et al. (2004). "Phase I trial of large multivalent immunogen derived from melanoma lysates in patients with disseminated melanoma." Clinical Cancer Research **10**(1 Pt 1): 76-83.

PURPOSE: The purpose of this research was to determine the toxicity and immunological activity of large multivalent immunogen (LMI), a preparation of tumor cell membranes affixed to amorphous silica microbeads, in patients with melanoma.

EXPERIMENTAL DESIGN: Nineteen patients with metastatic (stage IV) melanoma were entered into the study, of whom 15 received the full 3 months of treatment with LMI. LMI was administered without adjuvant, one-half intradermally (i.d.) and the other half s.c. Because we expected little toxicity, we first treated 2 patients at each dose level, 10-, 30-, or 100-million tumor cell equivalents on weeks 0, 4, and 8, and subsequently randomized the remaining 13 patients to receive treatment with one of those dosage schedules, for a total of 19 patients. Two patients who were registered were found to be ineligible because of brain metastases, and 2 others did not complete the course of treatment for reasons other than toxicity. Thus, 15 patients were fully evaluable. Patients with evidence of a clinical response (at least stable disease at the 12-week checkpoint) had the option of continuing treatment at 4-week intervals. Frequencies of cytolytic T cell precursors against HLA-A2 matched melanoma cells, and delayed-type hypersensitivity to a melanoma cell membrane preparation from a component melanoma cell line were performed to measure immunological efficacy, and serum chemistries and complete blood counts were performed every 2 weeks throughout the study to measure possible toxicity. Computed tomography scans were performed pretreatment and at week 12 to measure

possible beneficial effects on known lesions.
RESULTS: Eight of the 15 evaluable patients had an increase in cytolytic T-cell precursors during the course of therapy, usually by day 42. No patient had demonstrable delayed-type hypersensitivity to a melanoma membrane preparation before or after treatment. No toxicity of any kind was observed. A degree of clinical effectiveness of LMI was suggested by the elicitation of stable disease in 5 patients at 12 weeks. One patient had >50% regression of a lung nodule but progression of disease to the brain, whereas a second patient had a bona fide partial remission of a 3-cm diameter solitary lung nodule.
CONCLUSIONS: LMI was nontoxic, improved immunological reactivity to melanoma cells, and showed evidence of clinical effectiveness (shrinkage of tumor) in 1 patient. Additional studies with LMI with added adjuvant materials, in melanoma and other cancers, appear warranted.

Mitra, I. N., et al. (1998). "Improving stability of anaerobic biological reactors using composite ion exchangers." Water Science & Technology **38**(8/9): 369-376.

The problem of instability in anaerobic biological processes, arising from the inhibition of methanogenesis by accumulated volatile fatty acids and heavy metals, was addressed by introducing composite ion exchangers (CIX) to the anaerobic reactors. CIX was a polymeric ion exchanger with imino-diacetate functional groups which could prevent pH decline and immobilize heavy metals. It consisted of spherical microbeads of ion exchangers physically trapped in fibrous PTFE. Its thin sheet, cloth-like texture made CIX compatible in a biological medium with high solids concentration; it was easily introduced and withdrawn from such an environment. When excess hydrogen ion or heavy metal ions were present, CIX removed them and then slowly released them when the concentrations were lower. During 3 years, the resin did not foul and retained its original exchange capacity. Its use was particularly attractive for high-strength wastewater given to unforeseen fluctuations.

Mitra, I. N., et al. (1998). "Evaluating composite ion exchangers (CIX) for improved stability of anaerobic biological reactors." Water Research **32**(11): 3267-3280.

The ability of polymeric composite ion exchangers (CIX) to maintain the stability of anaerobic biological reactors under severe conditions of organic overloading and heavy metal contamination was studied. The CIX consisted of microbeads of chelating exchanger encapsulated in fibrous polytetrafluoroethylene or Teflon. During the stress period, the CIX dissipated any build-up of hydrogen or dissolved heavy metal ions. Once the source of instability in the feed was removed, the reactor returned to steady-state conditions, slowly releasing sorbed species from the CIX. The CIX was chemically stable and durable. It did not require intermittent cleaning or regeneration. There are 35 references.

Miura, H., et al. (2005). "[IgG heterophile antibody causes false positivity for CA19-9, which is overcome with bovine immunoglobulin]." Rinsho Byori - Japanese Journal of Clinical Pathology **53**(12): 1103-1108.

Immunoassay using antibodies is widely applied to measure various clinical parameters such as tumor markers. However, many mechanisms of interference for this method have been reported. We studied serum sample showing false positive CA19-9 values in the range of 24 to approximately 286U/ml depending on the reagent lots used. PEG-pretreated serum did not show false positivity. Using high performance liquid chromatography (HPLC), the CA19-9 false positive peak was obtained around 160kD, which is the same as IgG. Antibody-coated microbeads, labeled antibody and buffer were used in different combinations between different lots, and the buffer was found to be the cause of false positive findings. The amount of bovine IgG contaminated in bovine serum albumin(BSA) in the reagent buffer markedly differed between lots of BSA, and reagent with a low amount of bovine IgG showed false positive results. Bovine immunoglobulin was superior to mouse IgG in the attempt to avoid a false positive reaction. We concluded that the cause of false positive CA19-9 findings in this serum sample was IgG heterophile antibody, which reacts with both of mouse and bovine IgG. The heterophile antibody had greater affinity to bovine IgG than to mouse IgG. The difference between CA19-9 values obtained by different reagent lots was due to different amounts of bovine IgG contaminated in BSA used in the reagent. Bovine immunoglobulin was superior to mouse IgG in the attempt to absorb the heterophile antibody and avoid false positive reaction in this case.

Miyata, K., et al. (2000). "Sarpogrelate, a selective 5-HT(2A) serotonergic receptor antagonist, inhibits serotonin-induced coronary artery spasm in a porcine model." Journal of Cardiovascular Pharmacology **35**(2): 294-301.

Serotonin is one of the most important vasoactive substances and has been implicated in the pathogenesis of coronary artery spasm and of acute coronary syndrome. We have recently demonstrated that local and long-term treatment with interleukin-1beta (IL-1beta) causes coronary arteriosclerotic changes and hyperconstrictive responses to serotonin in pigs in vivo. However, it remains to be examined which serotonergic (5-HT) receptor subtype mediates coronary spasm and whether alterations in serotonergic receptors are involved in the abnormality. In this study, we examined the inhibitory effect of sarpogrelate, a selective 5-HT(2A) serotonergic receptor antagonist, on the serotonin-induced coronary spasm as well as the possible alterations of serotonergic receptors in our porcine model. A segment of the porcine coronary artery was carefully dissected and aseptically wrapped with cotton mesh absorbing IL-beta-bound microbeads from the adventitia. Two weeks after the procedure, angiographic study was performed, followed by binding assay for 5-HT(1B) and 5-HT(2A) serotonergic receptors and reverse transcription- polymerase chain reaction (RT-PCR) analysis for mRNA of those receptors. Angiographic study showed coronary vasospastic responses to serotonin at the IL-1beta-treated site. Sarpogrelate dose-dependently inhibited the serotonin-induced coronary spasm, but it did not affect the prostaglandin F(2alpha)- induced vasoconstriction. Radiolabeled receptor-binding assay showed that receptor affinity or receptor number of the 5-HT(1B) or 5-HT(2A) receptors did not differ significantly between the spastic and the control sites. Furthermore, RT-PCR analysis showed that the expression of neither 5-HT(2A) nor 5-HT(1B) receptor mRNA was significantly altered at the spastic site. These results indicate that serotonin-induced coronary spasm is mediated primarily by 5-HT(2A) receptor in our porcine model, although the 5-HT(2A) receptor was not upregulated, suggesting that alteration in the signal- transduction pathway for vascular smooth muscle contraction beyond the 5- HT(2A) receptor plays a primary role in the pathogenesis of coronary spasm in our porcine model.

Miyata, K., et al. (1999). "Endothelial vasodilator function is preserved at the spastic/inflammatory coronary lesions in pigs." Circulation **100**(13): 1432-1437.

Background - The question of whether or not endothelial vasodilator function in the spastic coronary artery is preserved is still controversial. We recently developed a porcine model in which long-term and local treatment with interleukin-1beta (IL-1beta) from the adventitial site causes coronary arteriosclerotic changes and vasospastic responses to autacoids. The aim of this study was to examine the endothelial vasodilator function in our new porcine model of the spasm both in vivo and in vitro. Methods and Results - A segment of the porcine coronary artery was aseptically wrapped with cotton mesh that held absorbed IL-1beta-bound microbeads. Two weeks after the procedure, intracoronary administration of serotonin caused coronary vasospasm at the IL-1beta-treated site (n = 10). Coronary vasodilatation to bradykinin, substance P, or an increase in coronary blood flow was preserved at the spastic site. Vasodilator responses to 3-morpholinosydnonimine (an NO donor) and nitroglycerin also were comparable between the 2 sites. The vasoconstricting response to N(G)-monomethyl-L-arginine and the extent of the augmentation of the serotonin-induced vasoconstriction were comparable between the 2 sites. Organ chamber experiments showed that endothelium- dependent relaxations to bradykinin, the calcium ionophore A23187, and even the vasospastic agonist serotonin were preserved at the spastic site, whereas contractions to serotonin were augmented at the spastic site regardless of the presence or absence of the endothelium (n=6). Endothelium-independent relaxations to sodium nitroprusside were also preserved at the spastic site. Conclusions - These results indicate that endothelial vasodilator function is preserved at the spastic site and that the spasm is caused primarily by smooth muscle hypercontraction in our porcine model.

Miyazaki, M., et al. (2009). "Determination of enzymatic source of alanine aminotransferase activity in serum from dogs with liver injury." Journal of Pharmacological & Toxicological Methods **60**(3): 307-315.

INTRODUCTION: Increase of serum alanine aminotransferase (ALT) activity is widely used as a surrogate marker for tissue damage. Two ALT isoforms, ALT1 and ALT2, have been cloned recently in mammals. The study investigated the source of elevated ALT activity in serum of dogs treated with a hepatotoxic compound.

METHODS: ALT activity was measured by enzyme assay. Immunoblot analysis was performed using generated specific peptide antibodies against dog ALTs. LC-MS/MS-based proteomics analysis was conducted to independently identify dog ALT peptides. Serum samples immunodepleted of major serum components by Seppro IgY-D11 microbead spin column were evaluated by the immunoblot analysis, and compared with those of the ALT activity.

RESULTS: Involvement of ALT enzyme(s) is consistent with the following observations: 1) all the substrates (L-alanine and alpha-ketoglutarate) were required for serum ALT activity as purified porcine ALT1 needed for activity, 2) serum ALT activity was inhibited by L-cycloserine, a known ALT inhibitor, and 3) apparent Km value for the ALT reaction catalyzed by the serum, liver, and skeletal muscle was roughly similar. Immunoblot analysis showed that ALT1 was detected in liver and both ALTs were detected in the skeletal muscle. The relative expression level of ALTs was -: liver ALT1>skeletal muscle ALT1>skeletal muscle ALT2. LC-MS/MS-based proteomics analysis gave similar results. Immunoblot analysis of the depleted serum samples revealed the presence of ALT1 in compound-treated dogs. Intensity of the ALT1 band detected in the sera correlated well with the ALT activity measured by the enzyme assay.

DISCUSSION: Based on these findings, we conclude that the elevation of serum ALT activity in dogs with liver injury is attributed to elevation of ALT1 protein level in serum. The methodology to directly detect ALT proteins in serum could be a tool to facilitate our understanding of biological and toxicological significance of the ALT isoenzymes.

Mizraji, R., et al. (2017). "Is the feeding type related with the content of microplastics in intertidal fish gut?" Marine Pollution Bulletin **116**(1/2): 498-500.

Microplastics pollution is a growing global concern that affects all aquatic ecosystems. Microplastics in the environment can be in the form of fibers and/or particles, being the former the most abundant in the marine environment, representing up to 95% of total plastics. The aim of this work was to compare the content of microplastics among intertidal fish with different feeding type. Our results show that omnivorous fish presented a higher amount of microplastic fibers than registered in herbivores and carnivores. Moreover, lower condition factors (K) were found in omnivorous specimens with higher microplastic content. We hypothesized that the type of feeding resulted in different microplastic ingestion, with species with wider range of food sources as omnivores with higher rates. Futures studies carried out to evaluate the biological impacts of microplastics on marine organisms, and microplastics cycling on the marine environment should consider the type of feeding of the studied species.

Mizubuti, Y. G., et al. (2016). "Effect of whey protein consumption in inflammatory response by patients waiting for liver transplantation-a pilot study." Clinical Nutrition **35 (Supplement 1)**: S194.

Rationale: Whey protein may contribute to inflammation control in patients with chronic liver disease. Method(s): Baseline characteristics related to inflammation were established in blood samples from 8 patients with chronic liver disease (CLD) on the waiting list for liver transplantation at Hospital das Clinicas, Brazil and 8 healthy individuals (HI) using a kit of Luminex microbeads. Patients received whey protein isolate (WP) to take 20g in the morning and 20g at night, as a supplement to their usual diet, during 30 days. They were monitored by regularly phone calls. Plasmatic cytokines were measured before (WP<inf>0</inf>) and after (WP<inf>f</inf>) protein supplementation by Cytometric bead array. Data were analyzed by Mann-Whitney and paired T tests. The protocol was approved by the Ethics Committee. Result(s): sICAM-1 and sVCAM-1 were higher in CLD patients, contributing to the inflammatory response. However, no differences in pro-inflammatory cytokines were observed after protein supplementation (Table 1). Conclusion(s): Adhesion molecules are increased in CLD patients, however the whey protein supplementation was not able to reduce the inflammation, maybe due to the small sample size. This study is still in progress. (Table Presented).

Mizukawa, K., et al. (2013). "Monitoring of a wide range of organic micropollutants on the Portuguese coast using plastic resin pellets." Marine Pollution Bulletin **70**(1-2): 296-302.

We analyzed polychlorinated biphenyls (PCBs), dichlorodiphenyl dichloroethane and its metabolites, hexachlorocyclohexanes (HCHs), polycyclic aromatic hydrocarbons (PAHs), and hopanes, in plastic resin pellets collected from nine locations along the Portuguese coast. Concentrations of a sum of 13 PCBs were one order of magnitude higher in two major cities (Porto: 307. ng/g-pellet; Lisboa: 273. ng/g-pellet) than in the seven rural sites. Lower chlorinated congeners were more abundant in the rural sites than in the cities, suggesting atmospheric dispersion. At most of the locations, PAH concentrations (sum of 33 PAH species) were ~100 to ~300. ng/g-pellet; however, three orders of magnitude higher concentrations of PAHs, with a petrogenic signature, were detected at a small city (Sines). Hopanes were detected in the pellets at all locations. This study demonstrated that multiple sample locations, including locations in both urban and remote areas, are necessary for country-scale pellet watch. © 2013 Elsevier Ltd.

Mizutani, H., et al. (1991). "Sensitive detection of viral antigens with a new method, "laser magnet immunoassay"." Microbiology & Immunology **35**(9): 717-727.

A new method, "laser magnet immunoassay" (LMIA), has been developed for sensitive detection of viral antigens. Target viruses captured on microbeads were made to react with antibodies labeled with magnetite particles. In a magnetic field, magnetically labeled antigens dispersed in water were attracted to and concentrated at one point on the surface, resulting in the lifting up of a small surface area. A laser beam which was incident on the point reflected, making an interference fringe. The intensity of the fringe indicates the amount of the magnetite conjugated with antigen. A very low concentration of antigens, such as 5 particles of influenza virus and 0.1 pg/ml of human immunodeficiency virus (HIV) p24 antigen in human serum, could be detected by this method. Application of this method to diagnoses of viral diseases in early stages is discussed.

Mizutani, K., et al. (2009). "Prostate cancer promotes CD11B positive cells to differentiate into osteoclasts." Journal of Urology **1)**: 513.

INTRODUCTION AND OBJECTIVES: Prostate cancer continues to be an incurable disease once it has metastasized to bone. A key step in the successful establishment of prostate cancer metastases is activation of osteoclast function to induce bone resorption. Bone resorption causes the release of growth factors from the bone matrix that stimulates prostate cancer cell proliferation, thereby enabling the "vicious cycle" of tumor growth and bone destruction. We have investigated what factors are secreted by prostate cancer cells to determine the cellular and humoral mechanisms by which osteoclast formation is induced by metastatic prostate cancer cells within the tumor microenvironment. METHOD(S): Previously, investigators have demonstrated that human bone marrow mononuclear cells (HBMCs) treated with prostate cancer conditioned medium could induce osteoclast formation but it has been unclear what cells were induced to cause bone resorption. Cells of the monocyte fraction (CD11b) were isolated from healthy men's PBMCs by MACS CD11b Micro Beads. CD11b cells were cultured with Macrophage-Colony Stimulating Factor (MCSF) and conditioned media from PC-3 cells or IL-6, IL-8 and Monocyte chemoattractant protein -1 (MCP-1, CCL2) in various conditions. Osteoclast fusion was evaluated with TRAP and vitronectin staining and osteoclast function was measured by a bone resorption assay. RESULT(S): Conditioned media from prostate cancer PC-3 cells induces human mononuclear cells to differentiate into functional osteoclasts with subsequent bone resorption. Analysis of PC-3 conditioned media revealed high amounts of IL-6 and IL-8. CD11b+ cells were cultured with MCSF and IL-6 and IL-8 and CCL2, alone or in combination. All of them induced osteoclast fusion but these cells were capable of limited bone resorption. Prostate cancer conditioned media induced osteoclast fusion and bone resorption, which was not inhibited by IL-6 and IL-8 neutralizing antibodies. Co-incubation with IL-6 and IL-8 and RANKFc failed in inhibiting osteoclast fusion and bone resorption, suggesting a potential RANKL independent mechanism of functional osteoclast formation. CONCLUSION(S): This is the first study that demonstrates that functional osteoclasts can be derived from CD11b PBMCs. These findings indicate that prostate cancer cells produce multiple factors that are capable of inducing osteoclast differentiation and bone resorption. It appears that IL-6 and IL-8 induce osteoclast fusion and limited bone resorption by a RANKL-independent mechanism.

Mobasheri, A. (2016). "Year in review: Biomarkers." Osteoarthritis and Cartilage **1)**: S6-S7.

Purpose: Biomarkers have the capacity to detect early joint degradation in degenerative diseases such as osteoarthritis (OA). They can provide useful diagnostic and prognostic information by reflecting pathophysiologically relevant biological activity in the joint and predict the course of disease progression. In addition, they can serve as surrogate endpoints in the discovery and development process for disease modifying osteoarthritis drugs (DMOADs). The 'Year in Review' Plenary Session at the end of theWorld Congress on Osteoarthritis has become a well-established tradition. It provides a unique opportunity to build on the reviews from the previous years and summarize the key published papers related to OA biomarkers. The aim of this presentation is to discuss selected 'wet' biomarker related papers published between the OARSI 2015 Congress held from 30 April to 3 May 2015 in Seattle, Washington and the OARSI 2016 Congress, which will be held from 31 March to 3 April 2016 in Amsterdam, The Netherlands. The presenter will use this opportunity to review on-going 'wet' biomarker-related progress in the OA research community and focus on new biochemical and molecular studies that have advanced knowledge in this area in the previous 12 months. The review will include the results of a PubMed bibliographic search using the terms 'biomarker' and 'osteoarthritis' and summarize findings from papers published in the most relevant musculoskeletal, orthopaedics and rheumatology journals. Method(s): The PubMed/MEDLINE bibliographic database was searched using the following keywords: 'biomarker' and 'osteoarthritis'. The PubMed/MEDLINE literature search was conducted using the Advanced Search Builder function (http://www.ncbi.nlm.nih.gov/pubmed/ advanced) and specifically focused on the period between the 2015 OARSI meeting and the December 2015 deadline for the submission of abstracts for the 2016 congress. Result(s): Approximately sixty-eight new OA biomarker papers were published at the time this abstract was written (11 December, 2015). It is estimated that another fifty or so papers will be published by the end of March 2015. A small number of these papers are likely to identify new biomarkers whereas others may explore the biological properties and clinical utility of existing markers in greater detail. The biomarkers studied included some of the usual suspects such as cartilage oligomeric matrix protein (COMP), hyaluronic acid (HA), ADAMTS-4, the aggrecan ARGS neo-epitope and the type II collagen markers CTX-II, C2C and COLL2-1NO2. There were specific references to 'inflammatory biomarkers' of OA in some papers and several adipocytokine suspects were added to the line-up of offenders including leptin and adiponectin, providing molecular and mechanistic links between obesity and OA. Interestingly, ADAMTS-4 activity in synovial fluid was reported as a biomarker of inflammation and effusion. Serum and synovial fluid resistin was implicated in knee OA. ARGS-aggrecan was also implicated in a localized repair response involving an increase in aggrecan turnover following severe knee trauma. Plasma CCL3 was reported as a potential serum biomarker for knee OA with the capacity to detect preradiographic changes. New biomarker technologies were also developed including a fluoro-microbead guiding chip (FMGC) for measuring CTX-II in serum and urine and a novel magnetic nanoparticle-based technology was described for collecting and concentrating CTX-II, termed magnetic capture. Conclusion(s): The last 12 months have witnessed solid progress in the area of OA biomarker research. Several novel biomarkers have been identified and new technologies have been developed for measuring existing biomarkers. However, identification of early OA biomarkers remains a challenging and arduous task. Combining advanced imaging techniques and biochemical markers with bioinformatics (i.e. machine learning, clustering, data visualization) should increase the predictive power of new 'combination biomarkers' in the future. The refinement of proteomic, metabolomic and immunoassay technologies is also likely to contribute to improvements in diagnostic assays for wet biomarkers in serum, synovial fluid and urine.

Moeini, A., et al. (2018). "Effect of pH and TPP concentration on chemico-physical properties, release kinetics and antifungal activity of Chitosan-TPP-Ungeremine microbeads." Carbohydrate Polymers **195**: 631-641.

In this study, chitosan based microbeads containing Ungeremine, an antimicrobial alkaloid particularly active against Penicillium roqueforti, a filamentous fungus responsible of the bakery products deterioration, were prepared by external gelation by using sodium tripolyphosphate (TPP) as crosslinking agent. The stability of the beads, as well as the loading efficiency of the bioactive molecule, were assessed at different pH and TPP concentrations resulting particularly enhanced at low pH. All the microbeads evidenced antimicrobial activity against Penicillium roqueforti. The release kinetics of Ungeremine was tailored by opportunely modulating pH and TPP concentrations. Morphological analysis evidenced the improvement of the structural crosslinking density of microbeads including Ungeremine and spectroscopic analysis emphasized the active participation of Ungeremine to the crosslinking process occurring between chitosan and TPP. Finally, thermogravimetric analysis confirmed the increasing of free volume in

three-dimensional networks and their liability to thermal degradation.

Moghtader, F., et al. (2017). "Phages in modified alginate beads." Artificial Cells, Nanomedicine, & Biotechnology **45**(2): 357-363.

In order to increase stabilities and controlled/sustained released of T4 phages were encapsulated within alginate beads which were then coated with chitosan, polyethylene imine (PEI). Quite high loading capacities (over 90%) were achieved in these pH-sensitive microbeads. Coating with those polycations increased significantly stability both in "simulated gastric fluid" and bile salts especially in the case of PEI coating. The tests conducted in "simulated intestinal fluid" demonstrated that phages were released from the beads which were active at basic pH in which the release rates were smaller in case of chitosan. PEI concluded to be a better coating then chitosan.

Mohamed, A., et al. (2019). "Single microbead-based fluorescence "turn on" detection of biothiols by flow cytometry." Talanta **195**: 197-203.

Biological thiols (biothiols), such as glutathione (GSH), cysteine (Cys) and homocysteine (Hcy), play a vital role in the process of reversible redox reactions in physiological systems. In this work, flow cytometry-based fluorescent sensor is for the first time developed for the detection of biothiols in a fluorescence "turn on" manner. The probe which we name "Polystyrene/Quantum Dots/Gold Nanoparticles" or (PS/QDs/Au) is constructed by immobilizing QDs onto the surface of PS microbeads to obtain fluorescent microbeads. The probe (PS/QDs/Au) is constructed by immobilizing QDs onto the surface of PS microbeads to obtain fluorescent microbeads, followed by gold NPs absorption through electrostatic interaction to quench their fluorescence. In the presence of biothiols, the fluorescence of our probe can be restored in less than 5min, and the detection limits for GSH, Cys and Hcy are 0.5muM, 0.1muM and 0.3muM, respectively. Most importantly, the fluorescence signal of each of our probe microbeads can be collected individually by flow cytometry, realizing single microbead-based biothiols detection for the first time. Moreover, the probe is successfully applied to imaging of intracellular biothiols in A549 cells, demonstrating its potential in biological application.

Mohamed, F., et al. (2017). "Nephrotoxicity-induced proteinuria increases biomarker diagnostic thresholds in acute kidney injury." BMC Nephrology **18**(1): 122.

BACKGROUND: Paraquat ingestion is frequently fatal. While biomarkers of kidney damage increase during paraquat-induced acute kidney injury (AKI), significant concurrent proteinuria may alter diagnostic thresholds for diagnosis and prognosis to an unknown extent. This study evaluated the effect of albuminuria on biomarker cutoffs for diagnosis and outcome prediction.

METHODS: This was a multi-centre prospective clinical study of patients following acute paraquat self-poisoning in 5 Sri Lankan hospitals. Biomarker concentrations were quantified using ELISA and microbead assays and correlated with urinary albumin. Functional-AKI was defined by the Acute Kidney Injury Network serum creatinine definition and alternatively by a >=50% increase in serum cystatin C. Albuminuria was defined as albumin-creatinine ratio >30 mg/g. The study outcomes were compared with a retrospective analysis of a pre-clinical study of paraquat-induced nephrotoxicity with appropriate controls.

RESULTS: Albuminuria was detected in 34 of 50 patients, and increased with functional-AKI severity. The concentrations of uNGAL, uCysC, uClusterin, ubeta2M, and uKIM-1 were higher in albuminuric compared to non-albuminuric patients ($p < 0.001$). Albuminuria correlated with biomarker concentration ($r > 0.6$, $p < 0.01$) and was associated with death ($p = 0.006$). Optimal biomarker cutoffs for prediction of death were higher in the albuminuric group. Similar outcomes with

more detailed analysis were obtained in experimental paraquat nephrotoxicity.
CONCLUSION: Albuminuria was associated with paraquat-induced nephrotoxicity and increased excretion of low-molecular weight protein biomarkers. AKI biomarker cutoffs for diagnosis, outcome prediction and AKI stratification increased in the presence of albuminuria. This may lead to over-diagnosis of AKI in conditions independently associated with proteinuria.

Mohamed Nor, N. H. and A. A. Koelmans (2019). "Transfer of PCBs from Microplastics under Simulated Gut Fluid Conditions Is Biphasic and Reversible." Environmental Science & Technology **53**(4): 1874-1883.

The role of plastic as a vector for bioaccumulation of toxic chemicals is central to the risk assessment of microplastic for human health and the environment. However, transfer kinetics of sorbed contaminants from ingested microplastics are poorly understood. We develop and parametrize a chemical exchange model on microplastics in a gut fluid mimic of aquatic biota, and also included food to provide a better representation of contaminant dynamics when plastic and food are ingested, as would occur in nature. The transfer kinetics of 14 polychlorinated biphenyls (PCBs) were measured in gut fluid mimic systems under three environmentally relevant exposure scenarios of plastic ingestion by organisms, for low-density polyethylene (LDPE) and polyvinyl chloride (PVC), and were evaluated with the model. Chemical transfer was demonstrated to be biphasic and fully reversible, with fast exchange within hours followed by a slow transfer lasting for weeks to months. In clean gut systems, the bioavailability of plastic-associated PCBs for lugworms and cod ranged from 14 to 42% and 45-83% respectively. However, in contaminated gut systems, clean microplastic was capable of rapidly extracting ("cleaning") PCBs from food inside the gut, thus demonstrating that the effect of microplastic is context dependent. Therefore, chemical contamination and cleaning are likely to occur simultaneously due to the ingestion of microplastic.

Mohammed, J. M., et al. (2017). "The impact of different N sources on the growth and yield of cucumber varieties under the plastic greenhouse." Lucrari Stiintifice, Universitatea de Stiinte Agricole Si Medicina Veterinara "Ion Ionescu de la Brad" Iasi, Seria Horticultura **60**(2): 99-110.

Studies were conducted to determine the effect of various nitrogen (N) fertilizer sources on the growth and yield of cucumber under greenhouse condictions. Two cucumber cultivars (Ansor F1 and Trilogy F1) were planted under 10 microplastic greenhouses. The fertilizer treatments included 300 g DIX 10 N (D), 50 and 100 g NovaTec (N1 and N2), 200 g Orgevit (O)/m² and unfertilized control. Results indicated that there were significant differences among treatments, but it was observed that for all characters studied, there was an increase with significantly difference with an increase in the N level. Generally, all N fertilizer treatments (organic and inorganic) increased the soil N-NH₄, N-NO₃, P-PO₄ and K levels in the soil. Results also showed that Ansor F1 fertilized with DIX 10 N (AD) and Ansor F1 and Trilogy F1 with NovaTec 100 g/m² (AN2) and (TN2) gave strongly positive effects on the plant length and plant and root dry matter. The highest content of pigments was found in Ansor F1 fertilized with DIX 10 N (AD), NovaTec 100 g/m² (AN2) and Trilogy with DIX 10 N (TD). A significant increase in leaf content of N-NO₃ represented by inorganic fertilizer treatments were also observed, while the highest content of P-PO₄ was represented by TN2 and TO (657.86 and 728.93 ppm, respectively). It was clearly shown the highest K content affected strongly the increase of inorganic fertilizers, which was recorded with AN2 and TN2 (4513 and 4640 ppm, respectively). Results showed that all inorganic treatments gave normal and healthy concentrations of N-NO₂ and K in fruits. All treatments had strong effects on fruit length, but the greatest diameter were recorded with TN1 and TN2. The best yield results were recorded by

Trilogy F1 fertilized with DIX 10 N (TD) and Orgevit (TO), followed by Ansor F1 with Orgevit (AO) treatment, which were 4.10, 4.04 and 4.05 kg, respectively.There were significant variations between the cultivars regarding CO₂ concentrations in response to the different commercial fertilizers. The highest values was observed in the control (1449.97 and 1516.76 ppm). All treatments showed significant increase in O₂ compared to the control variants.

Mohammed, M. I., et al. (2018). "Physiological and biochemical changes analysis to labors blood samples in plastics recycling factory in Mosul-Iraq." Journal of Global Pharma Technology **10**(6): 281-288.

In this study, the healthy impacts of environmental and emitted pollutants from the recycling plastics factories in the Right Bank district of Mosul City were investigated. Urine and blood samples were collected from workers who exposed to these pollutants. Some of physiological and biochemical tests have been achieved which including Blood Pressure, Hb (Hemoglobin), PCV, ESR, blood urea, serum total protein, serum total cholesterol, serum triglycerides, ALT (GPT) and AST (GOT). Also, General Urine Examination has been performed. All results were compared with 20 unaffected persons as a control group. The results of the current study showed significant differences in some testes compared with the control group. Hemoglobin increased to 17.00 g/dl in the workers which had >20 years-work compared with the control (14.00 g/dl). Furthermore, PCV have a significant increase ranging from 55.53% to 90.53% in workers who have <10, 11-20 and >20 years-work. Blood Urea recorded highest value 50 g/dl for workers >20 years-work, while declined to the lowest value 37 g/dl in case <10 years-work. Also, liver enzymes (Aspartate Transaminase and Alanine Transaminase) were recorded slight increase reached to 13.3 and 6.6 IU/dl respectively. In addition, General Urine Examination exhibited various kinds of cells besides highest percentages of Calcium Oxalate, pus cells, amorphous and RBC (Red Blood Cells) reached to 40.85%, 13.85%, 8.71% and 3.85% respectively. ©2009-2018, JGPT. Mohammed, S., et al. (2019). "Optimization of the culture conditions for production of Polyhydroxyalkanoate and its characterization from a new Bacillus cereus sp. BNPI-92 strain, isolated from plastic waste dumping yard." International Journal of Biological Macromolecules **18**: 18.

The aim of this study was to optimize the culture conditions for production, recovery and characterization of polyhydroxyalkanoate (PHA) from potential Bacillus cereus strain BNPI-92. Cost effective carbon sources such as crude oil (CO), rice bran (RB), sugar cane molasses (SCM) and wheat bran (WB) were evaluated for PHA production using the isolate. Higher cell dry weight (CDW) (g/L), PHA concentration (P conc.) (g/L) PHA contents (PC) (%) and PHA synthesis rate (PSR) were obtained from Glucose (60.67% w/v) as a carbon source at 37 degreeC and pH 7 using Taguchi DOE methods. The polymer was characterized by FTIR and its functional groups (C=O) (1719.41 cm⁻¹ wavenumber) was a characteristic feature of PHB polymer. For ¹HNMR, signals of methyne (CH) (5.28 ppm), methylene (-CH2-) (2.45 ppm) and methyl (CH3) (1.27 ppm) and copolymers were predicted. Copolymers such as P (3HB-co-3 HV) and P(3HB-co-3HHX) i.e. characteristic feature of PHB were obtained from a sample of glucose, WB, and RB, respectively. XRD pattern also confirmed the presence of PHA. The major compounds obtained from GC/MS analysis of the polymer recovered from the isolate BNP-92 were 2-butenoic acid, methyl ester (8.6%), ethyl cyclopropanecarboxylate (45.99%), 1-Undecanol (10.18%) which corresponds to and have produced from PHA after thermal degradation.

Mohammed, S., et al. (2019). "An investigation for recovery of polyhydroxyalkanoates (PHA) from

Bacillus sp. BPPI-14 and Bacillus sp. BPPI-19 isolated from plastic waste landfill." International Journal of Biological Macromolecules **134**: 1085-1096.

Bio-plastic synthesis from renewable and cheap agro-based materials is a sustainable solution for replacing conventionally produced plastic with environmental contamination. The current study was aimed at screening and characterization of Polyhydroxyalkanoates (PHA) producing bacterial isolates, evaluation of their potential and recovery of PHA using the isolates. The PHA compounds were characterized using FT-IR. Based on 16SrRNA sequence analyses the isolates were designated as Bacillus sp. BPPI-14 and Bacillus sp. BPPI-19. The isolates were gram-positive, rod-shaped, endospore former, and citrate test positive. Intracellular PHA granules were observed when these isolates were stained with Sudan black B (SBB) and Nile blue A (NBA) preliminary and specific staining dyes, respectively. Effect of pH, temperature and carbon sources on the PHA production by the isolates BPPI-14 and BPPI-19 was studied. Maximum PHA production was recorded for Glucose (49.46+/-2.79%) by Bacillus sp. BPPI-14 and followed by molasses (45.86+/-2.17%) by Bacillus sp. BPPI-19, respectively at 37degreeC and pH7. The obtained PHA polymers were confirmed by preparation of plastic films for both the isolates. Fourier transform infrared spectrum for BPPI-14 and BPPI-19 showed the peak (carboxylic acid group) at 1706-1719.39cm⁻¹ was a characteristic feature of PHA and corresponds functional group (C=O).

Mohan, N. and R. Usha (2018). "Bio-augmentation - Effective method of treating plastic waste - A field study." Journal of Pure and Applied Microbiology **12**(3): 1641-1646.

Polythene waste is a serious threat to our environment. There are many methods available for its degradation. The present study shows light for eco friendly approach for mitigating the ecological problem of the century. By using bio-augmentation, microorganisms having specific metabolic capabilities are introduced into the contaminated site for enhancing the degradation of plastic waste. The field trials for a period of 3 months shows clearly that the LDPE sheets are better degraded with augmented microorganism (1.6%,4%,5.2%,8%,8.8%) than non bio augmented soil (4%,1.6%,2.8%3.6%4%). The ecological importance of this study is that we will be able to tackle plastic waste by adding bio-augmented strains in to an area or dumpyard filled in with plastic waste. Mohankar, R. H., et al. (2017). "Behaviour of soil reinforced with plastic waste." International Journal for Research in Applied Science and Engineering Technology **5**(6): 1058-1063.

In this paper the study of behaviour of black cotton soil, reinforced with plastic waste is done. Various tests are performed to study the properties of soil, various percentage of plastic waste are added and results are compared with the soil without plastic waste. The results shown considerable improvement in the properties of soil.

Mohapatra, A., et al. (2018). "Magnetic stimulus responsive vancomycin drug delivery system based on chitosan microbeads embedded with magnetic nanoparticles." Journal of Biomedical Materials Research. Part B, Applied Biomaterials **106**(6): 2169-2176.

Local antibiotic delivery can overcome some of the shortcomings of systemic therapy, such as low local concentrations and delivery to avascular sites. A localized drug delivery system (DDS), ideally, could also use external stimuli to modulate the normal drug release profile from the DDS to provide efficacious drug administration and flexibility to healthcare providers. To achieve this objective, chitosan microbeads embedded with magnetic nanoparticles were loaded with the antibiotic vancomycin and stimulated by a high frequency alternating magnetic field. Three such stimulation sessions separated by 1.5 h were applied to each test sample. The chromatographic analysis of the supernatant from these stimulated samples showed more than approximately 200% higher release of vancomycin from the DDS after the stimulation periods compared to nonstimulated samples. A 16-day long term elution study was also conducted where the DDS was allowed to elute drug through normal diffusion over a period of 11 days and stimulated on day 12 and day 15, when vancomycin level had dropped below therapeutic levels. Magnetic stimulation boosted elution of test groups above minimum inhibitory concentration (MIC), as compared to control groups (with no stimulation) which remained below MIC. The drug release from test groups in the intervals where no stimulation was given showed similar elution behavior to control groups. These results indicate promising possibilities of controlled drug release using magnetic excitation from a biopolymer-based DDS. © 2017 Wiley Periodicals, Inc. J Biomed Mater Res Part B: Appl Biomater, 106B: 2169-2176, 2018.

Mohd Armi, A. S., et al. (2013). "Household solid waste composition in Balakong City, Malaysia: trend and management." Polish Journal of Environmental Studies **22**(6): 1807-1816.

Waste is an obvious by-product that comes from human activities. Urbanization, economic development, and improving living standards in cities all have an impact on the increase of the quantity and difficulty of generated waste. Fast population growth and industrialization degrades the urban environment and places serious stress on natural resources. Inefficient management and disposal of solid waste is a noticeable cause of degradation of the environment in most cities of the developing world. MSW generation depends on township size and level of economic standards. Thus, it was proven by the MSW generated in the selected area of Kluang (a small town in the southern part of Peninsular Malaysia) amounted to as little as 45 tons and as much as 3,000 tons in Kuala Lumpur (Malaysia's capital). More analysis reported that the largest sources of MSW generation come from household waste, followed by industrial and commercial wastes. In Selangor State, the highest percentage of MSW consisted of putrescible waste of approximately 46%, followed by plastic and paper at 15% and 14%, respectively. This paper focuses on the trend and management of household solid waste composition generated in Balakong City, Malaysia. A survey for household residents in eight housing areas was carried out for one month and data were collected on a daily basis. The composition of solid waste collected was segregated into different components (organic waste, plastic, paper, glass, metal, and other). For overall household solid waste composition generated in the Balakong area, organic waste recorded the highest percentage at 555.5%. Then, followed by plastic waste 82.2%, paper 74.4%, other waste 42.9%, glass 25.8%, the lowest waste generated was metal at 18.9%. There is a relation between the economic position of a country and per capita waste generation rate. While the standard of living rises, waste generation rates also are increasing. The world trend of solid waste generation nowadays (including Malaysia) is mostly dependent on the changing consumption pattern, and also related to climate and seasonal differences. Thus, the management and planning of solid waste generated must be enhanced to improve sustainable solid waste management in Malaysia. Besides, public awareness, funding, expertise, equipment, and facilities that are currently lacking must be provided.

Mohd, S., et al. (2010). "Study of knowledge, attitude and practices regarding biomedical waste among paramedical workers." Indian Journal of Community Medicine **35**(2): 369-370.

A hospital-based cross-sectional study was carried out between March and September 2009 to assess the knowledge, attitude and practices of hospital staff regarding biomedical waste management. Of 267 private nursing homes and clinics in Karimnagar, Andhra Pradesh, India, 47

were selected by systematic random sampling. A total of 500 study subjects (201 males and 299 females) were selected from these hospitals and informed consent was obtained from them. Of the 500 study subjects, 237 were nurses, 132 were lab technicians and 131 were housekeeping staff. A total of 266 study subjects knew about BMW correctly, of which 138 (51.8%) were nurses, 114 (42.85%) were technicians and 14 (5.26%) were housekeepers. Only 8 (1.6%) study subjects knew about categories of BMW of which 5 (62.5%) were technicians. A total of 353 (70.6%) study subjects were having an idea about segregation of BMW. Seventy-two (14.4%) subjects had knowledge about various methods of disposal of BMW. Majority of the study subjects had knowledge about various health problems caused by BMW, of which 234 (48.8%) were nurses. The attitude of the study subjects toward separation of infectious and non-infectious waste, proper disposal and implementation of rules was positive i.e. 496 (99.2%), 494 (98.8%), and 492 (98.4%), respectively. 278 (55.6%) study subjects committed that they will cooperate in BMW management. The nurses had a better attitude toward separation of wastes (n=236; 99.5%), proper disposal (n=234; 98.7%), implementation of rules (233; 98.3%) and cooperation in programmes (149; 62.8%). The attitude of technicians and housekeeping staff was found to be almost similar. Of the 482 (96.4%) study subjects who minimized waste, 227 (47%) were nurses, 129 (26.76%) were technicians and 126 (26.14%) were housekeepers. A total of 335 (67%) study subjects segregated BMW, of which majority were nurses, 169 (50.44%). Of the 297 (59.4%) subjects who collected waste into colour-coded bags, 150 (50.5%) were nurses. Segregation and separation of plastic waste was done better by the nurses i.e. 169 (50.4%) of 335 (67%) and 56 (11.2%) of 95 (58.9%), respectively. None of the subjects disinfected the waste before disposal. 490 (98%) subjects were sending BMW to private agency for disposal and treatment.

Mohsen, M., et al. (2019). "Heavy metals in sediment, microplastic and sea cucumber Apostichopus japonicus from farms in China." Marine Pollution Bulletin **143**: 42.

The concentrations of eight heavy metals (As, Cd, Cr, Cu, Mn, Ni, Pb and Zn) were measured in the sediment, the isolated microplastics from the sediment and the body wall of sea cucumbers from farms in China. Accordingly, the heavy metal concentrations in the sediment were below the class I upper limit of Chinese sediment quality guidelines. Among heavy metals, the median concentrations of Cd and As were higher in the body wall than in the corresponding sediment. Additionally, the median concentrations of Cd, Pb, and Zn were higher on the microplastics than in the corresponding sediment. Furthermore, there was no significant correlation among heavy metals in sediment, sea cucumber and microplastics. This study contributes to the understanding of the heavy metal accumulation in the sediment, the microplastics and the body wall of the sea cucumber.

Mohsen, M., et al. (2019). "Microplastic ingestion by the farmed sea cucumber Apostichopus japonicus in China." Environmental Pollution **245**: 1071-1078.

Microplastic ingestion by the farmed sea cucumber is undocumented. Microplastics were isolated from the sea cucumber Apostichopus japonicus that was collected from eight farms along the Bohai Sea and the Yellow Sea in China. To examine microplastic ingestion, the intestines were isolated, digested and then subjected to the floatation test. The microplastic abundance in the sediment ranged from 20 to 1040 particles kg⁻¹ of dry sediment, while the ingested microplastics ranged from 0 to 30 particles intestine⁻¹. After filtering the coelomic fluid, the extracted microplastics from the coelomic fluid ranged from 0 to 19 particles animal⁻¹. Thus, we speculated that microplastics may transfer to the coelomic fluid of sea cucumber. The ingested microplastics did not correlate with the animal

body weight but was site dependent, suggesting that sea cucumber may serve as sentinel for microplastic pollution monitoring in the sediment. The microplastics were identified by Fourier transform infrared micro spectroscopy, and the polymer types were mainly cellophane, polyester, and polyethylene terephthalate. This study revealed that, microplastics widely existed in sea cucumber farms, and that sea cucumbers ingest microplastics as suitable with their mouth open. Moreover, the microplastics might transfer to the coelomic fluid of the sea cucumber. Further investigations are needed to assess the chronic effect of the microplastics on the growth and physiological status of the sea cucumber.

Mohsen, M., et al. (2019). "Microplastic fibers transfer from the water to the internal fluid of the sea cucumber Apostichopus japonicus." Environmental Pollution: 113606.

Microplastics (MPs) are small plastic particles less than 5mm in diameter. MPs in the form of microfibers (MFs) are widely detected in aquatic habitats and are of high environmental concern. Despite many reports on the effects of MFs on marine animals, their effect on sea cucumbers is still unclear. In addition, our previous filed study has shown that MFs may transfer to the coelomic fluid of the sea cucumber Apostichopus japonicus (A. japonicus). Here, we show how MFs transfer to the coelomic fluid of the sea cucumber. We captured the MFs during their transfer from the water to the coelomic fluid through the respiratory tree. A. japonicus ingested in the MFs along with the water during respiration; the MFs got stuck in the respiratory tree or transferred to the coelomic fluid. The transferred MFs increased during 72h of exposure and persisted for 72h after the transfer to clean water. Among the immunity indices, lysozyme (LZM) levels increased in response to the transferred MFs, which confirms the defensive role of LZMs against strange substances. Additionally, non-significantly decreased levels of total antioxidant capacity (T-AOC), malondialdehyde (MDA), peroxidase (POD) and phenol oxidase (PPO) were observed at 24h and 48h post-exposure, suggesting minimal oxidative imbalance. Furthermore, there were no significant changes in the speed and the total distance moved by A. japonicus post MFs transfer. This study revealed that MFs transfer and accumulate in the coelomic fluid of A. japonicus.

Mokhtar, M., et al. (2018). The Utilisation of Shredded PET as Aggregate Replacement for Interlocking Concrete Block. Les Ulis, EDP Sciences. **34**.

The consumption of plastic has grown substantially all over the world in recent years and this has created huge quantities of plastic-based waste. Plastic waste is now a serious environmental threat to the modern way of living, although steps were taken to reduce its consumption. This creates substantial garbage every day, which is much unhealthy. Plastic bottles such as Polyethylene terephthalate (PET) was use as the partially component in this making of interlocking blocks concrete. This project investigates the strength and workability of the interlocking block concrete by replacing course aggregate with % PET. The suitability of recycled plastics (PET) as course aggregate in interlocking block concrete and its advantages are discussed here. Moreover, there were more benefits when using interlocking block than using conventional block such as it easy for construction because they are aligning, easy to place, high speed stacking and they offer more resistance to shear and buildings would be even stronger. Based on the test perform, the failure parameter were discussed .From the compressive strength test result, it shows that the strength of concrete block decreased with increased of PET used. From the results, it shows that higher compressive strength was found with 5% natural course aggregate replaced with PET compared to other percentages.

Mokhtari, S., et al. (2017). "The cell wall compound of Saccharomyces cerevisiae as a novel wall material

for encapsulation of probiotics." Food Research International **96**: 19-26.

Yeast cell wall is known as a food grade ingredient which is recently being used increasingly as a novel coating for encapsulation of different materials in the food industry. This application is limited to core materials smaller than yeast in size. In this study, we have tried to encapsulate larger particles by crushing yeast cells. Hence, probiotic bacteria of Lactobacillus acidophilus and Bifidobacterium bifidum were encapsulated firstly by calcium alginate using the emulsion method and these microbeads were coated again by Saccharomyces cerevisiae cell wall compound and another layer of calcium alginate. The average diameter of microcapsules for single layer microbeads (M), microbeads coated by two layers of alginate (MCA), and microbeads coated by a layer of yeast cell and two layers of alginate (MCYA) were 54.25+/-0.18, 77.43+/-8.24 and 103.66+/-13.33mum, respectively. In simulated gastrointestinal conditions, there was a significant (P<0.05) enhancement in resistance of L. acidophilus when applying a layer of S. cerevisiae cell wall compound. For MCA and MCYA after 2h exposure to simulated gastric juice, it was revealed a log reduction of 1.53+/-0.1 and 1.1+/-0.02 with pH1.55 and in simulated intestinal juice, 2.92+/-0.04 and 2.42+/-0.06 with 0.6% bile after previous 1h incubation in gastric conditions, respectively. It can be concluded that the cell wall compound of S. cerevisiae is a suitable protective coating for probiotics and it can improve the survival of probiotics within food products.

Mokhtari, S., et al. (2017). "Descriptive analysis of bacterial profile, physicochemical and sensory characteristics of grape juice containing Saccharomyces cerevisiae cell wall-coated probiotic microcapsules during storage." International Journal of Food Science & Technology **52**(4): 1042-1048.

In this study the feasibility of incorporation of probiotic microcapsules coated with fragmented yeast cell wall in grape juice was evaluated during 60 days at 4 degrees C. Lactobacillus acidophilus and Bifidobacterium bifidum were encapsulated in alginate microbeads and coated with fragmented Saccharomyces cerevisiae cell wall and calcium alginate and were added into grape juice. At the end of storage, the survival of probiotics was higher than recommended minimum value (10⁷ cfu mL⁻¹) and the results demonstrated that applying yeast cell wall layer for L. acidophilus microcapsules significantly enhanced its survival while did not affect the survival of B. bifidum (P>0.05). Generally, probiotic grape juice showed decrease in degrees Brix, pH and colour and increase in acidity and turbidity during storage and the presence of yeast wall layer had no significant effect on its properties expect colour and turbidity. Overall acceptance of grape juices containing yeast cell wall-coated microcapsules scored the least.

Molina-Moya, B., et al. (2018). "Mycobacterium tuberculosis complex genotypes circulating in Nigeria based on spoligotyping obtained from Ziehl-Neelsen stained slides extracted DNA." PLoS Neglected Tropical Diseases **12 (2) (no pagination)**(e0006242).

Tuberculosis (TB) remains one of the most threatening diseases and Nigeria has one of the world's largest burdens. This study performed high-throughput spoligotyping directly on sputum smears to describe the Mycobacterium tuberculosis strains circulating among new TB patients in Nigeria. Method(s): All State TB control programmes in Nigeria were requested to submit 25-50 smear-positive Ziehl-Neelsen (ZN) stained slides for screening during 2013-2014. DNA was extracted from 929 slides for spoligotyping and drug-resistance analysis using microbead-based flow-cytometry suspension arrays. Result(s): Spoligotyping results were obtained for 549 (59.1%) of 929 samples. Lineage 4 Cameroon sublineage (L4.6.2) represented half of the patterns, Mycobacterium africanum (L5 and L6) represented one fifth of the patterns, and all other lineages, including other L4 sublineages, represented one third of the patterns. Sublineage

L4.6.2 was mostly identified in the north of the country whereas L5 was mostly observed in the south and L6 was scattered. The spatial distribution of genotypes had genetic geographic gradients. We did not obtain results enabling the detection of drug-resistance mutations. Conclusion/Significance: We present the first national snapshot of the M. tuberculosis spoligotypes circulating in Nigeria based on ZN slides. Spoligotyping data can be obtained in a rapid and high-throughput manner with DNA extracted from ZN-stained slides, which may potentially improve our understanding of the genetic epidemiology of TB. Mondal, M. K., et al. (2019). "Recycling waste thermoplastic for energy efficient construction materials: An experimental investigation." Journal of Environmental Management **240**: 119-125.

A large stream of research has studied the performance of waste plastics impregnated concrete, reporting multiple benefits and advocating its use in construction works. But no study has reported the merits of bricks impregnated with waste plastics. The present paper reports the results of experiments done on bricks made up of varying percentages of waste thermoplastics (0 - 10% by weight) and sand (60 - 70% by weight), holding percentages of fly ash and ordinary Portland cement constant at 15% (by weight) each. Three types of waste thermoplastics were used, forming three separate batches of bricks. The plastics were polycarbonates, polystyrenes, and mixed plastics. The bricks were cured under water for 28 days. Some of the batches were baked at temperatures ranging from 90 degreeC to 110 degreeC for 2 hours in order to melt the plastics to form voids. The bricks made with the above-stated compositions were found to possess low thermal conductivity and adequately high compressive strength. The compressive strength of these bricks is observed to be more than 17 MPa, which lies within the upper half of the range of strengths specified for bricks in the IS 1077:1992 standard. The waste plastics impregnated bricks display high thermal resistance, a feature that can add economic value to the brick manufacturers, motivating them to establish the necessary logistics for collection and use of all types of waste thermoplastics. The paper also presents a regression model to predict the compressive strength of bricks at varying plastic contents. The study, thus, introduces a new strand of research on sustainable recycling of waste thermoplastics in the context of the circular economy. Copyright © 2019 Elsevier Ltd

Monk, J. M., et al. (2013). "n3 PUFAs reduce mouse CD4⁺ T-cell ex vivo polarization into Th17 cells." Journal of Nutrition **143**(9): 1501-1508.

Little is known about the impact of n3 (omega 3) PUFAs on polarization of CD4⁺ T cells into effector subsets other than Th1 and Th2. We assessed the effects of dietary fat [corn oil (CO) vs. fish oil (FO)] and fermentable fiber [cellulose (C) vs. pectin (P)] (2x2 design) in male C57BL/6 mice fed CO-C, CO-P, FO-C, or FO-P diets for 3 wk on the ex vivo polarization of purified splenic CD4⁺ T cells (using magnetic microbeads) into regulatory T cells [Tregs; forkhead box P3 (Foxp3⁺) cells] or Th17 cells [interleukin (IL)-17A⁺ and retinoic acid receptor-related orphan receptor (ROR) gamma tau ⁺ cells] by flow cytometry. Treg polarization was unaffected by diet; however, FO independently reduced the percentage of both CD4⁺ IL-17A⁺ (P<0.05) and CD4⁺ ROR gamma tau ⁺ cells (P<0.05). Moreover, expression of another critical Th17-cell-related transcription factor, signal transducer and activator of transcription 3, was reduced by FO. Dietary FO reduced the surface expression of both IL-6R and IL-23R on polarized Th17 cells (P<=0.05), thus interfering with the promotive effects of these critical cytokines on Th17 polarization. Additionally, C57BL/6 mice fed diets enriched in eicosapentaenoic acid (EPA), docosahexaenoic acid (DHA), or DHA+EPA similarly reduced Th17-cell polarization in comparison

to CO by reducing expression of the Th17-cell signature cytokine (IL-17A; P=0.0015) and transcription factor (ROR gamma tau P=0.02), whereas Treg polarization was unaffected. Collectively, these data show that n3 PUFAs exert a direct effect on the development of Th17 cells in healthy mice, implicating a novel n3 PUFA-dependent, anti-inflammatory mechanism of action via the suppression of the initial development of this inflammatory T-cell subset.

Monk, J. M., et al. (2015). "Fish-oil-derived n-3 PUFAs reduce inflammatory and chemotactic adipokine-mediated cross-talk between co-cultured murine splenic CD8⁺ T cells and adipocytes." Journal of Nutrition **145**(4): 829-838.

Background: Obese adipose tissue (AT) inflammation is characterized by dysregulated adipokine production and immune cell accumulation. Cluster of differentiation (CD) 8⁺ T cell AT infiltration represents a critical step that precedes macrophage infiltration. n-3 (omega -3) Polyunsaturated fatty acids (PUFAs) exert anti-inflammatory effects in obese AT, thereby disrupting AT inflammatory paracrine signaling.

Monson, C. F. and M. Majda (2007). "Ion diffusion in channels containing random arrays of microspheres: an electrochemical time-of-flight method." Analytical Chemistry **79**(24): 9315-9320.

Rates of chloride ion diffusion in narrow (ca. 3 microm thick), rectangular (ca. 0.1 x 1.0 mm(2)) channels partially filled with polystyrene microspheres are investigated by a potentiometric electrochemical time-of-flight (P-ETOF) method. Lithographically fabricated on glass slides, P-ETOF devices consist of a centrally positioned 10 microm wide, ca. 1 mm long generator microelectrode and two sensor microelectrodes of the same dimensions symmetrically positioned on both side of the generator at a distance of 50 microm. The electrodes are silver-plated and partially oxidized in a chloride electrolyte to form Ag/AgCl deposits. Constant current reduction of AgCl on the generator electrode is used to produce chloride ions at a constant rate. Ag/AgCl deposited on the sensor microelectrodes allows time-dependent potentiometric monitoring of the increasing concentration of chloride ions diffusing across the interelectrode gap. The device is enclosed with a parallel glass plate to form a narrow channel with the polystyrene microbeads serving as spacers. The packing density of the microspheres expressed in terms of the fractional void volume (rho) varied from ca. 0.6 to 1.0. Using rho, we modified a diffusion equation describing the change of chloride ion concentration at the sensor microelectrode to include the effect of the microspheres restricting the void volume. We rely on digital simulations as well as on direct P-ETOF experiments to show that the proposed equation does accurately account for the effect of rho on the diffusion processes. We thus demonstrate that P-ETOF can be used to measure the number of identical microspheres in the active region of a narrow channel device. In the latter context, a future application of P-ETOF as a signal transduction mechanism in biosensors is outlined.

Montanucci, P., et al. (2015). "Insights in Behavior of Variably Formulated Alginate-Based Microcapsules for Cell Transplantation." BioMed Research International **2015**: 1-11.

Alginate-based microencapsulation of live cells may offer the opportunity to treat chronic and degenerative disorders. So far, a thorough assessment of physical-chemical behavior of alginate-based microbeads remains cloudy. A disputed issue is which divalent cation to choose for a high performing alginate gelling process. Having selected, in our system, high mannuronic (M) enriched alginates, we studied different gelling cations and their combinations to determine their eventual influence on physical-chemical properties of the final microcapsules preparation, in vitro and in vivo. We have shown that used of ultrapure alginate allows for high biocompatibility of the formed microcapsules, regardless of gelation agents, while use of different gelling cations is associated with corresponding variable effects on the capsules' basic architecture, as originally reported in this work. However, only the final application which the capsules are destined to will ultimately guide the selection of the ideal, specific gelling divalent cations, since in principle there are no capsules that are better than others.

Monteleone, A., et al. (2019). "Development of an extraction method for microplastics from biological materials and fast prognosis of contamination based on autofluorescence." Biomedizinische Technik **64 (2)**: S207.

Since the beginning of industrial production in 1950, plastic production has continued to grow strongly worldwide and is now at 335 million tonnes in the year 2016. From these very high production volumes ever larger quantities are found in the environment. There the plastics degradate to microplasticity and spread ubiquitously in the world. The present work deals with the possible uptake of microplastic particles in human organisms. For the detection of these plastic particles, an extraction method was developed and validated. Biological materials consist of human blood (healthy volunteers, n = 5) and different tissues of pigs and cattles. Various lysis solutions were tested for degradation efficiency of biological material and for effects on the plastics. The mass loss, surfaces and structure variations as well as the physiochemical spectrum of the material were observed after treatment by electron microscopy (EM), Fluorescent microscope and Fourier transform infrared spectrometry (FTIR). The different plastic types as polyamides (PA), polycarbonate (PC), polyethylene (PE), polypropylene (PP), polystyrene (PS), polyvinyl chloride (PVC) could be clearly differentiated and identified by FTIR. Regarding the surface control, especially PVC showed detectable alterations: After extraction an irregular surface structure caused by protuberances or bubbles could be observed. However, instead of these alterations an equivalent count of plastic particles was found in correlation to the applied plastic amount (recovery rate overall was 99,35 0,43%).). Increasing the intensity of autofluorescence by means of temperature treatment makes the particles visible on the membranes, which can be counted automatically by the computer program ImageJ. The autofluorescence can be used for an initially and fast prognosis of microplastic contamination on the membranes. The applied method can be used for plastic extractions from human or animal tissues without remarkable effects on the plastics.

Moore, C. J. (2008). "Synthetic polymers in the marine environment: A rapidly increasing, long-term threat." Environmental Research **108**(2): 131-139.

Synthetic polymers, commonly known as plastics, have been entering the marine environment in quantities paralleling their level of production over the last half century. However, in the last two decades of the 20th Century, the deposition rate accelerated past the rate of production, and plastics are now one of the most common and persistent pollutants in ocean waters and beaches worldwide. Thirty years ago the prevailing attitude of the plastic industry was that "plastic litter is a very small proportion of all litter and causes no harm to the environment except as an eyesore" [Derraik, J.G.B., 2002. The pollution of the marine environment by plastic debris: a review. Mar. Pollut. Bull. 44(9), 842-852]. Between 1960 and 2000, the world production of plastic resins increased 25-fold, while recovery of the material remained below 5%. Between 1970 and 2003, plastics became the fastest growing segment of the US municipal waste stream, increasing nine-fold, and marine litter is now 60-80% plastic, reaching 90-95% in some areas. While undoubtedly still an eyesore, plastic debris today is having significant harmful effects on marine biota. Albatross, fulmars, shearwaters and petrels mistake floating plastics for food, and many individuals of these species are affected; in fact, 44% of all seabird species are known to ingest plastic. Sea turtles ingest plastic bags, fishing line and other plastics, as do 26

species of cetaceans. In all, 267 species of marine organisms worldwide are known to have been affected by plastic debris, a number that will increase as smaller organisms are assessed. The number of fish, birds, and mammals that succumb each year to derelict fishing nets and lines in which they become entangled cannot be reliably known; but estimates are in the millions. We divide marine plastic debris into two categories: macro, >5 mm and micro, <5 mm. While macro-debris may sometimes be traced to its origin by object identification or markings, micro-debris, consisting of particles of two main varieties, (1) fragments broken from larger objects, and (2) resin pellets and powders, the basic thermoplastic industry feedstocks, are difficult to trace. Ingestion of plastic micro-debris by filter feeders at the base of the food web is known to occur, but has not been quantified. Ingestion of degraded plastic pellets and fragments raises toxicity concerns, since plastics are known to adsorb hydrophobic pollutants. The potential bioavailability of compounds added to plastics at the time of manufacture, as well as those adsorbed from the environment are complex issues that merit more widespread investigation. The physiological effects of any bioavailable compounds desorbed from plastics by marine biota are being directly investigated, since it was found 20 years ago that the mass of ingested plastic in Great Shearwaters was positively correlated with PCBs in their fat and eggs. Colonization of plastic marine debris by sessile organisms provides a vector for transport of alien species in the ocean environment and may threaten marine biodiversity. There is also potential danger to marine ecosystems from the accumulation of plastic debris on the sea floor. The accumulation of such debris can inhibit gas exchange between the overlying waters and the pore waters of the sediments, and disrupt or smother inhabitants of the benthos. The extent of this problem and its effects have recently begun to be investigated. A little more than half of all thermoplastics will sink in seawater. © 2008 Elsevier Inc. All rights reserved.

Moore, C. J., et al. (2001). "A comparison of plastic and plankton in the North Pacific Central Gyre." Marine Pollution Bulletin **42**(12): 1297-1300.

The potential for ingestion of plastic particles by open ocean filter feeders was assessed by measuring the relative abundance and mass of neustonic plastic and zooplankton in surface waters under the central atmospheric high-pressure cells of the North Pacific Ocean. Neuston samples were collected at 11 random sites, using a manta trawl lined with 333 u mesh. The abundance and mass of neustonic plastic was the largest recorded anywhere in the Pacific Ocean at 334271 pieces km² and 5114gkm², respectively. Plankton abundance was approximately five times higher than that of plastic, but the mass of plastic was approximately six times that of plankton. The most frequently sampled types of identifiable plastic were thin films, polypropylene/monofilament line and unidentified plastic, most of which were miscellaneous fragments. Cumulatively, these three types accounted for 98% of the total number of plastic pieces. Copyright © 2001 Elsevier Science Ltd.

Moore, C. J., et al. (2002). "A comparison of neustonic plastic and zooplankton abundance in southern California's coastal waters." Marine Pollution Bulletin **44**(10): 1035-1038.

The density of neustonic plastic particles was compared to that of zooplankton in the coastal ocean near Long Beach, California. Two trawl surveys were conducted, one after an extended dry period when there was little land-based runoff, the second shortly after a storm when runoff was extensive. On each survey, neuston samples were collected at five sites along a transect parallel to shore using a manta trawl lined with 333 mu mesh. Average plastic density during the study was 8 pieces per cubic meter, though density after the storm was seven times that prior to the storm. The mass of plastics was also higher after the storm, though the storm effect on mass was less than it was for density, reflecting a smaller average size of plastic particles after the storm. The average mass of plastic was two and a half times greater than that of plankton, and even greater after the storm. The spatial pattern of the ratio also differed before and after a storm. Before the storm, greatest plastic to plankton ratios were observed at two stations closest to shore, whereas after the storm these had the lowest ratios. © 2002 Elsevier Science Ltd. Moore, D., et al. (2009). "The analysis of high density lipoprotein components in serum to identify biomarkers for cardiovascular disease." Atherosclerosis Supplements. Conference: 15th International Symposium on Atherosclerosis. Boston, MA United States. Conference Publication: **10**(2).

Objectives: Develop an array of methods for the isolation and analysis of high density lipoprotein (HDL) components that can be used to identify biomarkers for cardiovascular disease. Method(s): HDL fractions were isolated by density gradient ultracentrifugation (DGU) using a dicesium cadmium ethylenediaminetetraaceticacid gradient and immunospecific-DGU (I-DGU) using IgY Anti-Apo C-I microbeads. Matrix Assisted Laser Desorption Ionization (MALDI-MS) was used for the identification of apolipoproteins. HDL fractions were analyzed for their in vitro effects on aortic smooth muscle cells. Result(s): The distribution of lipoproteins was visualized by lipoprotein density profiling prior to and following I-DGU. MALDI results showed the reduction of Apo C-I in depleted samples following immunoaffinity chromatography and an increase in Apo C-I in recovered samples. Treatment of aortic smooth muscle cells with fractions prior to and following I-DGU showed correlations between the amount of Apo C-I and the percentage of apoptotic cells. Conclusion(s): The depletion and recovery of Apo C-I was shown by profiling, confirmed by MALDI and provided results relating to Apo C-I and its role in apoptosis. A marked increase in apoptotic cells was seen with the recovered Apo C-I sample as well as a corresponding decrease with the depleted Apo C-I samples; such results strongly support the hypothesis that Apo C-I may play a role in atherogenesis.

Moore, R. C., et al. (2020). "Microplastics in beluga whales (Delphinapterus leucas) from the Eastern Beaufort Sea." Marine Pollution Bulletin **150**: 110723.

Microplastics (MPs, particles <5mm) represent an emerging global environmental concern, having been detected in multiple aquatic species. However, very little is known about the presence of MPs in higher trophic level species, including cetaceans. We worked with community based monitors and Inuvialuit hunters from Tuktoyaktuk (Northwest Territories, Canada) to sample seven beluga whales (Delphinapterus leucas) in 2017 and 2018. Microplastics were detected in the gastrointestinal tracts in every whale. We estimate that each whale contained 18 to 147 MPs in their GI tract (average of 97+/-42 per individual). FTIR-spectroscopy revealed over eight plastic polymer types, with nearly half being polyester. Fibres made up 49% of MPs. The diversity of MP shapes and polymeric identities in beluga points to a complex source scenario, and ultimately raises questions regarding the significance and long-term exposure of this pollutant in this ecologically and culturally valuable species.

Moos, N. v., et al. (2012). "Uptake and effects of microplastics on cells and tissue of the blue mussel Mytilus edulis L. after an experimental exposure." Environmental Science & Technology **46**(20): 11327-11335.

In this study, we investigated if industrial high-density polyethylene (HDPE) particles, a model microplastic free of additives, ranging >0-80 micro m are ingested and taken up into the cells and tissue of the blue mussel Mytilus edulis L. The effects of exposure (up to 96 h) and plastic ingestion were observed at the cellular and subcellular level. Microplastic uptake into the gills and digestive gland was analyzed by a new method using polarized light microscopy. Mussel

health status was investigated incorporating histological assessment and cytochemical biomarkers of toxic effects and early warning. In addition to being drawn into the gills, HDPE particles were taken up into the stomach and transported into the digestive gland where they accumulated in the lysosomal system after 3 h of exposure. Our results show notable histological changes upon uptake and a strong inflammatory response demonstrated by the formation of granulocytomas after 6 h and lysosomal membrane destabilization, which significantly increased with longer exposure times. We provide proof of principle that microplastics are taken up into cells and cause significant effects on the tissue and cellular level, which can be assessed with standard cytochemical biomarkers and polarized light microscopy for microplastic tracking in tissue.

Morath, S. J. (2019). "Our Plastic Problem." Natural Resources & Environment **33**(4): 45-49.
The article discusses the issue of plastic pollution around the world and the efforts to resolve it. Other topics include the multimodal strategy to address the problem including educational campaigns, industrial design, and institutional pledges, the increasing cases of plastic pollution in the ocean, and the dangers it poses to aquatic ecosystems, fish, and animals.

Morawski, C. and S. Millette (2019). "THE RISE OF REUSABLES." Resource Recycling **38**(5): 32-34.
The article offers information on increment of reusable items in business enterprises in order to tackle plastic pollution. Topics discussed include information of ReCircle that uses reusable lunchboxes to restaurants; lack of standardization of reuse initiatives which impact on costs; and information of Reusable Packaging Platform which aims to building a coalition of all three reusable packaging sectors consumer packaging, transport packaging, and industrial packaging.

Moreira, F. T., et al. (2016). "Revealing accumulation zones of plastic pellets in sandy beaches." Environmental Pollution **218**: 313-321.
Microplastics such as pellets are reported worldwide on sandy beaches, and have possible direct and indirect impacts on the biota and physical characteristics of the habitats where they accumulate. Evaluations of their standing stock at different spatial scales generate data on levels of contamination. This information is needed to identify accumulation zones and the specific beach habitats and communities that are likely to be most affected. Standing stocks of plastic pellets were evaluated in 13 sandy beaches in Sao Paulo state, Brazil. The sampling strategy incorporated across-shore transects from coastal dunes and backshores, and vertical profiles of the accumulated pellets down to 1 m depth below the sediment surface. Accumulation zones were identified at regional (among beaches) and local (between compartments) scales. At the regional scale pellet density tended to increase at beaches on the central and southwestern coast, near ports and factories that produce and transport the largest amounts of pellets in the country. At the local scale coastal dunes showed larger accumulations of pellets than backshores. For both compartments pellets tended to occur deeper in areas where standing stocks were larger. Most of the pellets were concentrated from the surface down to 0.4 m depth, suggesting that organisms inhabiting this part of the sediment column are more exposed to the risks associated with the presence of pellets. Our findings shed light on the local and regional scales of spatial variability of microplastics and their consequences for assessment and monitoring schemes in coastal compartments.

Morel, N., et al. (2004). "Selective and efficient immunoprecipitation of the disease-associated form of the prion protein can be mediated by nonspecific interactions between monoclonal antibodies and scrapie-associated fibrils." Journal of Biological Chemistry **279**(29): 30143-30149.

Transmissible spongiform encephalopathies are characterized by the accumulation in brain tissues of an abnormal isoform of the prion protein named PrPsc, which is the only direct marker known for transmissible spongiform encephalopathies. Here we show that PrPsc can be specifically immunoprecipitated by using several monoclonal antibodies (mAbs) of various specificities independently of the properties of their binding site (paratope). These results strongly suggest that a significant proportion of mAbs can interact with PrPsc aggregates through nonspecific paratope-independent interactions allowing selective immunoprecipitation of PrPsc when these mAbs are immobilized on a polydisperse solid phase like microbeads.

Moreno, D. D. P. and C. Saron (2018). "Influence of compatibilizer on the properties of low-density polyethylene/polyamide 6 blends obtained by mechanical recycling of multilayer film waste." Waste Management & Research **36**(8): 729-736.

Polymeric wastes have caused increasing environmental problems, mainly in oceans that accumulate large amounts of non-degradable plastic waste. Particularly, waste of polymeric multilayer films for packaging presents low interest for mechanical recycling due to the poor properties and low commercial value of the recycled material generated as polymeric blends. Multilayer films of low-density polyethylene (LDPE) and polyamide 6 (PA6) is a typical material used for packaging applications. The aim of this study was to evaluate the action of the concentration of maleic anhydride grafted polyethylene (PE- g-MA) on the compatibilization of LDPE/PA6 blends generated from mechanical recycling of multilayer films containing both polymers. The action of the PE- g-MA on the properties of the LDPE/PA6 blends was evaluated by tensile tests, optical microscopy, melt flow rate, and scanning electron microscopy. The use of PE- g-MA at 2.5 wt% as a compatibilizer during reactive extrusion of the multilayer films waste has showed the best result for production of the respective recycled LDPE/PA6 blends.

Moreno Martin Retortillo, L., et al. (2011). "Isolation of neuroblastoma cells as a substrate for pharmacodynamic biomarker assays to accompany early clinical trials of Neuroblastoma." European Journal of Cancer **1)**: S285.

Background: Pharmacodynamic (PD) biomarkers provide proof-ofprinciple of target modulation and evaluate downstream biological effects of novel targeted therapeutics.Repeat tumour biopsies in children are problematic, complicating the implementation of these assays into paediatric trials.Neuroblastoma (NB) is a high-risk childhood cancer in which bone marrow (BM) metastases are frequent.Our aim is to obviate the need for biopsies by developing a methodology to obtain pure or highly enriched bone marrow-derived tumour cells as a substrate for assays.Material and Methods: Peripheral blood (PB) and BM samples were spiked with cells from the NB Kelly cell line.MACS MicroBeads Technology was used for the cell separation: Purity and recovery of positive selection for GD2+ neuroblastoma antigen and negative selection of CD45+ cells were compared using flow cytometry.To determine the suitability of the samples (1) total protein concentration (bicinchoninic acid assay), and (2) changes in total and phosphoprotein signals of the PI3K pathway (MesoScale Discovery) before and after the separation were compared. Result(s): CD45 negative selection achieved a median 3.6-fold (range 2.0 - 6.3), 2.5-fold (2.0-11.0) and 6.1-fold (2.8 - 9.3) enrichment of NB cells in spiked PB, spiked BM and clinically involved BM samples respectively.Cell recovery with CD45 negative selection was superior to GD2 positive selection (73%+/-25 vs.21%+/-20 cells recovered, p < 0.001).Cellular losses were manageable permitting the realisation of

protein-based assays.Each sample was lysed to a final volume of 100 mL.In these lysates, total protein concentration was 10.4 mg/mL+/-3.0 for samples prevs.5.7+/-3.2 post-immunomagnetic separation (p = 0.10).Median sample volume required for our PI3K protein analyses was 13.9 mL (range 8.6- 50.2).PI3K assay ranges were tested in spiked cells.There was a moderate decrease in the total protein signals (-0.24 log difference, p = 0.35) and increase in the phospho protein signals (+0.14 log difference, p = 0.51) after the separation. Conclusion(s): Immunomagnetic separation was able to obtain samples with high purity in neuroblastoma cells in spiked and clinical samples.The number of cells recovered was sufficient for protein analyses.The procedure had a moderate impact in the total and phospho-protein signals for the PI3K pathway but signals were detectable and consistent.Neuroblastoma cells isolated from BM could be a source of tissue for PD assays in future clinical trials.

Moreno Villegas, Z., et al. (2010). "Effects of ultraviolet radiation in different subpopulations of peripheral blood monocytes." Inmunologia **1)**: 31.

Background: Ultraviolet (UV) irradiation has cytotoxic effects on the skin and the immune system as a consequence of oxidative stress. Several effects have been described in different immune cellular types. However, there are no studies about its effects in recently described monocyte subpopulations. Objetive: To determine the UV irradiation effects on the different subsets of peripheral blood monocytes. Material(s) and Method(s): Peripheral blood mononuclear cells were isolated from healthy donors by standard Ficoll-Paque density gradient centrifugation. Monocytes were irradiated with an UV-emitting lamp (I=1319W/m²) over different times (7, 14 and 28 minutes). Later, cells were cultured for 3, 6, 24 and 48 hours and were adquired in a FACSCalibur flow cytometer using fluorochrome-labeled monoclonal antibodies. Monocytes were selected in a FSC-SSC dot plot, and defined as CD3 negative and CD14 positive. Monocyte subpopulations were identified as classic monocytes (CD14+ CD16-), inflammatory monocytes (CD14^{+high} CD16⁺) and resident monocytes (CD14^{+dim} CD16⁺). The absolute number of viable (7-AAD-) monocytes were calculated using microbeads as an internal reference. Results. We observed that in both CD16+ monocyte subsets UV exposure caused a rapid and dramatical decrease in the absolute number of viable cells. However, the absolute number of viable classic monocytes (CD14+ CD16-) increased progressively after 7 minutes of UV exposition. Meanwhile, 14 minutes of irradiation caused at 3 hours a slow increase of viable cell number, but after 6 h decreased strongly. For all subpopulations studied, 28 minutes of UV induced a massive cell death. We also observed a very slight and progressive increase in viable classic monocytes absolute number from 6 and 24 yours for 28 and 14 minutes of irradiation respectively. Conclusion. Classic monocytes are much more resistant to ultraviolet emissions than inflammatory and residents subsets, which disappear at 3 hours of cultured.

Moreno, Z., et al. (2011). "Photoprotective effect of a Polypodium leucotomos extract against ultraviolet radiation on human peripheral blood monocytes." Journal of Investigative Dermatology **1)**: S111.

Exposure to ultraviolet radiation (UVR) induces local and systemic damage on the skin and on the immune system, mainly due to oxidative stress. We have previously reported that a Polypodium leucotomos extract (PL) possesses antioxidant and immunoprotective properties against UVR. Our objective was to determine the effects of PL on the viability of peripheral blood classical or inflammatory and resident monocytes after UVR. Human peripheral blood mononuclear cells were isolated from 6 healthy donors, cultured in presence of several dilutions of PL (4 mg/ml to 0.0625 mg/ml) for 1 hr and then were radiated with an UVA-emitting lamp (I=1319W/m2) during 7 min. Later, cells were cultured for additional 24 hrs and analyzed by

flow cytometry using 1) fluorochromelabeled monoclonal antibodies to identify classical (CD14+CD16-) or inflammatory and resident (CD16+) monocytes, 2) 7-aminoactinomycin (viable cells) and 3) microbeads as an internal reference for absolute cell count. The % of protection conferred by PL (%P) was calculated dividing the absolute number of viable UV-irradiated monocytes by the absolute number of control non-irradiated viable monocytes. Result(s): %P granted by PL against UV-induced damage on CD14+CD16- classical monocytes was dose-dependent. %P ranged from 29.87 (0.06 mg/ml) to 123.07 (4 mg/ml). We found full UV protection at PL doses of 1 mg/ml (%P=96.13) and 2 mg/ml (%P=97.73). Surprisingly, PL had not protective effect on the CD16+ monocyte which completely disappeared after UV irradiation. in conclusion, our data indicate that PL exerts dose-dependent protection against UVR on human peripheral blood monocytes. They also show that classical monocytes are much more resistant to UVR than inflammatory and resident subsets.

Moreno-Altamirano, M. M. B., et al. (2012). "Proliferation of human T lymphocytes is down-regulated by dengue virus." Immunology **1)**: 643-644.

Purpose/Objective: To analyze some mechanisms involved in the lack of activation and proliferation of T Lymphocytes exposed to dengue virus serotype-2, in vitro. Material(s) and Method(s): Peripheral blood mononuclear cells (PBMC) were obtained from Buffy coats from healthy donors. The T lymphocyte subpopulation was purified by anti-CD3-coated magnetic microbeads. T cells were cultured under: (1) Concanavalin A, (2) dengue virus, (3) dengue virus plus Concanavalin A and (4) medium alone. After incubation for 4-16 h at 37degreeC in 5% CO2, T cell were Analyzed for (1) proliferation by using carboxy-fluorescein diacetate, succinimidyl ester (CFSE) and flow cytometry, (2) Expression of CD25, by flow cytometry, (3) Synthesis of IL-2, by ELISA and (4) activation and nuclear translocation of the transcription factors NFAT and NF-kB, by confocal microscopy in whole cells, and by flow cytometry of isolated and labeled nuclei. Result(s): The proliferation of T lymphocytes was inhibited in Concanavalin A stimulated cells when pre-incubated with dengue virus. The synthesis of IL-2 was inhibited when these cells were incubated with DENV-2 before addition ofCon A. A reduction in IL-2Ra expression was also observed, by flow cytometry. The nuclear translocation of NFAT and NF-kB was diminished when Con A-stimulated T cells were previously exposed to DENV-2. Conclusion(s): Understanding the role of the immune system in the pathogenesis related to dengue virus will help to improve patients' treatment. Some reports indicate that patients infected with dengue virus have a dysfunctional proliferation of T lymphocytes. However, studies in vitro have not been performed to analyze in more detail the DEN-2-mediated mechanism(s) of inhibition. As shown in this study, inhibition of nuclear translocation of NFAT and NFkB by DEN-2, as well as inhibition of IL-2 synthesis and IL2Ra expression could be accountable for the observed dysfunctional proliferation of T cells.

Moreno-Maroto, J. M., et al. (2017). "Development of lightweight aggregates from stone cutting sludge, plastic wastes and sepiolite rejections for agricultural and environmental purposes." Journal of Environmental Management **200**: 229-242.

Three different wastes have been assessed for lightweight aggregate (LWA) manufacturing: granite and marble sludge (COR), sepiolite rejections (SEP) and polyethylene-hexene thermoplastics (P). A preliminary study of the physical and chemical properties of the raw materials was carried out to design proper batches. It was mixed 10% SEP with 90% COR to confer plasticity, and in turn, 0, 2.5, 5 and 10% (w/w) of P was added to check its suitability as a bloating agent. The mixtures were milled, kneaded with water, extruded, shaped into pellets, oven-dried and finally fired at 1100, 1125 and 1150 °C for 4, 8 and 16 min. The main

technological properties of the aggregates related to bloating, density, porosity, loss on ignition, water absorption and compressive strength were measured. Scanning Electron Microscopy was used to study the microstructure of some LWAs. 23 out of 29 types of aggregate were lightweight, although neither bloating effect was observed, nor the typical cellular structure comprised of shell and core with relatively large pores was obtained, but a structure consisting of micropores and microchannels. The increase of temperature and time of firing involved a greater sintering, which in turn was translated into higher shrinkage, density and compressive strength values, but less porosity and water absorption. The addition of P did not involve any improvement, indeed it caused a significant decrease in compressive strength. The LWA sintered without P at the minimum time (4 min) and temperature of firing (1100 °C) was selected to assess its water suction capability. The results pointed out that this LWA could be suitable in hydroponics and/or water filtration systems, even better than the commercial LWA Arlita G3. A new and most environment-friendly perspective in LWA industry arises from here, promoting LWA production at relative low temperatures (prior to significant sintering occurs) and using non-plastic silty wastes instead of clays as major components. [ABSTRACT FROM AUTHOR]

Moreno-Sader, K., et al. (2020). "Environmental sustainability analysis of chitosan microbeads production for pharmaceutical applications via computer-aided simulation, WAR and TRACI assessments." Sustainable Chemistry and Pharmacy **15 (no pagination)**(100212).

In recent decades, pharmaceutical uses of chitosan microbeads have been identified owing to their low toxicity, biocompatibility and biodegradability. However, many contributions have limited such microbeads preparation to lab-scale and there are no works reported in the literature about the scaling-up of chitosan microbeads production. To fill the knowledge gap, this research attempts to simulate and evaluate the environmental performance of large-scale production of chitosan microbeads under sustainability concept using computer-aided process engineering (CAPE). The extended energy and mass balances were provided by process simulation using the commercial software Aspen Plus . The environmental assessment was performed through two computer-aided tools: waste reduction (WAR) algorithm and Tool for the Reduction and Assessment of Chemical and other Environmental Impacts (TRACI). Results reported negatives values for total generation rate of Potential Environmental Impacts (PEI) (-1.16 x 10⁺², -9.25 x 10⁺¹, -1.00 x 10⁺² and -7.66 x 10⁺¹ PEI/hr) and highest total output rate of PEI for cases 4 and 3 (considering energy flows contributions). For TRACI tool, potential environmental impacts were low, however, the freshwater ecotoxicity potential for freshwater emissions was higher (6.03E+02 CTUeco/hr) than for natural soil emissions (1.55E+02 CTUeco/hr). These results showed good environmental performance of the process and can be used as a benchmark in the production of more environmental-friendly chitosan microbeads at large-scale. Morét-Ferguson, S. and A. N. S. Siuda (2011). "Beyond our Beaches: Ocean Trash." Green Teacher(92): 6-8.

The article focuses on studies concerning plastic marine debris. According to scientists, although disposal by ships is part of the reason for the plastic litter in oceans, the bigger proportion of the debris is likely from land-based sources. The authors report that scientists saw the first open ocean plastic trash during the early 1970s. In the middle of the 1980s, students aboard the Sea Education Association's research vessel found out that the northern Sargasso Sea has the highest concentration of plastic debris in the western North Atlantic region.

Morgana, S., et al. (2018). "Microplastics in the Arctic: a case study with sub-surface water and fish samples off Northeast Greenland." Environmental Pollution **242**(Part B): 1078-1086.

The Arctic is a unique and fragile ecosystem that needs to be preserved and protected. Despite its remoteness, plastic pollution has been documented in this region. In the coming years, it is likely to worsen since, with climate changes and the opening of new shipping routes, the human presence is going to increase in the whole area. Here, we investigated the presence of microplastics (MPs) in sub-surface water and in two mid-trophic level Arctic fishes collected off Northeast Greenland: the demersal bigeye sculpin, Triglops nybelini, and the pelagic polar cod, Boreogadus saida. Plastics debris were found in the water samples at a concentration of 2.4 items/m³ +or-0.8 SD which is higher than in most seas at lower latitudes. Both fish species had eaten MPs with different proportion among the species, 34% for T. nybelini (n=71) and 18% for B. saida (n=85). The significant difference in the occurrence of MPs between the two species is likely a consequence of their feeding behavior and habitat. Polyethylene was the main plastic polymer for water samples (41%, n=17) and polyester (34%, n=156) for fish samples as analyzed by Fourier Transformed Infrared (FT-IR) spectroscopy. Our data underscore that the Arctic regions are turning into a hotspot for plastic pollution, and this calls urgently for precautionary measures.

Morganti, P. and Y. H. Li (2015). "Innovation in cosmetic and medical science. The role of chitin nanofibrils composites." Journal of Applied Cosmetology **33**(1-2): 9-24.

The main substrate of interest in cosmetic dermatology are hair, covered with hard keratin-scales, and skin Stratum Corneum (SC), being with corneocytes the outermost cell layer of the skin. Both, directly exposed to onslaught of pro-oxidative stressors and composed of dead cells filled with specific type of lipids and cross-linked proteins in the form of alpha-helix structure, represent the barrier of our body to the environment. The barrier function of both skin and hair depends, therefore, on the physicochemical properties of corneocytes and scales, which by their lipid-keratin structures, regulate and interchange water loss, oxygen and carbon dioxide, modulating the penetration of active ingredients and preventing the entrance of pathogenic microorganisms. While the skin lipid structure consists predominantly of ceramides (~50%) connected with fatty acids and cholesterol, the hair epicuticle membrane (scale) contains highly cross linked proteins (~75%) and adsorbed fatty acids (~25%), 18-methyleicosanoic acid (18-MEA) being the most abundant. In addition, skin and hair are equipped with a network of enzymatic and non-enzymatic antioxidant system, that counteract the oxidative injury. An imbalance of this complex structure leads to modifications of DNA, lipids, and proteins, resulting in loss of functionality of the barrier key components of both hair and skin. As a consequence, skin wrinkling appears and hair lose luster and alignment, decreasing its thickness and combability. The challenge of cosmetic dermatology is to produce effective and safeness cosmetic products capable to modulate both the keratin-lipid production and the antioxidant synthesis at level of skin and hair. These innovative products should slowdown skin wrinkling formation and ameliorate structure and function of the hair, giving the body a more younger appearance. For obtaining these results it is necessary to develop topical systems capable to deliver the right concentration of the right active ingredient to the right site in the body in the right period of time (4 R's), without disrupting the respective protective structures, but having the capability to stimulate the synthesis of both skin extra cellular matrix (ECM) and hair cortex components. These results have to be produced by a low consume of water and energy and by the use of green raw materials extract, for example, from fishery's waste, as Chitin Nanofibrils, and plant biomass, as lignocellulosic compounds. Thus, natural material, and biodiversity of our planet will be preserved. In this paper innovative products realized by two EU research projects Biomimetic (www.biomimetic-EU-project.eu) and n-Chitopack (www.n-Chitopack.eu) will be presented and discussed. These products, made by the use of biopolymers such as Chitin Nanofibrils (CN), Lignin (LN) and Polylactic acid (PLA), are in accordance with the incoming Bio-green economy supported by EU and UNEP. The use of these biopolymers, is, in fact, necessary to reduce the production of the actual petrol-derived polymers and stop the plastic waste in the land and in the oceans where 5 trillion pieces afloating, have been recovered, ranging a weight of over 250,000 tons. Finally it is to underline that this plastic waste causes the death of ~1 million bird and ~100,000 seamammals every year, so that scientists, opinion leaders and politic people worldwide have to work all together to solve this important problem.

Morgenroth, A., et al. (2011). "Two-step strategy for efficient killing of multiple myeloma stem cells using Auger-electrons emitting nucleoside analogue 5-Iod-4'-thio-2'-desoxyuridin (I-125-ITdU)." Molecular Cancer Therapeutics. Conference: AACR NCI EORTC International Conference: Molecular Targets and Cancer **10**(11 SUPPL. 1).

Background: Despite advances in treatment, multiple myeloma (MM) remains an incurable disease. Tumor relapse is at least in part due to the existence of drug resistant cancer stem cells (CSCs). A new therapeutic paradigm that effectively eradicates bulk MM cells and CSC needs to be developed. Auger-electrons emitting nucleoside analogues are attractive for nano-irradiation therapy when incorporated into the DNA. For this proposal, the quiescent CSCs need to be awaked. Although dormant hematopoietic stem cells (HSC) are mostly highly resistant to therapeutic regiments, they can be activated by pro-drug 5-FU to enter active cell cycle and to generate proliferative, therapy sensitive progenitor and mature cells. In analogy to HSC, the activation of highly resistant dormant CSC may present the crucial step for achieving long-term cure of cancers. Therefore in this study we evaluated the therapeutic potential of I-125-ITdU for targeting of multiple myeloma CSCs after priming with a potent thymidylate synthase (TS) inhibitor FdUrd, an active metabolite of 5-FU. Method(s): For CSCs isolation, KMS12BM cells were incubated with CD138 and CD27 MicroBeads. The CD Marker expression was investigated by flow cytometry. For FdUrd treatment, cells were incubated with 0.1 muM FdUrd for 2 d. The expression level of aldehyde dehydrogenase (ALDH) was evaluated using Aldefluor assay by flow cytometry. Cell cycle was investigated by Nicoletti. The uptake and DNA incorporation of I-125-ITdU (50kBq/2*10 4 cells) were assessed after 4 d using gamma counter. Apoptotic cells were identified using Annexin-V by flow cytometry. Result(s): The purity of isolated CSC was more than 97% (CD27⁺CD138⁻). FdUrd treatment of CD27⁺CD138⁻ cells yielded a decreased ALDH activity (65.2% vs. 29.8%). Furthermore, FdUrd induced CSC to enter the cell cycle (48.5% vs. 18.7% and 29.2% vs. 47.7% of cells in G0/G1 and S phase, respectively) and increased the CD138 expression. The treatment with a non-toxic dose of FdUrd was essential for effective incorporation of ITdU and inducing of irreparable DNA damage. The activation with FdUrd increased the cellular uptake by a factor of 25. KMS12BM CSC incorporated 46.3% +/- 2.8% of internalized activity into DNA. Most important, I-125-ITdU showed a potent antimyeloma effect on isolated CSC. More than 95% of treated cells were detected as apoptotic. Conclusion(s): This is the first report to demonstrate that DNA is a promising target for endoradio- therapy of CSC of multiple myeloma

using two-step-strategy: FdUrd for activating and Auger-radiation emitting thymidine analogue ITdU for eliminating of malign cells.

Morin, N. A. O., et al. (2017). "The presence and partitioning behavior of flame retardants in waste, leachate, and air particles from Norwegian waste-handling facilities." Journal of Environmental Sciences (China) **62**: 115-132.

Flame retardants in commercial products eventually make their way into the waste stream. Herein the presence of flame retardants in Norwegian landfills, incineration facilities and recycling sorting/defragmenting facilities is investigated. These facilities handled waste electrical and electronic equipment (WEEE), vehicles, digestate, glass, combustibles, bottom ash and fly ash. The flame retardants considered included polybrominated diphenyl ethers (BDE-10) as well as dechlorane plus, polybrominated biphenyls, hexabromobenzene, pentabromotoluene and pentabromoethylbenzene (collectively referred to as FR-7). Plastic, WEEE and vehicles contained the largest amount of flame retardants (BDE-10: 45,000-210,000mug/kg; FR-7: 300-13,000mug/kg). It was hypothesized leachate and air concentrations from facilities that sort/defragment WEEE and vehicles would be the highest. This was supported for total air phase concentrations (BDE-10: 9000-195,000pg/m³ WEEE/vehicle facilities, 80-900pg/m³ in incineration/sorting and landfill sites), but not for water leachate concentrations (e.g., BDE-10: 15-3500ng/L in WEEE/Vehicle facilities and 1-250ng/L in landfill sites). Landfill leachate exhibited similar concentrations as WEEE/vehicle sorting and defragmenting facility leachate. To better account for concentrations in leachates at the different facilities, waste-water partitioning coefficients, K_{waste} were measured (for the first time to our knowledge for flame retardants). WEEE and plastic waste had elevated K_{waste} compared to other wastes, likely because flame retardants are directly added to these materials. The results of this study have implications for the development of strategies to reduce exposure and environmental emissions of flame retardants in waste and recycled products through improved waste management practices.

Morritt, D., et al. (2014). "Plastic in the Thames: a river runs through it." Marine Pollution Bulletin **78**(1-2): 196-200.

Although contamination of the marine ecosystems by plastics is becoming recognised as a serious pollution problem, there are few studies that demonstrate the contribution made by freshwater catchments. Over a three month period from September to December 2012, at seven localities in the upper Thames estuary, 8490 submerged plastic items were intercepted in eel fyke nets anchored to the river bed. Whilst there were significant differences in the numbers of items at these locations, the majority were some type of plastic. Additionally in excess of 20% of the litter items were components of sanitary products. The most contaminated sites were in the vicinity of sewage treatment works. While floating litter is visible, this study also demonstrates that a large unseen volume of submerged plastic is flowing into the marine environment. It is therefore important that this sub-surface component is considered when assessing plastic pollution input into the sea.

Morsbach, S., et al. (2018). "Quantification of fluorescent dyes in organ tissue samples via HPLC analysis." Journal of Chromatography B: Analytical Technologies in the Biomedical and Life Sciences **1072**: 34-39.

The determination of regional blood flow via the accumulation of fluorescent microspheres is a concept regularly used in medical research. Typically, the microbeads get extracted from the tissue of interest and are then quantified by measuring the absorption or fluorescence of the incorporated dyes without further separation from the medium. However, in that case the absorption spectra of different dyes can overlap when used simultaneously, leading to an overestimation of the concentration. Additionally, background absorption from the medium can be problematic. Therefore, a high performance liquid chromatography method for the simultaneous detection of four dyes (orange, crimson, yellow-green and red) incorporated in different microbeads in samples from biological media such as organ tissue (brain, heart and kidneys) was developed. Since for biological samples often a large sample size is required for sufficient statistics, the method was optimized to yield very short run times. With this method it was possible to detect very low concentrations of only one microsphere per gram of organ tissue. By applying this sensitive quantification technique, it was demonstrated that the application of microbeads for perfusion measurements might not be reliable due to different organ distributions in each animal. Copyright © 2017 Elsevier B.V.

Morsy, M. A., et al. (2005). "Isolation, purification and flow cytometric analysis of human intrahepatic lymphocytes using an improved technique." Laboratory Investigation **85**(2): 285-296.

Intrahepatic lymphocytes (IHL) with their diverse and distinctive subsets emphasise the importance of the liver as a site of immunological activity, but special care is required for their isolation and characterisation. Protocols for IHL isolation, purification and FACS analysis were devised and compared with published extraction protocols. We have reduced the time that IHL are exposed to potentially damaging enzymes during extraction and purified specific subsets using monoclonal antibody (mAb)-coated magnetic microbeads. This has yielded IHL populations with higher viability than previously described protocols (92-95%, compared with 39-86%). Flow cytometric characterisation of IHL subset immunophenotypes was optimised by combining CD45 staining (fluorescence gating) with traditional light scatter properties. Using a panel of mAb and liver biopsies obtained from 23 cadaveric liver transplant donors, we show that the normal liver contains a heterogeneous IHL population with distinctive phenotypes. CD8+ IHL was the predominant population with a mean CD4/CD8 ratio of 1:1.7. Up to 40% of IHL expressed gammadeltaTCR and a third expressed CD56 NK marker; indicating a site of intense immunological activity. The techniques described will allow these cell types to be isolated, fully characterised and their physiological functions to be determined. The histologically normal liver contains heterogeneous and diverse IHL with large numbers of CD8+, NK, NKT and gammadelta+ cells.

Mortensen, N. P., et al. (2019). "Biological interactions between nanomaterials and placental development and function following oral exposure." Reproductive Toxicology **90**: 150-165.

We summarize the literature involving the deposition of nanomaterials within the placenta following oral exposure and the biological interactions between nanomaterials and placental development and function. The review focuses on the oral exposure of metal and metal oxide engineered nanomaterials (ENMs), carbon-based ENMs, and nanoplastics in animal models, with a minor discussion of intravenous injections. Although the literature suggests that the placenta is an efficient barrier in preventing nanomaterials from reaching the fetus, nanomaterials that accumulate in the placenta may interfere with its development and function. Furthermore, some studies have demonstrated a decrease in placental weight and association with adverse fetal health outcomes following oral exposure to nanomaterials. Since nanomaterials are increasingly used in food, food packaging, and have been discovered in drinking water, the risk for adverse impacts on placental development and functions, with secondary effects on embryo-fetal development, following unintentional maternal ingestion of nanomaterials requires further investigation.

Moscelli, N., et al. (2011). A real-time cell proliferation and motility monitoring system. BIODEVICES 2011 - Proceedings of the International Conference on Biomedical Electronics and Devices.

In this contribution we present a compact imaging system to monitor the proliferation and the motility of cells in real-time. Our monitoring system is compatible with standard multi-well plates and operates in CO2, temperature and humidity controlled cell-culture incubators. Adherent grown epithelial cells in a multi-well plate well, positioned on top of a custom made holder, have been monitored in real-time with a fixed CCD image sensor. As light source an LED is placed above the plate holder. A field of view of 3.3 × 2.5 mm2 was achieved by using a 4.6 × 4.0 mm2 image sensor and mini lens system. The image sensor has a resolution of 640 x 480 pixels. Consequently, the obtained sensing resolution of the imaging system is about 5 µm. The cell monitoring system has first been validated by visualizing micro-beads of known dimensions. Then, our system has been successfully tested, tracking the migration paths and proliferation of respectively adherent grown MDCK (Madin-Darby canine kidney) and A549 (human lung carcinoma) epithelial cells.

Moser, M. L. and D. S. Lee (1992). "A fourteen-year survey of plastic ingestion by western North Atlantic seabirds." Colonial Waterbirds **15**(1): 83-94.

To evaluate the incidence of ocean-borne plastic particle ingestion by western North Atlantic seabirds, we analyzed the gut contents of 1033 birds collected off the coast of North Carolina from 1975-1989. Twenty-one of 38 seabird species (55%) contained plastic particles. Procellariiform birds contained the most plastic and the presence of plastic was clearly correlated with feeding mode and diet. Plastic ingestion by procellariiforms increased over the 14 year study period, probably as a result of increasing plastic particle availability. Some seabirds showed a tendency to select specific plastic shapes and colors, indicating that they may be mistaking plastics for potential prey items. We found no evidence that seabird health was affected by the presence of plastic, even in species containing the largest quantities: Northern Fulmars (Fulmarus glacialis), Red Phalaropes (Phalaropus fulicaria) and Greater Shearwaters (Puffinus gravis).

Moser, N. (2015). "Ethical Spectacles." Alternatives Journal **41**(3): 44-45.

Zeal has also partnered with not-for-profits such as Second Mile Water, 5 Gyres Institute and Protect Our Winters to address climate change, plastic pollution and access to safe drinking water. Designers like Vinylize, ROLF Spectacles and Zeal Optics are making waves in the optical industry by choosing strong environmental platforms without compromising on quality and style.

Moshaverinia, A. (2012). Encapsulated periodontal ligament and Gingival mesenchymal stem cells in 3D, injectable, and biodegradable scaffold: A unique platform for bone tissue engineering.

The need for hard tissues repair has increased in modern esthetic and reconstructive dentistry. Bone grafts are currently the major modality of treatment. Tissue engineering provides a new concept for tissue regeneration and reconstruction. Stem cell-scaffold constructs seem to be a promising approach for bone tissue engineering. Stem cells in particular have drawn interest because they are undifferentiated cells with the ability to differentiate into one or more types of cells and are capable of self-renewal. Tissue regeneration using mesenchymal stem cells might be an advantageous therapeutic option since it provides high-quality regeneration of damaged tissues without forming fibrous tissue, minimum donor-site morbidity compared to autografts, and a low risk of autoimmune rejection and disease transmission. Therefore, the objectives of this study were to: (1) develop an injectable scaffold based on oxidized alginate microbeads encapsulating PDL (PDLSCs) and Gingival mesenchymal stem cells (GMSCs); and (2) investigate microsphere degradation profile, cell viability, and osteogenic differentiation of the stem cells (in vitro and in vivo) for the first time. Alginate microspheres with sizes of about 2 plus or minus 0.1 mm were fabricated with 1 x10 super(6) stem cell/ mL of alginate. Microspheres containing PDLSCs, GMSCs and hBMMSCs were further implanted subcutaneously and ectopic bone formation was analyzed by mu CT and histological analysis at 8 weeks post-implantation. The encapsulated stem cells remained viable in vitro and both osteo-differentiated and adipo-differentiated after 4 weeks of culturing in the respective induction media. Scanning electron microscopy and X-ray diffraction results confirmed that apatitic mineral was deposited by the stem cells. It was found that the degradation profile of alginate hydrogel strongly depends on the degree of oxidation demonstrating its tunable chemistry and degradation rate. In the animal study ectopic mineralization was observed inside and around the implanted microspheres containing the immobilized stem cells. These findings demonstrate for the first time that immobilization of PDLSCs and GMSCs in the alginate microspheres provides a promising strategy for bone tissue engineering.

Mosko, S. (2013). "Toxic Debris Delivers Triple Whammy." E THIS WEEK: 6-6.

The article reports that according to a new study, ocean plastic debris is a threat to human beings. The study, which is published in the December 2013 issue of the journal "Environmental Science & Technology," found that plastics introduce toxic chemicals into the ocean food web. It compared how mass-produced plastics accumulate hazardous chemicals from local seawater.

Mosko, S. S. (2014). "Youthful Skin Versus Ocean Food Web." Natural Life: 8-10.

The article talks about the products containing plastic micro-beads profess to speed up skin rejuvenation, acts like a chemical pollutant when released in lakes, rivers, & oceans. It also focuses on the plastic debris ingested by sea creatures causing a threat to the ocean food chain. In addition United Nations Environment Program estimated around forty-six thousand pieces of plastic per square mile of ocean distributed throughout the water column.

Moslemy, P., et al. (2002). "Production of size-controlled gellan gum microbeads encapsulating gasoline-degrading bacteria." Enzyme and Microbial Technology **30**(1): 10-18.

Controlling the mean diameter of polymeric carriers is crucial to the successful application of encapsulated cells for in situ bioaugmentation of contaminated aquifers. The cell carriers should be small enough to be transported through a granular soil matrix, thus an emulsification-internal gelation technique for production of cell-encapsulating gellan gum microbeads is proposed. Mean diameter and size distribution of microbeads were investigated as a function of the water-in-oil emulsion parameters. The mean diameter of the microbeads ranged from 12 to 135 mum, varying as a descending function of the stirring rate (1000-5500 rpm) and emulsifier concentration (0-0.20% w/w), and as an ascending function of the disperse phase volume fraction (0.08-0.25). A bacterial consortium encapsulated within the microbeads (23 mum mean diameter) showed improved biodegradation activity in the removal of gasoline (400 mg L⁻¹), as compared to free cells. A high degree of repeatability in the microbead formation process and particle size measurements was demonstrated. The results of this study suggest that the emulsification process can potentially be used for the large-scale production of controlled-diameter gellan gum-encapsulated cell microbeads for subsurface bioremediation applications. © 2002 Elsevier Science Inc. All rights reserved.

Moslemy, P., et al. (2004). "Activated sludge encapsulation in gellan gum microbeads for gasoline biodegradation." Bioprocess & Biosystems Engineering **26**(4): 197-204.

A two-phase dispersion technique, termed emulsification-internal gelation, is proposed for encapsulation of activated sludge in gellan gum microbeads. The influence of emulsion parameters on size distribution of microbeads was investigated. Mean diameter of microbeads varied within a range of 34-265 microm as a descending function of emulsion stirring rate (1,000-5,000 rpm), emulsification time (10-40 min), and emulsifier concentration (0-0.1% w/w), and as an ascending function of disperse phase volume fraction (0.08-0.25). Encapsulated sludge expressed a high biodegradation activity compared with non-encapsulated sludge cultures even at 4.4 times lower level of overall biomass loading. Over 90% of gasoline at an initial concentration of 35 and 70 mg l(-1) was removed by both encapsulated and non-encapsulated sludge cultures in sealed serum bottles within 7 days. Encapsulation of activated sludge in gellan gum microbeads enhanced the biological activity of microbial populations in the removal of gasoline hydrocarbons. The results of this study demonstrated the feasibility of the production of size-controlled gellan gum-encapsulated sludge microbeads and their use in the biodegradation of gasoline.

Moslemy, P., et al. (2002). "Biodegradation of gasoline by gellan gum-encapsulated bacterial cells." Biotechnology & Bioengineering **80**(2): 175-184.

Encapsulated cell bioaugmentation is a novel alternative solution to in situ bioremediation of contaminated aquifers. This study was conducted to evaluate the feasibility of such a remediation strategy based on the performance of encapsulated cells in the biodegradation of gasoline, a major groundwater contaminant. An enriched bacterial consortium, isolated from a gasoline-polluted site, was encapsulated in gellan gum microbeads (16-53 microm diameter). The capacity of the encapsulated cells to degrade gasoline under aerobic conditions was evaluated in comparison with free (non-encapsulated) cells. Encapsulated cells (2.6 mg(cells) x g(-1) bead) degraded over 90% gasoline hydrocarbons (initial concentration 50-600 mg x L(-1)) within 5-10 days at 10 degrees C. Equivalent levels of free cells removed comparable amounts of gasoline (initial concentration 50-400 mg x L(-1)) within the same period but required up to 30 days to degrade the highest level of gasoline tested (600 mg x L(-1)). Free cells exhibited a lag phase in biodegradation, which increased from 1 to 5 days with an increase in gasoline concentration (200-600 x mg L(-1)). Encapsulation provided cells with a protective barrier against toxic hydrocarbons, eliminating the adaptation period required by free cells. The reduction of encapsulated cell mass loading from 2.6 to 1.0 mg(cells) x g(-1) bead caused a substantial decrease in the extent of biodegradation within a 30-day incubation period. Encapsulated cells dispersed within the porous soil matrix of saturated soil microcosms demonstrated a reduced performance in the removal of gasoline (initial concentrations of 400 and 600 mg x L(-1)), removing 30-50% gasoline hydrocarbons compared to 40-60% by free cells within 21 days of incubation. The results of this study suggest that gellan gum-encapsulated bacterial cells have the potential to be used for biodegradation of gasoline hydrocarbons in aqueous systems.

Moslemy, P., et al. (2003). "Transport of gellan gum microbeads through sand: an experimental evaluation for encapsulated cell bioaugmentation." Journal of Environmental Management **69**(3): 249-259.

Transport of 10-40 microm gellan gum microbeads was studied in horizontal sand columns to evaluate the feasibility of using gel-encapsulated bacteria for bioaugmentation of contaminated aquifers. Three 5.2 x 110 cm columns were packed with sand (column A: 0.5-2 mm, column B:

0.25-2 mm, and column C: 0.125-2 mm). Microbeads in artificial groundwater were injected at 0.5 l h(-1) during intermittent 12-h periods. Breakthrough of microbeads increased with injection time, varying as a descending function of travel distance. After 72 h of injection, about 75% of injected microbeads were dispersed across a 5-110 cm distance from the inlet in column A, compared to 78% across a 5-50 cm in column B, and 76% across a 5-20 cm in column C. The wider dispersion of microbeads across the length of column A, compared to those observed in columns B and C, suggests a higher potential for the formation of a uniform bioactive zone of encapsulated cells across a sandy aquifer with such grain size distribution and hydrodynamic properties.

Mostafa, H. M., et al. (2010). "Mechanical properties of some bioplastics under different soil types used as biodegradable drip tubes." Agricultural Engineering International: CIGR Journal **12**(1): 12-21.

A lack of degradability and the closing of landfill sites, as well as growing water and land pollution problems, have led to concern about plastics. With the excessive use of plastics and increasing pressure being placed on capacities available for plastic waste disposal, the need for biodegradable plastics and biodegradation of plastic wastes has assumed increasing importance in the last few years. Awareness of the waste problem and its impact on the environment has awakened new interest in the area of degradable polymers. The biodegradation of five different types of commercial bioplastics available on the market as agricultural mulch film (Bioflex, Ecoflex, Mater Bi, Chitosan and Bi-OPL foil) was evaluated under different soil types (Sandy, Sandy Loam and Loamy soil) to study the material stability and life expectancy, and to establish which was better to be used in the production of biodegradable drip tubes for drip irrigation system. Weight loss, tensile strength (TS) loss and loss of percentage elongation (%E) were measured in 0, 1, 2, 3, 4, and 5 months. Bi-OPL appeared to possess a high resistance to soil types, as indicated by lower changes in tensile strength, weight losses and with maximum 26% decreased in elongation at break. At the end of the experiments, Chitosan films were completely degraded in all soil types and both surface and subsurface positions. The starch contained in Mater Bi samples was degraded after 60 days with 4% weight losses and leads to 3% observed losses in tensile strength. Weight losses of Ecoflex and Bioflex were greater after three months (more than 30%) than that previously (5% to 10%). The tensile strength of both Ecoflex and Bioflex films decreased about 4% and 3% respectively in loamy soil and loamy sand soil by Week 12, More than 40% of the elongation capacity of the films were lost by Month 3 in both soil types. The decrease of %E in both films was slightly faster in loamy and loamy sand soil than in sandy soil.

Mouchi, V., et al. (2019). "Long-term aquaria study suggests species-specific responses of two cold-water corals to macro-and microplastics exposure." Environmental Pollution **253**: 322-329.

Plastic pollution has been identified as a major threat for coastal marine life and ecosystems. Here, we test if the feeding behaviour and growth rate of the two most common cold-water coral species, Lophelia pertusa and Madrepora oculata, are affected by micro- or macroplastic exposures. Low-density polyethylene microplastics impair prey capture and growth rates of L. pertusa after five months of exposure. Macroplastic films, mimicking plastic bags trapped on deep-sea reefs, had however a limited impact on L. pertusa growth. This was due to an avoidance behaviour illustrated by the formation of skeletal 'caps' that changed the polyp orientation and allowed its access to food supply. On the contrary, M. oculata growth and feeding were not affected by plastic exposure. Such a species-specific response has the potential to induce a severe change in coral community composition and the associated biodiversity in deep-sea environments.

Mourgkogiannis, N., et al. (2018). "Questionnaire-based survey to managers of 101 wastewater treatment plants in Greece confirms their potential as plastic marine litter sources." Marine Pollution Bulletin **133**: 822-827.

Marine pollution by plastics and microplastics (plastic particles 1nm to 5mm) is a recognized environmental issue. There are a few studies measuring the concentration of microplastics in the wastewater treatment plants (WWTP) effluent to the sea. Although microplastic concentrations are low in the WWTP effluent, the actual amount of microplastic ending up in the marine environment through WWTPs is quite significant. The present study is an extensive questionnaire-based survey to untrained managers of 101 WWTPs located all over Greece reporting visually-observed plastic items. 94 of the WWTPs have screens with gaps larger than 5mm. This suggests that microplastics are passing through pretreatment to the main WWTP. In addition, 89 of the WWTP managers observed plastics in different tanks of the WWTPs. Cotton swab sticks are identified as the most common plastic found in WWTPs and the surrounding marine and coastal areas of the effluent pipes.

Mourshed, M., et al. (2017). "Towards the effective plastic waste management in Bangladesh: a review." Environmental Science & Pollution Research **24**(35): 27021-27046.

The plastic-derived product, nowadays, becomes an indispensable commodity for different purposes. A huge amount of used plastic causes environmental hazards that turn in danger for marine life, reduces the fertility of soil, and contamination of ground water. Management of this enormous plastic waste is challenging in particular for developing countries like Bangladesh. Lack of facilities, infrastructure development, and insufficient budget for waste management are some of the prime causes of improper plastic management in Bangladesh. In this study, the route of plastic waste production and current plastic waste management system in Bangladesh have been reviewed extensively. It emerges that no technical and improved methods are adapted in the plastic management system. A set of the sustainable plastic management system has been proposed along with the challenges that would emerge during the implementation these strategies. Successful execution of the proposed systems would enhance the quality of plastic waste management in Bangladesh and offers enormous energy from waste.

Movilla-Quesada, D., et al. (2019). "Use of plastic scrap in asphalt mixtures added by dry method as a partial substitute for bitumen." Waste Management **87**: 751-760.

In recent decades, the generation of plastic waste has increased substantially worldwide, with the result that more of such waste is introduced into the environment. Currently, most polymers (polyethylene terephthalate, polyethylene, polyvinyl chloride, and others) are recycled. However, some are rejected for recycling in the primary separation processes due to their physical condition, contamination, or size. These materials are called plastic scrap. In this research, the use of plastic scrap added by dry method was evaluated as a replacement for bitumen in asphalt mixtures. Two sizes of plastic scrap, coarse and fine, were considered. An AC16S semi-dense mixture was designed for this purpose, with a 10% reduction in binder, and 10% and 20% of plastic scrap binder was added in coarse and fine sizes. The results obtained in the Marshall stability and flow test showed reduced moisture damage, greater indirect tensile strength, higher air void content, and a 2% decrease in the conserved tensile strength ratio while the same usage field as the conventional mixture was maintained. Meanwhile, significant decreases in plastic deformations, as compared to traditional values, were obtained from resilient modulus and rutting tests.

Moya, M. L., et al. (2010). "The effect of FGF-1 loaded alginate microbeads on neovascularization and adipogenesis in a vascular pedicle model of adipose tissue engineering." Biomaterials **31**(10): 2816-2826.

Engineered vascularized adipose tissue could serve as an alternative to traditional tissue reconstruction procedures. Adipose formation occurs in a coordinated fashion with neovascularization. Previous studies have shown that extracellular matrix-based materials supplemented with factors that stimulate neovascularization promote adipogenesis in a number of animal models. The present study examines the ability of fibroblast growth factor (FGF-1) delivered from alginate microbeads to induce neovascularization and adipogenesis in type I collagen gels in a vascular pedicle model of adipose tissue engineering. FGF-1 loaded microbeads stimulated greater vascular network formation in an in vitro 3D co-culture model than a single bolus of FGF-1. In in vivo studies, FGF-1 loaded beads suspended in collagen and implanted in a chamber surrounding the exposed femoral pedicle of a rat resulted in a significant increase in vascular density at 1 and 6 weeks in comparison to bolus administration of FGF-1. Staining for smooth muscle actin showed that over 48% of vessels had associated mural cells. While an increase in neovascularization was achieved, there was less than 3% adipose under any condition. These results show that delivery of FGF-1 from alginate beads stimulated a more persistent neovascularization response than bolus FGF-1 both in vitro and in vivo. However, unlike previous studies, this increased neovascularization did not result in adipogenesis. Future studies need to provide a better understanding of the relationship between neovascularization and adipogenesis in order to design advanced tissue engineering therapies.

Moya, M. L., et al. (2011). "A novel in vitro platform of perfused human microtissues for the study of neovascularization." Circulation. Conference: American Heart Association's Scientific Sessions **124**(21 SUPPL. 1).

Understanding the process of vascular network formation and remodeling is key to designing effective strategies for the treatment of ischemic vascular diseases. Much of our current understanding of the neovascularization process is limited to in vivo studies, which require extrapolation of results to human, or in vitro models that lack the dynamic feature of perfusion. In this work we report the development of an in vitro model system of metabolically active microtissues that exchange nutrients and waste through perfused capillaries. For such design, a device consisting of 2 fluidic channels on either side of a central tissue channel, containing fibroblasts seeded in a fibrin matrix (Fig 1A), was microfabricated in polydimethylsiloxane. To study vasculogenic-like processes, ECs were co-seeded with the fibroblasts in the tissue channel. The devices were grown at 5% oxygen tension and formation of perfused vessel networks was encouraged by mechanical (pressure gradients, interstitial flow) and chemical stimuli (hypoxia and nutrient deprivation). Vessel network formation was observed within a week of culture and as early as day 1. Perfusion of the network was confirmed at day 18. Fluorescent dextran (70kDa) introduced on one end of one of the fluidic channel (Fig 1B-C) was shown to reach the other side of the device by traveling through the capillaries of the microtissues as evidence by the presence of dextran in the tissue channel and the absence of dextran in the fluidic channel. (Fig 1D) Anastomosis of vessels in the tissue channel with the fluidic channels was verified by tracking movement of fluorescent 1mum beads introduced into the fluidic channel and through patent capillaries (20-105 mum/s) in the tissue channel. Confocal microscopy of devices stained for CD31 (EC marker) and DAPI (nuclear marker) showed the extensive vessel network (Fig 1E)

and further demonstrated the presence of capillary lumens containing microbeads (Fig 1F).

Moya, M. L., et al. (2012). "Stability of alginate microbead properties in vitro." Journal of Materials Science-Materials in Medicine **23**(4): 903-912.

Alginate microbeads have been investigated clinically for a number of therapeutic interventions, including drug delivery for treatment of ischemic tissues, cell delivery for tissue regeneration, and islet encapsulation as a therapy for type I diabetes. The physical properties of the microbeads play an important role in regulating cell behavior, protein release, and biological response following implantation. In this research alginate microbeads were synthesized, varying composition (mannuronic acid to guluronic acid ratio), concentration of alginate and needle gauge size. Following synthesis, the size, volume fraction, and morphometry of the beads were quantified. In addition, these properties were monitored over time in vitro in the presence of varying calcium levels in the microenvironment. The initial volume available for solute diffusion increased with alginate concentration and mannuronic (M) acid content, and bead diameter decreased with M content but increased with needle diameter. Interestingly, microbeads eroded completely in saline in less than 3 weeks regardless of synthesis conditions much faster than what has been observed in vivo. However, microbead stability was increased by the addition of calcium in the culture medium. Beads synthesized with low alginate concentration and high G content exhibited a more rapid change in physical properties even in the presence of calcium. These data suggest that temporal variations in the physical characteristics of alginate microbeads can occur in vitro depending on synthesis conditions and microbead environment. The results presented here will assist in optimizing the design of the materials for clinical application in drug delivery and cell therapy.

Moyer, H. R., et al. (2010). "Alginate microencapsulation technology for the percutaneous delivery of adipose-derived stem cells." Annals of Plastic Surgery **65**(5): 497-503.

BACKGROUND: Autologous fat is the ideal soft-tissue filler; however, its widespread application is limited because of variable clinical results and poor survival. Engineered fillers have the potential to maximize survival. Alginate is a hydrogel copolymer that can be engineered into spheres of <200 mum, thus facilitating mass transfer, allowing for subcutaneous injection, and protecting cells from shearing forces.

METHODS: Alginate powder was dissolved in saline, and adipose-derived stem cells (ADSCs) were encapsulated (1 million cells/mL) in alginate using an electrostatic bead generator. To assess effects of injection on cell viability, microspheres containing ADSCs were separated into 2 groups: the control group was decanted into culture wells and the injection group was mixed with basal media and injected through a 21-gauge needle into culture wells. Microbeads were cultured for 3 weeks, and cell number and viability were measured weekly using electron and confocal microscopy. To assess effects of percutaneous injection in vivo, twenty-four male nude mice were randomly separated into 2 groups and injected with either empty microcapsules or ADSC-laden microcapsules. Mice were harvested at 1 and 3 months, and the implants were examined microscopically to assess bead and cell viability.

RESULTS: A flow rate of 5 mL/h and an electrostatic potential of 7 kV produced viable ADSC-laden microbeads of <200 mum. There were no differences in bead morphology and ADSC viability between microcapsules placed versus injected into tissue culture plates for up to 3 weeks. Microspheres implanted in a nude mouse model show durability up to 3 months with a host response around each individual sphere. ADSCs remained viable and showed signs of mitosis.

CONCLUSIONS: ADSCs can be readily cultured, encapsulated, and injected in alginate microspheres. Stem cells suspended in alginate microspheres survive in vivo and are seen to replicate in vitro.

Mrkun, J., et al. (2014). "Elimination of apoptotic boar spermatozoa using magnetic activated cell sorting." Acta Veterinaria Brno **83**(1): 13-18.

One of the features of apoptosis is the externalization of phosphatidylserine which could be used to remove apoptotic cells from semen preparations. Magnetic-activated cell sorting using annexin V-conjugated microbeads which bind to phosphatidylserine could be used to enhance semen quality. Twelve boar semen samples after 3 days of liquid storage at 16-17 degrees C were subjected to magnetic-activated cell sorting. Bound and unbound fractions and control samples were subjected to flow cytometry following the staining of spermatozoa with Annexin V conjugated with Alexa Fluor 488 and propidium iodide. Four subpopulations were obtained: live, early apoptotic live, late apoptotic, early necrotic dead and late necrotic dead. The frequency of early apoptotic and late necrotic spermatozoa was significantly higher (P<0.05) in bound (14.1+or-10.6% and 24.1+or-10.2%, respectively) than in unbound fractions (3.4+or-2.1% and 12.7+or-3.1%) and control (3.5+or-1.6% and 12.0+or-5.0%). The lowest concentration of live spermatozoa was found in the bound fraction (10.6+or-8.0%), which differed significantly (P<0.05) from the control. In unbound fractions there was a significantly higher concentration (P<0.05) of morphologically normal spermatozoa (31.8+or-12.6%) compared to bound ones (5.9+or-7.3%). A significantly (P<0.05) lower proportion of morphologically normal spermatozoa was observed in both fractions compared to control (67.2+or-17.0%). Boar spermatozoa were separated by the above method for the first time, however, the results showed this method to be inappropriate for boar semen separation under the tested conditions.

Mrokowska, M. M. and A. Krzton-Maziopa (2019). "Viscoelastic and shear-thinning effects of aqueous exopolymer solution on disk and sphere settling." Scientific Reports **9**(1): 7897.

In this study, xanthan gum is used as a model exopolymer to demonstrate potential effects of non-Newtonian properties of natural aquatic systems on settling dynamics of particles. Rheological measurements combined with settling experiments using visualization methods revealed that instantaneous velocity fluctuations and a flow pattern formed around a particle are the effects of solution viscoelasticity and shear-thinning properties and that the average settling velocity depends on the exopolymer concentration and particle size. Our study showed that in the considered conditions a disk-shaped particle settles preferably in vertical position with a negative wake behind. The understanding of these processes is essential in technology and engineering and is necessary to improve prediction accuracy of large-scale sedimentation processes and biogeochemical cycles in the ocean involving settling of minerals, marine snow, microplastics, and locomotion of microorganisms.

Mu, C., et al. (2015). "Development of a highly effective multi-stage surface acoustic wave SU-8 microfluidic concentrator." Sensors and Actuators B: Chemical **215**: 77-85.

As an important step in sample preparation, sample concentration step helps to improve sampling techniques that are often necessary to detect low levels of pathogenic bacteria in food safety inspections, reducing or completely eliminating the need for time-consuming cell enrichment process for detection. In this study, we investigated strategies to significantly enhance performances of a surface acoustic wave (SAW) microfluidic device to concentrate various particles, including microbeads, bacterial and mammalian cells in suspensions. A low acoustic energy loss material, SU-8, was used to fabricate the microfluidic concentrator, and SAW reflectors were designed to efficiently use the SAW generated acoustic energy for particle concentration. The concentration performance was further improved by using a two-stage concentration design. We demonstrated that the SU-8 microfluidic concentrator with a two-stage concentration configuration was able to concentrate 2.00 mu m bead samples at an overall concentration factor of 65-fold with a particle recovery efficiency of 81.9 plus or minus 5.9% at a inflow rate of 300 mu l/h. Similarly, when the concentrator was used to concentrate E. coli DH5 alpha and NIH/3T3 cells, overall concentration factors of 59 and 75-fold with particle recovery efficiencies of 81.0 plus or minus 17.2% and 90.8 plus or minus 5.0% were obtained, respectively. These results show significant improvements upon those previously reported for either bacterial or mammalian cell concentration applications. In addition, the device fabrication process developed in this work is fully compatible with regular microfabrication processes, making this microfluidic concentrator readily integrable with other on-chip functionalities for cell manipulation and detection applications.

Mu, J., et al. (2019). "Abundance and distribution of microplastics in the surface sediments from the northern Bering and Chukchi Seas." Environmental Pollution **245**: 122-130.

Worldwide the seafloor has been recognized as a major sink for microplastics. However, currently nothing is known about the sediment microplastic pollution in the North Pacific sector of the Arctic Ocean. Here, we present the first record of microplastic contamination in the surface sediment from the northern Bering and Chukchi Seas. The microplastics were extracted by the density separation method from collected samples. Each particle was identified using the microscopic Fourier transform infrared spectroscopy (muFTIR). The abundances of microplastics in sediments from all sites ranged from not detected (ND) to 68.78 items/kg dry weight (DW) of sediment. The highest level of microplastic contamination in the sediment was detected from the Chukchi Sea. A negative correlation between microplastic abundance and water depth was observed. Polypropylene (PP) accounted for the largest proportion (51.5%) of the identified microplastic particles, followed by polyethylene terephthalate (PET) (35.2%) and rayon (13.3%). Fibers constituted the most common shape of plastic particles. The range of polymer types, physical shapes and spatial distribution characteristics of the microplastics suggest that water masses from the Pacific and local coastal inputs are possible sources for the microplastics found in the study area. In overall, our results highlight the global distribution of these anthropogenic pollutants and the importance of management action to reduce marine debris worldwide.

Mueller, M.-T., et al. (2020). "Surface-Related Toxicity of Polystyrene Beads to Nematodes and the Role of Food Availability." Environmental Science & Technology.

Microplastics released into freshwaters from anthropogenic sources settle in the sediments, where they may pose an environmental threat to benthic organisms. However, few studies have considered the ecotoxicological hazard of microplastic particles for nematodes, one of the most abundant taxa of the benthic meiofauna. This study investigated the toxic effects of polystyrene (PS) beads (0.1-10.0 µm) and the underlying mechanisms thereof on the reproduction of the nematode Caenorhabditis elegans. The observed effect of the PS beads on the nematodes correlated well with the total surface area of the beads per volume, with a 50% inhibition of reproduction at 55.4 ± 12.9 cm2/mL, independent of the bead size. The adverse effects were not explained by styrene monomers leaching from the beads because chemical activities of styrene in PS suspensions were well below the toxic levels. However, the observed effects could be related to the bead material because the same-sized silica (SiO2) beads had considerably less impact, probably due to their higher specific density. PS and SiO2 beads affected the food availability of C. elegans, with greater effects by the PS beads. Our results demonstrate the importance of including indirect food web effects in studies of the ecological risks posed by microplastics.

Mugnozza, G. S., et al. (1994). "A proposal for the management of agricultural plastic wastes in a region of southern Italy." 13th International congress on plastics in agriculture [Congresso internazionale del C.I.P.A.]. Proceedings of a conference held in Verona, Italy **2**(13).

In the Metapuntin area, Italy, approx. 5000 tons/year of plastic wastes, derived from agricultural applications such as mulching, small tunnels, greenhouse and pergola coverings, and pesticide containers, requires disposal. A functional model of simple application, based on a system of withdrawal from growers and a network of centres for gathering, storage, and initial treatment of plastic waste, was studied. A suitable distribution between plastic consumer farms and gathering centres was investigated, and the technical characteristics gathering centres require to obtain plastic wastes suitable for the selected final treatment (i.e. landfills, recycling or energetic use) were analysed. The results are easily transferable to other situations and areas by means of appropriate adjustments in gathering centre dimensions and land disposition.

Mugo, S. M., et al. (2019). "Integrated microcentrifuge carbon entrapped glucose oxidase poly (N-isopropylacrylamide) (pNIPAm) microgels for glucose amperometric detection." Analytical Letters **52**(5): 825-838.

This study demonstrates a miniaturized integrated glucose biosensor based on a carbon microbeads entrapped by glucose oxidase (GOx) immobilized on poly (N-isopropylacrylamide) (pNIPAm) microgels. Determined by the Lowry protein assay, the pNIPAm microgel possesses a high enzyme loading capacity of 31 mg/g. The pNIPAm GOx loaded on the microgel was found to maintain a high activity of approximately 0.140 U determined using the 4-aminoantipyrine colorimetric method. The integrated microelectrochemical cell was constructed using a microcentrifuge vial housing packed with (1:1, w/w) carbon entrapped by pNIPAm GOx microgels, which played the dual role of the microbioreactor and the working electrode. The microcentrifuge vial cover was used as a miniaturized reference electrode and an auxiliary electrode holder. The device can work as biosensor, effectively converting glucose to H₂O₂, with subsequent amperometric detection at an applied potential of -0.4 V. The microelectrochemical biosensor was used to detect glucose in wide linear range from 30 micro M to 8.0 mM, a low detection limit of 10 micro M, a good linear regression coefficient (R²) of 0.994, and a calibration sensitivity of 0.0388 micro A/mM. The surface coverage of active GOx, electron transfer rate constant (ks), and Michaelis-Menten constant (K_M^{app}) of the immobilized GOx were 4.0x10⁻¹¹mol/cm², 5.4 s⁻¹, and 0.086 mM, respectively. To demonstrate the applicability and robustness of the biosensor for analysis of high sample matrix environment, glucose was analyzed in root beer. The microelectrochemical device was demonstrated for analysis of small sample (<50 micro L), while affording high precision and fast signal measurement (<=5 s).

Muhlbacher, J., et al. (2017). "Blockade of HLA Antibody-Triggered Classical Complement Activation in Sera from Subjects Dosed with the Anti-C1s Monoclonal Antibody TNT009-Results from a Randomized First-in-Human Phase 1 Trial." Transplantation **101**(10): 2410-2418.

Background Complement may play a key role in antibody-mediated rejection. A promising therapeutic approach may be classical pathway (CP) inhibition at the level of early component C1. Methods In this first-in-human, double-blind, randomized placebo-controlled phase 1 trial, we evaluated the safety and complement inhibitory effect of TNT009, a humanized monoclonal anti-C1s antibody. Sixty-four adult healthy volunteers received either single (n = 48; 7 consecutive cohorts, 0.3-100 mg/kg) or 4 weekly infusions (n = 16; 2 consecutive cohorts, 30 and 60 mg/kg per infusion) of TNT009 or placebo. To assess the effect of treatment on complement activity, sera from dosed subjects were analyzed in a CP activation assay evaluating C3d deposition on HLA-coated microbeads spiked with alloantibodies. Results Single doses of TNT009 at 3 to 100 mg/kg uniformly and profoundly inhibited HLA antibody-mediated C3d deposition (>=86% after 60 minutes), whereby the duration of CP inhibition (2-14 days) was dose-dependent. Four weekly doses persistently blocked complement for 5 to 6 weeks. Ex vivo serum CP activity was profoundly inhibited when TNT009 concentrations exceeded 20 mug/mL. Infusions were well tolerated without serious or severe adverse events. Conclusions Treatment with TNT009 was safe and potently inhibited CP activity. Future studies in patients are required to assess the potential of TNT009 for preventing or treating antibody-mediated rejection. Copyright © 2017 Wolters Kluwer Health, Inc.

Muhlschlegel, P., et al. (2017). "Lack of evidence for microplastic contamination in honey." Food Additives and Contaminants - Part A Chemistry, Analysis, Control, Exposure and Risk Assessment **34**(11): 1982-1989.

Honey samples from Switzerland were investigated with regard to their microplastic particle burden. Five representative honey samples of different origin were processed following a standardized protocol to separate plastic-based microparticles from particles of natural origin, such as pollen, propolis, wax, and bee-related debris. The procedure was optimized to minimize post-sampling microplastic cross-contamination in the laboratory. The isolated microplastic particles were characterized and grouped by means of light microscopy as well as chemically characterized by microscopically coupled Raman and Fourier transform infrared spectroscopy. Five particle classes with an abundance significantly above blank levels were identified: black particles (particle count between 1760/kg and 8680/kg), white transparent fibres (particle count between 132/kg and 728/kg), white transparent particles (particle count between 60/kg and 172/kg), coloured fibres (particle count between 32/kg and 108/kg), and coloured particles (particle count between 8/kg and 64/kg). The black particles, which represented the majority of particles, were identified as char or soot and most probably originated from the use of smokers, a widespread practice in beekeeping. The majority of fibres were identified as cellulose or polyethylene terephthalate and were most likely of textile origin. In addition to these particle and fibre groups lower numbers of fragments were detected that were related to glass, polysaccharides or chitin, and few bluish particles contained copper phthalocyanine pigment. We found no indications that the honey samples were significantly contaminated with microplastic particles. Copyright © 2017 Informa UK Limited, trading as Taylor & Francis Group.

Mukai, R., et al. (2019). "Mouse model of ocular hypertension with retinal ganglion cell degeneration." PLoS ONE **14**(1).

Objectives Ocular hypertension is a primary risk factor for glaucoma and results in retinal ganglion cell (RGC) degeneration. Current animal models of glaucoma lack severe RGC cell death as seen in glaucoma, making assessment of physiological mediators of cell death difficult. We developed a modified mouse model of ocular hypertension whereby long-lasting elevation of intraocular pressure (IOP) is achieved, resulting in significant reproducible damage to RGCs. Results In this model, microbeads are mixed with hyaluronic acid and injected into the anterior chamber of C57BL/6J mice. The hyaluronic acid allows for a gradual release of microbeads, resulting in sustained blockage of Schlemm's canal. IOP elevation was bimodal during the course of the model's progression. The first peak occurred 1 hours after beads injection, with an IOP value of 44.69 ± 6.00 mmHg, and the second peak occurred 6–12 days post-induction, with an IOP value of 34.91 ± 5.21 mmHg. RGC damage was most severe in the peripheral retina, with a loss of 64.1% compared to that of untreated eyes, while the midperiphery exhibited a 32.4% loss, 4 weeks following disease induction. Conclusions These results suggest that sustained IOP elevation causes more RGC damage in the periphery than in the midperiphery of the retina. This model yields significant and reproducible RGC degeneration.

Mukai-Correa, R., et al. (2004). "Controlled release of protein from hydrocolloid gel microbeads before and after drying." Current Drug Delivery **1**(3): 265-273.

Casein entrapped within gel microbeads using alginate, amidated LM pectin, gellan gum and a system containing a mixture of these polysaccharides (pectin:gellan:alginate, 1/3: 1/3: 1/3), were obtained by ionic gelation in a high-pressure capillary apparatus. Hydrogenated vegetable fat was also added to produce the gel microbeads and protein release in all the systems was measured, including from freeze-dried capsules containing protein and fat. Encapsulation efficiency, capsule size and morphology were evaluated as well as the protein release profile. Encapsulation efficiencies from 83.7 to 90.7% were obtained for the protein capsules and from 71.8 to 95.4% for those containing protein and fat. Greater release was observed from gel microbeads without fat where alginate presented the greatest diffusion (100%) and the system with a mixture of polyssacharides, the best barrier, with protein retention of 90% after 240 min in solution. The fat containing gel microbeads presented good percent retentions and both the gel microbeads and the dry microbeads showed similar percentages for release. The majority of the systems studied showed a burst effect on release. Gel microbeads size distribution was similar, both with and without fat, and independent of the matrix material, the mean size being 150microm. The morphological observations showed that the gel microbeads were spheroidal with a homogenous distribution of fat droplets in the microcapsules. Agglomeration occurred on drying but many particles maintained a partially spheroidal form, with a configuration of solid material.

Mukherjee, M. and B. H. Desai (1993). "Platelet adhesiveness in coronary heart disease." Indian Heart Journal **45**(3): 195-198.

A simple reproducible method of determination of whole blood platelet adhesiveness, on columns of unsiliconised glass microbeads, was developed and validated. Platelet adhesiveness was determined in 180 subjects who were classified into four groups. The subjects of Groups I and II had negative cardiac stress and were free from coronary heart disease (CHD). While the 42 subjects of Group I had none of the conventional coronary risk factors, the 46 subjects of Group II had one or more coronary risk factors. Group III consisted of 68 subjects who had positive cardiac stress test. They were patients with myocardial ischemia. Group IV consisted of 24 survivors of myocardial infarction. The percent of subjects with platelet retention values exceeding 50.5% were, 9.5% in Group I, 26.1% in Group II, 32.4% in Group III and 37.5% in Group IV ($p < 0.05$). Although Group II consisted of subjects free from CHD, its difference from Group I, and closeness to Groups III and IV probably indicate that asymptomatic subjects with coronary risk factors and with increased platelet adhesiveness may be on the threshold of the symptomatic phase of CHD. Increased platelet adhesiveness may thus be a predictive marker of CHD.

Mulay, S. R., et al. (2012). "Calcium-oxalate crystals induce renal inflammation and acute kidney injury by activating nlrp3 inflammasome-mediated interleukin-1 secretion in renal dendritic cells." Nephrology Dialysis Transplantation **2)**: ii338.

Introduction and Aims: Calcium oxalate (CaOx) crystal nephropathy can lead to renal failure by causing intrarenal inflammation and tissue damage but the molecular mechanisms remain elusive. The aim of the study was to investigate whether CaOx crystals have the potential to activate IL-1beta-dependent innate immunity via the NLRP3-ASC-caspase-1 axis in the kidney, and how Methods: C57BL/6, NOD/ShiLt, NOD/Casp1-/-, IL-1r1-/-, IL-18-/-, Myd88-/- male mice were procured from Jackson Laboratories (Bar Habour, MA). Nlrp3-/- and Asc-/- mice were generously provided by Dan Muruve, Calgary, Canada. All experimental procedures were approved by the local government authorities. Immunostaining, scanning electron microscope (SEM), freeze fracture (FFEM), and transmission electron microscope (TEM) were used for analysing kidney pathology. Bone marrow derived dendritic cells were generated by established protocols. Renal dendritic cells (DC) were isolated from whole kidneys by magnetic beads separation (MACS) using CD11c MicroBeads (Miltenyi Biotech, Germany). Fluorescence Activated Cell Sorter, ELISA and Immunoblot analysis was used for further data analysis. Result(s): We show that CaOx crystals activate renal DC (but not any type of renal parenchymal cell) to secrete IL-1beta. This process depended on the presence of the NLRP3 inflammasome, its adaptor molecule ASC, and caspase-1. CaOx crystal phagocytosis and potassium efflux were required for NLRP3 activation in DC. CaOx crystals dose-dependently killed tubular epithelial cells in culture, a process that lead to the release of the NLRP3 agonist ATP but ATP-degradation with apyrase did not abrogate IL-1beta release by DC upon exposure to supernatants of tubular cells killed by CaOx crystals. In experimental oxalate nephropathy, CaOx localized to tubular lumen but are also found inside tubular cells and interstitial cells as detected by Pizzolato staining, TEM, SEM, FFEM. Intrarenal crystal desposition induced severe tubular damage, cytokine expression, neutrophil recruitment, and renal dysfunction. These effects were abrogated upon DC-depletion or in mice deficient in MyD88, IL1-r1, NLRP3, ASC, or caspase-1 despite a similar extent of CaOx crystal deposition. In addition, ATP depletion with apyrase or therapeutic IL-1 antagonism with anakinra had the same effect. Conclusion(s): We conclude that CaOx crystals directly damage tubular epithelial cells. In addition, CaOx crystals are taken up by renal DC which activates the NLRP3-ASC-caspase-1 axis to trigger IL-1beta release. Subsequent

IL-1R signaling sets off MyD88-dependent renal inflammation, neutrophil recruitment and accelerates tubular damage and renal dysfunction. Therapeutic blockade of IL-1 is protective in murine CaOx nephropathy and might potentially be protective in human crystal nephropathies.

Muller, A., et al. (2018). "The effect of polymer aging on the uptake of fuel aromatics and ethers by microplastics." Environmental Pollution **240**: 639-646.

Microplastics are increasingly entering marine, limnic and terrestrial ecosystems worldwide, where they sorb hydrophobic organic contaminants. Here, the sorption behavior of the fuel-related water contaminants benzene, toluene, ethyl benzene and xylene (BTEX) and four tertiary butyl ethers to virgin and via UV radiation aged polypropylene (PP) and polystyrene (PS) pellets was investigated. Changes in material properties due to aging were recorded using appropriate polymer characterization methods, such as differential scanning calorimetry, Fourier transform infrared spectroscopy, gel permeation chromatography, X-ray photoelectron spectroscopy, and microscopy. Pellets were exposed to water containing BTEX and the ethers at 130-190mugL⁻¹ for up to two weeks. Aqueous sorbate concentrations were determined by headspace gas chromatography. Sorption to the polymers was correlated with the sorbate's K_{ow} and was significant for BTEX and marginal for the ethers. Due to substantially lower glass transition temperatures, PP showed higher sorption than PS. Aging had no effect on the sorption behavior of PP. PS sorbed less BTEX after aging due to an oxidized surface layer.

Muller, P., et al. (2017). "Intramyocardial fate and effect of iron nanoparticles co-injected with MACS purified stem cell products." Biomaterials **135**: 74-84.

BACKGROUND: Magnetic activated cell sorting (MACS) is routinely used to isolate stem cell subpopulations intended for the treatment of cardiovascular diseases. In strong contrast, studies examining the amount, effect and intramyocardial distribution of iron nanoparticles used for magnetic cell labelling are missing, although iron excess can cause functional disorders in the heart.

METHODS AND RESULTS: CD133⁺ haematopoietic and CD271⁺ mesenchymal stem cells were purified from bone marrow using automatically and manually MACS based systems. Flow cytometric measurements demonstrated a rapid loss of MACS MicroBeads from cells under culture conditions, while storage under hypothermic conditions decelerated their detachment. Moreover, an average loading of ~11 fg iron/cell caused by magnetic labelling was determined in magnetic particle spectroscopy. Importantly, hemodynamic measurements as well as histological examinations using a myocardial ischemia/reperfusion mouse model showed no influence of MACS MicroBeads on cardiac regeneration, while the transplantation of stem cells caused a significant improvement. Furthermore, immunostainings demonstrated the clearance of co-injected iron nanoparticles from stem cells and the surrounding heart tissue within 48 h post transplantation.

CONCLUSIONS: Our results indicate that iron amounts typically co-injected with MACS purified stem cells do not harm cardiac functions and are cleared from heart tissue within a few hours. Therefore, we conclude that MACS MicroBeads exhibit a good compatibility in the cardiac environment.

Muller, R. J., et al. (2001). "Biodegradation of polyesters containing aromatic constituents." Journal of Biotechnology **86**(2): 87-95.

Polymers, which undergo a controlled biological degradation by micro-organisms came to remarkable interest during the last years. Composting for instance could so be established as an

alternative waste management system for parts of the plastic waste. Within this group of innovative polymer, polyesters play a predominant role, due to their potentially hydrolyzable ester bonds. While aromatic polyesters such as poly(ethylene terephthalate) exhibit excellent material properties but proved to be almost resistant to microbial attack, many aliphatic polyesters turned out to be biodegradable but lack in properties, which are important for application. To combine good material properties with biodegradability, aliphatic-aromatic copolyesters have been developed as biodegradable polymers for many years. This article reviews the attempts to combine aromatic and aliphatic structures in biodegradable plastics and work, which has been done to evaluate the degradation behaviour and environmental safety of biodegradable polyesters, containing aromatic constituents. © 2001 Elsevier Science B.V.

Muller-Karanassos, C., et al. (2019). "Antifouling paint particles in intertidal estuarine sediments from southwest England and their ingestion by the harbour ragworm, Hediste diversicolor." Environmental Pollution **249**: 163-170.

Antifouling paint particles (APPs) of between 500 mum and >2 mm in diameter have been identified in silty, intertidal estuarine sediments through a combination of microscopy and x-ray fluorescence spectrometry. APPs were heterogeneously distributed, with maximal concentrations of 430 particles L⁻¹ (0.2 g L⁻¹) near to a facility where boats are regularly maintained and 400 particles L⁻¹ (4.2 g L⁻¹) at a location where old boats had been abandoned, with the majority of particles encountered in the finest size fraction retrieved. APPs contained variable concentrations of Cu, Zn, Sn and Pb, with respective maxima of 562,000, 269,000, 9,970 and 126,000 mg kg⁻¹. These characteristics are attributed to a multitude of contemporary and historic sources of an assortment of formulations and result in significant but heterogeneous metal contamination of local sediments. APPs were also identified in the guts of the deposit-feeding ragworm, Hediste diversicolor, that inhabited sediments impacted by abandoned boats or boating activities. The tissue of H. diversicolor was particularly enriched in Cu where ingested APPs were observed, with a significant correlation between dry weight Cu concentrations in the two media (r = 0.734) presumably reflecting the inability of the animal to regulate this metal. While the toxicity of APPs requires further investigation, there is clearly a need for stricter regulations on antifouling wastes in boatyards and marinas and a requirement to better manage abandoned boats. Antifouling paint particles in contaminated estuarine sediments can be ingested by Hediste diversicolor and result in the bioaccumulation of copper. Copyright © 2019

Muller-Marschhausen, K., et al. (2008). "Physiological hydrostatic pressure protects endothelial monolayer integrity." American Journal of Physiology - Cell Physiology **294**(1): C324-C332.

Endothelial monolayer integrity is required to maintain endothelial barrier functions and has found to be impaired in several disorders like inflammatory edema, allergic shock, or artherosclerosis. Under physiologic conditions in vivo, endothelial cells are exposed to mechanical forces such as hydrostatic pressure, shear stress, and cyclic stretch. However, insight into the effects of hydrostatic pressure on endothelial cell biology is very limited at present. Therefore, in this study, we tested the hypothesis that physiological hydrostatic pressure protects endothelial monolayer integrity in vitro. We investigated the protective efficacy of hydrostatic pressure in microvascular myocardial endothelial (MyEnd) cells and macrovascular pulmonary artery endothelial cells (PAECs) by the application of selected pharmacological agents known to alter monolayer integrity in the absence or presence of hydrostatic pressure. In both endothelial cell lines, extracellular Ca²⁺ depletion by EGTA was followed by a loss of vascular-endothelial cadherin (VE-caherin) immunostaining at cell junctions. However, hydrostatic pressure (15 cmH<inf>2</inf>O) blocked this effect of EGTA. Similarly, cytochalasin D-induced actin depolymerization and intercellular gap formation and cell detachment in response to the Ca²⁺/calmodulin antagonist trifluperazine (TFP) as well as thrombin-induced cell dissociation were also reduced by hydrostatic pressure. Moreover, hydrostatic pressure significantly reduced the loss of VE-cadherin-mediated adhesion in response to EGTA, cytochalasin D, and TFP in MyEnd cells as determined by laser tweezer trapping using VE-cadherin-coated microbeads. In caveolin-1-deficient MyEnd cells, which lack caveolae, hydrostatic pressure did not protect monolayer integrity compromised by EGTA, indicating that caveolae-dependent mechanisms are involved in hydrostatic pressure sensing and signaling. Muller-Schulte, D. and H. Brunner (1995). "Novel magnetic microspheres on the basis of poly(vinyl alcohol) as affinity medium for quantitative detection of glycated haemoglobin." Journal of Chromatography. A **711**(1): 53-60.

A water-in-oil suspension cross-linking technique using poly(vinyl alcohol) as polymer phase to prepare novel magnetic microbeads is described. By dispersing a conventional Fe3O4 pigment in the polymer phase and subsequently suspending the mixture in a vegetable oil phase with a defined viscosity, spherical magnetic microspheres are obtained. Bead sizes ranging from 1 to 50 microns and above can be obtained by exploiting well defined preparation parameters such as polymer concentration and oil and polymer viscosity. The performance of the magnetic matrices for the separation and quantification of glycated haemoglobin was tested using a m-aminophenylboronic acid matrix. The feasibility of this detection method for blood sugar diagnosis is discussed using a commercial column test kit for comparison.

Mulligan, J. K., et al. (2008). "Tumors skew endothelial cells to disrupt NK cell, T-cell and macrophage functions." Cancer Immunology, Immunotherapy **57**(7): 951-961.

Introduction: Patients and mice with solid tumors, such as Lewis lung carcinoma (LLC), have defects in functions of immune effector cells. Endothelial cells, a component of the tumor vasculature, are potential regulators of immune cell functions. Therefore, these studies examined the impact of exposure to LLC tumor on the ability of endothelial cells to modulate immune cell functions. Materials and methods: Endothelial cells were pre-treated with LLC tumor-conditioned medium (Endo super(T-sup)) for 24 h. Control endothelial cells that were exposed to medium (Endo super(Media)) or epithelial cell-conditioned medium (Endo super(Epi-sup)). After the initial 24 h incubation, endothelial cells were washed and fresh media was added. Cells were allowed to incubate for an additional 24 h. Supernatants from Endo super(Media), Endo super(Epi-sup) or Endo super(T-sup) were collected and assayed for immune modulatory products and for immune modulatory activity. Results: Supernatant from Endo super(T-sup) contained increased levels of PGE sub(2), IL-6 and VEGF as compared to Endo super(Media) and Endo super(Epi-sup) controls. NK cell activity, as measured by TNF- alpha and IFN- gamma secretion, was increased following exposure to media conditioned by Endo super(Media) and Endo super(Epi-sup). Exposure of NK cells to supernatants of Endo super(T-sup), also increases TNF- alpha and IFN- gamma secretion, but to a lesser extent than by Endo super(Media) and Endo super(Epi-sup). Examination of macrophage functions demonstrated that supernatant from Endo super(T-sup) decreased microbead phagocytosis and increased production of the immune suppressive mediators, IL-10 and PGE sub(2). Lastly, T-cell responses to stimulation with anti-CD3 in the presence of supernatants from Endo super(T-sup) were examined. IFN- gamma production by CD8 super(+) T-cells was reduced after exposure to Endo super(T-sup)-conditioned medium, as compared to cells treatments with medium or

control conditioned medium. Production of IFN- gamma by CD4 super(+) T-cells exposed to Endo super(T-sup) was not altered. Conclusions: Taken together, these studies demonstrate that tumors skew endothelial cells to disrupt NK cell, T-cell and macrophages functions, and represents a novel mechanism of tumor-induced immune suppression.

Mulvaney, S. P., et al. (2007). "Rapid, femtomolar bioassays in complex matrices combining microfluidics and magnetoelectronics." Biosensors & Bioelectronics **23**(2): 191-200.

A significant challenge for all biosensor systems is to achieve high assay sensitivity and specificity while minimizing sample preparation requirements, operational complexity, and sample-to-answer time. We have achieved multiplexed, unamplified, femtomolar detection of both DNA and proteins in complex matrices (including whole blood, serum, plasma, and milk) in minutes using as few as two reagents by labeling conventional assay schemes with micrometer-scale magnetic beads, and applying fluidic force discrimination (FFD). In FFD assays, analytes captured onto a microarray surface are labeled with microbeads, and a controlled laminar flow is then used to apply microfluidic forces sufficient to preferentially remove only nonspecifically bound bead labels. The density of beads that remain bound is proportional to the analyte concentration and can be determined with either optical counting or magnetoelectronic detection of the magnetic labels. Combining FFD assays with chip-based magnetoelectronic detection enables a simple, potentially handheld, platform capable of both nucleic acid hybridization assays and immunoassays, including orthogonal detection and identification of bacterial and viral pathogens, and therefore suitable for a wide range of biosensing applications.

Mulvaney, S. P., et al. (2004). "Incorporating fluorescent dyes and quantum dots into magnetic microbeads for immunoassays." Biotechniques **36**(4): 602-606, 608-609.

Microbeads that are both paramagnetic and fluorescently labeled are commercially available in colors spanning the visible spectrum. Although these commercial beads can be bright, polydispersity in both size and fluorescent intensity limit their use in quantitative assays. Very recently, more monodisperse beads have become available, but their large size and surface properties make them less than ideal for some bioassay applications. Here we describe methods to customize commercial nonfluorescent magnetic microparticles with fluorescent dyes and quantum dots (QDs) without affecting their magnetic or surface chemical properties. Fluorescent dyes and 3.3-nm diameter CdSe/ZnS QDs were sequestered within 0.8-micron diameter magnetic beads by swelling the polystyrene matrix of the bead in organic solvent, letting the chromophores partition, and then collapsing the matrix in polar solvents. Chromophore incorporation has been characterized using both UV-visible absorption spectroscopy and fluorescence microscopy, with an average of 3 x 10(8) rhodamine 6G molecules/bead and 6 x 10(4) QDs/bead. The modified beads are uniform in size and intensity, with optical properties comparable to currently available commercial beads. Immunoassay results obtained with our custom fluorescent magnetic microbeads are consistent with those obtained using conventional magnetic microbeads.

Mulvaney, S. P., et al. (2009). "Attomolar protein detection in complex sample matrices with semi-homogeneous fluidic force discrimination assays." Biosensors and Bioelectronics **24**(5): 1109-1115.

We describe a semi-homogenous (SH) implementation of a fluidic force discriminationTM (FFD) assay using only two reagent mixtures and three assay steps that can be performed in as little as 10 min. Previously microbead labels and FFD have been combined to achieve multiplexed, femtomolar nucleic acid hybridization and immunoassays in a microarray format [Mulvaney, S.P., Cole, C.L., Kniller, M.D., Malito, M., Tamanaha, C.R., Rife, J.C., Stanton, M.W., Whitman, L.J., 2007. Biosen. Bioelectron. 23, 191-200.]. In SH FFD assays, the microbeads and any required intermediate receptors (e.g., secondary antibodies) are first mixed directly with a sample, allowing target analytes to be efficiently captured onto the beads. The target-loaded beads are then specifically captured onto a microarray surface, with nonspecifically bound beads removed by controlled, laminar fluidic forces. The remaining beads on each microarray capture spot are counted to determine the targets' identities and concentrations. SH target collection provides a 1000-fold improvement in the assay sensitivity, down to attomolar concentrations, as demonstrated by our detection of staphylococcal enterotoxin B (SEB) at 35 aM (1 fg/ml). We also show that SH assays are adaptable for extraction, preconcentration, and identification of analytes in complex sample matrices, including assays for SEB and ricin toxoid in serum and whole blood. Finally, we present a detailed model of the reaction kinetics that reveals how capturing the targets onto the beads in solution provides a significant kinetic advantage at low target concentrations where mass transport to a microarray surface is most limited. © 2008 Elsevier B.V.

Mumbach, G. D., et al. (2019). "Dissolution of adhesive resins present in plastic waste to recover polyolefin by sink-float separation processes." Journal of Environmental Management **243**: 453-462.

This study investigated the dissolution of adhesive resins present in polyolefin films that cause plastic materials to adhere to each other. The process of dissolution was made by the use of ethyl acetate and followed by separation through the sink-float process. The objective was to separate and characterize polyolefin films from plastic solid waste derived from recycled post-consumer paper. Through these procedures, 6% polyethylene of high-density (HDPE), 14% polyethylene of low-density (LDPE) and 39% polypropylene (PP) were separated and recovered from plastic waste. Fourier transform infrared spectroscopy (FTIR), thermal gravimetric analyzes (TGA), differential scanning calorimetry (DSC), and dynamic mechanical analysis (DMA) were conducted to determine the chemical, thermal and mechanical properties of the recovered polymers and to establish a comparison with standard commercial polymers. It demonstrated that recovered material kept their chemical, thermal, and mechanical properties. This process indicates possible economic viability considering the demand, the market value of the PP, and the required investment to be implemented in the recycling process that could be amortized in a short period of time. Moreover, the organic solvent used in the dissolution process can be easily recovered by distillation.

Munari, C., et al. (2017). "Microplastics in the sediments of Terra Nova Bay (Ross Sea, Antarctica)." Marine Pollution Bulletin **122**(1-2): 161-165.

This is the first survey to investigate the occurrence and extent of plastic contamination in sediments collected in Terra Nova Bay (Ross Sea, Antarctica). Plastic debris extracted from 31 samples of sediments were counted, weighted and identified by Fourier-transform infrared spectroscopy (FT-IR). All sediment samples contained plastics: a total of 1661 items of debris (3.14g) were recorded from the 31 samples of sediment. Plastic particles in the samples ranged from 0.3 to 22mm in length. Fibres were the most frequent type of small plastics debris detected. In terms of abundance, microplastics (<5mm) accounted for 78.4% of debris. 9 polymer types were found: the most common material (94.13% by weight) was styrene-butadiene-styrene copolymer (SBS), widely used in pneumatic tires, etc. A decreasing concentration of plastic debris at increasing distances from the Mario Zucchelli Base was evidenced.

Munier, B. and L. I. Bendell (2018). "Macro and micro plastics sorb and desorb metals and act as a point source of trace metals to coastal ecosystems." PLoS ONE [Electronic Resource] **13**(2): e0191759.

Nine urban intertidal regions in Burrard Inlet, Vancouver, British Columbia, Canada, were sampled for plastic debris. Debris included macro and micro plastics and originated from a wide diversity of uses ranging from personal hygiene to solar cells. Debris was characterized for its polymer through standard physiochemical characteristics, then subject to a weak acid extraction to remove the metals, zinc, copper, cadmium and lead from the polymer. Recently manufactured low density polyethylene (LDPE), nylon, polyethylene terephthalate (PET), polypropylene (PP), polystyrene (PS) and polyvinyl chloride (PVC) were subject to the same extraction. Data was statistically analyzed by appropriate parametric and non-parametric tests when needed with significance set at $P < 0.05$. Polymers identified in field samples in order of abundance were; PVC (39), LDPE (28), PS (18), polyethylene (PE, 9), PP (8), nylon (8), high density polyethylene (HDPE, 7), polycarbonate (PC, 6), PET (6), polyurethane (PUR, 3) and polyoxymethylene (POM, 2). PVC and LDPE accounted for 46% of all samples. Field samples of PVC, HDPE and LDPE had significantly greater amounts of acid extracted copper and HDPE, LDPE and PUR significantly greater amounts of acid extracted zinc. PVC and LDPE had significantly greater amounts of acid extracted cadmium and PVC tended to have greater levels of acid extracted lead, significantly so for HDPE. Five of the collected items demonstrated extreme levels of acid extracted metal; greatest concentrations were 188, 6667, 698,000 and 930 mugg-1 of copper, zinc, lead and cadmium respectively recovered from an unidentified object comprised of PVC. Comparison of recently manufactured versus field samples indicated that recently manufactured samples had significantly greater amounts of acid extracted cadmium and zinc and field samples significantly greater amounts of acid extracted copper and lead which was primarily attributed to metal extracted from field samples of PVC. Plastic debris will affect metals within coastal ecosystems by; 1) providing a sorption site (copper and lead), notably for PVC 2) desorption from the plastic i.e., the "inherent" load (cadmium and zinc) and 3) serving as a point source of acute trace metal exposure to coastal ecosystems. All three mechanisms will put coastal ecosystems at risk to the toxic effects of these metals.

Munno, K., et al. (2018). "Impacts of temperature and selected chemical digestion methods on microplastic particles." Environmental Toxicology & Chemistry **37**(1): 91-98.

Alkaline and wet peroxide oxidation chemical digestion techniques used to extract microplastics from organic matrices were assessed for recoveries and for impacts on ability to identify polymer types. Methods using wet peroxide oxidation generated enough heat to result in the complete loss of some types of microplastic particles, and boiling tests confirmed that temperatures >70 °C were responsible for the losses. Fourier transform infrared spectroscopy (FT-IR) confirmed minimal alteration of the recovered polymers by the applied methods. Environ Toxicol Chem 2018;37:91-98. © 2017 SETAC [ABSTRACT FROM AUTHOR]

Munoz, P., et al. (2004). "Using LCA for the improvement of waste management in greenhouse tomato production." DIAS Report, Animal Husbandry **61**: 205-209.

Protected cultivation is aimed to obtain higher yields by modifying and improving natural climatic conditions. In spite of the fact that Mediterranean horticulture is mainly based on low-technology cold greenhouses, and therefore input resources are less than those used by more complex greenhouses, protected cultivation has a certain environmental impact. One of the bottlenecks associated to this system of production is the large amount of solid waste production. Waste can be biologic such as non-yield biomass and organic substrates, plastics (cover film, mulching etc...) or minerals (such as steel and mineral substrates). Life Cycle Assessment, LCA, has been used to assess different scenarios of waste treatment generated in a greenhouse tomato crop. The production of plastic waste from the different material used was estimated in 1750 kg ha⁻¹ year⁻¹. Soilless closed systems, which reduce contamination from fertilisers and use of water, generated an estimated waste of 1150 kg ha⁻¹ year⁻¹ of polyethylene used in substrate bags and soil cover. Finally there is a non-yield biomass of 20000 kg of dry matter ha⁻¹ year⁻¹. Different scenarios such as landfill, incineration and compost of the biomass have been evaluated. Results shows that for most indicators categories the waste management is important in the life cycle of greenhouse tomato production.

Muntohar, A. S. (2011). "Effect of specimen size on the tensile strength behavior of the plastic waste fiber reinforced soil - lime - rice husk ash mixtures." Civil Engineering Dimension **13**(2): 82-89.

Improvement of tensile strength in fiber reinforced soil is an important research topic. A study has been undertaken to investigate the strength of stabilized clay-soil reinforced with randomly distributed discrete plastic waste fibers by carrying out split tensile strength test. In this study, the clay soil was stabilized with lime and rice husk ash mixtures. The main purpose of this research is to investigate the effect of specimen size to the tensile strength behavior. Testing procedure was formulated using extended ASTM C496 standard. The laboratory investigation results showed that split-tensile strength of reinforced specimens increased with increase in size. The limitations of the dataset indicate that specimen size of 70 mm in diameter is the threshold to produce reasonable representative strengths.

Murakami, C. D., et al. (2014). "Where Does the Plastic Go?" Green Teacher(102): 27-30.

The article focuses on teaching strategies for exposing students to socio-scientific issues (SSI) related to plastic pollution, which could be used by teachers to promote better understanding of global climate change and genetic engineering. Topics discussed include the benefits of introducing SSI to students including greater interest in science, techniques teachers can use to discuss SSI in the classroom and strategies to assess students' understanding of SSI.

Murakawa, T., et al. (2008). "Improvement of bioactive bead-mediated transformation by concomitant application of electroporation." Plant Biotechnology **25**(4): 387.

Techniques of exogenous gene introduction in plant cells have been actively applied for producing transgenic cultured cells that produce high levels of useful biological substances and are used for the molecular breeding of plants. A novel gene transfer technique has been developed using calcium alginate micro-beads (bioactive beads) to entrap genetic material. Although this technique has several advantages such as high transformation efficiency and the ability to introduce large DNA molecules, the precise optimal application conditions remain to be determined. Here, the optimal conditions for the concomitant use of bioactive beads and electroporation, such as polyethylene glycol (PEG) concentration, alginate concentration, electric field intensity, pulse duration, and pulse numbers, were determined for improved gene transfer efficiency of bioactive bead-mediated plant transformation. Consequently, highly efficient transient transgene expression (up to 4.7%) was achieved by applying electrical pulses

(0.75 kV CM-1, 30 µs, 3×) to a protoplast suspension in 12% polyethylene glycol (PEG).

Muramatsu, K. (1975). "Recycling of rubber and plastic wastes." Int.Polymer Sci.Technol **2**(1): 93-102.
It is now several years since the need to recycle rubber and plastic waste was first advocated, and since then a good start has been made on the development of techniques. However, the present state of recycling techniques cannot be said to have been perfected. In order to accelerate practical recycling, together with the research and development of techniques, it is necessary to establish economic recycling systems. This paper presents a general view of the present state of recycling. Since many authors have already discussed this theme in various ways, in order to avoid repetition, descriptions are made only of recent techniques, particularly those connected with town refuse.

Muramatsu, T., et al. (2011). "Electrochemical flow injection immunoassay for cortisol using magnetic microbeads." International Journal of Environmental Analytical Chemistry **91**(2): 161-173.
We developed a novel flow injection assay for cortisol based on competitive immunologic reactions, magnetic separation, and electrochemical measurement. The proposed flow assay system was composed of two reaction units. An anti-cortisol antibody was immobilised on magnetic beads and injected into the reaction coil of a competitive reaction unit with a blood sample and a specific quantity of acetylcholinesterase-labelled cortisol (cort-AChE). After reacting in the reaction coil, the sample was separated magnetically using a neodymium magnet. The cort-AChE was detached from the magnetic beads and transferred into the enzyme reaction unit with acetylthiocholine (ATCh). ATCh was hydrolysed by the cort-AChE to produce thiocholine. The thiocholine was quantified downstream by electrochemical detection using a Pt-Ir electrode. The performance of the proposed flow assay system was optimised under the following conditions: pH 7.5, temperature 25 degrees C, flow rate 170 micro l min⁻¹, ATCh concentration in the substrate buffer 5 mmol L⁻¹. The output current was well correlated with the concentration of the cortisol standard solution (range: 7.8-500 pg mL⁻¹). The results obtained using the proposed flow method were compared with those obtained using conventional ELISA (correlation coefficient 0.9585 [y=-0.9797+1.173(x), n=11]). These findings suggest that the EFIIA system can be used to analyse cortisol in fish plasma samples.

Murphy, A. A., et al. (2010). "Pathogenic B cell expansion observed in HCV mixed cryoglobulinemic vasculitis patients results in activation of monocytes and innate immune activation." Hepatology **1)**: 671A.
Background: Mixed Cryoglobulinemic vasculitis (MC) is a rare extrahepatic manifestation of chronic HCV infection characterized by monoclonal expansion of B cells producing pathogenic IgM with rheumatoid factor activity. High levels of innate immune activation in PBMCs have been a hallmark of untreated MC, which are normalized with B cell depletion therapy and resolution of symptoms. AIM: To determine the phenotypic and functional characteristics of B cells and their role in inducing immune activation in MC subjects undergoing Rituximab (RTX) therapy. Method(s): Seven MC patients received 4 weekly doses of RTX (375mg/m2) and were followed for 1 year. Seven normal volunteers served as controls. DNA microarray analysis was performed using RNA from PBMCs before and after treatment. Fractionation of cell types in vitro was performed using subset-specific antibodies conjugated with magnetic MicroBeads. IFIG expression was analyzed via QuantiGene Plex 2.0 assay in these human PBMCs, monocyte depleted, monocyte enriched, B cell depleted, and B cell enriched samples from both pre and post RTX treatment. B cell phenotyping was performed with a panel of anti-human mAbs

obtained from BD Biosciences, and FACS analyses were performed on a FACSCalibur flow cytometer using FlowJo software. Result(s): HCV MC subjects had a significant increase in mean IFIG expression when compared to normal volunteers (p<0.001), which normalized after RTX therapy (p=0.5). Monocytes and no B cells accounted for the IFIG expression. Specifically, the expression of IFI6, ISG20, IRF7, IFIT1, IFI44, LY6E, IFIT3, MX1, and ISG15 were upregulated at baseline and were normalized with therapy while OAS1, MX2, and STAT1 levels were unchanged even after therapy. The following table displays the results of the B cell phenotype characterization. Conclusion(s): Expansion of tissue like exhausted memory B cells, down regulation of CD21 and a reduction in memory phenotype observed in HCV MC patients may represent the expansion of pathogenic B cells in these patients. This pathognomonic B cell expansion in HCV MC contributes to innate immune activation indirectly by activation of monocytes.(Table presented).

Murphy, F., et al. (2016). "Wastewater Treatment Works (WwTW) as a Source of Microplastics in the Aquatic Environment." Environmental Science and Technology **50**(11): 5800-5808.

Municipal effluent discharged from wastewater treatment works (WwTW) is suspected to be a significant contributor of microplastics (MP) to the environment as many personal care products contain plastic microbeads. A secondary WwTW (population equivalent 650-000) was sampled for microplastics at different stages of the treatment process to ascertain at what stage in the treatment process the MP are being removed. The influent contained on average 15.70 (+/-5.23) MP.L⁻¹. This was reduced to 0.25 (+/-0.04) MP.L⁻¹ in the final effluent, a decrease of 98.41%. Despite this large reduction we calculate that this WwTW is releasing 65 million microplastics into the receiving water every day. A significant proportion of the microplastic accumulated in and was removed during the grease removal stage (19.67 (+/-4.51) MP/2.5 g), it was only in the grease that the much publicised microbeads were found. This study shows that despite the efficient removal rates of MP achieved by this modern treatment plant when dealing with such a large volume of effluent even a modest amount of microplastics being released per liter of effluent could result in significant amounts of microplastics entering the environment. This is the first study to describe in detail the fate of microplastics during the wastewater treatment process. Copyright © 2016 American Chemical Society.

Murphy, F. and B. Quinn (2018). "The effects of microplastic on freshwater Hydra attenuata feeding, morphology & reproduction." Environmental Pollution **234**: 487-494.

Microplastic pollution has been a growing concern in the aquatic environment for several years. The abundance of microplastics in the environment has invariably led them to interact with a variety of different aquatic species. The small size of microplastics may make them bioavailable to a great range of species however, the impact this may have is not fully understood. Much of the research on microplastic pollution has focused on the marine environment and species with little research undertaken in freshwater. Here we examine the effect of microplastics on the freshwater cnidarian, Hydra attenuata. This study also describes the development and use of a bioassay to investigate the impact of microplastic on freshwater organisms. Hydra attenuata play a vital role in the planktonic make up of slow moving freshwater bodies which they inhabit and are sensitive environmental indicators. Hydra attenuata were exposed to polyethylene flakes (<400 im) extracted from facewash at different concentrations (Control, 0.01, 0.02, 0.04, 0.08 g mL⁻¹). The ecologically relevant endpoint of feeding was measured by determining the amount of prey consumed (Artemia salina) after 30 and 60 min. The amount of microplastics ingested was also recorded at 30 min and 60 min. After which Hydra attenuata

were transferred to clean media and observed after 3, 24, 48 & 96 h with changes in their morphology and reproduction (Hydranth numbers) recorded. The results of this study show that Hydra attenuata are capable of ingesting microplastics, with several individuals completely filling their gastric cavities. Significant reductions in feeding rates were observed after 30 min in 0.02 & 0.08 g mL⁻¹ and after 60 min in 0.04 & 0.08 g mL⁻¹ exposures. Exposure to the microplastics caused significant changes to the morphology of Hydra attenuata, however these changes were non-lethal. This study demonstrates that freshwater Hydra attenuata is capable of ingesting microplastics and that microplastic can significantly impact the feeding of freshwater organisms.

Murphy, F., et al. (2017). "The uptake of macroplastic & microplastic by demersal & pelagic fish in the Northeast Atlantic around Scotland." Marine Pollution Bulletin **122**(1/2): 353-359.

This study reports plastic ingestion in various fish found from coastal and offshore sites in Scottish marine waters. Coastal samples consisted of three demersal flatfish species (n=128) collected from the East and West coasts of Scotland. Offshore samples consisted of 5 pelagic species and 4 demersal species (n=84) collected from the Northeast Atlantic. From the coastal fish sampled, 47.7% of the gastrointestinal tracts contained macroplastic and microplastic. Of the 84 pelagic and demersal offshore fish, only 2 (2.4%) individuals from different species had ingested plastic identified as a clear polystyrene fibre and a black polyamide fibre. The average number of plastic items found per fish from all locations that had ingested plastic was 1.8 (+or-1.7) with polyamide (65.3%), polyethylene terephthalate (14.4%) and acrylic (14.4%) being the three most commonly found plastics. This study adds to the existing data on macroplastic and microplastic ingestion in fish species.

Murphy, M. R., et al. (1989). "Passage and rumination of inert particles varying in size and specific gravity as determined from analysis of faecal appearance using multicompartment models." British Journal of Nutrition **62**(2): 481-492.

Plastic particles of defined length (2, 5 mm) and specific gravity (sp.gr. 1.10, 1.34, 1.77) were administered just before feeding into the reticulo-rumen of four cattle and four swamp buffaloes given a diet predominantly of rice straw ad lib. Simultaneously, doses of ground rice straw marked with Cr and Yb were likewise given. Plastic particles were recovered from faeces for 12 d after dosing, and divided into non-ruminated (NR) and ruminated (R) particles. Excretion data of plastic particles were interpreted using a four-pool model incorporating passage of NR (k(p)) and R from the reticulo-rumen, post-ruminal passage, rate of chewing (k(r)) and two lag times. An inverse relationship was found between k(r) and sp.gr. The k(r) was higher for 5 mm than that for 2 mm particles. In contrast, k(p) was greatest for particles of sp.gr. 1.34, with higher k(p) for 2 mm than for 5 mm particles. Rates of passage and rumination (k(p), k(r)) were higher for buffaloes than for cattle. Rumination time was related to k(r), most highly (r² 0.96) with k(r) of 2 mm, 1.10 sp.gr. particles. Fragmentation of 5 mm particles by rumination tended to increase the rate of passage from the rumen. Ruminal passage rates of Yb and Cr markers were poorly correlated with each other and with k(p) of any of the plastic markers. Reanalysis of published data from plastic particle studies supported the relationships between sp.gr., size, k(p) and k(r). In view of the additional information (k(r) obtained using plastic particles, we suggest their use may be appropriate in studies which investigate specific differences in digestive function, while being less suitable for investigating differences between diets.

Musil, J., et al. (2014). "Antitumor activity and immunogenicity of recombinant vaccinia virus expressing

HPV 16 E7 protein SigE7LAMP is enhanced by high-level coexpression of IGFBP-3." Cancer Gene Therapy **21**(3): 115-125.

We constructed recombinant vaccinia viruses (VACVs) coexpressing the insulin-like growth factor-binding protein-3 (IGFBP-3) gene and the fusion gene encoding the SigE7Lamp antigen. The expression of the IGFBP-3 transgene was regulated either by the early H5 promoter or by the synthetic early/late (E/L) promoter. We have shown that IGFBP-3 expression regulated by the H5 promoter yielded higher amount of IGFBP-3 protein when compared with the E/L promoter. The immunization with P13-SigE7Lamp-H5-IGFBP-3 virus was more effective in inhibiting the growth of TC-1 tumors in mice and elicited higher T-cell response against VACV-encoded antigen than the P13-SigE7Lamp-TK super(-) control virus. We found that high-level production of IGFBP-3 enhanced virus replication both in vitro and in vivo, resulting in more profound antigen stimulation. Production of IGFBP-3 was associated with a higher adsorption rate of P13-SigE7Lamp-H5-IGFBP-3 to CV-1 cells when compared with P13-SigE7Lamp-TK super(-). Intracellular mature virions (IMVs) of the IGFBP-3-expressing virus P13-SigE7Lamp-H5-IGFBP-3 have two structural differences: they incorporate the IGFBP-3 protein and they have elevated phosphatidylserine (PS) exposure on outer membrane that could result in increased uptake of IMVs by macropinocytosis. The IMV PS content was measured by flow cytometry using microbeads covered with immobilized purified VACV virions.

Musunuri, S., et al. (2015). "Micellar extraction possesses a new advantage for the analysis of Alzheimer's disease brain proteome." Analytical and bioanalytical chemistry **407**(4): 1041-1057.

Issue Title: A different way of looking at vibrational hyperspectral data/Micellar extraction for the analysis of Alzheimer's disease brain proteome/Quantification of polyolefin microplastics in personal-care products/Removal of Triton X-100 by microdialysis Integral membrane proteins (MPs), such as transporters, receptors, and ion channels, are of great interest because of their participation in various vital cellular functions including cell-cell interactions, ion transport, and signal transduction. However, studies of MPs are complicated because of their hydrophobic nature, heterogeneity, and low abundance. Cloud-point extraction (CPE) with the non-ionic surfactant Triton X-114 was performed to simultaneously extract and phase separate hydrophobic and hydrophilic proteins from Alzheimer's disease (AD) and unaffected control brain tissue. Quantitative proteomics analysis of temporal neocortex samples of AD patients and controls was performed using a shotgun approach based on stable isotope dimethyl labeling (DML) quantification technique followed by nanoLC-MS/MS analysis. A total of 1096 unique proteins were identified and quantified, with 40.3 % (211/524) predicted as integral MPs with at least one transmembrane domain (TMD) found in the detergent phase, and 10 % (80/798) in the detergent-depleted phase. Among these, 62 proteins were shown to be significantly altered (p-value <0.05), in AD versus control samples. In the detergent fraction, we found 10 hydrophobic transmembrane proteins containing up to 14 putative TMDs that were significantly up- or down-regulated in AD compared with control brains. Changes in four of these proteins, alpha-enolase (ENOA), lysosome-associated membrane glycoprotein 1 (LAMP1), 14-3-3 protein gamma (1433G), and sarcoplasmic/endoplasmic reticulum calcium ATPase2 (AT2A2) were validated by immunoblotting. Our results emphasize that separating hydrophobic MPs in CPE contributes to an increased understanding of the underlying molecular mechanisms in AD. Such knowledge can become useful for the development of novel disease biomarkers.

Mutha, N. H., et al. (2006). "Plastics materials flow analysis for India." Resources, Conservation and Recycling **47**(3): 222-244.

Forecasting material flows is essential for sound policy making on issues relating to waste management. This paper presents the results of the plastics materials flow analysis (MFA) for India. In the recent past, India has witnessed a substantial growth in the consumption of plastics and an increased production of plastic waste. Polyolefins account for the major share of 60% in the total plastics consumption in India. Packaging is the major plastics consuming sector, with 42% of the total consumption, followed by consumer products and the construction industry. The relationship observed between plastic consumption and the gross domestic product for several countries was used to estimate future plastics consumption (master curve). Elasticities of the individual material growth with respect to GDP were established for the past and for the next three decades estimated for India thereby assuming a development comparable with that of Western Europe. On this basis, the total plastics consumption is projected to grow by a factor of 6 between 2000 and 2030. The consumption of various end products is combined with their corresponding lifetimes to calculate the total waste quantities. The weighted average lifetime of plastics products was calculated as 8 years. Forty-seven percent of the total plastics waste generated is currently recycled in India; this is much higher than the share of recycling in most of the other countries. The recycling sector alone employs as many people as the plastics processing sector, which employs about eight times more people than the plastics manufacturing sector. Due to the increasing share of long-life products in the economy, and consequently in the volume of waste generated, the share of recycling will decrease to 35% over the next three decades. The total waste available for disposal (excluding recycling) will increase at least 10-fold up to the year 2030 from its current level of 1.3 million tonnes. © 2005 Elsevier B.V. All rights reserved.

Muthuraj, R. and T. Mekonnen (2018). "Recent progress in carbon dioxide (CO^sub 2^) as feedstock for sustainable materials development: Co-polymers and polymer blends." Polymer **145**: 348.

Combustion of fossil fuels and many other industrial activities inevitably produces carbon dioxide (CO2) that is released into the atmosphere and is currently deemed to be among the major contributors to global warming. One of the prominent solutions proposed to mitigate global warming concerns from CO2, capture and storage (CCS), did not attract many CO2 emitting industries as expected, mainly because of economic reasons. On the contrary, environmental pollution concerns associated with plastic waste, and the demand for sustainable feedstock for their production constitute grand challenges facing our society with regard to the production and use of plastics. As a result, the materials science community is striving to generate sustainable and biodegradable plastics to substitute conventional synthetic plastics from resources that do not pose direct completion with food production. This manuscript aims to provide a general overview of the recent progress achieved in CO2 based polymers for sustainable biopolymers such as co-polymers, and polymer blends. The synthesis, material properties, processability, and performances of important CO2 based co-polymers are critically reviewed. Furthermore, a critical review of CO2 co-polymers as components of polymer blend with a focus on the most relevant CO2 based aliphatic polycarbonates, poly (propylene carbonates) (PPC), is conducted.

Mutlu, Y., et al. (2019). "Solid waste seasonal characteristics related to economic conditions: Hatay northern west as case study." The Journal of Material Cycles and Waste Management **21**(4): 743-752.

This paper studied solid waste components in six districts of Hatay (Iskenderun, Dortyol, Payas, Erzin, Belen, and Arsuz) for the period 2015 until 2018. Solid wastes were categorized, and the relationship between the population and the waste categories were determined using Pearson’s correlation test. It was mainly categorized using The Standard Method of Determination of Compositions of Unprocessed Urban Wastes by ASTM D5231-92 into 11 categories. Solid waste

in the study area consist of food waste (63%), paper (6%), plastic (9%), glass (3%), metal (1%), composite waste (1%), electric–electronic waste (0%), hazardous waste (0%), garden waste (3%), incombustible waste (5%) and combustible waste (9%). Food waste showed strong negative correlation with population ($r = -0.875$, $p < 0.05$), while plastic($r = 0.888$, $p < 0.05$), glass($r = 0.813$, $p < 0.05$) and composite waste ($r = 0.890$, $p < 0.05$) showed strong positive correlation. The other categories showed weak or moderate correlation. The socio-economic factor effects were studied in each district. Food waste showed strong negative correlation with the income level ($r = -0.72$, $p < 0.01$). Paper and plastic waste were positively correlated to the income level with the maximum correlation of ($r = 0.871$, $p < 0.01$) and ($r = 0.843$, $p < 0.01$), respectively. The seasonal variation effect also had been considered in the study. It was concluded that the food portion in the winter season was higher than summer in Belen and Payas, and this could be attributed to the internal migration. Finally, a cost analysis of the recycling aspect for the categories of paper, plastic, glass, and metal (PPGM) was assessed. The result of the cost analysis reflected the effect of inflation on the recycling market. It showed that even though the maximum PPGM generation was estimated in 2018 with value of 15994.66 kg/day, the maximum daily income was recorded in 2017 with a value of 3256.37 $/day.

Muzard, J., et al. (2012). "M13 bacteriophage-activated superparamagnetic beads for affinity separation." SMALL **8**(15): 2403-2411.

The growth of the biopharmaceutical industry has created a demand for new technologies for the purification of genetically engineered proteins.The efficiency of large-scale, high-gradient magnetic fishing could be improved if magnetic particles offering higher binding capacity and magnetization were available. This article describes several strategies for synthesizing microbeads that are composed of a M13 bacteriophage layer assembled on a superparamagnetic core. Chemical cross-linking of the pVIII proteins to a carboxyl-functionalized bead produces highly responsive superparamagnetic particles (SPM) with a side-on oriented, adherent virus monolayer. Also, the genetic manipulation of the pIII proteins with a His(6) peptide sequence allows reversible assembly of the bacteriophage on a nitrilotriacetic-acid-functionalized core in an end-on configuration. These phage-magnetic particles are successfully used to separate antibodies from high-protein concentration solutions in a single step with a >90% purity. The dense magnetic core of these particles makes them five times more responsive to magnetic fields than commercial materials composed of polymer-(iron oxide) composites and a monolayer of phage could produce a 1000 fold higher antibody binding capacity. These new bionanomaterials appear to be well-suited to large-scale high-gradient magnetic fishing separation and promise to be cost effective as a result of the self-assembling and self-replicating properties of genetically engineered M13 bacteriophage.

Myers, S. S. (2016). "Sea change." The Lancet **388**(10058): 2341-2342.

This rapid transformation of Earth's life support systems is the terrain of the emerging, multidisciplinary field of planetary health, and it is the setting for A Plastic Ocean. This documentary film is an impassioned, if occasionally meandering, exploration of the enormous mess we are making in the world's oceans as a result of the sheer volume of plastic waste that deliberately or accidentally makes its way into our seas.

Na, W., et al. (2018). "Rapid molecular diagnosis of infectious viruses in microfluidics using DNA hydrogel formation." Biosensors & Bioelectronics **108**: 9-13.

There has been an urgent need to quickly screen and isolate patients with viral infections from

patients with similar symptoms at point-of-care. In this study, we introduce a new microfluidic method for detection of various viruses using rolling circle amplification (RCA) of pathogens on the surface of thousands of microbeads packed in microchannels. When a targeted pathogen meets the corresponding particular template, the DNAs are rapidly amplified into a specific dumbbell shape through the RCA process, forming a DNA hydrogel and blocking the flow path formed between the beads. Due to the significant increase in reaction surface area, the detection time was shortened to less than 15min and the detection limit of various pathogens has been reached to 0.1pM. By injecting the stained liquid, the existence of the target pathogens in a sample fluid can be determined with the naked eye. Furthermore, by integrating multi-channel design, simultaneous phenotyping of various infective pathogens (i.e., Ebola, Middle East respiratory syndrome (MERS), and others) in biological specimens can be performed at a point-of-care.

Nabgan, B., et al. (2017). "Parametric study on the steam reforming of phenol-PET solution to hydrogen production over Ni promoted on Al^sub 2^O^sub 3^-La^sub 2^O^sub 3^ catalyst." Energy Conversion and Management **142**: 127.

Production of hydrogen from plastic waste could be a prospective key to the ecological problems resulted from waste. To further explore the process, a 32-runs parametric study on the steam reforming of Polyethylene terephthalate (PET) dissolved in phenol was conducted in a fixed bed reactor using Ni over La2O3-AI2O3 support. The five factors studied were temperature (A), feed flow rate (B), mass flow (C), phenol concentration (D), and concentration of PET solution (E), whereas the responses were phenol conversion (Y1) and hydrogen selectivity (Y2). From the result, it was observed that significant influence resulted for all the main independent variables on the dependent variable of Y1 and Y2 with the range of 47.24-97.6% and 49-70.96%, respectively. Moreover, the Y1 and Y2 responses have influenced by some interaction variables like AC, CD, CE, ACE, and BCE. As evident from the design, initial variables such as 800 °C, 0.10 ml/min feed flow rate, 10 SCCM mass flow, 10 wt.% of phenol in the feed, and 7% PET concentration were the best preliminary conditions that formed maximum Y1 (94%) and Y2 (71%) responses. However, analyses on the product composition revealed that high amount of aliphatic branched-chains along with moderate amount of cyclic compounds were produced from steam reforming of PET-phenol. Due to the short retention time of the compounds on the catalysts bed, the aromatization of PET cracking products was small.

Nabizadeh, R., et al. (2019). "Microplastic pollution on the Persian Gulf shoreline: A case study of Bandar Abbas city, Hormozgan Province, Iran." Marine Pollution Bulletin **145**: 536-546.

Microplastic particles (<5mm), which are an emerging threat, are commonly found in marine ecosystems worldwide. This study investigated the effect of different types of coastal land use on microplastic frequency and distribution on the coastline of Bandar Abbas city; this study used a large sample compared to that used in other studies conducted in this region. The average number of microplastics was determined as 3252+/-2766 microplastics/m² (+/-SD). ATR FT-IR spectroscopy showed that the dominant microplastic particles are expanded polystyrene, polyethylene terephthalate, polypropylene, and polyethylene. Statistical analysis showed a significant difference in microplastic contamination levels between the urban and nonuse beaches. This shows that heavily urbanized areas and human activities have significant effects on the dispersion and frequency of microplastics in the coastal areas of Bandar Abbas. Periodical coast-based cleanup and studies on microplastic pollution and their fluxes by comprehensive sampling are mostly recommended for the Persian Gulf coastline.

Nada, S., et al. (2015). "Isolation and initial characterization of dermal vascular smooth muscle cells in systemic sclerosis." Arthritis and Rheumatology. Conference: American College of Rheumatology/Association of Rheumatology Health Professionals Annual Scientific Meeting, ACR/ARHP **67**(SUPPL. 10).

Background/Purpose: Nearly all patients with Systemic sclerosis (SSc) suffer from vascular dysfunction as illustrated by the uniform presence of Raynaud's phenomena. The role of vascular smooth muscle cells (VSMCs) in the development of vascular dysfunction is still unknown. In this study, we isolated VSMCs from skin biopsy, and we examined their functional phenotype. Method(s): We obtained 4 mm punch-skin-biopsy from 3 patients with diffuse cutaneous SSc and 3 matched healthy controls. Skin specimens were treated with a mixture of proteases, then after digestion we plated cells in culture media and harvested the primary cell culture after 10 days. VSMCs were isolated by magnetic microbeads using cell surface markers. First, we depleted total cells from CD31+ cells, followed by positive selection for CD146 + cells. To confirm the identity of this cell population (CD31- CD146+), we performed immunoflorocytometry staining for smooth muscle myosin heavy chain 11 (MYH11), Desmin and NG2. We investigated cell proliferation by using Bromodeoxyuridine (BrdU) assay, and cell viability in normal culture conditions as well as low serum conditions using MTT assay. Result(s): Out of the total cells obtained from primary cell culture, 15% were CD31- CD146 + (VSMCs). The majority of cells in this population stained for smooth muscle MYH11 (89.1%), in addition to Desmin and NG2, while the CD31+ and the fibroblast cell populations did not. This staining pattern differentiates VSMCs from pericytes. Next, we evaluated cell proliferation using BrdU, and we demonstrated uptake of BrdU by 19% of the control-VSMCs compared to 34% of SSc-VSMCs (P= 0.0031). The MTT assay showed increase cell proliferation of SSc-VSMCs compared to control-VSMCs (0.44 and 0.25, respectively. P= 7.38E-08). Under serum starvation conditions, SSc-VSMCs exhibited more proliferation capacity than control-VSMCs (0.30 and 0.21, respectively. P= 5.73E-13). Also, we performed immunoflorocytometry staining for B-catenin and we demonstrate a cytoplasmic to nuclear translocation of B-catenin in SSc-VSMCs but not in control-VSMCs. This finding may imply potential involvement of B-catenin in the induction of VSMCs activation in SSc. Conclusion(s): This is the first report of the successful isolation and initial characterization of SSc-VSMCs. We believe that increased proliferation of SSc- VSMCs in association with resistance to apoptosis may greatly impact the vascular lesion in SSc. Further studies are warranted to fully understand the trigger and maintenance of the abnormal SSc-VSMCs phenotype.

Nadal, M. A., et al. (2016). "High levels of microplastic ingestion by the semipelagic fish bogue Boops boops (L.) around the Balearic Islands." Environmental Pollution **214**: 517-523.

For the first time this study reports on the presence of microplastics (1 nm to <5 mm) in the gastrointestinal tracts of small semipelagic fish (Boops boops) in the Balearic Islands (Mediterranean Sea) from March to May 2014. The results show microplastic ingestion in 68% of full stomach samples with an average of 3.75 items per fish. Only filament type microplastics were observed in B. boops full gastrointestinal tracts. The frequency of occurrence of microplastics was high, with values ranging from 42% to 80%, in comparison to the other ingested items. Spatial variability among locations is high, which suggests that this type of contamination is ubiquitously distributed and originates from multiple sources. The results are important and indirectly provide further evidence of the presence of microplastics, which can be ingested by biota, in the marine environment.

Nadjem, H. and E. Logemann (1998). "[A case of suicidal chloroform poisoning]." Archiv fur Kriminologie

202(1-2): 29-37.

A 33-year-old man who had suffered from phobia and depressions was found dead in his kitchen. He was entirely covered by plastic waste disposal bags stuck together. The corpse was lying flat on his stomach with his face on a towel soaked with chloroform. Within the plastic cover, on either side of the body's head, there was located a can half way filled with chloroform. Autopsy revealed cauterized lips and mucous membranes of the mouth. The morphological findings of the inner organs were unspecific. For toxicological analyses, air samples from the pleural cavities of the corpse were taken by way of charcoal tubes and a microprocessor aided pump. The solvents adsorbed on the charcoal were desorbed with benzyl alcohol and analyzed by gas chromatography according to standard procedures. The quantification of the chloroform levels of the body fluids and the tissue samples of the corpse was performed by extraction with pentane followed by addition of trichloroethylene as internal standard and consecutive gas chromatographic analysis. The results of the toxicological analyses confirmed the diagnosis of a fatal chloroform intoxication.

Nagl, S. and O. S. Wolfbeis (2007). "Optical multiple chemical sensing: status and current challenges." Analyst **132**(6): 507-511.

Multiple optical sensors for chemical species are sensitive, non-toxic and non-invasive and enable spatially and temporally resolved multianalyte detection. Recent advances are highlighted with a focus on fluorescence-based methods and the biologically and clinically important analytes oxygen, pH, carbon dioxide and temperature. Indicator chemistries such as permeation-selective microbeads and nanoparticles allow the production of microscopically homogeneous sensor layers. The use of combinations of spectral discriminations along with time-resolved monitoring schemes based on luminescence lifetime or intensity-lifetime ratios enables all-optical real-time multianalyte determination.

Nagy, E. M., et al. (2015). "Water degradation effect on some starch-based plastics." Proceedings of the 43rd International Symposium on Agricultural Engineering, Actual Tasks on Agricultural Engineering, Opatija, Croatia.

The use of starch resources in order to obtain degradable bioplastics has experienced a great development in the last years, due to environmental problem concerning the plastic waste disposal and reducing of oil resources. The starch represents a possible solution to this challenge, due to its hydrophilic nature, which plays an important role in initiating biodegradation process. Polymer hydrolytic degradation may be defined as the scission of the polymeric chain by the attack of water to form oligomers and finally monomers. Among the techniques that can be used to obtain information about the degradation mechanism of biopolymer are water uptake and rheological measurements This paper presents the results of water absorption and rheological investigations for two types of starch-based packaging materials obtained by thermoplastic extrusion of native starch, (with an amylase content of 21%), with different starch, glycerol and water ratios, subjected to natural degradation after absorption of distillate water. It was observed that the sample containing starch/glycerol/water ratio of 68/17/15 is rapidly degraded-after 8 hours forming a colloidal solution, and sample with a content of 78/19.5/2.5 starch/glycerol/water reaches the limit of swelling after 5 days, after which it begins to decompose slowly. The rheological measurements for the samples show that at low temperature (30 degrees C) there is a dependence of viscosity function of shear rate which does not comply with the Newtonian model. If the temperature increases further than 60 degrees C the dependence between viscosity and share rate tends to linearity. Switching from a non-Newtonian behavior to a Newtonian one indicates that the large conglomerates of

polymeric structures transforms in smaller elements with spherical symmetry, characteristic of simple Newtonian liquids. It is clear evidence of degradation.

Naidoo, T. and D. Glassom (2019). "Decreased growth and survival in small juvenile fish, after chronic exposure to environmentally relevant concentrations of microplastic." Marine Pollution Bulletin **145**: 254.

Glassfish, Ambassis dussumieri (Cuvier, 1828), was used as a sentinel species to investigate the effects of the ingestion of environmentally relevant microplastic concentrations on juvenile fish growth and survival. Both virgin plastic and plastic collected from an urban harbour were fed to small juvenile fish daily for 95 days. Fish standard length, body depth and mass were recorded at intervals of 20 days, while survival was continuously recorded. All fish were fed tropical flakes, measured at 1.7% of the body mass per tank. Overall, fish in in plastic treatments grew less in body length and body depth compared to those control treatments. Fish mass was also lower in the virgin plastic treatment than control fish; however, the growth in mass was not significantly lower than fish in the harbour plastic treatment. The survival probability of fish in both plastic fed treatments was also lower than fish in controls.

Naidoo, T. and D. Glassom (2019). "Sea-surface microplastic concentrations along the coastal shelf of KwaZulu-Natal, South Africa." Marine Pollution Bulletin **149**: 110514.

Ocean pollution is a global issue; yet limited quantitative data on microplastic concentrations are available for the South African coastal shelf. Estuarine outlets within industrial areas that are found along the coastline serve as conduits for plastics and other pollutants to the ocean. This study investigated coastal plastic concentrations around KwaZulu-Natal. Forty-three manta trawl samples were collected and analysed over a period of one year. An average of 4.01+/-3.28 plastic particles/100m² was found in surface trawls. Plastic concentrations in winter were significantly higher than those in summer (5.54+/-3.26 and 2.96+/-2.94 particles/100m² respectively). The highest concentrations of plastics were found south of the city of Durban, with the highest concentration at Isipingo winter with 12.2 particles/100m². Among the summer samples, the highest concentration of particles was off Amanzimtoti (9.54 particles/100m²). The main plastic forms were fragments, films and fibres that were commonly white, clear, opaque, blue and black in colour. High plastic concentrations in the Durban area and sites close-by were expected due to the high levels of urbanization in the area, however, the difference in concentrations found between winter and summer was not expected and may have been due to the prevailing wind and/or current conditions on the sampling date.

Naidoo, T., et al. (2015). "Plastic pollution in five urban estuaries of KwaZulu-Natal, South Africa." Marine Pollution Bulletin **101**(1): 473-480.

Monitoring plastic concentrations in estuaries is vital in assessing the magnitude of terrestrial inputs to oceanic environments. Data on plastics <= 5 mm in estuaries are scant. This study determined microplastic levels within five estuaries along the Durban coastline and on intervening beaches. Plastics were isolated from estuarine sediment, beach sediment and the surface water of each estuary and characterised. Sediment at the Bayhead area of Durban harbour had the highest average plastic concentrations (745.4 +/- 129.7 particles per 500 ml) and an attenuating concentration trend away from the city centre was found. Prevailing south to north longshore drift was hypothesised to result in plastic accumulation on the northern shores of beaches with estuarine effluents, however, this was not found. Fragments composed the largest percent of plastics (59%) found in Bayhead, whereas fibres dominated other

estuaries with proportions ranging from 38% of total plastics in the uMgeni estuary to 66% in the Mdloti.

Naidoo, T., et al. (2017). "Are nitric acid (HNO₃) digestions efficient in isolating microplastics from juvenile fish?" Water, Air, and Soil Pollution **228**(12).

A standard method for the detection and isolation of microplastics is required to adequately investigate plastic ingestion by juvenile fish. Dissections of juvenile fish guts require precise handling, which can affect the processing time if sample numbers are high. To investigate the efficacy of nitric acid (HNO₃) in aiding the isolation of microplastics using whole fish, we digested juvenile glassfish, Ambassis dussumieri (Cuvier, 1828), at room temperature and at 80 degrees C. For a complete digestion, overnight incubation in 10 mL of 55% analytical-reagent (AR) HNO₃ was sufficient for a whole fish of 1 g at room temperature. When coupled with elevated temperature, the digestion time is shortened to a few minutes and larger fish of 3 g can be digested in 30 min. Four of the five types of plastic survived the process, with nylon being the exception. This is a shortfall to the method; however, until a better method replaces it, we still value the use of HNO₃ for its simple, inexpensive, swift and complete digestions of whole fish. Four fish species from two feeding guilds were digested using this method to validate its use. The number of plastic particles ingested did not differ between benthic and pelagic species and microplastic fibres comprised the majority of the plastic types found.

Naidoo, T., et al. (2019). "Quantification and characterisation of microplastics ingested by selected juvenile fish species associated with mangroves in KwaZulu-Natal, South Africa." Environmental Pollution: 113635.

Though the number studies on microplastic ingestion by fish is growing, data on fish species characteristic of the South African coastline are scarce. This study quantified and characterised (physically and chemically) microplastics ingested by four species of juvenile fish (viz. Oreochromis mossambicus [Peters, 1852], Terapon jarbua [Forsskal, 1775], Ambassis dussumieri [Cuvier, 1828] and Mugil sp.), within four mangroves along the east coast of South Africa. Microplastics were isolated from whole fish using a proteinase K digestion method, and then quantified and characterised in terms of shape, chemical nature (plastic type), colour and length. Fibres (68%) and fragments (21%) were the dominant shapes found. Of the 174 fish sampled, 52% contained microplastic particles, with 0.79 +/- 1.00 particles per fish. The average number of particles per fish did not differ significantly across species within sites and across sites but was higher than in juvenile fish of other species sampled in oceanic habitats. The main plastic types collected using 10 mum filters and identified with Fourier Transform Infrared Spectroscopy (FTIR), were rayon (70.4%), polyester (10.4%), nylon (5.2%) and polyvinylchloride (3.0%). Particle length ranged from 0.1 to 4.8 mm, averaging 0.89 +/- 0.77 mm, but irrespective of length, particles were mostly blue in colour. This study provides evidence that juvenile fish inhabiting mangroves are consuming significant quantities of microplastics. Importantly, it should be noted that rayon, though the most abundant plastic type found, is a semi-synthetic fibre made from regenerated cellulose that is commonly reported in studies of this nature. The habitats studied serve as nurseries for numerous fish species; however, more detailed studies are needed to assess whether microplastic ingestion could compromise the health of these fish or whether these effects are dependent on species, feeding habit and/or plastic type.

Naidoo, T., et al. (2016). "Plastic ingestion by estuarine mullet Mugil cephalus (Mugilidae) in an urban harbour, KwaZulu-Natal, South Africa." African Journal of Marine Science **38**(1): 145-149.

Coastal urban environments have high plastic pollution levels, and hence interactions between plastic debris and marine life are frequent. We report on plastic ingestion by mullet Mugil cephalus in Durban Harbour, KwaZulu-Natal, South Africa. Of 70 mullet (13.0-19.5 cm total length), 73% had plastic particles in their guts, with a mean of 3.8 particles per fish (SD 4.7). Plastic ingestion showed no relation to digestive tract content or fish length. White and clear plastic fibres were ingested most commonly. This urban population of M. cephalus had a higher incidence of plastic ingestion than has been reported in studies on fish from other coastal areas or the oceanic environment.

Naik, A., et al. (2019). "Temperature dissociation of liquids in reusable thermoplastic containers-An eco-friendly scald risk?" Burns **45**(7): 1621-1624.

Recent global concern regarding the impact of plastic waste on the environment has resulted in efforts to utilise reusable drink containers. Research is lacking regarding temperature dissociation of drinks in reusable thermoplastic cups. This study aimed to compare the cooling time of two common hot drinks sold at a UK retailer, in the three vessels they are sold; ceramic, disposable paper (with and without lid) and reusable thermoplastic cups (with and without lid). All temperatures were collated from 250 ml volumes of black Americano coffee or cafe latte in the three different containers. The cooling time was measured every sixty seconds using a standardised digital thermocouple thermometer until a threshold liquid temperature of 43 degreeC was reached. All experiments were performed in triplicate and temperatures converted to a dimensionless logarithmic scale prior to statistical analysis. Cooling time was significantly slower for lidded cups irrespective of material. Unlidded thermoplastic cups significantly slowed cooling times for both black Americano coffee and cafe latte compared to ceramic and unlidded disposable paper cups. The growing trend in reusable cups does not in itself pose an increased risk of scald injury. However, we consider that the potentially increased ambulatory behaviour associated with using a lidded rather than unlidded cup may increase scald risk. We propose that further consumer guidance should be disseminated regarding the use of any lidded takeaway container to prevent scalds in both adults and children.

Naik, R. K., et al. (2019). "Microplastics in ballast water as an emerging source and vector for harmful chemicals, antibiotics, metals, bacterial pathogens and HAB species: A potential risk to the marine environment and human health." Marine Pollution Bulletin **149**: 110525.

Microplastic pollution in marine waters around the globe is increasing exponentially. This is the first comprehensive review which focuses on microplastics as a source and vector for metals, antibiotics, toxic chemicals, pathogenic bacteria (Vibrio cholerae), and Harmful Algal Bloom (HAB)-forming dinoflagellates across the continents through ballast water. Microplastics in ballast waters serve as 'hotspots' for the development and spread of multiple drug-resistant human pathogens through co-selection mechanisms. Microplastic inoculation at distant countries through ballast water may pose a serious threat to human health due to higher incidences of bacterial disease outbreaks and HABs. The 2017 ballast water management convention lacks a provision for on-board treatment of microplastic-contaminated ballast water. We conclude that there is a pressing need to include microplastics in the ballast water management convention as a hazardous material. Efficient on-board ballast water treatment strategies and effective limits for microplastics in ballast waters need to be developed.

Najafi, R., et al. (2014). "Development of a rapid capture-cum-detection method for Escherichia coli O157 from apple juice comprising nano-immunomagnetic separation in tandem with surface enhanced Raman scattering." International Journal of Food Microbiology **189**: 89-97.

A combined capture and detection method comprising of nano-immunomagnetic separation (NIMS) and surface enhanced Raman spectroscopy (SERS) was developed to detect Escherichia coli O157 from liquid media including apple juice. The capture antibodies (cAbs) were immobilized on magnetite-gold (Fe3O4/Au) magnetic nanoparticles (MNPs) which were used for separation and concentration of the E. coli O157 cells from model liquid food matrix. The capture efficiency (CE) for E. coli O157 using MNP was found to be approximately 84-94%. No cross reactivity was observed with background non-target organisms. There was a significant difference in the mean CE of bacteria captured by MNP and commercially sourced immunomagnetic microbeads (p<0.05). For the detection of target pathogen, SERS labels were prepared by conjugating gold nanoparticles with Raman reporter molecules and the detector antibody (dAb). Au-Raman label-dAb was interacted with gold coated MNP-cAb-E. coli O157 complex. The ability of this immunoassay to detect E. coli O157 in apple juice was investigated. We have successfully applied the synthesized Fe3O4/Au nanoclusters to E. coli O157 detection in apple juice using the SERS method. The lowest detectable bacterial cell concentration in apple juice was 10(2)CFU/mL with a total analysis time of less than an hour. This method presents a convenient way of preconcentration, separation, and detection of low levels of target pathogen from liquid food matrix.

Naji, A., et al. (2017). "Plastic debris and microplastics along the beaches of the Strait of Hormuz, Persian Gulf." Marine Pollution Bulletin **114**(2): 1057-1062.

Currently little is known about the prevalence of plastics and microplastics (MPs) in the Persian Gulf. Five sampling stations were selected along the Strait of Hormuz (Iran) that exhibited different levels of industrialization and urbanization, and included a marine protected area. Debris was observed and sediments were collected for MPs extraction via fluidization/floatation methodology. The order of MP abundance (par/kg) generally reflected the level of anthropogenic activity: Bostanu (1258+/-291)>Gorsozan (122+/-23)>Khor-e-Yekshabeh (26+/-6)>Suru (14+/-4)>Khor-e-Azini (2+/-1). Across all sites fibers dominated (83%, 11% film, 6% fragments). FT-IR analysis showed polyethylene (PE), nylon, and PET (polyethylene terephthalate) were the commonly recovered polymers. Likely sources include beach debris, discarded fishing gear, and urban and industrial outflows that contain fibers from clothes. This study provides a 'snapshot' of MP pollution and longitudinal studies are required to fully understand plastic contamination in the region.

Naji, A., et al. (2017). "The occurrence of microplastic contamination in littoral sediments of the Persian Gulf, Iran." Environmental Science & Pollution Research **24**(25): 20459-20468.

Microplastics (MPs; <5 mm) in aquatic environments are an emerging contaminant of concern due to their possible ecological and biological consequences. This study addresses that MP quantification and morphology to assess the abundance, distribution, and polymer types in littoral surface sediments of the Persian Gulf were performed. A two-step method, with precautions taken to avoid possible airborne contamination, was applied to extract MPs from sediments collected at five sites during low tide. MPs were found in 80% of the samples. Across all sites, fiber particles were the most dominate shape (88%), followed by films (11.2%) and fragments (0.8%). There were significant differences in MP particle concentration between sampling sites (p value <0.05). The sediments with the highest numbers of MPs were from sites in the vicinity of highly populated centers and municipal effluent discharges. FTIR analysis showed that polyethylene (PE), nylon, and polyethylene terephthalate (PET) were the most abundant polymer types. More than half of the observed MPs (56%) were in the size category of 1-4.7 mm length, with the remaining particles (44%) being in the size range of 10 mum to <1 mm. Compared to literature data from other regions, intertidal sediments in the Persian Gulf cannot be characterized as a hot spot for MP pollution. The present study could, however, provide useful background information for further investigations and management policies to understand the sources, transport, and potential effects on marine life in the Persian Gulf.

Naji, A., et al. (2017). "The occurrence of microplastic contamination in littoral sediments of the Persian Gulf, Iran. (Special Issue: Efficient & sustainable water systems management toward worth living development.)." Environmental Science and Pollution Research **24**(25): 20459-20468.

Microplastics (MPs; <5 mm) in aquatic environments are an emerging contaminant of concern due to their possible ecological and biological consequences. This study addresses that MP quantification and morphology to assess the abundance, distribution, and polymer types in littoral surface sediments of the Persian Gulf were performed. A two-step method, with precautions taken to avoid possible airborne contamination, was applied to extract MPs from sediments collected at five sites during low tide. MPs were found in 80% of the samples. Across all sites, fiber particles were the most dominate shape (88%), followed by films (11.2%) and fragments (0.8%). There were significant differences in MP particle concentration between sampling sites (p value <0.05). FTIR analysis showed that polyethylene (PE), nylon, and polyethylene terephthalate (PET) were the most abundant polymer types. More than half of the observed MPs (56%) were in the size category of 1-4.7 mm length, with the remaining particles (44%) being in the size range of 10 micro m to <1 mm. Compared to literature data from other regions, intertidal sediments in the Persian Gulf cannot be characterized as a hot spot for MP pollution. The present study could, however, provide useful background information for further investigations and management policies to understand the sources, transport, and potential effects on marine life in the Persian Gulf.

Naji, A., et al. (2019). "Small microplastic particles (S-MPPs) in sediments of mangrove ecosystem on the northern coast of the Persian Gulf." Marine Pollution Bulletin **146**: 305-311.

We present a study of small microplastic particles (S-MPPs) in the sediments of mangrove ecosystem of Khor-e- Khoran, a Ramsar site in Iran. The spatial distribution of S-MPPs (<1mm) in mangrove surface sediments were investigated, which provided new insights into the detection and composition of S-MPPs in the study area. S-MPPs were extracted via the air-induced overflow (AIO) extraction procedure, and then they were counted and categorized according to the particle shape, color and size. The mean number of S-MPPs at the five sampling sites ranged from 19.5 to 34.5 particles per kg dry sediment in Bandar Gelkan and Bandar Lengeh, respectively. In general, microfibres followed by fragments were the most common type of S-MPPs isolated in each site (>56% and ~35%, respectively). Sewage discharge is probably the main source of extracted fibres in almost all the sites. The observed S-MPPs were classified into two size groups (10-300mum and 300-1000mum). The majority of S-MPPs fell into the smallest size group which accounted for 70-97% of the total S-MPPs. Fourier transform infrared (FTIR) analysis of some subsamples showed that polyethylene (PE) was the most common recovered polymer. Some non-plastic particles were also isolated from plastic-like particles of suspected S-MPPs in the mangrove sediments using a Scanning Electron Microscope (FE-SEM). This study provided the first evidence of S-MPPs contamination in the mangroves of the Iranian coast of the Persian Gulf. Long-term studies are required to understand, monitor and prevent further microplastics pollution in the region.

Naji, A., et al. (2018). "Microplastics contamination in molluscs from the northern part of the Persian

Gulf." Environmental Pollution **235**: 113-120.

Microplastics (MPs) are well-known emerging contaminants in the marine environment. A key route by which MPs can directly affect marine life is through ingestion. The objective of the present study was to evaluate the occurrence of MPs in marine life and seafood for human consumption in the Persian Gulf. We conducted a whole body analysis of MP (between 10 and 5000mum in diameter) abundance in five species of molluscs with different feeding strategies, including both gastropods and bivalves from the littoral zone of the Iranian coast of the Persian Gulf. The mean number of total encountered MPs in all species ranged from 0.2 to 21.0 particles per g of soft tissue (wet weight) and from 3.7 to 17.7 particles per individual. Overall, microfibres followed by fragments were the most common type of MP isolated in each species (respectively>50% and =26%). Film (=14%) and pellets (=2%) were less commonly observed. The observed MPs were classified into three size groups (ca. 10-25mum, 25-250mum and 250-5000mum), and 37-58% of MPs fell into the smallest size group. Fourier transform infrared (FT-IR) analysis confirmed the presence of polyethylene (PE), polyethylene terephthalate (PET), and nylon (PA). Our results indicated that molluscan shellfish from the Persian Gulf contain MPs, with higher concentrations in a predatory species, suggesting trophic transfer of MPs in the food web. The consumption of edible species may be a source of human microplastic intake. We compared our results with those previously reported for other regions of the world and identified the need for further studies in the Persian Gulf.

Naji, M. and Y. S. H. Najjar (2019). "Modelling of a novel infrared recycler for reclaiming waste plastics from automotive vehicles." International Journal of Sustainable Energy **38**(8): 740-751.

An infrared recycler was modelled mathematically to investigate its performance and ability to recycle waste plastics from automotive vehicles following their retirement. It uses infrared energy to heat and dry a washed stream of unsorted plastics. Because the sorting process is sensitive to many parameters, this paper discusses the effect of recycler size, temperature and emissivity on the plastic mixture. A characteristic curve was obtained for the recycler that relates the heater, drums and pellets temperatures. With this curve, if the recycler material is known, then the maximum temperatures that the heater and drum can reach are sited. Moreover, if a certain pellet temperature is required, then using this curve, the temperatures of the heater and drum are known. Results also show that lower emissivity for both the heater and pellets enhance evaporation and drying process. This increases heater and drum temperatures and consequently the pellets temperature. Minimum power consumption corresponds to (Dh/Dd) ratio of about 0.25. [ABSTRACT FROM AUTHOR]

Nakagome, K., et al. (2005). "Antigen-sensitized CD4+CD62Llow memory/effector T helper 2 cells can induce airway hyperresponsiveness in an antigen free setting." Respiratory research **6**: 46.

BACKGROUNDAirway hyperresponsiveness (AHR) is one of the most prominent features of asthma, however, precise mechanisms for its induction have not been fully elucidated. We previously reported that systemic antigen sensitization alone directly induces AHR before development of eosinophilic airway inflammation in a mouse model of allergic airway inflammation, which suggests a critical role of antigen-specific systemic immune response itself in the induction of AHR. In the present study, we examined this possibility by cell transfer experiment, and then analyzed which cell source was essential for this process.METHODSBALB/c mice were immunized with ovalbumin (OVA) twice. Spleen cells were obtained from the mice and were transferred in naive mice. Four days later, AHR was assessed. We carried out bronchoalveolar lavage (BAL) to analyze inflammation and cytokine production in the lung. Fluorescence and immunohistochemical studies were performed to identify T cells recruiting and proliferating in the lung or in the gut of the recipient. To determine the essential phenotype, spleen cells were column purified by antibody-coated microbeads with negative or positive selection, and transferred. Then, AHR was assessed.RESULTSTransfer of spleen cells obtained from OVA-sensitized mice induced a moderate, but significant, AHR without airway antigen challenge in naive mice without airway eosinophilia. Immunization with T helper (Th) 1 elicited antigen (OVA with complete Freund's adjuvant) did not induce the AHR. Transferred cells distributed among organs, and the cells proliferated in an antigen free setting for at least three days in the lung. This transfer-induced AHR persisted for one week. Interleukin-4 and 5 in the BAL fluid increased in the transferred mice. Immunoglobulin E was not involved in this transfer-induced AHR. Transfer of in vitro polarized CD4+ Th2 cells, but not Th1 cells, induced AHR. We finally clarified that CD4+CD62Llow memory/effector T cells recruited in the lung and proliferated, thus induced AHR.CONCLUSIONThese results suggest that antigen-sensitized memory/effector Th2 cells themselves play an important role for induction of basal AHR in an antigen free, eosinophil-independent setting. Therefore, regulation of CD4+ T cell-mediated immune response itself could be a critical therapeutic target for allergic asthma.

Nakajima, R., et al. (2019). "A small, stainless-steel sieve optimized for laboratory beaker-based extraction of microplastics from environmental samples." MethodsX **6**: 1677-1682.

Removing non-plastic materials is a mandatory process for studying microplastics in environmental samples, and non-plastic materials, both inorganic and organic matter, are often removed chemically through sequential processes. In the multiple chemical treatment processes, the samples need to be collected and the reagent removed at the end of each chemical treatment before the samples are again exposed to a different reagent in a separate container. This leads to a loss of microplastics to some extent. Here, we developed a new, yet simple, small sieve made of stainless-steel that can fit in a laboratory beaker (e.g. 200 ml volume), allowing it to be transferred as-is between chemical treatments of environmental samples, even being soakable in a beaker of acid solution. The collection rates of microplastics were significantly higher in the small stainless-steel sieve than the commonly used filter method for different size of microplastic particles. The use of the new sieve means the processes of rinsing off and filtering samples can be abbreviated throughout the entire process of non-plastic matter removal from environmental samples, contributing to a lower chance of microplastic loss. The time consumed in the sieve method was also significantly lower than for the filtering method due to the elimination of the collection and rinsing steps, thus the use of this sieve can reduce processing time for the samples. The new method is innovative in terms of reducing both the microplastic loss and processing time during chemical treatment processes. *The method developed allows the lower chance of microplastic loss during chemical digestion process*The method reduces the time of sequential processes during chemical digestion.

Nakajima, R., et al. (2019). "A new small device made of glass for separating microplastics from marine and freshwater sediments." PeerJ **7**: e7915.

Separating microplastics from marine and freshwater sediments is challenging, but necessary to determine their distribution, mass, and ecological impacts in benthic environments. Density separation is commonly used to extract microplastics from sediments by using heavy salt solutions, such as zinc chloride and sodium iodide. However, current devices/apparatus used for density separation, including glass beakers, funnels, upside-down funnel-shaped separators with a shut-off valve, etc., possess various shortcomings in terms of recovery rate, time consumption, and/or usability. In evaluating existing microplastic extraction methods using density separation, we identified the need for a device that allows rapid, simple, and efficient extraction of microplastics from a range of sediment types. We have developed a small glass separator, without a valve, taking a hint from an Utermohl chamber. This new device is easy to clean and portable, yet enables rapid separation of microplastics from sediments. With this simple device, we recovered 94-98% of <1,000 micro m microplastics (polyethylene, polypropylene, polyvinyl chloride, polyethylene terephthalate, and polystyrene). Overall, the device is efficient for various sizes, polymer types, and sediment types. Also, microplastics collected with this glass-made device remain chemically uncontaminated, and can, therefore, be used for further analysis of adsorbing contaminants and additives on/to microplastics.

Nakamura, J., et al. (2017). "Males without apparent alloimmunization could have HLA antibodies that recognize target HLA specificities expressed on cells." Immune Response Genetics **89**(5): 285-292.

BACKGROUND AND OBJECTIVES: Human leukocyte antigen (HLA) antibodies, which are involved in the development of transfusion-related side effects such as transfusion-related lung injury, are sometimes found in males without a history of alloimmunization (eg, transplantation and transfusion). Whether HLA antibodies in male donors can interact with their target HLA specificities expressed on cells have not been completely investigated.

MATERIALS AND METHODS: The HLA antibodies detected in 7 male donors were characterized. Flow cytometry and immunocomplex capture fluorescence analysis were performed to evaluate the ability of these antibodies to bind with target HLA specificities expressed on cells. The association of these antibodies with complement was examined using anti-C1q antibody. Sustainability of HLA antibodies over time was compared in 26 male vs 57 female donors.

RESULTS: The antibodies from all 7 donors recognized intact HLA molecules coated onto microbeads. The antibodies in 2 of 7 donors also recognized their target HLA specificities expressed on cells. Furthermore, the antibodies in one of these 2 donors showed HLA specificities that involved complement binding. Twenty-one of 26 initially positive male donors had turned negative for HLA antibody at least 1 year after their initial positive screening, whereas HLA antibody positivity was maintained for a long time in most female donors.

CONCLUSION: Males without apparent alloimmunization could have HLA antibodies that recognize their target HLA specificities on cells and that could potentially modify molecular events in affected cells.

Nakano, M., et al. (2017). "Comparison of Sensitivity and Quantitation between Microbead Dielectrophoresis-Based DNA Detection and Real-Time PCR." Biosensors **7**(4): 30.

In this study, we describe a microbead-based method using dielectrophoresis (DEP) for the fast detection of DNA amplified by polymerase chain reaction (PCR). This electrical method measures the change in impedance caused by DEP-trapped microbeads to which biotinylated target DNA molecules are chemically attached. Using this method, measurements can be obtained within 20 min. Currently, real-time PCR is among the most sensitive methods available for the detection of target DNA, and is often used in the diagnosis of infectious diseases. We therefore compared the quantitation and sensitivity achieved by our method to those achieved with real-time PCR. We found that the microbead DEP-based method exhibited the same detection limit as real-time PCR, although its quantitative detection range was slightly narrower at 10-105 copies/reaction compared with 10-107 copies/reaction for real-time PCR. Whereas real-time PCR requires expensive and complex instruments, as well as expertise in primer design and experimental principles, our novel method is simple to use, inexpensive, and rapid. This method could potentially detect viral and other DNAs efficiently in combination with conventional PCR.

Nakano, M., et al. (2018). "Fast and sensitive isothermal DNA assay using microbead dielectrophoresis for detection of anti-microbial resistance genes." Biosensors & Bioelectronics **117**: 583-589.

Antimicrobial resistant pathogens are a growing worldwide threat to human health. This study describes a novel method for rapid and sensitive detection of antimicrobial resistance (AMR) genes, specifically bla_{CTX-M-15} which encodes for the enzyme that offers resistance to extended spectrum beta-lactam antibiotics. The method combines isothermal DNA amplification by recombinase polymerase amplification (RPA), with microbead dielectrophoresis (DEP)-based DNA detection. The RPA amplicon is captured onto dielectric microbeads, and the amount of amplicon determined by dielectrophoretic impedance measurement (DEPIM) of the microbeads. Amplicon-labeled microbeads were prepared by either a two-step or one-step method. A purified recombinant plasmid containing bla_{CTX-M-15} and genomic DNA (with plasmid) extracted from an AMR bacteria (Escherichia coli NCTC 13441) were used as target samples. A one-step method in which RPA and DNA immobilization on the microbeads is carried out simultaneously, has a detection limit of 2 copies/reaction for pure plasmid and 50 copies/reaction for genomic DNA. The assays are quantitative with a dynamic range up to 10⁵ copies/reaction, with a total detection time of 26min. Both methods are easy, rapid, and unlike lateral flow detection are quantitative.

Nakao, S., et al. (2019). "Microplastics contamination in tidelands of the Osaka Bay area in western Japan." Water and Environment Journal.

Recently, researchers have been examining the actual state of microplastics contamination in the environment. However, pollution in high biodiversity environments such as tidelands has not been sufficiently investigated. Therefore, to assess the actual level of microplastics pollution therein, we conducted a survey of the tidelands of Osaka Bay in Japan to develop a model that included basins in urban and suburban areas. We quantified the levels of microplastics in the mud from four of Osaka Bay's tidelands and detected them based on three inhabitants of the main river estuary tideland, namely, bivalves (Corbicula japonica), crabs (Chiromantes dehaani) and a tufted duck (Aythya fuligula). Microplastics ranging in size from 300 mum to 5 mm were targeted, and the results indicated that the concentration of microplastics in the mud tended to increase with tideland proximity to an urban area where the density of the human population was the highest. Microplastics were detected in 10% of the bivalves and 6.7% of the crabs (n = 30 in both cases), and eight pieces of microplastics were detected in the stomach of one tufted duck. These results indicate that the mud in tidelands near urban areas had more microplastics. In addition, the results suggest that microplastics contamination levels may be higher in higher order predators in the food web. Copyright © 2019 CIWEM

Nakashima, E., et al. (2012). "Quantification of Toxic Metals Derived from Macroplastic Litter on Ookushi Beach, Japan." Environmental Science & Technology **46**(18): 10099-10105.

The potential risk of toxic metals that could leach into a beach environment from plastic litter washed ashore on Ookushi Beach, Goto Islands, Japan was estimated by balloon aerial photography, in situ beach surveys, and leaching experiments in conjunction with a Fickian diffusion model analysis. Chromium (Cr), cadmium (Cd), tin (Sn), antimony (Sb), and lead (Pb) were detected in plastic litter collected during the beach surveys. Polyvinyl chloride (PVC) fishing floats contained the highest quantity of Pb. Balloon aerial photography in conjunction with a beach survey gave an estimated mass of Pb derived from plastic litter of 313 ± 247 g. Lead leaching experiments on collected PVC floats showed that Pb in the plastic litter could leach into surrounding water on the actual beach, and that plastic litter may act as a "transport vector" of toxic metals to the beach environment. Using the experimental data, the total mass of Pb that could leach from PVC plastic litter over a year onto Ookushi Beach was estimated as 0.6 ± 0.6 g/year, suggesting that toxic metals derived from plastic beach litter are a potential "pathway" to contamination of the beach environment due to their accumulation in beach soil over time. [ABSTRACT FROM AUTHOR]

Nakashima, Y., et al. (2012). "Single bead detection with an NMR microcapillary probe." Journal of Magnetic Resonance **224**: 71-77.

We have developed a nuclear magnetic resonance (NMR) microcapillary probe for the detection of single magnetic microbeads. The geometry of the probe has been optimized so that the signal from the background water has a similar magnitude compared to the signal from the dephased water nearby a single magnetic bead within the probe detector coil. In addition, the RF field of the coil must be uniform within the effective range of the magnetic bead. Three different RF probes were tested in a 7 T (300 MHz) pulsed NMR spectrometer with sample volumes ranging from 5 nL down to 1 nL. The 1 nL probe had a single-shot signal-to-noise ratio (SNR) for pure water of 27 and a volume resolution that exhibits a 600-fold improvement over a conventional (5 mm tube) NMR probe with a sample volume of 18 muL. This allowed for the detection of a 1 mum magnetite/polystyrene bead (m=2x10(-14)Am(2)) with an estimated experimental SNR of 30. Simulations of the NMR spectra for the different coil geometries and positions of the bead within the coil were developed that include the B(0) shift near a single bead, the inhomogeneity of the coils, the local coil sensitivity, the skin effect of the coil conductor, and quantitated estimates of the proximity effect between coil windings.

Nakki, P., et al. (2017). "Bioturbation transports secondary microplastics to deeper layers in soft marine sediments of the northern Baltic Sea." Marine Pollution Bulletin **119**(1): 255-261.

Microplastics (MPs) are observed to be present on the seafloor ranging from coastal areas to deep seas. Because bioturbation alters the distribution of natural particles on inhabited soft bottoms, a mesocosm experiment with common benthic invertebrates was conducted to study their effect on the distribution of secondary MPs (different-sized pieces of fishing line < 1 mm). During the study period of three weeks, the benthic community increased MP concentration in the depth of 1.7-5.1 cm in the sediment. The experiment revealed a clear vertical gradient in MP distribution with their abundance being highest in the uppermost parts of the sediment and decreasing with depth. The Baltic clam Macoma balthica was the only study animal that ingested MPs. This study highlights the need to further examine the vertical distribution of MPs in natural sediments to reliably assess their abundance on the seafloor as well as their potential impacts on benthic communities. Nakki, P., et al. (2019). "Seafloor sediments as microplastic sinks in the northern Baltic Sea - Negligible upward transport of buried microplastics by bioturbation." Environmental Pollution **249**: 74-81.

Bioturbation by the common benthic invertebrates in the northern Baltic Sea does not markedly transport buried microplastics to the sediment surface. Microplastics (MPs) are ubiquitous in the marine environment. High concentrations of MPs are found from seafloor sediments, which have been proposed to act as their final sinks. Because bioturbation is an important process affecting the burial of MPs, a mesocosm experiment was established to study whether sediment infauna may also promote MP return to the sediment surface. Thin layers of frozen sediment containing an environmentally realistic concentration (<1300 MPs per kg of dry sediment) of MP fragments in two size classes (>500 mum and 100-300 mum) were added to depths of 2 cm and 5 cm in the experimental cylinders filled with sediment. The displacement of these MPs, made of acrylonitrile butadiene styrene (ABS), by a community of common benthic invertebrates in the northern Baltic Sea (clam Limecola balthica, polychaete Marenzelleria spp., gammarid Monoporeia affinis) was studied in a 10-week experiment. After the experiment, the MPs were extracted from each sediment layer and the animals were examined for MP ingestion. The results indicated that the transportation of MPs to the sediment surface by bioturbation was negligible. Thus, in the Baltic Sea, the seafloor may act as a sink for once sedimented MPs, reducing simultaneously the MP exposure of the macrofauna feeding on the sediment surface. Näkki, P., et al. (2019). "Seafloor sediments as microplastic sinks in the northern Baltic Sea – Negligible upward transport of buried microplastics by bioturbation." Environmental Pollution **249**: 74-81.

Microplastics (MPs) are ubiquitous in the marine environment. High concentrations of MPs are found from seafloor sediments, which have been proposed to act as their final sinks. Because bioturbation is an important process affecting the burial of MPs, a mesocosm experiment was established to study whether sediment infauna may also promote MP return to the sediment surface. Thin layers of frozen sediment containing an environmentally realistic concentration (<1300 MPs per kg of dry sediment) of MP fragments in two size classes (>500 µm and 100–300 µm) were added to depths of 2 cm and 5 cm in the experimental cylinders filled with sediment. The displacement of these MPs, made of acrylonitrile butadiene styrene (ABS), by a community of common benthic invertebrates in the northern Baltic Sea (clam Limecola balthica , polychaete Marenzelleria spp., gammarid Monoporeia affinis) was studied in a 10-week experiment. After the experiment, the MPs were extracted from each sediment layer and the animals were examined for MP ingestion. The results indicated that the transportation of MPs to the sediment surface by bioturbation was negligible. Thus, in the Baltic Sea, the seafloor may act as a sink for once sedimented MPs, reducing simultaneously the MP exposure of the macrofauna feeding on the sediment surface. Image 1 • Bioturbation does not markedly transport buried microplastics upwards in sediments. • Burial of microplastics reduce their availability to macrofauna. • The results support the hypothesis that seafloors may form a sink for microplastics. Bioturbation by the common benthic invertebrates in the northern Baltic Sea does not markedly transport buried microplastics to the sediment surface. [ABSTRACT FROM AUTHOR]

Nam, H. C. and W. H. Park (2019). "Eco-friendly poly(lactic acid) microbeads for cosmetics via melt electrospraying." International Journal of Biological Macromolecules **02**: 02.

Microbeads (MBs) are essential materials for cosmetic and healthcare applications. However, environmental pollution has recently emerged as a concern due to the non-degradability and adsorption property of persistent organic pollutants (POPs) in environmental conditions, particularly in the marine environment. Therefore, the development of biodegradable MBs via eco-friendly methods is urgently demanded. Poly(lactic acid) (PLA) is a biodegradable and melt-processable aliphatic polyester which can be obtained from raw materials in nature. In this study, the high molecular weight PLA was pre-treated by electron beam (E-beam) irradiation in order to adjust the melt viscosity. Subsequently, the PLA MBs were prepared by varying the processing parameters via an eco-friendly melt electrospraying process. During the time, the PLA MBs showed bulk degradation which lead to decrement of the residual weight, thermal and structural stability. On the other hand, the crystallinity of PLA MBs was significantly increased due to the degradation of amorphous region. Furthermore, the PLA MBs showed poor POPs adsorption behavior compare with the commercial MBs because of low specific surface area. From these results, the PLA MBs via green method have a great potential to replace the non-degradable MBs in cosmetics.

Nam Ngoc, P., et al. (2018). "Factors influencing the microplastic contamination of bivalves from the French Atlantic coast: location, season and/or mode of life?" Marine Pollution Bulletin **129**(2): 664-674.

Monitoring the presence of microplastics (MP) in marine organisms is currently of high importance. This paper presents the qualitative and quantitative MP contamination of two bivalves from the French Atlantic coasts: the blue mussel (Mytilus edulis) and the Pacific oyster (Crassostrea gigas). Three factors potentially influencing the contamination were investigated by collecting at different sampling sites and different seasons, organisms both wild and cultivated. Inter- and intra-species comparisons were also achieved. MP quantity in organisms was evaluated at 0.61+or-0.56 and 2.1+or-1.7 MP per individual respectively for mussels and oysters. Eight different polymers were identified. Most of the MPs were fragments; about a half of MPs were grey colored and a half with a size ranging from 50 to 100 micro m for both studied species. Some inter-specific differences were found but no evidence for sampling site, season or mode of life effect was highlighted.

Nam Ngoc, P., et al. (2018). "Quantification and characterization of microplastics in blue mussels (Mytilus edulis): protocol setup and preliminary data on the contamination of the French Atlantic coast. (Special Issue: Health and environmental risks associated with emerging pollutants and novel green processes.)." Environmental Science and Pollution Research **25**(7): 6135-6144.

Microplastics (MPs) constitute a main environmental issue due to their threat to marine organisms and so far to humans. The lack of a fast standard protocol in MP isolation and identification from living organisms bring to challenge for the science. In this paper, an optimized protocol using potassium hydroxide 10% (KOH 10%; m/v) for digestion of mussel soft tissues (Mytilus edulis) and multi-steps of sedimentation has been developed. Efficiency higher than 99.9% of organic and mineral matter elimination was shown by application on mussels sampled on the French Atlantic coast. The identification of MPs was performed by FTIR microscopy straight on the filter and the whole analysis can be compatible with a routine goal. Fourteen MPs of four different chemical natures were found and identified in 5 pools of 3 sampled mussels. Their size ranged from 30 to 200 micro m. Further investigations are now needed to evaluate the potential risk of such particles within this marine bivalve species and other filter feeders.

Nam, S. E., et al. (2018). "Observation about persistence of microbeads in Echinoderms and discussion to plastic riskness of the marine ecology system." Toxicology and Environmental Health Sciences **10 (4)**: S42.

There are largely sea cucumbers, starfish and sea starfish in echinoderms, which have a specific system of water vascular system. It is responsible for osmotic phenomena in echinoderms. First, it absorbs water through the Madreporite and stimulates the Ampullae to inflate the tube feet so that it can catch the attachment or food. Recently, microbeads (or microplastics) have emerged as an environmental problem. Especially, small pellets introduced from the land are likely to remain in the body of aquatic organisms, cause toxicity, and possibly affect the end-consumer. Echinoderms living in the sea are more likely to remain in plastic because they directly absorb and use the surrounding water. However, research on microplastics in echinoderms isn't yet to be found. Therefore, this study explored the persistence period of microbeads. Fluorescent beads were treated directly on the madreporite of sea cucumber and starfish, and immediately transferred to clean seawater. After two weeks, the beads decreased but were still partially found. It was estimated that the small particles stuck to the inside and outside of the tube, resulting in a slow release. After this experiment, I will aim to examine in detail the solution of microbeads problems in the marine ecology systems.

Namba, Y., et al. (1999). "Highly Sensitive Electrochemiluminescence Immunoassay Using the Ruthenium Chelate-Labeled Antibody Bound on the Magnetic Micro Beads." Analytical Sciences **15**(11): 1087.

The newer electrochemiluminescence (ECL) immunoassay system was established by using both an antibody coated on paramagnetic micro-beads (Capt-MB) as a carrier of the immunoassay and an antibody labeled with ruthenium(II) tris-bipyridine-NHS (Ru-Ab). The ECL excitations were designed to be generated upon the surface of the working electrode which collected the reacted Capt-MB by magnetic force. As a model of the immunoassay, the reaction between alpha-fetoprotein (AFP) and anti-AFP antibodies was used in accordance with the so-called sandwich method, where the sandwich conformation of AFP-(Ru-Ab) was made on the surface of the Capt-MB. The ECL immunoassay system revealed the following results: a) the ECL signal intensity was obtained in proportion to the AFP concentration of each specimen; b) the dynamic range of this ECL immunoassay system was extended to 10000 times of magnitude in the 2-step assay; and c) the detection sensitivity reached to the level of 5 pg/ml in the AFP concentration after 15 min in the 1-step immunoassay.

Nan, B., et al. (2019). "Identification of microplastics in surface water and Australian freshwater shrimp Paratya australiensis in Victoria, Australia." Environmental Pollution **259**: 113865.

Compared to marine microplastics research, few studies have bio-monitored microplastics in inland waters. It is also important to understand the microplastics' uptake and their potential risks to freshwater species. The Australian glass shrimp Paratya australiensis (Family: Atyidae) is commonly found in fresh waterbodies in eastern Australia, and are sensitive to anthropogenic stressors but have a wide tolerance range to the natural environmental conditions. This study aimed to understand the microplastics' occurrence and types in water samples and the shrimp P. australiensis, and identify if the shrimp could be a suitable bioindicator for microplastic pollution. Surface water and P. australiensis across ten urban and rural freshwater sites in Victoria were sampled. In total, 30 water samples and 100 shrimp were analysed for microplastic content, and shrimp body weights and sizes were also recorded. Microplastics were picked, photographed and identified using FT-IR microscopy: in water samples, 57.9% of items including suspect items were selected to identify; all microplastics found in shrimp samples were identified. Microplastics were present in the surface waters of all sites, with an average abundance of 0.40 +/- 0.27 items/L. A total of 36% of shrimp contained microplastics with an average of 0.52 +/- 0.55 items/ind (24 +/- 31 items/g). Fibre was the most common shape, and blue was the most frequent colour in both water and shrimp samples. The dominant plastic types were polyester in water samples, and rayon in shrimp samples. Even though results from this study show a relatively low concentration of microplastics in water samples in comparison with global studies, it is worth noticing that microplastics were regularly detected in fresh waterbodies in Victoria, Australia. Compared with water samples, shrimp contained a wider variety of plastic types, suggesting they may potentially behave as passive samplers of microplastics pollution in freshwater environments.

Nanda, H. S., et al. (2014). "Preparation of collagen porous scaffolds with controlled and sustained release of bioactive insulin." Journal of Bioactive and Compatible Polymers **29**(2): 95-109.

Controlled and local release of bioactive growth factors from porous scaffolds can provide an efficient strategy to control the complex and dynamic regulation of cellular processes in a three-dimensional microenvironment. In this study, hybrid scaffolds of collagen and poly(lactic-co-glycolic acid) microbeads were prepared by introducing insulin-releasing poly(lactic-co- glycolic acid) microbeads into collagen porous scaffolds. Insulin-incorporated poly(lactic-co-glycolic acid) microbeads of two distinct sizes, 19.4 +/- 1.6 and 4.4 +/- 0.9 mum, were used to prepare the hybrid scaffolds. The scaffolds had controlled pore structure, and the poly(lactic-co-glycolic acid) microbeads were well distributed on the pore walls of the scaffolds. The scaffolds had a lower initial burst and a more stable insulin release than did the free microbeads. Culture of human dermal fibroblasts in the hybrid scaffolds were affected the bioactivity of released insulin. The hybrid scaffold prepared with 19.4 +/- 1.6 mum microbeads had a more linear release of insulin and a higher promotion effect on cell proliferation than did the other hybrid group and control scaffolds. The hybrid scaffold should be useful for skin tissue engineering. © The Author(s) 2014.

Nandy, B., et al. (2015). "Recovery of consumer waste in India – A mass flow analysis for paper, plastic and glass and the contribution of households and the informal sector." Resources, Conservation & Recycling **101**: 167-181.

In most municipalities in India, the collection, transportation and disposal of municipal solid waste deviates from the mass flow envisaged by the municipal agencies and planning authorities. While multiple studies have focused on the environmental problems arising due to uncontrolled waste dumping and combustion, we present a qualitative study of the efforts towards resource conservation and recycling by various actors involved, and a quantitative estimate of the amount of material recovered at various stages. Both the informal sectors (garbage collectors, waste pickers, waste dealers, small stores and itinerant merchants) and the households in India, play a vital role in recovering consumer waste. In order to have an in-depth understanding, a case study has been performed to better understand the contribution of households, garbage collectors and itinerant waste merchants towards recovering consumer waste. Our study shows that consumer waste is far more efficiently recovered in India than what has been reported in literature until now. The waste recovery takes place in multiple-stages and the final waste that reaches the municipal corporation mostly comprises of biodegradable waste, inerts and highly non-recyclable waste. Households, itinerant waste merchants and garbage collectors in India jointly recover 1.2–2.4 million tonnes of newspapers, 2.4–4.3 million tonnes of cardboard and mixed paper, 6.5–8.5 million tonnes of plastic, more than1.3 million tonnes of glass, more than 2.6 million tonnes of metal waste and 4–6.2 million tonnes of other

recyclable material per year. Overall, 30–60% of all paper and cardboard, 50–80% of all plastic and close to 100% of all glass bottles produced in India are recycled. [ABSTRACT FROM AUTHOR]

Nandy, D. K., et al. (2011). "Chemokine induced diabetic monocyte activation occurs through unique PI3 kinase pathway." Diabetes **1)**: A559-A560.

Type 2 Diabetes (T2D) is a cardiovascular risk equivalent. Chemokine induced monocyte activation is important for initiation of atherosclerosis. Plasma concentration of the chemokine platelet activating factor (PAF) is elevated in diabetes. To explore the molecular mechanism of PAF induced monocyte activation we performed adhesion, migration and transmigration assays of ex vivo monocytes isolated from the peripheral blood of non diabetic (ND; n=35), type 2 diabetic (T2D; n=25) individuals and from THP-1 cell lines by using CD 14+ micro bead technique. Euglycemic (5mM glucose) starving condition was maintained during every experiment. PAF (100etaM for 5 minutes) exposure significantly increased (p=0.03) adhesion and migration of monocytes derived from ND, T2D individuals and THP-1 cells. Both properties were completely reversed by pretreatment with PI3 Kinase inhibitor LY (10 muM). Furthermore, PAF significantly increased (p=0.03) transendothelial migration of monocytes through compact monolayer of HUVEC (human umbilical vein endothelial cell) in ND and T2D subjects and THP-1 cell lines. PAF activated monocytes (ND, T2D and THP-1 cell lines) showed significant (p=0.02) upregulation of phosphorylation of p101 and p110gamma, unique PI3Kinase class IB isoforms. Priming with PI3 Kinase inhibitor LY diminished phosphorylation of both the isoforms. Genetic knock out of p101 and p110gamma in THP-1 cells by using dominant negative retroviral transfection technique blocked PAF induced migration of THP-1 cells. These data suggest that monocytes are activated by PAF through upregulated phosphorylation of p101 and p110gamma in both T2D and ND individuals. Thus modulation of class IB PI3K activity in T2D monocytes need to be further studied to explore the possibility of targeting tissue specific PI3 Kinase modulators in prevention of accelerated atherosclerosis in type 2 Diabetes.

Nanna, M., et al. (2018). "Mapping greenhouse plastic wastes in the west region of Portugal." Acta Horticulturae.

Plastic materials are used in many applications in agriculture, as greenhouse and tunnel covering films, direct coverings, shading and protective nets, irrigation pipes, fertilizers bags, pots and others. In Mediterranean countries, plastic film is the most common greenhouse covering material. Because of direct exposure to solar radiation and wind, greenhouse plastic covers need to be replaced every 6 to 45 months, depending on the material. The huge quantities of plastic waste produced need proper management in order to avoid environmental and economic impacts. The plastic waste is usually recycled by special companies that collect and treat this waste material. The aim of this study was to apply geographical information systems (GIS) and photointerpretation techniques to evaluate the amount of plastic waste produced in one of the most important regions of greenhouse production in Portugal, the west region, specifically the Torres Vedras municipality. The methodology has integrated the characterization of the type of plastic covering material and the cartography of the greenhouse land units. It used Land Use Map 2007, Bing Map images and administrative boundaries to determine the

geographical position and the type of greenhouses. For each administrative unit, the frequency and total greenhouse area were calculated. Identification of the type of plastic material was made by photointerpretation and direct interviews at one company that sells material for greenhouses in Torres Vedras. The database created allowed us to determine the amount of plastic used as greenhouse cover materials and to identify the needs for recycling in this area. The geodatabase produced is the first step to monitor plastic waste production in time and space.

Nanninga, G. B., et al. (2019). "Microplastic ingestion rates are phenotype-dependent in juvenile anemonefish." Environmental Pollution **259**: 113855.

The potential influence of microplastic debris on marine organisms is an issue of great ecological and socioeconomic concern. Experiments exposing fishes and invertebrates to constant concentrations of microplastics often yield high variation in particle ingestion rates among individuals. Yet, despite an increasing interest in microplastic ingestion in the wild, the potential intrinsic drivers of inter-individual variation have received little attention so far. Here we assessed individual-level ingestion of Polyethylene microspheres by laboratory-reared juvenile anemonefish, Amphiprion ocellaris, in relation to (a) ambient particle concentrations and (b) repeatable behavioural traits. We show that microplastic ingestion is highly variable at all tested particle concentrations and that this variation can partially be explained by individual activity levels. Moreover, the relationship between ingestion and behavioural variation increased notably when only the most behaviourally consistent individuals (n = 40 out of 60) were considered in the analysis. Our findings indicate that microplastic ingestion rates in juvenile reef fishes may be less dependent on ambient concentrations than expected; instead they are to some degree phenotype-dependent. Care should thus be taken when reporting mean responses to microplastic exposure treatments, because some individuals may not be affected in the same way as others due to differential ingestion behaviour. We also discuss potential ramifications of non-random ingestion variability on population- and community-level responses.

Nantakomol, D. (2012). "Oral abstract: Microparticles: Affordable counting bead by flow cytometry and atomic force imaging." International Journal of Laboratory Hematology **1)**: 38-39.

Objectives: Activation of vascular endothelium and blood cells in a range of inflammatory and infectious diseases is associated with the formation of cell-derived microparticles (MPs), which are membrane vesicles with diameter <1.5 mm. Analysis of circulating MPs is becoming more refined and clinically useful. The standard single-platform flow cytometric testing that uses the known reference microbeads is expensive; more affordable alternatives are therefore needed. In this study, we validated a quantitative method called "cell bead" to measure circulating MPs in the peripheral blood of patient with Glucose-6-phosphate dehydrogenase deficiency (G6PD). In parallel, atomic force microscope (AFM) was applied to demonstrate the production of MPs during red cell vesiculation. Method(s): Citrated blood samples were collected from 34 patients with G6PD Vaingchan (871 C->T), 4 patient with G6PD Mahidol (487 G->A), 2 patient with G6PD Union (1360 C->T), and 2 patient with double mutation variant of G6PD Mahidol-Vaingchan and Vaingchan-Union. AnnexinV-FITC, a specific marker for phosphatidylserine, was used to distinguish MPs from nonspecific noise. The cellular origin of MPs was identified using an antibody to a specific surface marker of the cells, PEconjugated anti-glycophorin A was used for RBCs, PEconjugated anti-CD51 for endothelial cell, and PE-conjugated anti-CD41a for platelet and counted by FACsCalibur flow cytometer. The absolute MPs numbers were measured by CB and the results were compared with the known reference microbeads (Trucount TM). Statistical correlation and agreement were analyzed using linear regression and Bland-Altman analysis. In order to observe the morphological changes of red cell vesiculation, the vesiculating cell was examined under AFM microscope. Result(s): Linear regression analyses revealed an excellent correlation of the CB with the standard microbead method (r(2) > 0.98; absolute counts, r(2) > 0.98. Mean percent bias for the CB method was +1.35% [limits of agreement (LOA): -2.86% to +3.57%]. Using Atomic Force Microscopy, the cursor statistic was applied to measure the size of G6PDdeficient RBC and MPs. G6PD-deficient RBC was smaller than that size of normal RBC (5.9 mm versus 7.5 mm), MP's size was ranged in 0.15 to 1.8 mm. MPs were producing from discoid RBCs. Conclusion(s): The use of CB is comparable with the use of commercial microbeads. This has resulted in major cost savings to resource-limited countries where the health care system is under increasing pressure to operate cost effectively. AFM demonstrated that MPs are shed by the discoid RBCs. This might reflect the capability to remove damaged cell components for the viability of the discoid RBC.

Napper, I. E., et al. (2015). "Characterisation, quantity and sorptive properties of microplastics extracted from cosmetics." Marine Pollution Bulletin **99**(1-2): 178-185.

Cosmetic products, such as facial scrubs, have been identified as potentially important primary sources of microplastics to the marine environment. This study characterises, quantifies and then investigates the sorptive properties of plastic microbeads that are used as exfoliants in cosmetics. Polyethylene microbeads were extracted from several products, and shown to have a wide size range (mean diameters between 164 and 327 mum). We estimated that between 4594 and 94,500 microbeads could be released in a single use. To examine the potential for microbeads to accumulate and transport chemicals they were exposed to a binary mixture of (3)H-phenanthrene and (14)C-DDT in seawater. The potential for transport of sorbed chemicals by microbeads was broadly similar to that of polythene (PE) particles used in previous sorption studies. In conclusion, cosmetic exfoliants are a potentially important, yet preventable source of microplastic contamination in the marine environment.

Narancic, T. and K. E. O'Connor (2017). "Microbial biotechnology addressing the plastic waste disaster." Microbial Biotechnology **10**(5): 1232-1235.

Oceans are a major source of biodiversity, they provide livelihood, and regulate the global ecosystem by absorbing heat and CO₂ . However, they are highly polluted with plastic waste. We are discussing here microbial biotechnology advances with the view to improve the start and the end of life of biodegradable polymers, which could contribute to the sustainable use of marine and coastal ecosystems (UN Sustainability development goal 14).

Narancic, T., et al. (2018). "Biodegradable Plastic Blends Create New Possibilities for End-of-Life Management of Plastics but They Are Not a Panacea for Plastic Pollution." Environmental Science & Technology **52**(18): 10441-10452.

Plastic waste pollution is a global environmental problem which could be addressed by biodegradable plastics. The latter are blended together to achieve commercially functional properties, but the environmental fate of these blends is unknown. We have tested neat polymers, polylactic acid (PLA), polyhydroxybutyrate, polyhydroxyoctanoate, poly(butylene succinate), thermoplastic starch, polycaprolactone (PCL), and blends thereof for biodegradation across seven managed and unmanaged environments. PLA is one of the world's best-selling biodegradable plastics, but it is not home compostable. We show here that PLA when blended with PCL becomes home compostable. We also demonstrate that the majority of the tested bioplastics and their blends degrade by thermophilic anaerobic digestion with high biogas output, but degradation times are 3-6 times longer than the retention times in commercial plants. While some polymers and their blends showed good biodegradation in soil and water, the majority of polymers and their blends tested in this study failed to achieve ISO and ASTM biodegradation standards, and some failed to show any biodegradation. Thus, biodegradable plastic blends need careful postconsumer management, and further design to allow more rapid biodegradation in multiple environments is needed as their release into the environment can cause plastic pollution.

Narvaez Valderrama, J. F., et al. (2016). "Implications of observed PBDE diffusion coefficients in low density polyethylene and silicone rubber." Environmental Science. Processes & Impacts **18**(1): 87-94.

A film-stacking technique was used to estimate diffusion coefficients of polybrominated diphenyl ethers (PBDEs) in low density polyethylene (LDPE) and silicone rubber. Substantially higher PBDE diffusion coefficients were observed for silicone rubber (AlteSilTM) than for LDPE. A much steeper decrease in LDPE diffusion coefficients was found with increasing PBDE molecular weight than that for silicone rubber. From a passive sampling point-of-view, this means that for equivalent polymer-water partition coefficients for these two materials, the mass transfer resistance for these substances in the LDPE will be significantly higher than that for silicone rubber. Boundary layer control of the uptake process for silicone rubber can be expected for PBDEs. With a microplastic perspective, the low diffusion coefficients of PBDEs and in particular of decabromo diphenyl ether (BDE 209) in LDPE imply that the polymer diffusion coefficients for these plastic additives used as flame retardants need to be taken into account when considering the risk posed by microplastic particle ingestion by marine organisms.

Nasir, B., et al. (2016). "Formulation development and characterization of 5-fluorouracil based microbeads using hydroxypropyl-beta-cyclodextrin for innovative drug delivery." Latin American Journal of Pharmacy **35**(Supplement 1): 1092-1101.

The aim of the study was to formulate microbeads of hydroxypropyl-beta-cyclodextrin (HP-beta-CD) using sodium alginate (SA) containing 5-fluorouracil (5-FU) by emulsion crosslinking technique. The microbeads were prepared by varying the concentration of hydroxypropyl-beta-cyclodextrin (HP-beta-CD) and sodium alginate (SA). The prepared microbeads were evaluated for swelling degree, drug entrapment, scanning electron microscopy (SEM), Fourier transforms infrared spectroscopy (FTIR), X-ray diffraction (XRD) and differential scanning calorimetry (DSC). SEM confirms the slight rough nature of microbeads. No significant drug polymer interactions were observed in FTIR studies. XRD and DSC revealed amorphous nature of drug after being entrapped. Gas chromatography confirms the absence of glutaraldehyde residue. The drug release shows excellent sustained drug release pattern. Copyright © 2016 Latin American Journal of Pharmacy. Nasr, S. H., et al. (2007). "Thin basement membrane nephropathy cannot be diagnosed reliably in deparaffinized, formalin-fixed tissue." Nephrology Dialysis Transplantation **22**(4): 1228-1232.

In diagnostic renal pathology, electron microscopy is ideally performed on glutaraldehyde-fixed, plastic resin-embedded tissue (EM-G). When no glomeruli are present in the portion of the biopsy fixed in glutaraldehyde, formalin-fixed, paraffin-embedded tissue can be reprocessed for electron microscopy (EM-F). The usefulness of this salvage technique for the diagnosis of thin basement membrane nephropathy (TBMN) has not been studied systematically. Here we compare the glomerular basement membrane (GBM) thickness by EM-G vs EM-F in 21 renal biopsies, including TBMN (eight patients), normals (two patients), minimal change disease (MCD) (six patients) and diabetic nephropathy (DN) (five patients). There was significant reduction of the GBM thickness by EM-F compared with EM-G across all diagnostic categories in

all 21 cases. The mean percentage reduction in GBM thickness was 23% for the TBMN cases, 40% for the normal/MCD cases and 34% for the DN cases. Four patients with MCD had a mean GBM thickness by EM-F that fell below the defining threshold for diagnosis of TBMN. For the TBMN cases, the 99th percentile for GBM thickness by EM-F was 194 nm, suggesting that the diagnosis of TBMN by EM-F can be excluded with confidence if the GBM thickness is above 200 nm. No clear criteria could be established to diagnose TBMN by EM-F. Renal pathologists should be aware that reprocessing of paraffin tissue for EM causes artifactual GBM thinning that precludes accurate diagnosis of TBMN.

Nasser, F. and I. Lynch (2016). "Secreted protein eco-corona mediates uptake and impacts of polystyrene nanoparticles on Daphnia magna." Journal of Proteomics **137**: 45-51.

UNLABELLEDNanoparticles (NPs) are defined as having at least one external dimension between 1 and 100 nm. Due to their small size, NPs have a large surface area to volume ratio giving them unique characteristics that differ from bulk material of the same chemical composition. As a result these novel materials have found numerous applications in medical and industrial fields with the result that environmental exposure to NPs is increasingly likely. Similarly, increased reliance on plastic, which degrades extremely slowly in the environment, is resulting in increased accumulation of micro-/nano-plastics in fresh and marine waters, whose ecotoxicological impacts are as yet poorly understood. Although NPs are well known to adsorb macromolecules from their environment, forming a biomolecule corona which changes the NP identity and how it interacts with organisms, significantly less research has been performed on the ecological corona (eco-corona). Secretion of biomolecules is a well established predator-prey response in aquatic food chains, raising the question of whether NPs interact with secreted proteins, and the impact of such interaction on NP uptake and ecotoxicity. We report here initial studies, including optimisation of protocols using carboxylic-acid and amino modified spherical polystyrene NPs, to assess interaction of NPs with biomolecules secreted by Daphnia magna and the impact of these interactions on NP uptake, retention and toxicity towards Daphnia magna.BIOLOGICAL SIGNIFICANCEDaphnia magna are an important environmental indicator species who may be especially sensitive to nanoparticles (NPs) as a result of being filter-feeders. This paper demonstrates for the first time that proteins released by Daphnia magna create an eco-corona around polystyrene NPs which causes heightened uptake of the NPs and consequently increases toxicity. The secreted protein eco-corona also causes the NPs to be less efficiently removed from the gut of D. magna and NPs remaining in the gut of D. magna affected the rate of subsequent feeding. Thus, fate of NPs in the environment should be evaluated and monitored under more realistic exposure scenarios.

Nateghi Rostami, M., et al. (2012). "Memory rather than naive CD8+ T cell population produce IFN-g in self-healed cutaneous leishmaniasis individuals." Clinical Microbiology and Infection **3)**: 60.

Objectives: In human leishmaniasis Th1/Th2 dichotomy and the role of CD8+ T cells in protection is not clearly defined. In this study based on CCR7 expression total memory vs. naive CD8+ T cell populations were isolated from volunteers with self-healed cutaneous leishmaniasis (CL) and cytokine productions were analysed. Method(s): Leishmanin skin test (LST) was performed for all volunteers. Blood samples were collected from 13 volunteers with history of CL caused by either L. major or L. tropica and 18 healthy volunteers from non-endemic area. Using enrichment cocktail mAbs and magnetic nanoparticles CD14+CD16- monocytes and total memory CD8+ T cells were isolated from autologous peripheral blood mononuclear cells (PBMC). For naive T cells, non-naive cells depleted and CD8+ T cells positively selected using CD8 microbeads. Monocyte derived macrophages (MDM) were produced by incubation of adherent monocytes in cRPMI at 37degreeC, 5% CO2 for 6 days. Isolated T lymphocyte populations were co-cultured with 1:10 autologous MDM in the presence of PHA or soluble Leishmania antigen (SLA). Cytokine productions were titrated on culture supernatant after 72 hours incubation at 37degreeC with 5% CO2. Part of the SLA cultured cells was harvested, stimulated with PMA/Ionomycin calcium, permeabilized, stained for intracellular IFN-g, and analyzed using flow cytometer. Result(s): The mean diameters of skin indurations were significantly higher in CL volunteers (8.7 +/- 3.62 mm) compared to healthy controls (0 mm) (p < 0.005). The mean +/- SD percentage of memory T cells was 5 +/- 1.8% and of naive T cells was 9 +/- 2.2% retrieving from PBMC. Stimulation of isolated CD8+ memory T cells from CL volunteers induced a significantly higher IFN-g production compared with that of controls (p < 0.005). No significant difference was seen in the production of IFN-g from naive T cells and in the production of IL- 10 from naive or memory T cells between CL and controls. Significantly higher numbers of memory CD8+ T cells from CL volunteers were positive for intracellular IFN-g than the same cells from controls (p < 0.001). No significant difference was found in the frequency of IFN-g positive naive CD8+ T cells between CL and controls. Conclusion(s): The role of CD8+ T cells as a source of IFN-g production has been suggested before, in this study memory population is shown responsible for IFN-g production in volunteers with history of CL. Purification of different memory subsets is needed for further study.

Nattie, E. E., et al. (1998). "Brain stem lesion size determined by DEAD red or conjugation of neurotoxin to fluorescent beads." Journal of applied physiology (Bethesda, Md. : 1985) **85**(6): 2370-2375.

Neurotoxin microinjected into the retrotrapezoid nucleus of anesthetized rats decreases phrenic activity and eliminates the response to CO2. In unanesthetized rats, such treatment has no effect on awake, resting breathing and decreases CO2 sensitivity by 40% (M. Akilesh, M. Kamper, A. Li, and E. E. Nattie. J. Appl. Physiol. 82: 469-479, 1997). One important factor in explaining these disparate results is the actual size of the anatomic lesion. In the present study, we injected ibotenic acid into the retrotrapezoid nucleus of anesthetized rats and evaluated lesion size by using two new approaches: 1) DEAD red, a fluorescent probe that enters impaired cells through leaky membranes and binds to nucleic acids, and 2) conjugation of toxin to fluorescent beads. With the use of DEAD red, the region containing labeled dying cells was 313 +/- 104 nl (n = 4), six times larger than the initial injected volume, and the physiological effects on phrenic amplitude, the CO2 response, and blood pressure began within minutes and were substantial. With conjugated toxin, in theory, neuronal damage would be limited to the region of detectable fluorescence (49 +/- 10 nl; n = 4). Effects on phrenic amplitude, CO2 sensitivity, and blood pressure were absent until approximately 2 h postinjection. Control experiments, with 2 h of in vitro incubation of the neurotoxin-microbead conjugate and injection of the supernatant after centrifugation, showed similar results that suggest release of conjugated neurotoxin. We conclude that DEAD red provides a useful means to monitor neuronal impairment in acute studies in vivo. Conjugation of neurotoxin to microbeads may be less reliable in this regard.

Naveca, F. G., et al. (2018). "Analysis of the immunological biomarker profile during acute Zika virus infection reveals the overexpression of CXCL10, a chemokine linked to neuronal damage." Memorias do Instituto Oswaldo Cruz **113**(6): e170542.

BACKGROUND: Infection with Zika virus (ZIKV) manifests in a broad spectrum of disease ranging from mild illness to severe neurological complications and little is known about Zika immunopathogenesis.

OBJECTIVES: To define the immunologic biomarkers that correlate with acute ZIKV infection.

METHODS: We characterized the levels of circulating cytokines, chemokines, and growth factors in 54 infected patients of both genders at five different time points after symptom onset using microbeads multiplex immunoassay; comparison to 100 age-matched controls was performed for statistical analysis and data mining.
FINDINGS: ZIKV-infected patients present a striking systemic inflammatory response with high levels of pro-inflammatory mediators. Despite the strong inflammatory pattern, IL-1Ra and IL-4 are also induced during the acute infection. Interestingly, the inflammatory cytokines IL-1beta, IL-13, IL-17, TNF-alpha, and IFN-gamma; chemokines CXCL8, CCL2, CCL5; and the growth factor G-CSF, displayed a bimodal distribution accompanying viremia. While this is the first manuscript to document bimodal distributions of viremia in ZIKV infection, this has been documented in other viral infections, with a primary viremia peak during mild systemic disease and a secondary peak associated with distribution of the virus to organs and tissues.
MAIN CONCLUSIONS: Biomarker network analysis demonstrated distinct dynamics in concurrence with the bimodal viremia profiles at different time points during ZIKV infection. Such a robust cytokine and chemokine response has been associated with blood-brain barrier permeability and neuroinvasiveness in other flaviviral infections. High-dimensional data analysis further identified CXCL10, a chemokine involved in foetal neuron apoptosis and Guillain-Barre syndrome, as the most promising biomarker of acute ZIKV infection for potential clinical application.

Naviaux, R. K. (2019). "Perspective: Cell danger response Biology-The new science that connects environmental health with mitochondria and the rising tide of chronic illness." Mitochondrion **51**: 40-45.

This paper is written for non-specialists in mitochondrial biology to provide access to an important area of science that has broad implications for all people. The cell danger response (CDR) is a universal response to environmental threat or injury. Once triggered, healing cannot be completed until the choreographed stages of the CDR are returned to an updated state of readiness. Although the CDR is a cellular response, it has the power to change human thought and behavior, child development, physical fitness and resilience, fertility, and the susceptibility of entire populations to disease. Mitochondria regulate the CDR by monitoring and responding to the physical, chemical, and microbial conditions within and around the cell. In this way, mitochondria connect cellular health to environmental health. Over 7,000 chemicals are now made or imported to the US for industrial, agricultural, and personal care use in amounts ranging from 25,000 to over 1 million pounds each year, and plastic waste now exceeds 83 billion pounds/year. This chemical load creates a rising tide of manmade pollutants in the oceans, air, water, and food chain. Fewer than 5% of these chemicals have been tested for developmental toxicity. In the 1980s, 5-10% of children lived with a chronic illness. As of 2018, 40% of children, 50% of teens, 60% of adults under age 65, and 90% of adults over 65 live with a chronic illness. Several studies now report the presence of dozens to hundreds of manmade chemicals and pollutants in placenta, umbilical cord blood, and newborn blood spots. New methods in metabolomics and exposomics allow scientists to measure thousands of chemicals in blood, air, water, soil, and the food chain. Systematic measurements of environmental chemicals can now be correlated with annual and regional patterns of childhood illness. These data can be used to prepare a prioritized list of molecules for congressional action, ranked according to their impact on human health.

Nayak, S., et al. (2014). "Silk sericin-alginate-chitosan microcapsules: hepatocytes encapsulation for enhanced cellular functions." International Journal of Biological Macromolecules **65**: 258-266.

The encapsulation based technology permits long-term delivery of desired therapeutic products in local regions of body without the need of immunosuppressant drugs. In this study microcapsules composed of sericin and alginate micro bead as inner core and with an outer chitosan shell are prepared. This work is proposed for live cell encapsulation for potential therapeutic applications. The sericin protein is obtained from cocoons of non-mulberry silkworm Antheraea mylitta. The sericin-alginate micro beads are prepared via ionotropic gelation under high applied voltage. The beads further coated with chitosan and crosslinked with genipin. The microcapsules developed are nearly spherical in shape with smooth surface morphology. Alamar blue assay and confocal microscopy indicate high cell viability and uniform encapsulated cell distribution within the sericin-alginate-chitosan microcapsules indicating that the microcapsules maintain favourable microenvironment for the cells. The functional analysis of encapsulated cells demonstrates that the glucose consumption, urea secretion rate and intracellular albumin content increased in the microcapsules. The study suggests that the developed sericin-alginate-chitosan microcapsule contributes towards the development of cell encapsulation model. It also offers to generate enriched population of metabolically and functionally active cells for the future therapeutics especially for hepatocytes transplantation in acute liver failure.

Nazareth, M., et al. (2019). "Commercial plastics claiming biodegradable status: Is this also accurate for marine environments?" Journal of Hazardous Materials **366**: 714-722.

Concerns about plastic pollution and global public policies have encouraged consumers to acquire environmentally friendly products. Thus, products made of biodegradable plastics have been preferred by the public, despite their costs. However, greenwashing practices, promising more environmental benefits than the products actually offer, has become frequent. Nevertheless, no studies assessing the occurrence of greenwashing in commercial plastic products sold in large world economies have been performed. The present study aimed to experimentally evaluate alterations in structure and chemical composition of selected plastic products marketed in Canada, USA and Brazil. The aging experiments carried out by seawater immersion for 180 days showed no evidence of degradation in 4 out of the 6 studied samples, despite product claims of biodegradability or 100% degradability status. This finding denotes unequivocal greenwashing practices, even including bags made of polyethylene, an ordinary non-biodegradable polymer. Thus, the inadequate adoption of green marketing is deceiving to consumers and may lead to improper disposal of these materials. These practices are highly counterproductive in view of the global public policies recently adopted to control plastic pollution. Therefore, considering the technologies currently available for identification of polymers, a strict control should be exercised over products that claim biodegradable status.

Nedovic, V. A., et al. (2001). "Electrostatic generation of alginate microbeads loaded with brewing yeast." Process Biochemistry **37**(1): 17-22.

The substantial concern with the possible use of immobilized yeast cells for beer production is reduction of internal mass transfer resistance during continuous fermentation. One way to minimise this problem is to use small-diameter beads. The effects of bead diameters in the range 0.3-2.0 mm on yeast cell immobilization and growth over a short-term cultivation were investigated. Bead diameters in the range 0.5-0.6 mm were optimal and provided rapid cell growth and the highest final cell concentration (2.33 x 10 super(9) cells/ml of beads). Electrostatic droplet generation was investigated as a technique for production of alginate microbeads. The effects of applied potential, internal needle diameter and electrode position on bead diameter were assessed. The results have shown that this method can be used for controlled production of small-size microbeads loaded with yeast. Depending on applied conditions it was possible to produce the beads in the range 250 mu m-2.0 mm in diameter.

Negorev, D., et al. (2018). "Human neutrophils can mimic myeloid-derived suppressor cells (PMN-MDSC) and suppress microbead or lectin-induced T cell proliferation through artefactual mechanisms." Scientific Reports **8**(1): 3135.

We report that human conventional CD15⁺ neutrophils can be isolated in the peripheral blood mononuclear cell (PBMC) layer during Ficoll gradient separation, and that they can impair T cell proliferation in vitro without concomitant neutrophil activation and killing. This effect was observed in a total of 92 patients with organ transplants, lung cancer or anxiety/depression, and in 18 healthy donors. Although such features are typically associated in the literature with the presence of certain myeloid-derived suppressor cell (PMN-MDSC) populations, we found that commercial centrifuge tubes that contained membranes or gels for PBMC isolation led to up to 70% PBMC contamination by CD15⁺ neutrophils, with subsequent suppressive effects in certain cellular assays. In particular, the suppressive activity of human MDSC should not be evaluated using lectin or microbead stimulation, whereas assays involving soluble or plate-bound antibodies or MLR are unaffected. We conclude that CD15⁺ neutrophil contamination, and associated effects on suppressor assays, can lead to significant artefacts in studies of human PMN-MDSC.

Neha, G., et al. (2011). "Effect of polymer and cross linking agent on in vitro release of quercetin from microbeads." Asian Journal of Pharmacy and Life Science **1**(4): 401-405.

This investigation describes the effect of polymers and cross linking agent on in vitro release of quercetin from sodium alginate beads. The formulations were prepared by utilizing 2³ factorial designs. Hydrophilic polymer hydroxy propyl methyl cellulose (15-24 cps) was used for its gel forming and release controlling properties. The effect of different concentrations of cross linking agent (calcium chloride) on entrapment efficiency and drug release profile were investigated. The beads were prepared by changing the experimental variables such as concentration of polymer and cross linking agent in order to optimize independent variables. The bead formulations were prepared by Ionotropic gelation method. Quercetin was used as model drug. The prepared beads were evaluated for its particle size, drug entrapment efficiency and in vitro release. The entrapment efficiency and particle size was between the range of 16.62% to 72.47% and 0.726+or-0.0088 mm to 1.179+or-0.0547 mm respectively. Results reveal that on increasing polymer concentration and cross linking agent, entrapment efficiency of drug increases with decrease in its release rate. The result indicates the possibility of getting controlled release system by varying the concentration of polymer and cross linking agent.

Neha, S. and J. Aishwary (2018). "Design and characterization of d-limonene and liquorice loaded nanosponge based drug delivery system for complete eradication of H. pylori infection." Asian Journal of Pharmaceutical and Clinical Research **11 (11)**: 95.

H. pylori is the prominent etiologic factor responsible for peptic ulcer disease. With the major conceptual fact that H. pylori plays a dominant role in majority of peptic ulcer, prevention of relapse is focused on eradication of this organism from the stomach. H. pylori is approximately involved in 100% of chronic active antral gastritis cases, 90% of duodenal ulcer patients, and 50-60% gastric ulcer patients. Single antibiotic regimens led to the result of failure in H. pylori treatment, due to above reason various combination regimens are suggested to increase the rate of H. pylori eradication. H. pylori deals with the utmost importance for choosing the drug delivery system. One of the best approaches followed to extend the residency of medication in the stomach is of lower density floating dosage form, so that the gastric fluid should be capable of floating on the gastric juice in the stomach. Conventional dosage forms are treatable for H. pylori but complete eradication does not take place. Some novely arrived drug deliverance technologies include double liposomes, microspheres, microbeads, microballons, as well as mucoadhesive drug delivery systems. The main aim of this research work deals with the fact of better, approachable as well as optimized drug delivery concepts specified for H. pylori eradication in less time interval. The formulation with a size of less than 100 nm was said to be prone to fusion with bacterial membrane, thereby directly releasing a high dose of active drug moiety into the bacterial membrane, which can further led to absorption of active content. In the present research work, design and characterization of D-Limonene and liquorice loaded nanosponge based drug delivery system for complete eradication of H. Pylori infection. Research initiated with the full over optimistic carry over approach which will enlighten the novel concept of the drug deliverance through a in situ gel based system integrating nanosponges loaded with combined regimen therapy based drugs.

Neigh, G. and M. Shurte (2009). "Affective and cognitive consequences of small cerebral infarcts." Journal of Cerebral Blood Flow and Metabolism **1)**: S220.

Objective: Together, late-life major depression and subsyndromal depression rob more than 15% of the elderly population of personal happiness and exacerbate comorbid conditions.¹ The most serious consequence of late-life depression is premature death due to increased mortality following myocardial infarction and stroke as well as an increased rate of suicide.² Although the etiology of late-life depression is not fully understood, it is associated with vascular pathology. Silent cerebral infarcts (SCI) have been identified in over 50% of patients with late onset depression,³ and these lesions are associated with more severe symptoms,⁴ more hospital admissions for depression, and longer hospitalizations for depression.⁵ Due to the inherent limitations of human research, it is unknown whether vascular changes in the elderly are causative of depressive behaviors or an unrelated but co-occurring event. Because small cerebral infarcts have been repeatedly associated with increased occurrence and severity of symptoms of depression, the current work tests the hypothesis that small cerebral infarcts induce anxiety-like and depressive-like behaviors in a rat model. Method(s): Male rats (3 or 18 mos old) were anesthetized and microembolism or SHAM procedures were performed. Briefly, the left or right common carotid was exposed and microbeads (50 mum in diameter) were injected via a 30-G needle. After 14d of recovery from the procedure, rats were tested for both depressive-like and anxiety-like behaviors. Tests included: social interaction, elevated plus maze, open field, sucrose preference, and forced swim. Result(s): Data indicate that rats that received microembolism infarcts demonstrate an increase in depressive-like behavior, as measured by deficits in sucrose preference and forced swim activity, as compared to SHAM operated rats. Results from the full panel of behavioral tests in both age groups will be presented. Analysis of the brain tissue from these rats will determine the role of lesion laterality and location in generation of behavioral changes. Conclusion(s): The data collected to date indicate that experimental induction of small cerebral infarcts is sufficient to induce depressive-like behavior. This suggests that small cerebral infarcts may be one underlying cause of late life depression in the elderly population. A better understanding of the behavioral consequences of small cerebral infarcts will provide insight into the neurobiology of vascularly-induced behavioral changes and guide the development of novel treatment strategies.

Nel, H., et al. (2019). "Simple yet effective modifications to the operation of the Sediment Microplastic

Isolation unit to avoid polyvinyl chloride (PVC) contamination." MethodsX **6**: 2656-2661.

Effective microplastic extraction from sediment and soil samples requires a density separation step, with the ability to remove >80 % of plastic particles without introducing substantial contamination. Additional benefits such as affordability and simplicity allow microplastic campaigns on limited budgets the ability to achieve high extraction efficacies. Coppock et al. (2017) designed the Sediment Microplastic Isolation (SMI) unit with these criteria in mind, warning that long-term use may lead to polyvinyl chloride (PVC) contamination. As part of the method validation work for a large-scale international project, collecting samples from more than 100 rivers globally, a pilot study of extraction efficiency and contamination potential of an SMI unit was performed. PVC contamination occurred during the extraction of 20 samples, with indicative grey shavings found in both negative controls and field samples. The original protocol was modified and artificially spiked sediments (positive blanks) were run to test extraction efficacy. The modification, requiring the PVC ball valve to remain open throughout the extraction. This modification eliminated contamination caused by wear and tear of the ball valve, while still maintaining recovery rates >80 %. Three points describing the change not the original: *The PVC ball valve is open while sample is agitated with a magnetic stirrer.*The PVC ball valve remains open while the solution is decanted.*The upper chamber is unscrewed and rinsed; recovering particles attached to the inner walls that would be lost using other filtration approaches.

Nel, H. A., et al. (2018). "Sinks and sources: assessing microplastic abundance in river sediment and deposit feeders in an Austral temperate urban river system." Science of the Total Environment **612**: 950-956.

Microplastics are important novel pollutants in freshwaters but their behaviour in river sediments is poorly understood due to the large amounts of coloured dissolved organic matter that impede sample processing. The present study aimed to (1.) estimate the microplastic pollution dynamics in an urban river system experiencing temporal differences in river flow, and (2.) investigate the potential use of chironomids as indicators of microplastic pollution levels in degraded freshwater environments. Microplastic levels were estimated from sediment and Chironomus spp. larvae collected from various sites along the Bloukrans River system, in the Eastern Cape South Africa during the summer and winter season. River flow, water depth, channel width, substrate embeddedness and sediment organic matter were simultaneously collected from each site. The winter season was characterised by elevated microplastic abundances, likely as a result of lower energy and increased sediment deposition associated with reduced river flow. In addition, results showed that particle distribution may be governed by various other external factors, such as substrate type and sediment organic matter. The study further highlighted that deposit feeders associated with the benthic river habitats, namely Chironomus spp. ingest microplastics and that the seasonal differences in sediment microplastic dynamics were reflected in chironomid microplastic abundance. There was a positive, though weakly significant relationship between deposit feeders and sediment suggesting that deposit feeders such as Chironomus spp. larvae could serve as an important indicator of microplastic loads within freshwater ecosystems.

Nel, H. A., et al. (2019). "Colour and size influences plastic microbead underestimation, regardless of sediment grain size." Science of the Total Environment **655**: 567-570.

The quantification of microplastics in environmental samples often requires an observer to determine whether a particle is plastic or non-plastic, prior to further verification procedures. This implies that inconspicuous microplastics with a low natural detection may be underestimated. The present study aimed at assessing this underestimation, looking at how colour (white, green and blue), size (large; ~1000 µm and small; <400 µm) and grain size fraction may affect detection. Sediment treatments varying in grain size were inoculated with known quantities of low-density polyethylene microbeads extracted from commercially bought facial scrubs. These microbeads varied in colour and size. Once extracted using a density separation method microbeads were counted. An overall underestimation of 78.59% may be a result of observer error and/or technical error. More specifically, the results suggested that microbeads varying in colour and size have a different detection probability and that these microbead features are more important in underestimation likelihoods than grain sizes. Graphical abstract Unlabelled Image Highlights • Microbeads, found in cosmetics, vary in colour and size. • Detection probabilities were significantly different between microbeads. • Microbead characteristics may explain underestimation in in situ sampling. [ABSTRACT FROM AUTHOR]

Nel, H. A., et al. (2017). "Do microplastic loads reflect the population demographics along the southern African coastline?" Marine Pollution Bulletin **115**(1/2): 115-119.

Plastic pollution is a major anthropogenic contaminant effecting the marine environment and is often associated with high human population densities and industrial activities. The microplastic (63 to 5000 micro m) burden of beach sediment and surf-zone water was investigated at selected sites along the entire length of the South African coastline. It was predicted that samples collected in areas of high population density, would contain a higher microplastic burden than those along coasts that demonstrate very low population densities. With the exception of water column microplastics within Richard's Bay Harbour (413.3+or-77.53 particles.m⁻³) and Durban Harbour (1200+or-133.2 particles.m⁻³), there were no significant spatial differences in microplastic loads. This supports the theory that harbours act as a source of microplastics for the surrounding marine environment. Additionally, the absence of any spatial variation highlights the possible long range distribution of microplastic pollutants by large scale ocean currents.

Nelms, S. E., et al. (2019). "Microplastics in marine mammals stranded around the British coast: ubiquitous but transitory?" Scientific Reports **9**(1): 1075.

Plastic pollution represents a pervasive and increasing threat to marine ecosystems worldwide and there is a need to better understand the extent to which microplastics (<5 mm) are ingested by high trophic-level taxa, such as marine mammals. Here, we perform a comprehensive assessment by examining whole digestive tracts of 50 individuals from 10 species whilst operating strict contamination controls. Microplastics were ubiquitous with particles detected in every animal examined. The relatively low number per animal (mean = 5.5) suggests these particles are transitory. Stomachs, however, were found to contain a greater number than intestines, indicating a potential site of temporary retention. The majority of particles were fibres (84%) while the remaining 16% was fragments. Particles were mainly blue and black (42.5% and 26.4%) in colour and Nylon was the most prevalent (60%) polymer type. A possible relationship was found between the cause of death category and microplastic abundance, indicating that animals that died due to infectious diseases had a slightly higher number of particles than those that died of trauma and other drivers of mortality. It is not possible, however, to draw any firm conclusions on the potential biological significance of this observation and further research is required to better understand the potential chronic effects of microplastic exposure on animal health, particularly as marine mammals are widely considered important sentinels for the implications of pollution for the marine environment.

Nelms, S. E., et al. (2018). "Investigating microplastic trophic transfer in marine top predators." Environmental Pollution **238**: 999-1007.

Microplastics are highly bioavailable to marine organisms, either through direct ingestion, or indirectly by trophic transfer from contaminated prey. The latter has been observed for low-trophic level organisms in laboratory conditions, yet empirical evidence in high trophic-level taxa is lacking. In natura studies face difficulties when dealing with contamination and differentiating between directly and indirectly ingested microplastics. The ethical constraints of subjecting large organisms, such as marine mammals, to laboratory investigations hinder the resolution of these limitations. Here, these issues were resolved by analysing sub-samples of scat from captive grey seals (Halichoerus grypus) and whole digestive tracts of the wild-caught Atlantic mackerel (Scomber scombrus) they are fed upon. An enzymatic digestion protocol was employed to remove excess organic material and facilitate visual detection of synthetic particles without damaging them. Polymer type was confirmed using Fourier-Transform Infrared (FTIR) spectroscopy. Extensive contamination control measures were implemented throughout. Approximately half of scat subsamples (48%; n=15) and a third of fish (32%; n=10) contained 1-4 microplastics. Particles were mainly black, clear, red and blue in colour. Mean lengths were 1.5 mm and 2 mm in scats and fish respectively. Ethylene propylene was the most frequently detected polymer type in both. Our findings suggest trophic transfer represents an indirect, yet potentially major, pathway of microplastic ingestion for any species whose feeding ecology involves the consumption of whole prey, including humans.

Nelms, S. E., et al. (2019). "What goes in, must come out: Combining scat-based molecular diet analysis and quantification of ingested microplastics in a marine top predator." Methods in Ecology and Evolution **10**(10): 1712-1722.

Microplastics (plastic particles <5 mm in size) are highly available for ingestion by a wide range of organisms, either through direct consumption or indirectly, via trophic transfer, from prey to predator. The latter is a poorly understood, but potentially major, route of microplastic ingestion for marine top predators.We developed a novel and effective methodology pipeline to investigate dietary exposure of wild top predators (grey seals; Halichoerus grypus) to microplastics, by combining scat-based molecular techniques with a microplastic isolation method. We employed DNA metabarcoding, a rapid method of biodiversity assessment, to garner detailed information on prey composition from scats, and investigated the potential relationship between diet and microplastic burden.Outcomes of the method development process and results of both diet composition from metabarcoding analysis and detection of microplastics are presented. Importantly, the pipeline performed well and initial results suggest the frequency of microplastics detected in seal scats may be related to the type of prey consumed.Our non-invasive, data-rich approach maximizes time and resource–efficiency, while minimizing costs and sample volumes required for analysis. This pipeline could be used to underpin a much-needed increase in understanding of the relationship between diet composition and rates of microplastic ingestion in high trophic level species.

Nemer, J. (2012). "Umbilical vascular access task trainer - An inexpensive and biohazardly safe DIY (do it yourself) model." Academic Emergency Medicine **1)**: S404-S405.

Background: Umbilical vascular access is an essential skill set for providers involved in neonatal resuscitation. It is imperative to learn, practice, and perfect these important skills prior to performing these procedures on a critically ill neonate. Umbilical cord procedures are infrequently performed in most emergency departments, which may lead to a lack of comfort and expertise. Simulation provides a valuable opportunity to acquire and maintain competency in umbilical vascular access. Simulation of umbilical vascular access currently involves two types of models: commercially available task trainers, and real umbilical cord sections. Commercial trainers are expensive, easily damaged, and require costly replacements after a limited number of uses. Real umbilical cords involve those plus additional challenges in supply, storage, and biohazard exposure. Objective(s): This DIY (Do It Yourself) umbilical cord model was created to provide an inexpensive biohazardly safe umbilical cord model which includes two arteries and a vein to simulate the experience of performing umbilical vein and artery catheterization. This model has realistic anatomy with twisting umbilical vessels, and realistic texture of rubbery exterior amniotic epithelium of the cord, and the slippery Wharton's jelly supporting the "vessels". The model can be refrigerated and reused or discarded like other food and plastic waste. Equipment needed: gelatin, food coloring, syrup, glove fingers, catheters, tubing, and syringes. Method(s): This presentation will include detailed instructions, and comparisons in cost and limitations of each type of umbilical cord trainer. Conclusion(s): This DIY umbilical cord task trainer is a low cost alternative to the expensive commercially available kits, and without the biohazard risks of a real umbilical cord.

Nemit, V. and A. K. Tripathi (2016). "Municipal solid waste (MSW) composition, quantification and characterization at the three MSW dumping sites of Himachal Pradesh: a case study." Indian Journal of Forestry **39**(1): 31-36.

Methane emission from landfills due to unmanaged dumping contributes significantly to greenhouse gas emissions and ultimately to climate change. The green house gas emission from the dumping sites depends on various factors like quantity of waste generated, composition of solid waste, and characteristics of solid waste. The quantification and characterization of urban solid waste generation is fundamental for adequate decision making in the management strategy of urban solid waste in a city. The objective of this study is to quantify and characterize the waste generated in the three cities of Himachal Pradesh i.e. Shimla, Solan and Nahan. The chemical characteristics study include pH, Moisture. Nitrogen, Phosphorus, Potassium, Carbon and C/N ration and physical studies includes the composition of different waste categories. The annual waste generation in Shimla, Solan and Nahan calculated in this study 17,426.52, 7,130.70 and 1,608.37 tons (t) respectively for the year (yr) 2012-13. The main fractions were: Food and Carbon waste, paper and plastic waste. The pH of MSW was found slight to highly acidic in nature whereas moisture content was found to be in the range from 42.60+or-1.95 in Nahan to 60.12+or-1.39% in Shimla. The N, K, P and C estimated were found maximum 0.81% (Shimla), 0.65% (Nahan), 0.33% (Shimla), and 40.49% (Solan) respectively.

Nemmaoui, A., et al. (2019). "DSM and DTM generation from VHR satellite stereo imagery over plastic covered greenhouse areas." Computers and Electronics in Agriculture **164**(104903).

Agriculture under Plastic Covered Greenhouses (PCG) has represented a step forward in the evolution from traditional to industrial farming. However, PCG-based agricultural model has been also criticized for its associated environmental impact such as plastic waste, visual impact, soil pollution, biodiversity degradation and local runoff alteration. In this sense, timely and effective PCG mapping is the only way to help policy-makers in the definition of plans dealing with the trade-off between farmers' profit and environmental impact for the remaining inhabitants. This work proposes a methodological pipeline for producing high added value 3D geospatial products (Digital Surface Models (DSM) and Digital Terrain Models (DTM)) from VHR satellite imagery over PCG areas. The 3D information layer provided through the devised approach could be very valuable as a complement to the traditional 2D spectral information offered by VHR satellite imagery to improve PCG mapping over large areas. This methodological approach has been tested in Almeria (Southern Spain) from a WorldView-2 VHR satellite stereo-pair. Once grid spacing format DSM and DTM were built, their vertical accuracy was assessed by means of lidar data provided by the Spanish Government (PNOA Programme). Regarding DSM completeness results, the image matching method based on hierarchical semi-global matching yielded much better scores (98.87%) than the traditional image matching method based on area-based matching and cross-correlation threshold (86.65%) when they were tested on the study area with the highest concentration of PCG (around 85.65% of PCG land cover). However, both image matching methods yielded similar vertical accuracy results in relation to the finally interpolated DSM, with mean errors ranging from 0.01 to 0.35 m and random errors (standard deviation) between 0.56 and 0.82 m. The DTM error figures also showed no significant differences between both image matching methods, although being highly dependent on DSM-to-DTM filtering error, in turn closely related to greenhouse density and terrain complexity.

Neri, P., et al. (2009). "miRNA expression in multiple myeloma as predictive model of response to bortezomib." Blood. Conference: 51st Annual Meeting of the American Society of Hematology, ASH. New Orleans, LA United States. Conference Publication: **114**(22).

Background: Bortezomib therapeutic efficacy is well established in multiple myeloma (MM) however response to this therapy remains difficult to predict with resistant disease observed in nearly 20% of MM patients. Through DNA microarrays, predictive models of response to stem cell transplant and Bortezomib were reported correlating mRNA expression data with disease outcomes and response to therapy. MicroRNAs (miRNAs) are a key class of small, non-coding RNA molecules that modulate post-transcriptional regulation of gene expression and were recently described to be involved in deregulation of gene expression in many cancers including MM. Little evidence however is available concerning the role of miRNA expression in the prediction of response to Bortezomib in MM. We aimed to assess the expression of miRNAs in a panel of Bortezomib highly sensitive and relatively resistant MM cell lines as well as primary MM cells and identify miRNA expression patterns that are associated with response to Bortezomib. Method(s): We have used miRNA microarrays (Affymetrix miRNA GeneChip) as well as liquid phase Luminex microbead miRNA profiling (Flexmir, Luminex) to profile miRNA expression in MM cell lines (MM1S, KMS11, INA6, U266) and sorted CD138+ bone marrow PCs from MM patients prior to treatment with Bortezomib (n=5; 3 sensitive and 2 resistant) and PCs from a healthy normal donor (n=1). The MM cell lines included in this analysis were classified as sensitive (S) or resistant (R) based on their Bortezomib IC50 at 48 hours (IC50 for MM1S and KMS11 ~ 5 nM versus INA6 and U266 ~ 20nM). For the microarray studies the hybridization signal values for the multiple probes for each miRNA were obtained and normalized with the use of miRNA QC tool (Affymetrix) and analyzed using Partek Genomics Suite software. Thereafter, filters were applied to identify the miRNA probes whose normalized signal were at least 2 folds differentially expressed between sensitive (MM1S) and resistant (INA6) cell lines with a P value < 0.05 (ANOVA) and a FDR of 0.05. Bortezomib sensitive (n=3) and resistant (n=2) primary MM samples were subjected to the same miRNA array analysis and filtering. Liquid phase Luminex microbead miRNA profiling (FlexmiR) was used for the confirmation (MM1S and

INA6) and validation of the array results in other MM cell lines KMS11 (IC50 5nM) and U266 (IC50 20nM). Result(s): Using Affymetrix miRNA GeneChip we identified 22 differentially expressed miRNA with overexpression of miR-155, miR-342-3p, miR-181a and b, miR-128, miR-20b and downregulation miR-let-7b, miR-let-7i, miR-let-7d, miR-let-7c, miR-222, miR-221, miR-23a, miR-27a and miR-29a in bortezomib relatively resistant (INA6) versus sensitive (MM1S) cell line. These results were confirmed in INA6 and MM1S cells with the use of Luminex microbead miRNA profiling and validated to be similarly differentially expressed between KMS11 (sensitive) and relatively U266 (resistant) cell lines. Furthermore, TargetScan algorithms and Ingenuity Pathway Analysis software were used to identify predicted miRNAstargeted mRNAs or potentially regulated networks and included genes involved in cell cycle regulation, cell growth, apoptosis and ubiquitin-conjugation pathways. Lastly to further investigate the clinical relevance of miRNAs in MM in terms of prediction of response and outcome to Bortezomib, we correlated miRNA expression profile of sorted CD138+ bone marrow PCs from Bortezomib sensitive (n=3) and resistant (n=2) MM patients with their response to therapy. Unsupervised analysis of the data revealed that the Bortezomib sensitive MM patients clustered with MM1S cell line while resistant patients segregated into the INA6 cluster. Conclusion(s): In summary, we have described a MM miRNA signature, which includes miRNAs that modulate the expression of proteins critical to myeloma pathogenesis and is predictive of response to Bortezomib. Further validation of this miRNA signature in a larger cohort of Bortezomib-treated MM patients is ongoing.

Neto, J. A. B., et al. (2019). "The impact of sediment dumping sites on the concentrations of microplastic in the inner continental shelf of Rio de Janeiro/Brazil." Marine Pollution Bulletin **149**: 1.

The marine environment is constantly being impacted by anthropogenic activities. Nowadays, microplastics (MPs) representing one of the most deleterious material among of all substances and material from anthropogenic origin. The Microplastics (MPs) are particles smaller than 5 mm. This study presents information on abundance, distribution, type and colour of microplastics in the bottom sediments of the continental Shelf of Rio de Janeiro State. This area is strongly impacted due to its location in front of one of the most polluted coastal bays in the Brazilian Coastline. It receives untreated sewage from an Ipanema Beach submarine emissary and also a great amount of sediments dredged from Rio de Janeiro Harbour, which strongly influences the distribution of MPs in the area. The analyses detected the presence of MP in 100% of the samples, composed mainly by secondary microplastics, and almost 50% were fibers, followed by plastic films, plastic fragments and pellets. Based on the nature of the sources of the MP, a great variety of colours was shown, dominated by four main colours: blue, white, transparent, and black, this pattern could potentially increase their bioavailability due to resemblance to prey items, especially to visual raptorial species.

Neves, D., et al. (2015). "Ingestion of microplastics by commercial fish off the Portuguese coast." Marine Pollution Bulletin **101**(1): 119-126.

The digestive tract contents of 263 individuals from 26 species of commercial fish were examined for microplastics. These were found in 17 species, corresponding to 19.8% of the fish of which 32.7% had ingested more than one microplastic. Of all the fish that ingested microplastics, 63.5% was benthic and 36.5% pelagic species. A total of 73 microplastics were recorded, 48 (65.8%) being fibres and 25 (34.2%) being fragments. Polymers were polypropylene, polyethylene, alkyd resin, rayon, polyester, nylon and acrylic. The mean of ingested microplastics was 0.27+or-0.63 per fish, (n=263). Pelagic fish ingested more particles and benthic fish ingested more fibres, but no significant differences were found. Fish with the

highest number of microplastics were from the mouth of the Tagus river. Scomber japonicus registered the highest mean of ingested microplastics, suggesting its potential as indicator species to monitor and investigate trends in ingested litter, in the MSFD marine regions.

Newhook, T. E., et al. (2014). "The MEK inhibitor trametinib delays tumor outgrowth and prolongs survival in a patient-derived mouse model of occult hepatic metastatic pancreatic cancer." Cancer Research. Conference: 105th Annual Meeting of the American Association for Cancer Research, AACR **74**(19 SUPPL. 1).

Background: Survival for patients with pancreatic ductal adenocarcinoma (PDAC) remains dismal and the majority of patients succumb to metastatic disease. Even for those with localized PDAC, most will die from metastatic disease despite margin-negative resection and adjuvant therapy. Therefore, these patients must harbor occult metastatic PDAC at presentation. We have developed a PDAC model of occult liver metastases using patient-derived xenografts (PDXs) to study the growth of PDAC within the metastatic microenvironment of the liver and evaluated the role of KRAS-MEK-ERK signaling on tumor progression. Methods and Results: Extensively characterized low passage, patient-derived KRAS-mutant (Tumors 608, 366, and 654) and wild-type (Tumors 738 and 215) PDAC cells expressing luciferase were injected into the spleens of athymic, nude mice and allowed to circulate for 10 minutes, after which a splenectomy was performed. To evaluate metastatic cell growth kinetics in the liver, tumor burden was monitored by sequential bioluminescent imaging. Each of the PDX tumors exhibited a characteristic and reproducible time to proliferative outgrowth ranging from 20 days (Tumor 608) to greater than 100 days (Tumor 654). To evaluate the role of KRAS signaling in maintaining dormant cell survival and proliferative outgrowth, tumor 608 cells were injected and mice were treated with the MEK inhibitor trametinib (0.3 mg/kg, daily) or control beginning 48 hours post-injection. Trametinib significantly reduced metastatic tumor burden, delayed time to proliferative outgrowth, and greatly prolonged survival as compared to control (med. survival: 114 vs. 43 days, p<0.001). In contrast, in an orthotopic model with 250-500 mm³ tumors trametinib led to limited inhibition in tumor growth for Tumor 608. To characterize these PDAC cells, we isolated Tumor 608 cells from the liver 48 and 72 hours, 10 and 28 days after splenic injection using magnetic column separation with human EpCAM (CD326)-targeted magnetically labeled microbeads. Flow cytometric analyses of retrieved cells revealed that decreased cellular markers of proliferation and increased PARP cleavage correlated with decreased tumor burden observed at these timepoints in mice treated with trametinib. Conclusion(s): Using a model of occult liver metastatic PDAC, patient-derived tumors exhibited characteristic, albeit different growth kinetics in the liver microenvironment. Further, inhibition of KRAS-MEK-ERK signaling with the MEK inhibitor trametinib decreased metastatic cellular proliferation, increased apoptosis, prolonged metastatic tumor outgrowth, and significantly increased survival. Further investigation into factors promoting PDAC cell survival within the hepatic microenvironment will lead to development of rational therapeutic strategies for patients with occult metastatic PDAC.

Ng, E. L., et al. (2018). "An overview of microplastic and nanoplastic pollution in agroecosystems." Science of the Total Environment **627**: 1377-1388.

Microplastics and nanoplastics are emerging pollutants of global importance. They are small enough to be ingested by a wide range of organisms and at nano-scale, they may cross some biological barriers. However, our understanding of their ecological impact on the terrestrial environment is limited. Plastic particle loading in agroecosystems could be high due to inputs of some recycled organic waste and plastic film mulching, so it is vital that we develop a greater understanding of any potentially harmful or adverse impacts of these pollutants to agroecosystems. In this article, we discuss the sources of plastic particles in agroecosystems, the mechanisms, constraints and dynamic behaviour of plastic during aging on land, and explore the responses of soil organisms and plants at different levels of biological organisation to plastic particles of micro and nano-scale. Based on limited evidence at this point and understanding that the lack of evidence of ecological impact from microplastic and nanoplastic in agroecosystems does not equate to the evidence of absence, we propose considerations for addressing the gaps in knowledge so that we can adequately safeguard world food supply.

Ng, K. L. and J. P. Obbard (2006). "Prevalence of microplastics in Singapore's coastal marine environment." Marine Pollution Bulletin **52**(7): 761-767.

Microplastics have been recently identified as marine pollutants of significant concern due to their persistence, ubiquity and potential to act as vectors for the transfer and exposure of persistent organic pollutants to marine organisms. This study documents, for the first time, the presence and abundance of microplastics (>1.6 microm) in Singapore's coastal environment. An optimized sampling protocol for the collection and analysis of microplastics was developed, and beach sediments and seawater (surface microlayer and subsurface layer) samples were collected from nine different locations around the coastline. Low density microplastics were separated from sediments by flotation and polymer types were identified using Fourier transform infrared (FTIR) spectrometry. Synthetic polymer microplastics identified in beach sediments included polyethylene, polypropylene, polystyrene, nylon, polyvinyl alcohol and acrylonitrile butadiene styrene. Microplastics were detected in samples from four out of seven beach environments, with the greatest quantity found in sediments from two popular beaches in the eastern part of Singapore. Polyethylene, polypropylene and polystyrene microplastics were also found in the surface microlayer (50-60 microm) and subsurface layer (1m) of coastal waters. The presence of microplastics in sediments and seawater is likely due to on-going waste disposal practices from industries and recreational activities, and discharge from shipping.

Ng, L. F., et al. (2009). "IL-1beta, IL-6, and RANTES as biomarkers of Chikungunya severity." PLoS ONE [Electronic Resource] **4**(1): e4261.

BACKGROUND: Little is known about the immunopathogenesis of Chikungunya virus. Circulating levels of immune mediators and growth factors were analyzed from patients infected during the first Singaporean Chikungunya fever outbreak in early 2008 to establish biomarkers associated with infection and/or disease severity.

METHODS AND FINDINGS: Adult patients with laboratory-confirmed Chikungunya fever infection, who were referred to the Communicable Disease Centre/Tan Tock Seng Hospital during the period from January to February 2008, were included in this retrospective study. Plasma fractions were analyzed using a multiplex-microbead immunoassay. Among the patients, the most common clinical features were fever (100%), arthralgia (90%), rash (50%) and conjunctivitis (40%). Profiles of 30 cytokines, chemokines, and growth factors were able to discriminate the clinical forms of Chikungunya from healthy controls, with patients classified as non-severe and severe disease. Levels of 8 plasma cytokines and 4 growth factors were significantly elevated. Statistical analysis showed that an increase in IL-1beta, IL-6 and a decrease in RANTES were associated with disease severity.

CONCLUSIONS: This is the first comprehensive report on the production of cytokines, chemokines, and growth factors during acute Chikungunya virus infection. Using these biomarkers, we were able to distinguish between mild disease and more severe forms of Chikungunya fever, thus enabling the identification of patients with poor prognosis and monitoring of the disease.

Ng, L. F. P., et al. (2009). "IL-1β, IL-6, and RANTES as Biomarkers of Chikungunya Severity." PLoS ONE **4**(1).

Ng, W., et al. (2020). "Convolutional neural network for soil microplastic contamination screening using infrared spectroscopy." Science of the Total Environment **702**: 134723.

Microplastics are emerging pollutants that exist in our environment. Microplastics are synthetic polymers that have particles size smaller than 5mm. Rapid screening of microplastics contamination in the soil could assist in identifying anomalous concentrations of microplastics in the terrestrial environment. Because there is no rule on the maximum concentration limit on how much microplastics can exist within the soil, the concentration of microplastics collected from industrial areas around metropolitan Sydney was used as a baseline. Spectra obtained from the visible-near-infrared (vis-NIR) spectra has been shown to be feasible in predicting microplastics in the soil. Instead of creating a regression model predicting the concentration of microplastic, a classification model for screening was proposed. A convolutional neural network (CNN) model was trained to classify the soil sample into various degrees of contamination based on concentration. We also delved into the CNN model to understand how the CNN model classifies the spectral data input. The model performance was first tested on two levels of classification (contaminated vs. non-contaminated). The model was able to classify the uncontaminated samples into the appropriate class more accurately than the contaminated samples. When the number of classes were gradually increased, the classification accuracy for the higher level of contaminated samples improved. Transfer learning CNN model further improved the classification prediction only on the extremes, but not the intermediate classes.

Ngo, H. T., et al. (2018). "Direct Detection of Unamplified Pathogen RNA in Blood Lysate using an Integrated Lab-in-a-Stick Device and Ultrabright SERS Nanorattles." Scientific Reports **8**(1): 4075.

Direct detection of genetic biomarkers in body fluid lysate without target amplification will revolutionize nucleic acid-based diagnostics. However, the low concentration of target sequences makes this goal challenging. We report a method for direct detection of pathogen RNA in blood lysate using a bioassay using surface-enhanced Raman spectroscopy (SERS)-based detection integrated in a "lab-in-a-stick" portable device. Two levels of signal enhancement were employed to achieve the sensitivity required for direct detection. Each target sequence was tagged with an ultrabright SERS-encoded nanorattle with ultrahigh SERS signals, and these tagged target sequences were concentrated into a focused spot for detection using hybridization sandwiches with magnetic microbeads. Furthermore, the washing process was automated by integration into a "lab-in-a-stick" portable device. We could directly detect synthetic target with a limit of detection of 200 fM. More importantly, we detected plasmodium falciparum malaria parasite RNA directly in infected red blood cells lysate. To our knowledge, this is the first report of SERS-based direct detection of pathogen nucleic acid in blood lysate without nucleic acid extraction or target amplification. The results show the potential of our integrated bioassay for field use and point-of-care diagnostics.

Ngo, P. L., et al. (2019). "Pathway, classification and removal efficiency of microplastics in wastewater treatment plants." Environmental Pollution **255**(Pt 2): 113326.

Microplastics (MPs) contamination in water environment has recently been documented as an emerging environmental threat due to their negative impact on the ecosystem. Their sources are many, but all of them are from synthetic materials. The sources of MPs are cosmetics and personal care products, breakdown or abrasion processes of other plastic products, textile and tyre, bitumen and road marking paints. Because of their low density and small particle size, they are easily discharged into the wastewater drainage systems. Therefore, the municipal wastewater treatment plants (WWTPs) are indicated to be the main recipients of MPs before getting discharged into the natural waterbodies. Therefore, understanding the occurrence and fate of MPs in WWTPs are of great importance towards its control. The aim of this article is to provide a comprehensive review to better understand the pathways of MPs before entering the WWTPs, characteristics of MPs in wastewater, and the removal efficiency of MPs of the existing wastewater treatment technologies adopted by the WWTPs. This review also covers the development of potential microplastics treatment technologies investigated to date. Based on the review of existing literature, it is found that the existing WWTPs are inefficient to completely remove the MPs and there is a risk that they may get discharged into the ambient water sources.

Nguyen, B., et al. (2019). "Separation and Analysis of Microplastics and Nanoplastics in Complex Environmental Samples." Accounts of Chemical Research **52**(4): 858-866.

The vast amount of plastic waste emitted into the environment and the increasing concern of potential harm to wildlife has made microplastic and nanoplastic pollution a growing environmental concern. Plastic pollution has the potential to cause both physical and chemical harm to wildlife directly or via sorption, concentration, and transfer of other environmental contaminants to the wildlife that ingest plastic. Small particles of plastic pollution, termed microplastics (>100 nm and <5 mm) or nanoplastics (<100 nm), can form through fragmentation of larger pieces of plastic. These small particles are especially concerning because of their high specific surface area for sorption of contaminants as well as their potential to translocate in the bodies of organisms. These same small particles are challenging to separate and identify in environmental samples because their size makes handling and observation difficult. As a result, our understanding of the environmental prevalence of nanoplastics and microplastics is limited. Generally, the smaller the size of the plastic particle, the more difficult it is to separate from environmental samples. Currently employed passive density and size separation techniques to isolate plastics from environmental samples are not well suited to separate microplastics and nanoplastics. Passive flotation is hindered by the low buoyancy of small particles as well as the difficulty of handling small particles on the surface of flotation media. Here we suggest exploring alternative techniques borrowed from other fields of research to improve separation of the

smallest plastic particles. These techniques include adapting active density separation (centrifugation) from cell biology and taking advantage of surface-interaction-based separations from analytical chemistry. Furthermore, plastic pollution is often challenging to quantify in complex matrices such as biological tissues and wastewater. Biological and wastewater samples are important matrices that represent key points in the fate and sources of plastic pollution, respectively. In both kinds of samples, protocols need to be optimized to increase throughput, reduce contamination potential, and avoid destruction of plastics during sample processing. To this end, we recommend adapting digestion protocols to match the expected composition of the nonplastic material as well as taking measures to reduce and account for contamination. Once separated, plastics in an environmental sample should ideally be characterized both visually and chemically. With existing techniques, microplastics and nanoplastics are difficult to characterize or even detect. Their low mass and small size provide limited signal for visual, vibrational spectroscopic, and mass spectrometric analyses. Each of these techniques involves trade-offs in throughput, spatial resolution, and sensitivity. To accurately identify and completely quantify microplastics and nanoplastics in environmental samples, multiple analytical techniques applied in tandem are likely to be required.

Nguyen, D. V., et al. (2015). "HLA-B 1502 and carbamazepine-induced severe cutaneous adverse drug reactions in Vietnamese." Asia Pacific Allergy **5**(2): 68-77.

BACKGROUND: In Vietnam, we observed a high incidence of carbamazepine (CBZ)-induced severe cutaneous adverse drug reactions (SCARs)-Stevens-Johnson syndrome (SJS)/toxic epidermal necrolysis (TEN), and drug-induced hypersensitivity rash with eosinophilia and systemic symptoms (DRESS). In other Asian countries, HLA-B(*)1502 is an established risk factor for SCARs.

OBJECTIVE: The aim of our study was to determine the frequency of HLA-B(*)1502 in SCARs patients at a large University Medical Center in Hanoi, Vietnam.

METHODS: Thirty-eight cases of SCARs caused by CBZ and 25 patients with epilepsy tolerating CBZ were enrolled in a case-controlled study. Clinical manifestations and laboratory findings were recorded for each subject. Genomic DNA was isolated using the QIAamp DNA purification system. The combination of polymerase chain reaction and sequence specific oligonucleotide probes with the Luminex 100xMAP flow cytometry dual laser system was then used to quantitate fluorescently labelled oligonucleotides attached to colour-coded microbeads.

RESULTS: Cases comprised 20 SJS (52.6%), 7 TEN (18.4%), 8 overlap syndrome (21.1%), and 3 DRESS patients (7.9%). A strong association between HLA B(*)1502 and bullous skin reactions such as SJS/TEN and overlap was confirmed with an odds ratio (OR) of 33.78 (95% confidence interval [CI], 7.55-151.03), $p < 0.0001$, Sensitivity 91.4%, Specificity 76.0%, positive predictive value 84.2%, and negative predictive value 86.4%. We did not, however, observe any correlation between the presence of this allele and CBZ-induced nonbullous skin reactions (DRESS) (OR, 6.33; 95% CI, 0.48-82.74; $p = 0.1592$).

CONCLUSION: Our results indicate the presence of HLA-B(*)1502 in Vietnamese is a pharmacogenetic risk factor for developing CBZ-induced SJS/TEN.

Nguyen, V. D., et al. (2013). "The association between the presence of HLA B*1502 and carbamazepine-induced stevens-johnson syndrome (SJS), toxic epidermal necrolysis (TEN) and druginduced hypersensitivity syndrome with rash, eosinophilia and systemic symptoms (DRESS) in Vietnamese." Allergy: European Journal of Allergy and Clinical Immunology **98)**: 71.

Background: In Vietnam, we observed a high incidence of drug-induced Severe Cutaneous Adverse Reactions (SCARs)-SJS/TEN/DRESS (common culprit, carbamazepine [CBZ]). In other

Asian countries, HLA-B*1502 is an established risk factor for SCARs (Chung et al., 2004). A high prevalence of HLA B*1502 exists in Hanoi (Bach Khanh Hoa et al., 2008). We designed a study to determine the frequency of HLA B*1502 in SCARs patients at Bach mai Hospital. Method(s): Thirty-eight cases of SCARs caused by CBZ and 25 patients with epilepsy (tolerating CBZ) were enrolled in a case-control study. Clinical manifestations and laboratory findings were recorded for each subject (RegiSCAR-Group Diagnostic Score-Roujeau et al., 2009). Genomic DNA was isolated using the QIAamp DNA purification system (Quiagen). The combination of PCR and sequence specific oligonucleotide probes with the Luminex 100xMAP flow cytometry dual laser system was then used to quantitate fluorescently labelled oligonucleotides attached to colour-coded microbeads, (Sonic Clinical Institute). Result(s): Cases comprised 20 SJS (52.6%), seven TEN (18.4%), eight Overlap Syndrome (21.1%), three DRESS (7.9%) patients-mean age 40.6 +/- 18.7 years. The 25 controls had a mean age of 22.4 +/- 13.1 years. Skin lesion areas in SCARs-affected 62.1 +/- 24.1% of BSA; Skin detachment 12.3 +/- 12.9% of Body Surface Area, SCORTEN (severity-ofillness score, Sekula et al., 2011)-mean 1.1 +/- 1.0 (range 1-4) and Index-day was 14.2 +/- 8.3 days (median 12.5 days). Indications for CBZ were epilepsy (34.2%), neuropathic pain (42.1%), mental disorders (18.4%) and other conditions (5.3%). The HLA B*1502 allele was detected in 34/38 (89.5%) with CBZ-induced SJS/TEN/ DRESS, but in only 6/25 (24.0%) controls. Odds Ratio for HLAB*1502 positivity was 26.9 (6.7-107.4 with CI = 95%, P < 0.001), Sensitivity 89.5%, Specificity 76%, Positive Predictive Value 85% and Negative Predictive Value 82.6%. Conclusion(s): Our results indicate the presence of HLA B*1502 is a pharmacogenetic risk factor for developing CBZinduced SCARs in Vietnamese.

Nhamo, G. (2008). "Regulating Plastics Waste, Stakeholder Engagement and Sustainability Challenges in South Africa." Urban Forum **19**(1): 83-101.

In May 2003, the South African government enacted regulations banning the production of thin-film plastic shopping bags. The government advocated that such thin-film plastic shopping bags were indiscriminately discarded because they had no economic and recycling value. However, in as much as the regulations led to significant reductions in plastic shopping bags in the environment, the law resulted in severe unintended negative consequences, as jobs were lost with some businesses in the plastic shopping bag manufacturing sector closing down. The paper also reveals that key stakeholders, such as industry, business and labour, lobbied against the introduction of the regulations but without success. On average, business went down by about 83% with a conservative 25% reduction in employment. Drawing insights from the Irish and Australian experiences, this paper critically reviews sustainability debates and responses surrounding environmental regulation and business, with a special focus on the Plastic Bag Regulations in South Africa. Lessons learnt are presented with the intention to provide insights for future waste product or other environmental regulation initiatives in South Africa and elsewhere in the region. [ABSTRACT FROM AUTHOR]

Ni, H. G., et al. (2016). "Brominated flame retardant emissions from the open burning of five plastic wastes and implications for environmental exposure in China." Environmental Pollution **214**: 70-76.

Based on the most widely used plastics in China, five plastic wastes were selected for

investigation of brominated flame retardant (BFR) emission behaviors during open burning. Considerable variations were observed in the emission factors (EF) of polybrominated diphenyl ethers (PBDEs) and hexabromocyclododecanes (HBCDs) from the combustion of different plastic wastes. Distribution of BFR output mass showed that SIGMAPBDE was emitted mainly by the airborne particle (51%), followed by residual ash (44%) and the gas phase (5.1%); these values for SIGMAHBCD were 62%, 24%, and 14%, respectively. A lack of mass balance after the burning of the plastic wastes for some congeners (output/input mass ratios>1) suggested that formation and survival exceeded PBDE decomposition during the burns. However, that was not the case for HBCD. A comparison with literature data showed that the open burning of plastic waste is major source of PBDE compared to regulated combustion activities. Even for state-of-the-art waste incinerators equipped with sophisticated complex air pollution control technologies, BFRs are released on a small scale to the environment. According to our estimate, SIGMAPBDE release to the air and land from municipal solid waste (MSW) incineration plants in China in 2015 were 105 kg/year and 7124 kg/year. These data for SIGMAHBCD were 25.5 and 71.7 kg/year, respectively. Considering the fact that a growing number of cities in China are switching to incineration as the preferred method for MSW treatment, our estimate is especially important. This study provides the first data on the environmental exposure of BFRs emitted from MSW incineration in China.

Ni, K., et al. (2013). "Polybrominated diphenyl ethers (PBDEs) in China: Policies and recommendations for sound management of plastics from electronic wastes." Journal of Environmental Management **115**: 114-123.

Polybrominated diphenyl ethers (PBDEs), used as flame retardants (BFRs), are incorporated in plastics of most electronic equipment. Among BFR mixtures, deca-BDE is the most widely used commercial additive in the polymer industry and the use of deca-BDE is currently not subject to any restrictions in China. However, debate over environmental and health risks associated with deca-BDE still remains. Regulatory agencies in developed countries have adopted and/or established environmentally sound strategies for the management of potential threat posed by PBDEs to the environment and human health. No regulations or management policies for PBDEs currently exist in China at either central or provincial government levels. Large amounts of plastics containing PBDEs are still in use and must be disposed of after their lifetimes, creating outdoor reservoirs for the future dispersal of PBDEs into the environment. Concerted action is needed not only to regulate the production and use of PBDEs but also to find ways to effectively manage waste electrical and electronic products that contain PBDEs. This article is the first to investigate the policy issues and current problems related to the use of PBDEs in China. In addition, we estimate the mass flows of PBDEs contained in Waste Electrical and Electronic Equipment (WEEE) in China. We suggest alternatives to PBDEs and sound management of plastics used in electrical and electronic equipment (EEE) that contain PBDEs. [Copyright &y& Elsevier]

Niazi, J. H., et al. (2015). "In vitro HER2 protein-induced affinity dissociation of carbon nanotube-wrapped anti-HER2 aptamers for HER2 protein detection." Analyst **140**(1): 243-249.

A new in vitro assay was developed to detect human epidermal growth factor receptor 2 (HER2) protein, based on affinity dissociation of carbon nanotube (CNT)-wrapped anti-HER2 ssDNA aptamers. First, we selected an anti-HER2 ssDNA aptamer (H2) using an in vitro serial evolution of ligands by an exponential enrichment (SELEX) process. Then the fluorescently labelled H2 ssDNAs were tightly packed on CNTs that had previously been coupled with magnetic microbeads (MBs), forming MB-CNT-H2 hybrids. The loading capacity of these MB-CNTs heterostructures (2.8 x 10(8)) was determined to be 0.025 to 3.125 muM of H2. HER2 protein-induced H2 dissociation occurred from MB-CNT-H2 hybrids, which was specifically induced by the target HER2 protein, with a dissociation constant (Kd) of 270 nM. The stoichiometric affinity dissociation ratio with respect to H2-to-HER2 protein was shown to be approximately 1 : 1. Our results demonstrated that the developed assay can be an effective approach in detecting native forms of disease biomarkers in free solutions or in biological samples, for accurate diagnosis.

Nichols, J. L., et al. (2010). "The effects of environmental cues on hematopoietic stem cell colony fetal hemoglobin production." Blood. Conference: 52nd Annual Meeting of the American Society of Hematology, ASH **116**(21).

Objective.: Increased fetal hemoglobin (HbF) levels are associated with increased life span and reduced pain crises in patients with Sickle Cell disease. An increased understanding of the mechanisms controlling HbF expression would be important to develop new therapies to increase HbF. The objective of these experiments was to test the hypothesis that interactions between bone marrow (BM) erythroid progenitor cells and the stromal microenvironment influence HbF expression. Materials and Methods.: Baboon CD34+ BM cells were harvested and purified by immunomagnetic column chromatography using the 12.8 anti-CD34 mouse monoclonal antibody and immunomagnetic microbeads conjugated to rat anti-mouse IgM (Miltenyi). CD34+ BM Cells were grown in liquid cultures in Iscove's media containing 30% fetal bovine serum, 200ng/ml stem cell factor, 2u/ml erythropoietin, and 1uM dexamethasone in the presence of an AFT024 mouse fetal liver cell line and an OP9 mouse bone marrow cell line as feeder layers, in methylcellulose media, and in liquid media. Globin chain synthesis in cultures was measured on d11 and d14 by biosynthetic radiolabeling. Cells were incubated overnight in leucine-free alpha-MEM media containing 50uCi/ml [3H leucine]. Globin chains were separated by High Performance Liquid Chromatography (HPLC), and the radioactivity in each fraction was determined by liquid scintillation counting. To correlate changes in gamma-globin expression with DNA methylation of the gamma-globin gene promoter, the methylation state of 5 CpG sites within the gamma-globin promoter region was determined by bisulfite sequencing. Erythroid cells were purified from cultures on d14 by immunomagnetic column chromatography using mouse anti-baboon RBC monoclonal antibody. DNA was isolated from purified erythroid cells using Qiagen kits. Bisulfite modification was performed using Epitect bisulfite kits. Two rounds of PCR amplification were performed using nested primers flanking 5 CpG residues within the baboon gamma-globin gene promoter. Minilysate DNA was prepared from at least 10 independent clones for each sample. Sequence analysis of purified DNA samples was performed at the University of Illinois DNA Sequence facility. Results.: Elevated levels of gamma-globin chain synthesis were observed in cells cultured in methylcellulose and liquid media in the absence of a feeder layer when compared to cells grown in the presence of feeder layers. On d11, the gamma/gamma+beta chain synthetic ratio was 0.623 in cells cultured in methylcellulose and 0.324 in cells cultured in liquid media, compared to 0.092 in cells cultured in the presence of AFT024 feeder layers and 0.178 in cells cultured in the presence of OP9 feeder layers. On d14, the gamma/gamma+beta chain synthetic ratio was 0.663 in cells cultured in methylcellulose and 0.349 in cells cultured in liquid media, compared to 0.135 in cells cultured in the presence of AFT024 feeder layers and 0.252 in cells cultured in the presence of OP9 feeder layers. The level of DNA methylation (%dmC) of 5 sites in the gamma-globin gene promoter negatively correlated with levels of HbF production. On d14, the level of DNA methylation was 79% in cells cultured in methylcellulose, 72% in cells cultured in liquid media, and 97% in cells grown in the presence of AFT024 feeder layers. Conclusions.: Cells grown in the presence of AFT024 feeder layers expressed physiologic levels of gamma-globin and cells grown in the presence of OP9 feeder layers expressed midrange levels of gamma-globin. Significantly increased gamma-globin expression was observed in cells cultured in the absence of a feeder layer. The gamma-globin promoter in cells grown in the presence of the AFT024 feeder layer exhibited a significantly higher degree of methylation than in cells grown in methylcellulose and liquid media. These results show that interactions between erythroid progenitor cells and the stromal microenvironment can influence both the level of gamma-globin expression and the DNA methylation of the gamma-globin gene promoter. These results ave clinical relevance; if the bone marrow microenvironment could be effectively altered in vivo, methylation of the gamma-globin promoter could be decreased and HbF production increased. Further experiments must be performed to determine what is mediating the methylation of the gamma-globin promoter when cells are grown on these feeder layers.

Nie, H., et al. (2019). "Microplastic pollution in water and fish samples around Nanxun Reef in Nansha Islands, South China Sea." Science of the Total Environment **696**: 134022.

Nanxun Reef is one of the typical reefs in Nansha Islands, South China Sea. As the Nansha Islands are surrounded by certain developing countries, the economic and population growth have resulted in increased surface runoff of persistent organic pollutants in offshore areas. Microplastic has been found in many freshwaters and sea areas in recent years. However, the levels of microplastics contamination in Nansha Islands are still uncharted. In this study, 15 water and 35 fish samples were collected around the Nanxun Reef. The average concentration of microplastics was 1733 items/m³ for surface water samples and 3.1 items per individual for fish samples. The majority of ingested microplastics by fish were fibers, mostly transparent or blue. In surface water samples, blue microbeads were the main types of microplastics, accounting for 76.5% of all the detected particles. The main size of microplastics was <0.5mm both in water and fish samples. Our results demonstrated that fishery activities and human domestic sewage might be the dominant sources of microplastic pollution in the Nansha Island, South China Sea.

Niederer, F., et al. (2010). "Pro-inflammatory activity of SIRT1 in monocytes." Arthritis and Rheumatism **10)**: 1528.

Purpose: Sirtuins are a conserved family of NAD+ dependent histone deacetylases (HDAC) and mono-ADP-ribosyltransferases. The human sirtuins are critical regulators of many cellular processes, including cell survival and inflammation. Here we focused on the expression of SIRT1 in monocytes and tissues from patients with rheumatoid arthritis (RA) and osteoarthritis (OA) and assessed the function of SIRT1 in monocytes. Method(s): To study the expression of SIRT1 in RA and OA tissues, Western blot and immunohistochemistry were performed. Monocytes from peripheral blood were negatively isolated from healthy donors or RA patients using magnetic MicroBeads (MACS separation). Levels of SIRT1 mRNA were measured with SYBR green Real-time PCR. Healthy monocytes were stimulated (n=9) with the Toll-like receptor 4 (TLR4) ligand LPS (10 ng/ml) for 8 hours in the presence or absence of a SIRT1 inhibitor, EX-527 (9 uM). Moreover, freshly isolated monocytes (n=5) were transfected to overexpress a wild type or an

enzymatically inactive mutant form of SIRT1 for 18 hours, following LPS-stimulation (10 ng/ml) for 8 hours. The levels of TNF-alpha protein were measured in the supernatants of stimulated monocytes by ELISA (BD Bioscience). Result(s): Performing Western blot analysis of SIRT1 in RA and OA tissues, we found an upregulation of SIRT1 in whole RA tissues. Immunohistochemistry in synovial tissues showed the expression of SIRT1 in monocytes/macrophages. Consistently, levels of SIRT1 mRNA in monocytes from RA patients were expressed at dCt = 7.55 +/- 0.31 and in healthy controls at dCt = 8.69 +/- 0.72, p=0.12. Treatment of LPS-stimulated monocytes with the SIRT1 inhibitor EX-527 significantly reduced TNF-alpha production by 37 +/- 17% (p<0.01). Monocytes transfected with a vector encoding an enzymatically inactive form of SIRT1 showed a prominent downregulation of TNF-alpha by 81 +/- 21% (p=0.04) compared to wild type SIRT1 transfected cells. Conclusion(s): SIRT1 is overexpressed in RA tissues and monocytes. The inhibition of SIRT1 activity significantly reduced the production of TNF-alpha in monocytes. Thus, SIRT1 appears to contribute to the characteristic inflammatory phenotype of synovial cells in rheumatoid arthritis.

Niedoszytko, M., et al. (2013). "Serum markers which could predict the risk of anaphylaxis in mastocytosis patients." Allergy: European Journal of Allergy and Clinical Immunology **97)**: 575.

Background: Patients suffering from mastocytosis are at risk of anaphylactic reactions which occur in 50% of patients with systemic and 15% of patients with cutaneus disease. There are no in vitro methods available which could be used to predict the risk of the reaction so far. The aim of the study was to analyze the cytokines levels in the serum which could indicate patients at risk of anaphylactic reaction. Method(s): Eighty-five patients suffering from systemic mastocytosis and 20 controls were included in the study. Among the mastocytosis patients 54 (63%) declared anaphylactic reaction in the medical history, while 31 (37%) did not suffer from such reaction so far. Cytokine levels (GMCSF, IL-13, IL 1 beta, IL-3, IL-4, IL-6, IL-8, MCP-1, RANTES, TNF-alfa, VEGF, bFGF) were measured in the serum of the patients using flow cytometry and microbead flex set. Result(s): The significant difference was found in the level of IL8 (mean 23.6 +/- 16.6 ng/ml in patients with anaphylaxis) vs (mean 31.3 +/- 63.7 ng/ml in patients without anaphylaxis) P = 0.038. MCP1 (mean 156.4 +/- 165 ng/ml in patients with anaphylaxis) vs (mean 86.2 +/- 45.6 ng/ml in patients without anaphylaxis) P = 0.016. The levels of other measured cytokines did not differ in analyzed populations. Conclusion(s): IL8 and MCP1 levels might be used in the further studies to create an in vitro method assessing the risk of anaphylaxis in mastocytosis patients.

Nies, J. H., et al. (2002). "IL-4 supplemented B-cell cultures of allergic children show reduced IgA and IgG production in response to additional stimulation with IL-10." Journal of Investigational Allergology & Clinical Immunology **12**(2): 99-106.

BACKGROUND: Cytokines play an important role in mediating immunoglobulin switch, the secretion of protective mucosal immunoglobulins, and the development of allergic diseases. This study investigates whether B cells from allergic and healthy children have different capacities to secrete immunoglobulins after stimulation with IL-4, IL-6, IL-10, IL-11, and IL13.

METHODS: We analyzed the peripheral venous blood of 44 healthy probands and of 109 allergic patients with a mean age of 13 years, allergic to grass pollen, birch pollen, and house dust mites. Lymphocytes were isolated by a density gradient and B cells were enriched by using a Magnetic Activated Cell Separator (MACS) and anti-CD19 microbeads. B Cells were co-cultured with human CDw32 (Fc gammaRII) expressing mouse Ltk fibroblasts and mouse anti-human CD40 monoclonal antibodies (CD40 system). The interleukins IL-4, IL-6, IL-10, IL-11, and IL-13 were supplemented in various combinations. After 14 days, concentrations of IgE, IgG, IgA, and IgM

were measured in the supernatants with ELISA.
RESULTS: Suppression of IgA-, IgG, and IgM- synthesis was induced by stimulation of B cells with IL-4. After additional application of IL-10, IgA, IgG, and IgM synthesis was significantly increased. When cultures stimulated with IL-4 were additionally supplemented with IL-10, IgA, and IgG synthesis of B cells obtained from allergic individuals was significantly decreased compared to nonallergic individuals. IgE-secretion of B cells from allergic individuals was significantly increased compared to nonallergic individuals after stimulation with IL-4.
CONCLUSION: Our results implicate that IL-4 is essential for the regulation of immunoglobulin class switch to IgE and that IL-4 is an important cytokine for the development of allergic diseases. The capacity of B cells in allergic children to produce less IgA and IgG in response to additional stimulation with IL-10 of cultures supplemented with IL-4 could play an important role in mediating a mucosal immune system vulnerable to allergens. This phenomenon could contribute to the pathogenesis of allergic diseases.

Niitsu, K., et al. (2019). "A 65-nm CMOS Fully Integrated Analysis Platform Using an On-Chip Vector Network Analyzer and a Transmission-Line-Based Detection Window for Analyzing Circulating Tumor Cell and Exosome." IEEE Transactions on Biomedical Circuits & Systems **13**(2): 470-479.

A fully integrated CMOS circuit based on a vector network analyzer and a transmission-line-based detection window for circulating tumor cell (CTC) and exosome analysis is presented for the first time. We have introduced a fully integrated architecture, which eliminates the undesired parasitic components and enables high-sensitivity, to analyze extremely low-concentration CTC in blood. The detection window was designed on the high-sensitive coplanar waveguide line. To validate the operation of the proposed system, a test chip was fabricated using 65-nm CMOS technology. Measurements were performed after adding a tiny lump of silicone or a droplet of water on its detection window. The measured results show
S_21
degradation of -1.96 dB and -6.04 dB for the silicone and the droplet, respectively, at 1.4 GHz. In addition, in another measurement using magnetic beads, it is confirmed that the proposed circuit can analyze even low concentrations of 20 beads/muL. As well as microbeads, measurement with CTCs was successfully demonstrated.

Nilmayer, O., et al. (2014). "Intravenous administration of human mesenchymal stromal cells (HMSC) in mice results in fragmentation into microvesicles and uptake of the fragments through immune cells." Transfusion Medicine and Hemotherapy **1)**: 22.

Background: In recent years, empirical clinical studies have shown a substantial potency of i.v. injected bone marrow-derived mesenchymal stromal cells (hMSCs) to modulate treatment-resistant graft-versus -host-disease after allogeneic stem cell transplantation. Animal models have suggested a beneficial effect of hMSCs in other diseases, such as inflammatory bowel disease or bacterial sepsis. But the fate of i.v. injected hMSC and exact mechanisms of immunosuppression are not fully understood. Method(s): The behaviour of hMSC in the vasculature was studied using specifically established flow cytometry protocols containing size-calibrated microbeads. In some experiments, we used intravital microscopy in the mouse cremaster model. To track the injected cells, hMSC were previously stained by fluorescent live dye pkh26. Pkh26+MSC were injected i.v. into the C57BL/6J mice, and mice were sacrificed after five min, six hours, one and two days. The organs (lung, liver, spleen, kidney and brain) were isolated, minced and analyzed by flow cytometry. The pkh26+events were re-isolated from the organs by using of magnetic columns separation and fluorescent activated sorting. The mixed

lymphocyte reaction (MLR) was used to study the functions of hMSC derived fragments. Result(s): Five min after i.v. injection, we found about 95% of pkh26+MSC in the lung, whereas no events were detected in the other organs of interest. Six hours after injection, the majority of pkh26+events were detected in the liver and spleen. The diameter of these events was now between 1 and 6 mum. These events were defined as fragments or microvesicles. After 24 and 48 hours, the pkh26+events with diameter over 6 mum were found in the liver and spleen. The analysis of these events by flow cytometry confirmed the hypothesis, that the MSC derived particles were contained in CD11c+ and CD11b+ cells. No phk26+events were found in brain and kidney. Fragmentation of hMSC could also be visualized by using of the intravital microscopy in cremaster muscle model, and under controlled shear in vitro. The immunosuppressive potential of hMSC fragments were analyzed by mixed lymphocyte reaction (MLR). Whereas ex vivo generated hMSC- fragments which were directly added to MLR failed to inhibit T-cell proliferation, uptake of pkh26+ MSCs or parts thereof into dendritic cells was visualized, demonstrating an implicate regulation of dendritic cell function by sequestration of hMSC. Conclusion(s): After i.v. injection, hMSC accumulate in the lungs and are fragmented by the blood stream. The fragments are flushed into the liver and spleen, where they are taken up by phagocytes. The hMSC derived fragments can be classified as microvesicles expressing the same surface markers as hMSC. Our findings help to explain an immunosuppressive function of intravenously injected hMSCs through 1) fragmentation to microvesicles in the blood stream and 2) uptake into CD11b+ and CD11c+ phagocytes.

Nilsen, F., et al. (2014). "Use of indicator chemicals to characterize the plastic fragments ingested by Laysan albatross." Marine Pollution Bulletin **87**(1/2): 230-236.

Laysan albatross (Phoebastria immutabilis) ingest plastic marine debris of a wide range of shape, sizes and sources. To better characterize this plastic and provide insights regarding its provenance and persistence in the environment, we developed a simple method to classify plastic fragments of unknown origin according to the resin codes used by the Society of Plastics Industry. Known plastics were analyzed by gas chromatography-mass spectroscopy (GC-MS) to identify indicator chemicals characteristic of each plastic resin. Application of this method to fragments of ingested plastic debris from boluses of Laysan albatross from Kure Atoll, Hawai'i, yielded proportions of 0.8% High Density Polyethylene, 6.8% Polystyrene, 8.5% Polyethylene Terephthalate, 20.5% Polyvinyl Chloride and 68.4% Polypropylene. Some fragments were composed of multiple resin types. These results suggest that infrequently recycled plastics are the dominant fragments ingested by albatross, and that these are the most prevalent and persistent resin types in the marine environment.

Nimmo, C. (2016). Concern about plastic waste, New South Wales Nurses' Association. **73:** 7-7.

A letter to the editor about the level of plastic waste generated by New South Wales Health is presented.

Nir, R., et al. (1990). "Single-cell entrapment and microcolony development within uniform microspheres amenable to flow cytometry." Applied & Environmental Microbiology **56**(9): 2870-2875.

A method is presented for encapsulating single microbial cells in small spheres suitable for analysis and sorting by flow cytometry. The entrapped cells are able to multiply and form colonies contained within their respective microspheres. The system is based on ejecting the cells suspended in a gellable liquid through an orifice vibrating at ultrasonic frequencies, thus shearing the cell-containing jet into uniform droplets. When low-melting-temperature agarose was used, the droplets could be gelled into solid spheres during flight by appropriately directed

colling air streams. This gelling was accompanied by significant dehydration, resulting in a twofold decrease in bead diameter and a corresponding increase in agarose concentration. Nevertheless, the microbeads obtained were highly uniform and had diameters which could be precisely controlled in the range of 10 to 40 microns. A variety of bacterial and yeast species were entrapped in agarose beads by using this system. In all cases the cells were able to develop into microcolonies containing as many as several hundred cells. This system enables one to apply the powerful method of flow cytometry to the analysis and sorting of whole microbial colonies. Potential applications of this technology in various areas of microbiology are considered.

Nir, R., et al. (1990). "Flow cytometry sorting of viable bacteria and yeasts according to beta-galactosidase activity." Applied & Environmental Microbiology **56**(12): 3861-3866.

We describe a novel method for quantitative measurement of beta-galactosidase (beta-gal) levels in bacteria and yeasts by using flow cytometry, a method which allows viable microbial cells to be sorted on the basis of the expressed activity and to be recultivated. The method is based on encapsulating single cells in agarose microbeads 20 to 30 microns in diameter and analyzing the beta-gal activity of the colonies that develop (containing several hundred cells) by using the fluorogenic substrate fluorescein-di-beta-D-galactopyranoside (FDG). Three strains of Escherichia coli, containing different levels of beta-gal, served as a model system. A high degree of correlation was found between the average fluorescence measured per bead and the level of the enzyme in extracts of the respective strain. Although the use of FDG necessitates cell permeabilization, conditions were found under which a small part of each colony remained viable, yet most of the enzyme was exposed to the substrate. This allowed sorting of microcolonies and plating with close to 100% efficiency. The potential of the technique was demonstrated by selecting beta-gal-positive cells from an artificial mixture of beta-gal-positive and beta-gal-negative E. coli strains.

Nishida, M., et al. (2014). "A new insight into the mechanism of atherosclerosis in hemodialysis patients through the evaluation of scavenger receptor expressions in peripheral monocyte." Nephrology Dialysis Transplantation **3)**: iii234.

Introduction and Aims: Atherosclerosis is accelerated in hemodialysis (HD) patients and closely associated with their morbidity and mortality. The nature of atherosclerosis is considered as chronic sterile micro-inflammation. The class A and B scavenger receptors (SRs) in peripheral monocytes play a key role in promoting foam cell formation by binding and internalizing oxidized low-density lipoprotein (ox-LDL). In addition, macrophage-colony stimulating factor (M-CSF) might facilitate the atherosclerotic process by priming monocytes, predisposed toward SR over-expression. Method(s): Transcriptional levels of SR class A and class B (CD36) were simultaneously measured in peripheral monocytes by quantitative real-time RT-PCR, using the comparative threshold (Ct) [DELTADELTACt] method. GAPDH was chosen as an endogenous reference gene. The fold difference between a patient gene DELTACt and the average of control gene DELTACts was used as an index of relative quantity of the gene (2-DELTADELTACt). Peripheral monocytes were isolated using magnetically-labeled Whole Blood CD14+ MicroBeads (Miltenyi Biotec). Plasma level of M-CSF was measured with an M-CSF ELISA kit (R&D Systems). Subjects included 52 chronic HD patients and 23 healthy controls. The HD patients were classified into 2 groups in presence or absence of prevalent cardiovascular disease (CVD). The statistical difference between the two subjects was analyzed by the Mann-Whitney U test. Result(s): The relative expressions of SR-A and CD36 mRNA were significantly greater in monocytes from HD patients than in those from healthy controls (mean [95% CI of the mean]:

1.76 [2.27-3.26] versus 0.61 [0.88-1.40], P <0.0001; and 1.07 [1.60-2.20] versus 0.52 [0.88-1.32], P=0.0004, respectively). Each SR receptor expression was significantly higher in HD patients who were affected with CVD than in those who were not: SR-A, 1.78 [2.66-3.94] versus 1.30 [1.26-2.48], P=0.0013; and CD36, 1.21 [1.74-2.61] versus 0.55 [1.18-1.69], P=0.0089, respectively. Plasma concentration of M-CSF was approximately 6-fold higher in HD patients than in controls (1044 +/- 266 versus 162 +/- 47.5 pg/ml, P <0.0001). The concentrations were significantly correlated with both mRNA expressions of SR-A (r2 = 0.139, P = 0.0010) and CD36 (r2 = 0.052, P = 0.0478) in overall subjects (n = 75). Conclusion(s): Our study indicates that highly elevated M-CSF concentration may prime peripheral monocytes, and thus may facilitate their uptake of ox-LDL through the over-expression of SRs. This collaboration between M-CSF and SRs could be one of the hidden mechanisms for atherosclerosis in HD patients. Prospective studies are warranted to ascertain the association between SR expression and incidence of CVD. (Figure presented).

Nishiguchi, S., et al. (2003). "Peripheral blood mononuclear cells are possible extrahepatic replication sites for hepatitis C virus." Hepato-Gastroenterology **50**(53): 1301-1304.

BACKGROUND/AIMS: Hepatitis C virus is a major causative agent of chronic liver disease and hepatocellular carcinoma and is considered to be a hepatotropic virus. It remains controversial whether hepatitis C virus exists in peripheral blood mononuclear cells and replicates there. In order to resolve this issue, we performed nested RT-PCR (reverse transcription polymerase chain reaction) and RT-PCR in situ hybridization in peripheral blood mononuclear cells of patients with chronic hepatitis C.

METHODOLOGY: We collected peripheral blood mononuclear cells from patients with chronic hepatitis C, extracted total RNA from the samples, and performed nested RT-PCR to detect hepatitis C virus RNA in the peripheral blood mononuclear cells lysates. We also fixed peripheral blood mononuclear cells of the patients in 4% paraformaldehyde and performed RT-PCR in situ hybridization with a digoxigenin-labeled RNA probe to detect hepatitis C virus RNA in the cells.

RESULTS: Using these methods, we detected both positive- and negative-stranded hepatitis C virus RNA in peripheral blood mononuclear cells of hepatitis C patients. To determine in which cell population of peripheral blood mononuclear cells hepatitis C virus is present, we performed PCR in situ hybridization after incubation with fluorescent latex microbeads which could be phagocytozed by monocytes. We obtained positive signals of the replicative hepatitis C virus genome not only in lymphocytes but also in monocytes.

CONCLUSIONS: RT-PCR in situ hybridization with a nonradioactive probe was found to be useful for in situ detection of hepatitis C virus RNA. Our findings suggest that peripheral blood mononuclear cells may be extrahepatic replication sites for hepatitis C virus.

Nizarudin, S. and B. Deepak (2016). Thermocatalytic degradation: Solution for plastic waste management in Kerala. 2016 IEEE Region 10 Humanitarian Technology Conference, R10-HTC 2016, December 21, 2016 - December 23, 2016, Dayalbagh, Agra, India, Institute of Electrical and Electronics Engineers Inc.

Kerala is struggling with the menace of Plastic Waste management due to its direct effects such as space consumption and littering and aftereffects such as spread of diseases and provision of mosquito breeding. The issue is critical in terms of the social and health implications it is causing especially because of the plastic wastes. This paper sheds light into the current scenario and also suggests a method for the adaptation of thermocatalytic degradation for the disposal of the plastic waste. The suggested methodology is designed particularly to suit the lifestyle of people here with emphasis to energy investment, costs associated and eco-friendliness. The adaptation

is facilitated by the design of a user-friendly and compact equipment which can be installed and run hassle-free. The experiment involves the catalytic degradation of waste plastic at thermal conditions. The vapors so produced are collected and processed thereby obtaining mixed composition of hydrocarbons. 2016 IEEE.

Nizzetto, L., et al. (2016). "A theoretical assessment of microplastic transport in river catchments and their retention by soils and river sediments." Environmental Science. Processes & Impacts **18**(8): 1050-1059.

The presence of microplastics (MPs) in the environment is a problem of growing concern. While research has focused on MP occurrence and impacts in the marine environment, very little is known about their release on land, storage in soils and sediments and transport by run-off and rivers. This study describes a first theoretical assessment of these processes. A mathematical model of catchment hydrology, soil erosion and sediment budgets was upgraded to enable description of MP fate. The Thames River in the UK was used as a case study. A general lack of data on MP emissions to soils and rivers and the mass of MPs in agricultural soils, limits the present work to serve as a purely theoretical, nevertheless rigorous, assessment that can be used to guide future monitoring and impact evaluations. The fundamental assumption on which modelling is based is that the same physical controls on soil erosion and natural sediment transport (for which model calibration and validation are possible), also control MP transport and storage. Depending on sub-catchment soil characteristics and precipitation patterns, approximately 16-38% of the heavier-than-water MPs hypothetically added to soils (e.g. through routine applications of sewage sludge) are predicted to be stored locally. In the stream, MPs < 0.2 mm are generally not retained, regardless of their density. Larger MPs with densities marginally higher than water can instead be retained in the sediment. It is, however, anticipated that high flow periods can remobilize this pool. Sediments of river sections experiencing low stream power are likely hotspots for deposition of MPs. Exposure and impact assessments should prioritize these environments.

Njenga, M., et al. (2013). "Implications of Charcoal Briquette Produced by Local Communities on Livelihoods and Environment in Nairobi Kenya." International Journal of Renewable Energy Development **2**(1): 19.

The residents of Nairobi, Kenya, use 700 tonnes of charcoal per day, producing about 88 tonnes of charcoal dust that is found in most of the charcoal retailing stalls that is disposed of in water drainage systems or in black garbage heaps. The high costs of cooking fuel results in poor households using unhealthy materials such as plastic waste. Further, poor households are opting to cook foods that take a short time to prepare irrespective of their nutritional value. This article presents experiences with community self-help groups producing charcoal fuel briquettes from charcoal dust in poorer nieghbourhoods of Nairobi for home use and sale. Households that produced charcoal fuel briquettes for own use and those that bought them saved 70% and 30% of money spent on cooking energy respectively. The charcoal fuel briquettes have been found to be environmentally beneficial since they produce less smoke and increase total cooking energy by more than 15%, thereby saving an equivalent volume of trees that would be cut down for charcoal. Charcoal briquette production is a viable opportunity for good quality and affordable cooking fuel. Bioenergy and waste management initiatives should promote recovery of organic by-products for charcoal briquette production.

Nnorom, I. C. and O. Osibanjo (2009). "Toxicity characterization of waste mobile phone plastics." Journal of Hazardous Materials **161**(1): 183-188.

Abstract: Waste plastic housing units (N =60) of mobile phones (of different models, and brands), were collected and analyzed for lead, cadmium, nickel and silver using atomic absorption spectrophotometry after acid digestion using a 1:1 mixture of H_2SO_4 and HNO_3. The mean (±S.D.) and range of the results are 58.3±50.4mg/kg (5.0–340mg/kg) for Pb, 69.9±145mg/kg (4.6–1005mg/kg) for Cd, 432±1905mg/kg (5.0–11,000mg/kg) for Ni, and 403±1888mg/kg (5.0–12,500mg/kg) for Ag. Approximately 90% of the results for the various metals were ≤100mg/kg. Results greater than 300mg/kg were generally less than 7% for each metal and could be attributed to exogenous contamination of the samples. These results suggest that there may not be any immediate danger from end-of-life (EoL) mobile phone plastic housing if appropriately treated/managed. However, considering the large quantities generated and the present low-end management practices in most developing countries, such as open burning, there appears a genuine concern over the potential for environmental pollution and toxicity to man and the ecology. Nobre, C. R., et al. (2015). "Assessment of microplastic toxicity to embryonic development of the sea urchin Lytechinus variegatus (Echinodermata: Echinoidea)." Marine Pollution Bulletin **92**(1/2): 99-104.

Apart from the physiological impacts on marine organisms caused by ingesting microplastics, the toxicity caused by substances leaching from these particles into the environment requires investigation. To understand this potential risk, we evaluated the toxicity of virgin (raw) and beach-stranded plastic pellets to the development of embryos of Lytechinus variegatus, simulating transfers of chemical compounds to interstitial water and water column by assays of pellet-water interface and elutriate, respectively. Both assays showed that virgin pellets had toxic effects, increasing anomalous embryonic development by 58.1% and 66.5%, respectively. The toxicity of stranded pellets was lower than virgin pellets, and was observed only for pellet-water interface assay. These results show that (i) plastic pellets act as a vector of pollutants, especially for plastic additives found on virgin particles; and that (ii) the toxicity of leached chemicals from pellets depends on the exposure pathway and on the environmental compartment in which pellets accumulate.

Nocon, W., et al. (2018). "Microplastics in surface water under strong anthropopression." Desalination and Water Treatment **134**: 174-181.

The occurrence of microplastics in the aquatic environment is discussed in the scientific literature mainly in the aspect of "large garbage spots" formed especially in the oceans. It is estimated that about 80% of plastics found in seas and oceans are introduced there via rivers. It seems to be very important the recognition of microplastics problems occurring in rivers and the substantive preparation for taking up the challenges posed by EU legal acts. The research was aimed at identifying the problem of microplastics contamination of surface water subjected to

strong anthropogenic influence. The research objects presented in the article are rivers flowing through urbanized areas. They are characterized by a high degree of transformation of the catchment and riverbed. Samples were taken from the Bytomka River, the Klodnica River and the Bielszowicki Stream. In case of the Bytomka River and the Klodnica River samples were collected upstream and downstream waste water treatment plants (WWTPs). Whereas samples from the Bielszowicki Stream were collected downstream the coal mine. The research showed that typical components of the microplastics in these samples were foil film fragments observed in all sampling points. There were also textile fibers, granules and particles of irregular shape, which are difficult to identify. It has been observed that the amount of microplastics particles is significantly higher in sampling points located under WWTPs. The research shows the need to identify sources of microplastics in surface water and to determine the degree of their harmfulness to aquatic ecosystems.

Nollens, H. H., et al. (2016). "Evaluation of anti-Erysipelothrix rhusiopathiae IgG response in bottlenose dolphins Tursiops truncatus to a commercial pig vaccine." Diseases of Aquatic Organisms **121**(3): 249-256.

Erysipelothrix rhusiopathiae is the causative agent of erysipeloid in humans and of erysipelas in various animals, including bottlenose dolphins Tursiops truncatus, in which an infection has the potential to cause peracute septicemia and death. The purpose of this study was to evaluate the efficacy of using an off-label porcine (ER BAC PLUSReg., Zoetis) E. rhusiopathiae bactrin in a bottlenose dolphin vaccination program by determining the anti-E. rhusiopathiae antibody levels in vaccinated dolphins over a 10 yr period. Serum samples (n=88) were analyzed using a modified fluorescent microbead immunoassay from 54 dolphins, including 3 individuals with no history of vaccination and 51 dolphins with an average of 5 vaccinations, 3 of which had previously recovered from a natural E. rhusiopathiae infection. A mean 311-fold increase in the immunoglobulin G (IgG) antibody index was measured in a subsample of 10 dolphins 14 d after the first booster vaccination. Serum IgG antibody titers were influenced by number of vaccines received (r²=0.47, p<0.05) but not by age, gender, history of natural infection, adverse vaccine reaction, vaccination interval or time since last vaccination. The commercial pig bacterin was deemed effective in generating humoral immunity against E. rhusiopathiae in dolphins. However, since the probability of an adverse reaction toward the vaccine was moderately correlated (p=0.07, r²=0.1) with number of vaccines administered, more research is needed to determine the optimal vaccination interval.

Nolte, M. W., et al. (2012). "Inhibition of coagulation factor XIIa: A promising treatment of embolic silent brain ischemia?" Hamostaseologie **32 (1)**: A27.

Aim: Improving imaging modalities reveal that silent brain ischemia (SBI), thought to be caused by diffuse microembolism from e.g. fragmented thrombi or air, can be observed in many patients after cardiovascular surgeries and invasive vascular interventions. Although its clinical symptoms are initially less tangible, presence of SBI increases the risk of dementia and stroke later in life. However, currently no adequate treatment exists. Therefore, the aim of this research was a) to better understand the pathophysiology of SBI and b) to identify promising therapeutic targets. Method(s): SBI was induced in Balb/c mice by a one-sided injection of either 500 fluorescent microbeads or 10muL of fluorescent fractionated clot into the internal carotid artery. Immediately after SBI induction, rHA-Infestin-4, a recombinant inhibitor of factor (F) XIIa, was injected i.v. in both models (200mg/kg). Then, SPECT-CT imaging of FXIII activity was performed 3 hours later, while MRI of myeloperoxidase (MPO) activity and TTC staining was performed 3 days later (including further daily injections). Presence of fluorescent emboli was

verified by fluorescence imaging and all results were compared to untreated controls. Only mice without overt stroke symptoms were included in the study. Result(s): Using sensitive molecular imaging, we found abnormal activation of the coagulation cascade and inflammation close to where emboli lodge in the brain. In both SBI models, rHA-Infestin-4 significantly reduced ischemic damage (54% (microbead) and 66% (clot) reduction of TTC-negative area) and pathological coagulation (35% (microbead) and 39% (clot) reduction of FXIII activity) without increasing hemorrhagic frequency. MPO activity was unchanged compared to untreated controls. Conclusion(s): Focal intracerebral clotting and inflammatory activity are part of the pathophysiology underlying SBI. Inhibiting FXIIa with rHA-Infestin-4 may present a safe and effective treatment to decrease the morbidity from SBI.

Nolte, T. M., et al. (2017). "The toxicity of plastic nanoparticles to green algae as influenced by surface modification, medium hardness and cellular adsorption." Aquatic Toxicology **183**: 11-20.

To investigate processes possibly underlying accumulation and ecological effects of plastic nano-particles we have characterized their interaction with the cell wall of green algae. More specifically, we have investigated the influence of particle surface functionality and water hardness (Ca²⁺ concentration) on particle adsorption to algae cell walls. Polystyrene nanoparticles with different functional groups (non-functionalized, -COOH and -NH₂) as well as coated (starch and PEG) gold nanoparticles were applied in these studies. Depletion measurements and atomic force microscopy (AFM) showed that adsorption of neutral and positively charged plastic nanoparticles onto the cell wall of P. subcapitata was stronger than that of negatively charged plastic particles.

Nomura, T., et al. (2013). "TGF-beta under non-inflammatory cytokine milieu converts naive CD4+ T cells into thymictype Helios+ regulatory T cells." Journal of Investigative Dermatology **1)**: S27.

CD4+Foxp3+ regulatory T (Treg) cells control various immune responses including contact hypersensitivity, and maintain homeostasis of cutaneous immune system. Adoptive therapy using Treg cells has been proposed to control cutaneous immune diseases. However, clinical use of Treg cells is hampered by contaminated quasi-Treg cells, which abandon their suppressive function by losing Foxp3. Helios, an Ikaros family transcription factor, is a good marker to identify thymic-type Treg cells, which express Foxp3 constitutively and are recognized as bona fide Treg cells. In this study, we aimed to convert naive CD4+ T cells into thymic-type Treg cells that express Helios. To address this issue, we screened optimal condition for conversion in vitro by monitoring the expression of Helios and Foxp3 as their markers. Stimulation with plate-bound anti-CD3epsilon in the presence of TGF-beta/IL-2 converted naive CD4+ T cells into induced-type Treg cells which express Foxp3 but not Helios. Contrary, conversion by anti-CD3epsilon/CD28 conjugated microbeads with TGF-beta/IL-2 resulted in Helios expression in half of the converted (Foxp3+) cells. The latter conversion was dependent on TGF-betaR signaling because SB431542, a TGF-betaR inhibitor, abrogated the expression of both Helios and Foxp3. Furthermore, IFN-gamma induced Helios but inhibited Foxp3 expression while IL-4 inhibited both Helios and Foxp3. Thus, we conclude that TGF-beta under non-inflammatory cytokine milieu converts CD3epsilon/CD28-stimulated naive CD4+ T cells into thymic-type Treg cells. Th1-cytokines seem to engender Helios+ non-regulatory T cell subset whose function and fate remain unexplored. On the other hand, Th2-cytokines interfere conversion. These findings will be exploitable for controlling immune response in the skin.

Nor, N. H. and J. P. Obbard (2014). "Microplastics in Singapore's coastal mangrove ecosystems." Marine Pollution Bulletin **79**(1-2): 278-283.

The prevalence of microplastics was studied in seven intertidal mangroves habitats of Singapore. Microplastics were extracted from mangrove sediments via a floatation method, and then counted and categorized according to particle shape and size. Representative microplastics from Berlayar Creek, Sungei Buloh, Pasir Ris and Lim Chu Kang were isolated for polymer identification using Attenuated Total Reflectance-Fourier Transform Infrared (ATR-FTIR) spectroscopy. Microplastics were identified in all seven habitats, with the highest concentration found in sediments at Lim Chu Kang in the northwest of Singapore. The majority of microplastics were fibrous and smaller than 20 mum. A total of four polymer types were identified, including polyethylene, polypropylene, nylon and polyvinyl chloride. The relationship between abundance of microplastics and sediment grain size was also investigated, but no relationship was apparent. The presence of microplastics is likely due to the degradation of marine plastic debris accumulating in the mangroves.

Nordgreen, A., et al. (2007). "Development of lipid microbeads for delivery of lipid and water-soluble materials to Artema." Aquaculture **273**(4): 614.

Lipid spray beads (LSB) containing high concentrations of phospholipids were produced in order to improve their dispersion in both fresh and saltwater. The beads were developed to deliver both fat-soluble and water-soluble micronutrients to Artemia and other suspension feeders. LSB were prepared by spraying molted lipid into a chamber that was cooled with liquid nitrogen in order to solidify the lipid beads. Addition of soy lecithin to LSB did not affect retention of glycine when the beads were suspended in distilled water. There was an initial loss of 80% incorporated glycine after LSB were suspended in water for 20min. Artemia readily ingested riboflavin-containing LSB and their full guts were evident within 30min of feeding. The riboflavin content of Artemia could be increased from 55 ± 0.6 mg kg^sup -1^ (dw) to 329 ± 62 mg kg^sup -1^ (dw) after 1h enrichment. LSB prepared with phospholipids are promising vehicles for enrichment of suspension-feeding organisms used as feed for larval marine fish and crustaceans as well as other suspension feeders. [PUBLICATION ABSTRACT]

Noriega, V., et al. (2010). "Dynamics of chimerism in regulatory t lymphocytes (Treg; CD4+/CD25+) after allogeneic stem cell transplantation." Blood. Conference: 52nd Annual Meeting of the American Society of Hematology, ASH **116**(21).

Introduction: CD4+CD25+ regulatory T-cells (Treg) play an important role in inducing and maintaining allogeneic tolerance and can inhibit graft-versus-host disease (GVHD) after allogeneic stem cell transplantation (SCT). However, the dynamics of donor and recipient Treg cell populations after Allo-SCT has not been studied yet. Objective(s): To analyze the dynamics of chimerism in Tregs and compare it to that of T lymphocytes (TL; CD3+) and whole blood leukocytes (WBL). Material(s) and Method(s): The study includes 53 patients subjected to Allo-SCT (myeloablative and non-myeloablative). PB samples were obtained weekly during the first month and every 14 days after day +30 until complete chimerism (CC) was achieved, and at fixed time-points (+30, +60, +90, +180, +365) thereafter. TL and Tregs were purified from PB until CC was achieved using inmunomagnetic technology (Miltenyi Biotec; CD3+ Microbeads and CD4+/CD25+ Treg Isolation Kit, respectively). Chimerism analysis was performed by microsatellite PCR (STR-PCR; AmpFlSTR SGM Plus; Applied Biosystems) on genomic DNA obtained from WBL as well as on cell lysates obtained from purified TL and Tregs. Complete chimerism was considered in samples with percentage of recipient cells <1% (sensitivity of the STR-PCR) for WBL samples and <5% (minimum purity of 95% as estimated by flow cytometry) for purified cell lineages. Result(s): Median follow up for the whole cohort of patients was 338 days. CC was spontaneously achieved in WBL, TL and Tregs in 45/53 patients (85%) in a median time of 35.41, 38.8 and 42.5 days respectively. 5/3 patients (9%) suffered from graft failure/rejection showing mixed chimerism (MC) with increasing percentages of recipient cells both in WBL and leukocyte lineages. 3/53 patients (6%) maintained mixed chimerism (MC) in WBL and leukocyte lineages at day +180, with no signs of graft rejection or disease relapse. Analysis of the chimerism dynamics of those patients who spontaneously achieve CC revealed two different groups: Group 1 included 25/45 patients who achieved CC at the same time in WBL, TL and Tregs. Group 2 included 20/45 patients who achieved CC in WBL while maintaining MC in TL and Tregs. Interestingly enough, 9/20 patients from Group 2 maintained MC in Tregs 7-75 days after achieving CC in both WBL and TL (Figure 1). In a preliminary analysis, the small sample size precluded from obtaining statistically significant associations between the dynamics of chimerism in Tregs and the development of complications such as relapse or GVHD after SCT. (Figure presented) Conclusion(s): To our knowledge, this is the first study dealing with Treg chimerism after SCT. We have shown it is feasible and can be performed on a routine basis together with standard lineage specific chimerism follow up. Although there is an association between chimerism dynamics in Tregs and TL, this is not absolute and a percentage of patients maintain residual Tregs of recipient origin after WTL and TL have become of complete donor origin. In this small cohort, Treg chimerism did not influence the development of post-SCT complications. Analysis of a larger and more homogeneous cohort would allow establishing the usefulness of Treg chimerism testing for the management of transplanted patients.

Norrby, K. (2006). "In vivo models of angiogenesis." Journal of Cellular & Molecular Medicine **10**(3): 588-612.

The process of building new blood vessels (angiogenesis) and controlling the propagation of blood vessels (anti-angiogenesis) are fundamental to human health, as they play key roles in wound healing and tissue growth. More than 500 million people may stand to benefit from anti- or pro-angiogenic treatments in the coming decades [National Cancer Institute (USA), Cancer Bulletin, volume 3, no. 9, 2006]. The use of animal models to assay angiogenesis is crucial to the search for therapeutic agents that inhibit angiogenesis in the clinical setting. Examples of persons that would benefit from these therapies are cancer patients, as cancer growth and spread is angiogenesis-dependent, and patients with aberrant angiogenesis in the eye, which may lead to blindness or defective sight. Recently, anti-angiogenesis therapies have been introduced successfully in the clinic, representing a turning point in tumor therapy and the treatment of macular degeneration and heralding a new era for the treatment of several commonly occurring angiogenesis-related diseases. On the other hand, pro-angiogenic therapies that promote compensatory angiogenesis in hypoxic tissues, such as those subjected to ischemia in myocardial or cerebral hypoxia due to occluding lesions in the coronary or cerebral arteries, respectively, and in cases of poor wound healing, are also being developed. In this review, the current major and newly introduced preclinical angiogenesis assays are described and discussed in terms of their specific advantages and disadvantages from the biological, technical, economical and ethical perspectives. These assays include the corneal micropocket, chick chorioallantoic membrane, rodent mesentery, subcutaneous (s.c.) sponge/matrix/alginate microbead, s.c. Matrigel plug, s.c. disc, and s.c. directed in vivo angiogenesis assays, as well as, the zebrafish system and several additional assays. A note on quantitative techniques for assessing angiogenesis in patients is also included. The currently utilized preclinical assays are not equivalent in terms of efficacy or relevance to human disease. Some of these assays have significance for screening, while others are used primarily in studies of dosage-effects, molecular structure activities, and the combined effects of two or more agents on angiogenesis. When invited to write this review, I was asked to describe in some detail the rodent

mesenteric-window angiogenesis assay, which has not received extensive coverage in previous reviews. [References: 158]

Norregaard, P., et al. (1996). "Gastric emptying of pancreatin granules and dietary lipids in pancreatic insufficiency." Alimentary Pharmacology & Therapeutics **10**(3): 427-432.

AIM: To investigate the emptying of enzyme granules and dietary lipids in patients with pancreatic insufficiency secondary to chronic pancreatitis.

PATIENTS AND METHODS: Seven patients with chronic pancreatitis and exocrine pancreatic insufficiency ingested a test meal including colloidal 99m-technetium-radiolabelled liver pate, and swallowed two pancreatin capsules, in which half of the granules had been replaced with 111-indium-radiolabelled plastic particles of comparable physical dimensions. The passage of the two isotopes was followed simultaneously by gamma camera imaging for direct visual judgement and calculation of mean gastric emptying time.

RESULTS: Pancreatin granules and dietary lipids were observed to empty simultaneously. In the duodenum the particles and the test meal were well mixed. Mean gastric emptying time of radiolabelled liver pate and radiolabelled plastic particles could be calculated in six patients. The median of these values were 47 and 43 min, respectively (P = 0.69).

CONCLUSION: Pancreatin granules sized 1.0-1.5 mm seem to empty together with dietary lipids.

Novotna, K., et al. (2019). "Microplastics in drinking water treatment - Current knowledge and research needs." Science of the Total Environment **667**: 730-740.

Microplastics (MPs) have recently been detected in oceans, seas and freshwater bodies worldwide, yet few studies have revealed the occurrence of MPs in potable water. Although the potential toxicological effects of MPs are still largely unknown, their presence in water intended for human consumption deserves attention. Drinking water treatment plants (DWTPs) pose a barrier for MPs to enter drinking water; thus, the fate of MPs at DWTPs is of great interest. This review includes a summary of the available information on MPs in drinking water sources and in potable water, discusses the current knowledge on MP removal by different water treatment processes, and identifies the research needs regarding MP removal by DWTP technologies. A comparison of MPs with other common pollution agents is also provided. We concluded that special attention should be given to small-size MPs (in the range of several micrometres) and that the relationship between MP character and behaviour during distinct treatment processes should be explored.

Nowek, M. (2016). Performance of sand-lime products made with plastic waste. Les Ulis, EDP Sciences. **10**.

The paper describes the studies on the sand-lime (silicate) masonry units modified with recycled plastics in various forms: regranulate, regrind and powder. The following materials were examined: high impact polystyrene (HIPS) and acrylonitrile butadiene styrene (ABS). The results of the functional properties tests, such as compressive strength, softening behavior, bulk density and water absorption are presented in the article. The microstructure of the products was analyzed using SEM and XRD methods.Obtained results show that the properties of modified product largely depend on the type, form and amount of used polymer. The highest compressive strength was achieved with 15% of HIPS regranulate in the product (by weight). ABS does not improve the strength of the sample, however, it does block the capillary action in the sand-lime product. The lowest softening coefficient was obtained in the sample modified with HIPS regranulate. The examined polymers contributed to decrease in bulk density of the samples as well as lowered their water absorption. The samples with pulverized polymer have the worst properties. All the results are compared with those of the traditional sand-lime bricks and sand-lime product modified with other additives. The analysis indicate that silicate masonry units with post-production and post-consumption plastic waste can possess interesting functional properties what brings a new potential possibility to dispose of still growing number of plastic waste.

Nuelle, M. T., et al. (2014). "A new analytical approach for monitoring microplastics in marine sediments." Environmental Pollution **184**: 161-169.

A two-step method was developed to extract microplastics from sediments. First, 1 kg sediments was pre-extracted using the air-induced overflow (AIO) method, based on fluidisation in a sodium chloride (NaCl) solution. The original sediment mass was reduced by up to 80%. As a consequence, it was possible to reduce the volume of sodium iodide (NaI) solution used for the subsequent flotation step. Recoveries of the whole procedure for polyethylene, polypropylene (PP), polyvinyl chloride (PVC), polyethylene terephthalate (PET), polystyrene and polyurethane with sizes of approximately 1 mm were between 91 and 99%. After being stored for one week in a 35% H2O2 solution, 92% of selected biogenic material had dissolved completely or had lost its colour, whereas the tested polymers were resistant. Microplastics were extracted from three sediment samples collected from the North Sea island Norderney. Using pyrolysis gas chromatography/mass spectrometry, these microplastics were identified as PP, PVC and PET.

Nunes Kirchner, C., et al. (2010). "Diffusion and reaction in microbead agglomerates." Analytical Chemistry **82**(7): 2626-2635.

Scanning electrochemical microscopy has been used to analyze the flux of p-aminonophenol (PAP) produced by agglomerates of polymeric microbeads modified with galactosidase as a model system for the bead-based heterogeneous immunoassays. With the use of mixtures of enzyme-modified and bare beads in defined ratio, agglomerates with different saturation levels of the enzyme modification were produced. The PAP flux depends on the intrinsic kinetics of the galactosidase, the local availability of the substrate p-aminophenyl-beta-D-galactopyranoside (PAPG), and the external mass transport conditions in the surrounding of the agglomerate and the internal mass transport within the bead agglomerate. The internal mass transport is influenced by the diffusional shielding of the modified beads by unmodified beads. SECM in combination with optical microscopy was used to determine experimentally the external flux. These data are in quantitative agreement with boundary element simulation considering the SECM microelectrode as an interacting probe and treating the Michaelis-Menten kinetics of the enzyme as nonlinear boundary conditions with two independent concentration variables [PAP] and [PAPG]. The PAPG concentration at the surface of the bead agglomerate was taken as a boundary condition for the analysis of the internal mass transport condition as a function of the enzyme saturation in the bead agglomerate. The results of this analysis are represented as PAP flux per contributing modified bead and the flux from freely suspended galactosidase-modified beads. These numbers are compared to the same number from the SECM experiments. It is shown that depending on the enzyme saturation level a different situation can arise where either beads located at the outer surface of the agglomerate dominate the contribution to the measured external flux or where the contribution of buried beads cannot be neglected for explaining the measured external flux.

Nunes, S., et al. (2007). "Tar Formation and Destruction in a Simulated Downdraft, Fixed-Bed Gasifier: Reactor Design and Initial Results." Energy & Fuels **21**(5): 3028-3035.

A suite of improved technologies is being developed to minimize the environmental impact of biomass/waste fired gasification processes. Downdraft, fixed-bed reactors are particularly favored because of their ability to destroy the majority of tars produced from the fuel volatiles. However, there is some concern about the impact of the low residual tar concentration on the long-term operational reliability. A two-stage laboratory scale fixed-bed reactor has been constructed for studying the release and destruction of tars in downdraft gasifiers. The reactor has been commissioned and its performance demonstrated using several biomass feedstocks. Experiments using the first stage only have shown that as the temperature is raised from 250 to 450 degree C, the gas and tar yields increase at the expense of the char residue. Four different biomass/waste materials (eucalyptus wood, sludge, plastic waste, and silver birch wood) showed qualitatively similar behavior. Volatile yields appear to stabilize around 450 degree C. With silver birch wood, the tar yield reached 47% of the initial fuel. Preliminary tests using a char bed in the second stage have been completed. The presence of the throat and the second-stage char bed results in a substantial reduction in the quantity of tar leaving the reactor. With a hot empty second stage (at 800 degree C), the tar content was reduced to 5.3% (by wt of initial fuel charge) in the exit gas from the reactor. Packing the second stage with char (at 800 degree C) further decreased the tar content to less than 0.1%. Gas analyses have been performed, showing that some of the initial tar is broken down mainly to CO and CH sub(4) in the second stage of the reactor. Further work is in progress to study the impact of the operating conditions in the second stage on the residual tar concentrations and gas analysis.

Núñez, M., et al. (2009). "Temporary structures as a generator of waste in covered trade fairs." Waste Management **29**(7): 2011-2017.

Events like trade fairs are a complex service activity with a considerable economic, social and environmental impact due, among other factors, to their high level of waste generation. There are few studies of the environmental impact associated with waste generation and typology. An environmental analysis methodology has been developed to characterise the waste associated with the temporary structures used at trade fair events: stands and communal spaces. This methodology has been checked in a pilot test at 6 closed trade fairs in Barcelona, with a range of between 60 and 4400 exhibitors. The methodology developed has made possible to obtain a waste generation profile according to the size of the fair and the types of stands. The stages with the largest amount of temporary structure wastes generated are the assembly and the dismantling of the trade fair. The results indicate that the most common wastes generated are the protective plastic from carpets at the assembly stage and the carpet itself at the dismantling stage. The stand carpet is collected in bulk, while the carpet from the communal spaces is recycled. As the size of the fair increases, and with it the proportion of stands with customised design (or non-reusable stands), the quantity of wood and hazardous waste increases. [Copyright &y& Elsevier]

Nunley, D. R., et al. (2013). "Clinical association of humoral and T-lymphocytic rejection responses in human lung transplantation." American Journal of Respiratory and Critical Care Medicine. Conference: American Thoracic Society International Conference, ATS **187**(MeetingAbstracts).

Introduction: Over the last 25 years of human lung transplantation (LTX), acute cellular rejection

(ACR) has been determined by the presence of a perivascular lymphocytic infiltration identified on biopsy specimens of the allograft (T-cell response). Recently, the significance of the recipient's humoral response to the allograft has been explored. The association of these two types of responses and their clinical interaction is uncertain. Method(s): A retrospective review was conducted of LTX recipients who had one or more determinations for the development of donor specific antibodies (DSA). Throughout the first year following LTX, each recipient also had sequential allograft biopsies, some of which were contemporaneous with the DSA determinations. Biopsies were assigned a grade of '0' (no ACR) to '4' (severe ACR). To ascertain the degree of ACR experienced throughout the first year following LTX, an acute rejection score (ARS) was generated for each recipient (cumulative grade of ACR divided by the number of biopsies graded). The DSA assay was performed by incubating the recipient's serum with an array of single antigen micro beads coated with purified single HLA antigen proteins (One Lambda). After incubation with a detector antibody the beads were analyzed for fluorescent signal on a Luminex microarray instrument. Signals greater than 1000 mean fluorescence intensity were interpreted as 'positive' for DSA. Result(s): Fifty-two allograft biopsies and 32 DSA determinations were performed in 11 LTX recipients. Each DSA determination was accompanied by a contemporaneous allograft biopsy. Nine determinations were 'positive' for DSA with the accompanying grades of ACR being: ACR=0 (4), ACR=1 (4), ACR=2 (1), ACR=3 (0), and ACR=4 (0). Of the remaining 23 'negative' determinations, the accompanying ACR grades were: ACR=0 (14), ACR=1 (6), ACR=2 (3), ACR=3 (0), ACR=4 (0). No correlation between the presence of DSA and the grade of ACR was identified (rs = 0.22, p=0.27). The sensitivity and specificity of a 'positive' DSA determination for identifying any non-zero grade of ACR on the biopsy was 41.6% and 75% respectively, while the positive predictive value was 50% and the negative predictive value was 68.2%. The ARS ranged from 0.2 to 2.0, and likewise did not correlate with the presence of DSA (rs = 0.03, p=0.93). Conclusion(s): In LTX the development of a recipient humoral response to donor antigens correlated poorly with the T-cell mediated ACR response. The role of humoral rejection and specifically any association with the T-cell mediated ACR response remains to be clarified.

Nur Khaliesah Abdul, M. and M. Latifah Abd (2018). "Potential recyclable materials derived from riverine litter at log boom Sungai Batu in Kuala Lumpur." The Journal of Material Cycles and Waste Management **20**(2): 1063-1072.

Monitoring the riverine litter was essential for the aesthetical value and reducing the negative impacts toward the human health, environment and socio-economic aspects. Riverine litter is mainly made up from the land-based sources. The lack of historical data on riverine litter generation and composition can affect the efficiency of policy makers in making any decision on riverine litter management plan. The purpose of this study is to assess the quantification of types and abundance of riverine litter at log boom Sungai Batu in Kuala Lumpur. The field sampling has been conducted for 14 days of operation day at log boom Sungai Batu, Kuala Lumpur, within the period month of March until April. The quantification of riverine litter and its composition was based on the time interval during the operation day. The result shows that the Event 3 has recorded the high abundance of riverine litter with 4654.6 kg/operation day. This study also shows that the river is highly dominated with plastic waste with 39% (62.96 ± 15.38 kg/operation day). This study provides the baseline information for the local authority and relevant agencies in reducing the riverine litter which subsequently provide a sustainable environmental and socio-economic condition.

Nurse, R. H., et al. (1976). "Recycling and Disposal of Plastics Waste in South Africa." South Africa

National Scientific Programmes Unit Report No 4, 1976. 14 ref, 13 tab, 2 fig.

Only the main thermoplastic types (high and low density polyethylene, polyvinyl chloride, polystyrene and polypropylene) are recyclable. These plastic types represent 67% of the total consumption of plastics in 1974. Approximately 130 000 tons of plastic waste generated in 1975 were available for recycling. Economic gain for the recycler is the strongest motivation for recycling. Resource conservation, reduction of waste disposal costs and ecological considerations are less important factors. Approximately 15 000 tons, or 12% of recyclable plastic is currently being recycled. A growth rate in recycled plastic of 12.5% per annum is expected until 1981. Due to the fact that plastic wastes provide no special problems in currently used waste disposal systems, it is concluded that there is no need for further research directed specifically at the disposal aspect of plastic in urban waste. (So Afr Water Info Ctr)

Nyangoga, H., et al. (2009). "Synthesis and use of pHEMA microbeads with human EA.hy 926 endothelial cells." Journal of Biomedical Materials Research. Part B, Applied Biomaterials **89**(2): 501-507.

Cancer has become a major problem in public health and the resulting bone metastases a worsening factor. Facing it, different strategies have been proposed and mechanisms involved in tumor angiogenesis are being studied. Enhanced permeability retention (EPR) effect is a key step in designing new anticancer drugs. We have prepared poly 2-hydroxyethyl methacrylate (pHEMA) microbeads to target human endothelial EA.hy 926 cells, a cell line derived from human umbilical vein endothelial cells. Microbeads were synthesized by emulsion precipitation method and carried positive or negative charges. EA.hy 926 cells were cultured in 24-well plates and microbeads were deposited on cells at various times. Scanning and transmission electron microscopy, flow cytometry, confocal microscopy, and three-dimensional (3D) reconstruction were used to characterize microbeads and their location outside and inside cells. Microbeads were uptaken by endothelial cells with a better internalization for negatively charged microbeads. 3D reconstruction of confocal optical sections clearly evidenced the uptake and internalization of microbeads by endothelial cells. pHEMA microbeads could represent potential drug carrier in tumor model of metastases.

Nypelo, T., et al. (2014). "Microbeads and hollow microcapsules obtained by self-assembly of pickering magneto-responsive cellulose nanocrystals." Acs Applied Materials & Interfaces **6**(19): 16851-16858.

Cellulose microbeads can be used as immobilization supports. We report on the design and preparation of magneto-responsive cellulose microbeads and microcapsules by self-assembled shells of cellulose nanocrystals (CNC) carrying magnetic CoFe2O4 nanoparticles, that is, a mixture of isotropic and anisotropic nanomaterials. The magnetic CNCs formed a structured layer, a mesh, consisting of CNCs and magnetic particles bound together on the surface of distinct droplets of hexadecane and styrene dispersed in water. Because of the presence of CNCs the highly crystalline mesh was targeted to provide an improved barrier property of the microbead shell compared to neat polymer shells, while the magnetic particles provided the magnetic response. In situ polymerization of the styrene phase led to the formation of solid microbeads (~8 mum diameter) consisting of polystyrene (PS) cores encapsulated in the magnetic CNC shells (shell-to-core mass ratio of 4:96). The obtained solid microbeads were ferromagnetic (saturation magnetization of ~60 emu per gram of the magnetic phase). The magnetic functionality enables easy separation of substances immobilized on the beads. Such a functionality was tested in removal of a dye from water. The microbeads were further utilized to synthesize hollow microcapsules by solubilization of the PS core. The CNC-based, magneto-responsive solid microbeads and hollow microcapsules were characterized by electron microscopy (morphology), X-ray diffraction (phase composition), and magnetometry (magnetic properties). Such hybrid systems can be used in the design of materials and devices for application in colloidal stabilization, concentration, separation, and delivery, among others.

O'neill, K. M., et al. (2017). "Distinct effects on the dendritic arbor occur by microbead versus bath administration of brain-derived neurotrophic factor." Cellular and Molecular Life Sciences **74**(23): 4369-4385.

Proper communication among neurons depends on an appropriately formed dendritic arbor, and thus, aberrant changes to the arbor are implicated in many pathologies, ranging from cognitive disorders to neurodegenerative diseases. Due to the importance of dendritic shape to neuronal network function, the morphology of dendrites is tightly controlled and is influenced by both intrinsic and extrinsic factors. In this work, we examine how brain-derived neurotrophic factor (BDNF), one of the most well-studied extrinsic regulators of dendritic branching, affects the arbor when it is applied locally via microbeads to cultures of hippocampal neurons. We found that local application of BDNF increases both proximal and distal branching in a time-dependent manner and that local BDNF application attenuates pruning of dendrites that occurs with neuronal maturation. Additionally, we examined whether cytosolic PSD-95 interactor (cypin), an intrinsic regulator of dendritic branching, plays a role in these changes and found strong evidence for the involvement of cypin in BDNF-promoted increases in dendrites after 24 but not 48 h of application. This current study extends our previous work in which we found that bath application of BDNF for 72 h, but not shorter times, increases proximal dendrite branching and that this increase occurs through transcriptional regulation of cypin. Moreover, this current work illustrates how dendritic branching is regulated differently by the same growth factor depending on its spatial localization, suggesting a novel pathway for modulation of dendritic branching locally.

Oana, K., et al. (2015). "Applicability assessment of ceramic microbeads coated with hydroxyapatite-binding silver/titanium dioxide ceramic composite earthplusTM to the eradication of Legionella in rainwater storage tanks for household use." International Journal of Nanomedicine **10**: 4971-4979.

Water environments appear to be the habitats of Legionella species. Legionellosis is considered as a preventable illness because bacterial reservoirs can be controlled and removed. Roof-harvested rainwater has attracted significant attention not only as a groundwater recharge but also as a potential alternative source of nonpotable water. We successfully developed ceramic microbeads coated with hydroxyapatite-binding silver/titanium dioxide ceramic composite earthplusTM using the thermal spraying method. The ceramic microbeads were demonstrated to have bactericidal activities against not only Legionella but also coliform and heterotrophic bacteria. Immersing the ceramic microbeads in household rainwater storage tanks was demonstrated to yield the favorable eradication of Legionella organisms. Not only rapid-acting but also long-lasting bactericidal activities of the ceramic microbead were exhibited against Legionella pneumophila. However, time-dependent attenuation of the bactericidal activities against Legionella were also noted in the sustainability appraisal experiment. Therefore, the problems to be overcome surely remain in constantly managing the Legionella-pollution by means of immersing the ceramic microbeads. The results of our investigation apparently indicate that the earthplusTM-coated ceramic microbeads would become the favorable tool for Legionella measures in household rainwater storage tanks, which may become the natural reservoir for Legionella species. Our investigation would justify further research and data collection to obtain more reliable procedures to microbiologically regulate the Legionella in rainwater storage tanks.

Obbard, R. W., et al. (2014). "Global warming releases microplastic legacy frozen in Arctic Sea ice." Earth's Future **2**(6): 315-320.

When sea ice forms it scavenges and concentrates particulates from the water column, which then become trapped until the ice melts. In recent years, melting has led to record lows in Arctic Sea ice extent, the most recent in September 2012. Global climate models, such as that of Gregory et al. (2002), suggest that the decline in Arctic Sea ice volume (3.4% per decade) will actually exceed the decline in sea ice extent, something that Laxon et al. (2013) have shown supported by satellite data. The extent to which melting ice could release anthropogenic particulates back to the open ocean has not yet been examined. Here we show that Arctic Sea ice from remote locations contains concentrations of microplastics are several orders of magnitude greater than those that have been previously reported in highly contaminated surface waters, such as those of the Pacific Gyre. Our findings indicate that microplastics have accumulated far from population centers and that polar sea ice represents a major historic global sink of man-made particulates. The potential for substantial quantities of legacy microplastic contamination to be released to the ocean as the ice melts therefore needs to be evaluated, as do the physical and toxicological effects of plastics on marine life.

Obeidat, M., et al. (2019). "Optimizing the response, precision, and cost of a DNA double-strand break dosimeter." Physics in Medicine & Biology **64**(10): 10NT02.

We developed a dosimeter that measures biological damage following delivery of therapeutic beams in the form of double-strand breaks (DSBs) to DNA. The dosimeter contains DNA strands that are labeled on one end with biotin and on the other with fluorescein and attached to magnetic microbeads. Following irradiation, a magnet is used to separate broken from unbroken DNA strands. Then, fluorescence is utilized to measure the relative amount of broken DNA and determine the probability for DSB. The long-term goal for this research is to evaluate whether this type of biologically based dosimeter holds any advantages over the conventional techniques. The purpose of this work was to optimize the dosimeter fabrication and usage to enable higher precision for the long-term research goal. More specifically, the goal was to optimize the DNA dosimeter using three metrics: the response, precision, and cost per dosimeter. Six aspects of the dosimeter fabrication and usage were varied and evaluated for their effect on the metrics: (1) the type of magnetic microbeads, (2) the microbead to DNA mass ratio at attachment, (3) the type of suspension buffer used during irradiation, (4) the concentration of the DNA dosimeter during irradiation, (5) the time waited between fabrication and irradiation of the dosimeter, and (6) the time waited between irradiation and read out of the response. In brief, the best results were achieved with the dosimeter when attaching 4.2 micro g of DNA with 1 mg of MyOne T1 microbeads and by suspending the microbead-connected DNA strands with 200 micro l of phosphate-buffered saline for irradiation. Also, better results were achieved when waiting a day after fabrication before irradiating the dosimeter and also waiting an hour after irradiation to measure the response. This manuscript is meant to serve as guide for others who would like to replicate this DNA dose measurement technique.

Oberbeckmann, S., et al. (2017). "Environmental Factors Support the Formation of Specific Bacterial Assemblages on Microplastics." Frontiers in Microbiology **8**: 2709.

While the global distribution of microplastics (MP) in the marine environment is currently being critically evaluated, the potential role of MP as a vector for distinct microbial assemblages or even pathogenic bacteria is hardly understood. To gain a deeper understanding, we investigated how different in situ conditions contribute to the composition and specificity of MP-associated bacterial communities in relation to communities on natural particles. Polystyrene (PS), polyethylene (PE), and wooden pellets were incubated for 2 weeks along an environmental gradient, ranging from marine (coastal Baltic Sea) to freshwater (waste water treatment plant, WWTP) conditions. The associated assemblages as well as the water communities were investigated applying high-throughput 16S rRNA gene sequencing. Our setup allowed for the first time to determine MP-dependent and -independent assemblage factors as subject to different environmental conditions in one system. Most importantly, plastic-specific assemblages were found to develop solely under certain conditions, such as lower nutrient concentration and higher salinity, while the bacterial genus Erythrobacter, known for the ability to utilize polycyclic aromatic hydrocarbons (PAH), was found specifically on MP across a broader section of the gradient. We discovered no enrichment of potential pathogens on PE or PS; however, the abundant colonization of MP in a WWTP by certain bacteria commonly associated with antibiotic resistance suggests MP as a possible hotspot for horizontal gene transfer. Taken together, our study clarifies that the surrounding environment prevailingly shapes the biofilm communities, but that MP-specific assemblage factors exist. These findings point to the ecological significance of specific MP-promoted bacterial populations in aquatic environments and particularly in plastic accumulation zones.

Oberbeckmann, S., et al. (2015). "Marine microplastic-associated biofilms - a review." Environmental Chemistry **12**(5): 551-562.

The accumulation of plastic in the marine environment is a long-known issue, but the potential relevance of this pollution for the ocean has been recognised only recently. Within this context, microplastic fragments (<5 mm) represent an emerging topic. Owing to their small size, they are readily ingested by marine wildlife and can accumulate in the food web, along with associated toxins and microorganisms colonising the plastic. We are starting to understand that plastic biofilms are diverse and are, comparably with non-plastic biofilms, driven by a complex network of influences, mainly spatial and seasonal factors, but also polymer type, texture and size of the substratum. Within this context, we should raise the question about the potential of plastic particles to serve as vectors for harmful microorganisms. The main focus of the review is the discussion of first insights and research gaps related to microplastic-associated microbial biofilm communities.

Oberbeckmann, S., et al. (2014). "Spatial and seasonal variation in diversity and structure of microbial biofilms on marine plastics in Northern European waters." FEMS Microbiology Ecology **90**(2): 478-492.

Plastic pollution is now recognised as a major threat to marine environments and marine biota. Recent research highlights that diverse microbial species are found to colonise plastic surfaces (the plastisphere) within marine waters. Here, we investigate how the structure and diversity of marine plastisphere microbial community vary with respect to season, location and plastic substrate type. We performed a 6-week exposure experiment with polyethylene terephthalate (PET) bottles in the North Sea (UK) as well as sea surface sampling of plastic polymers in Northern European waters. Scanning electron microscopy revealed diverse plastisphere communities comprising prokaryotic and eukaryotic microorganisms. Denaturing gradient gel electrophoresis (DGGE) and sequencing analysis revealed that plastisphere microbial communities on PET fragments varied both with season and location and comprised of bacteria belonging to Bacteroidetes, Proteobacteria, Cyanobacteria and members of the eukaryotes Bacillariophyceae and Phaeophyceae. Polymers sampled from the sea surface mainly comprised polyethylene, polystyrene and polypropylene particles. Variation within plastisphere communities on different polymer types was observed, but communities were primarily dominated by Cyanobacteria. This research reveals that the composition of plastisphere microbial communities in marine waters varies with season, geographical location and plastic substrate type.

Obradovic, B., et al. (2012). "Novel alginate based nanocomposite hydrogels with incorporated silver nanoparticles." Journal of Materials Science-Materials in Medicine **23**(1): 99-107.

Alginate colloid solution containing electrochemically synthesized silver nanoparticles (AgNPs) was investigated regarding the nanoparticle stabilization and possibilities for production of alginate based nanocomposite hydrogels in different forms. AgNPs were shown to continue to grow in alginate solutions for additional 3 days after the synthesis by aggregative mechanism and Ostwald ripening. Thereafter, the colloid solution remains stable for 30 days and could be used alone or in mixtures with aqueous solutions of poly(vinyl alcohol) (PVA) and poly(N-vinyl-2-pyrrolidone) (PVP) while preserving AgNPs as verified by UV-Vis spectroscopy studies. We have optimized techniques for production of Ag/alginate microbeads and Ag/alginate/PVA beads, which were shown to efficiently release AgNPs decreasing the Escherichia coli concentration in suspensions for 99.9% over 24 h. Furthermore, Ag/hydrogel discs based on alginate, PVA and PVP were produced by freezing-thawing technique allowing adjustments of hydrogel composition and mechanical properties as demonstrated in compression studies performed in a biomimetic bioreactor.

Occhionero, M. A., et al. (2019). "Biodegradation of silobags by the wax moth larvae of Achroia grisella F. and Galleria mellonella L. (Lepidoptera, Pyralidae)." Biocell. Conference: 35th Annual Scientific Meeting of the Tucuman Biology Association. Argentina. **43**(Supplement 1).

Human consumption leads to an excess of plastic waste on the planet that results in 5,700 million tons not recycled per year. Some insects are able to consume and degrade plastics. In Tucuman, we recorded larvae of the moths Achroia grisella F. and Galleria mellonella L. (Pyralidae, Lepidoptera) consuming silobags (SB). Although we do not know the origin and mechanisms of plastic degrading enzymes, they could be related to bacteria on the body surface or in the digestive tract of larvae. The objectives of our work were to determine if the degrading agents are on the surface of the larvae and to evaluate differences in SB consumption among larvae bathed with antibiotics. To eliminate the superficial microbiota, we washed larvae with 6 (A. grisella) and 7 (G. melonella) antibiotics plus a control group (n=6-10 per treatment, respectively). We monitored the development of each larva in Petri dishes containing previously weighted SB disks. Comparing the initial vs. final SB weights, we did not find significant differences in SB consumption by species between treatments and control, but the larvae completed their development. We conclude that the degrading bacteria are not found in the body surface of the larvae and that this activity would be due to agents in the digestive tract. We are currently isolating the microbiota of the digestive tract for identification and studying the chemical composition of larval feces.

O'Connor, D., et al. (2019). "Microplastics undergo accelerated vertical migration in sand soil due to small size and wet-dry cycles." Environmental Pollution **249**: 527-534.

Microplastics (MPs) are an emerging concern and potential risk to marine and terrestrial environments. Surface soils are reported to act as a sink. However, MP vertical mobility in the subsurface remains uncertain due to a lack of scientific data. This study focused on MP penetration in sand soil column experiments. Here we report the mobility of five different MPs, which consisted of polyethylene (PE) and polypropylene (PP) particles of various sizes and densities. We observed that the smallest sized PE MPs (21mum) had the greatest movement potential. Moreover, it was found that when these MPs were subjected to greater numbers of wet-dry cycles, the penetration depth significantly increased, with an apparent linear relationship between depth and wet-dry cycle number (r²=0.817). In comparison, increasing the volume of infiltration liquid or the surface MP concentration had only negligible or weak effects on migration depth (r²=0.169 and 0.312, respectively). Based on the observed wet-dry cycle trend, we forecast 100-year penetration depths using weather data for 347 cities across China. The average penetration depth was calculated as 5.24m (95% CI=2.78-7.70m), with Beijing Municipality and Hebei, Henan and Hubei provinces being the most vulnerable to MP vertical dispersion. Our results suggest that soils may not only represent a sink for MPs, but also a feasible entryway to subsurface receptors, such as subterranean fauna or aquifers. Finally, research gaps are identified and suggested research directions are put forward to garner a better understanding MP vertical migration in soil.

Odabas, S., et al. (2008). "Separation of mesenchymal stem cells with magnetic nanosorbents carrying CD105 and CD73 antibodies in flow-through and batch systems." Journal of Chromatography B: Analytical Technologies in the Biomedical & Life Sciences **861**(1): 74-80.

The aim of this study is to develop magnetically loaded nanosorbents carrying specific monoclonal antibodies (namely CD105 and CD73) for separation of mesenchymal stem cells from cell suspensions. Super-paramagnetic magnetite (Fe3O4) nanoparticles were produced and then coated with a polymer layer containing carboxylic acid functional groups (average diameter: 153 nm and polydispersity index: 0.229). In order to obtain the nanosorbents, the monoclonal antibodies were immobilized via these functional groups with quite high coupling efficiencies up to 80%. These nanosorbents and also a commercially available one (i.e., microbeads carrying CD105 antibodies from Miltenyi Biotec., Germany) were used for separation of CD105+ and CD73+ mesenchymal stem cells from model cell suspension composed of peripheral blood (97.6%), human bone marrow cells (1.2%) and fibroblastic cells (1.2%). The initial concentrations of the CD105+ and CD73+ cells in this suspension were measured as 5.86% and 6.56%, respectively. A flow-through separation system and a very simple homemade batch separator unit were used. We were able to increase the concentration of CD105+ cells up to about 86% in the flow-through separation system with the nanosorbents produced in this study, which was even significantly better than the commercial one. The separation efficiencies were also very high, especially for the CD73+ cells (reached to about 64%) with the very simple and inexpensive homemade batch unit.

Odeku, O. A., et al. (2013). "Microbead design for sustained drug release using four natural gums." International Journal of Biological Macromolecules **58**: 113-120.

Four natural gums, namely albizia, cissus, irvingia and khaya gums have been characterized and evaluated as polymers for the formulation of microbeads for controlled delivery of diclofenac sodium. The natural gums were characterized for their material properties using standard methods. Diclofenac microbeads were prepared by ionotropic gelation using gel blends of the natural gums and sodium alginate at different ratios and zinc chloride solution (10%w/v) as the crosslinking agent. The microbeads were assessed using SEM, swelling characteristics, drug entrapment efficiencies and release properties. Data obtained from in vitro dissolution studies were fitted to various kinetic equations to determine the kinetics and mechanisms of drug release, and the similarity factor, f2, was used to compare the different formulations. The results showed that the natural gum polymers varied considerably in their material properties. Spherical and discrete microbeads with particle size of 1.48-2.41 mum were obtained with

entrapment efficiencies of 44.0-71.3%w/w. Drug release was found to depend on the type and concentration of polymer gum used with formulations containing gum:alginate ratio of 3:1 showing the highest dissolution times. Controlled release of diclofenac was obtained over for 5h. Drug release from the beads containing the polymer blends of the four gums and sodium alginate fitted the Korsmeyer-Peppas model which appeared to be dependent on the nature of natural gum in the polymer blend while the beads containing alginate alone fitted the Hopfenberg model. Beads containing albizia and cissus had comparable release profiles to those containing khaya (f2>50). The results suggest that the natural gums could be potentially useful for the formulation controlled release microbeads.

Odeku, O. A., et al. (2014). "Formulation and in vitro evaluation of natural gum-based microbeads for delivery of ibuprofen." Tropical Journal of Pharmaceutical Research **13**(10): 1577-1583.

Purpose: To investigate the effectiveness of three natural gums, namely albizia, cissus and khaya gums, as excipients for the formulation of ibuprofen microbeads. Methods: Ibuprofen microbeads were prepared by the ionotropic gelation method using the natural gums and their blends with sodium alginate at various concentrations using different chelating agents (calcium chloride, zinc chloride, calcium acetate and zinc acetate) at different concentrations. Microbeads were assessed using SEM, swelling characteristics, drug entrapment efficiencies, release properties and drug release kinetics. Results: The natural gums alone could not form stable microbeads in the different chelating agents. Stable small spherical discrete microbeads with particle size of 1.35 +/- 0.11 to 1.78 +/- 0.11 mm, were obtained using the blends of natural gum: alginate at total polymer concentration of 2% w/v using 10% w/v calcium chloride solution at a stirring speed of 300 rpm. The encapsulation efficiencies of the microbeads ranged from 35.3 to 79.8% and dissolution times, t<inf>15</inf> and t<inf>80</inf> increased with increase in the concentration of the natural gums present in the blends. Controlled release was obtained for over 4 h and the release was found to be by a combination of diffusion and erosion mechanisms from spherical formulations. Conclusion: The three natural gums would be useful in the formulation of ibuprofen microbeads and the type and concentration of natural gum in the polymer blend can be used to modulate the release properties of the microbeads. Odigure, J. O., et al. (2015). "Synthesis and Characterization of Lubricant Additives From Waste Plastic." Energy Sources Part A: Recovery, Utilization & Environmental Effects **37**(17): 1846-1852.

This study attempted to synthesize and characterize engine oil additives from plastic waste, i.e., low density polyethylene, high density polyethylene, and poly propylene for the purpose of improving the viscosity index and pour point of engine oils. To do this, the starting polymers were reacted with maleic anhydride in a chain growth addition polymerization. The reactions took place in a muffle furnace at 230°C. The product poly (alkenymaleic anhydride) was then reacted with a glycerol at 140°C in a step growth addition polyesterification in the presence of xylene and nitrogen. The product formed, i.e., monoester acid, was then reacted with diethylene triamine in a step growth condensation polyamidation to produce the additive. The results obtained showed that the utilization of the additive produced from poly propylene as an additive on the base oils, i.e., SN150, SN500, BS 150 and commercially available oil (YT3513), gave the best results. The optimum blending concentration of 60 g/dl was achieved for the base oils except BS 150, which was 50 g/dl. Results also indicated that the optimum weight percentage of the blended additives was 3 wt%, while the optimum viscosity index was 162, 160, 159, and 186 corresponding to an increment of 80, 64.42, 36.76, and 36. 76% for SN150, SN500, BS150, and YT3513, respectively. [ABSTRACT FROM PUBLISHER]

O'Donnell, B. and E. Lee (2019). "Characterizing Microplastic Fibers Using Raman Spectroscopy." Spectroscopy **34**(s6): 32-34,36-40.

Microplastics have become a growing area of research, as concern over harm to the environment, and potential harm to humans, has increased. Recently, legislation passed in California has mandated the testing for, and reporting of, plastic in drinking water (SB 1422). In this study, Raman spectroscopy is used to characterize two different commercial fabric fiber samples that include synthetic polymer materials. Both macro- and microscopic Raman measurements are carried out, and chemical identification of the individual components is made through database searches. Raman microscopy is demonstrated as a powerful technique for microplastic fiber characterization, especially for samples that contain mixtures of components, including multiple polymers, or additives.

O'Driscoll, K. K. M., et al. (2009). "The effect of floor surface on dairy cow immune function and locomotion score." Journal of Dairy Science **92**(9): 4249-4261.

This study evaluated the effect of 2 dairy cow housing systems on cow locomotion, immune status, and expression of genes associated with lameness during the dry and periparturient periods. Cows were assigned to freestall housing with either rubber (RUB; n=13) or concrete (CON; n=14) at the feed-bunk and alley immediately after their first calving, and managed on this system during all subsequent lactations. At dry off, cows were moved to a straw bedded-pack dry cow pen, and remained there until about 2 d before subsequent calving. To investigate whether greater exposure to RUB or CON increased the differences between cows on each treatment, cows at the end of either their first (n=16) or second (n=11) lactations were included in the experiment. Locomotion scores and blood samples were obtained at -60 (beginning of the dry period), -30, 0 (after calving), +10 and +18 d relative to calving. Leukocyte counts were obtained by using an automated cell counter. Phagocytic activity, and cells positive for CD14 and CD18 expression were measured by flow cytometry using labeled microbeads and antibodies. Expression of tachikinin 1(TAC1), histamine receptor 1 (H1), and metalloproteinase (MMP)13 in blood leukocytes was estimated using quantitative real-time PCR. Treatment effects were determined using a repeated measures model. Provision of rubber flooring did not improve dairy cow locomotion during the subsequent study period. However, time relative to calving had an effect on locomotion score and speed, which were worst on d 0, probably because of the discomfort associated with calving. An interaction occurred between treatment and time for neutrophil and lymphocyte counts. The RUB cows had greater neutrophil and lesser lymphocyte numbers postpartum than CON. These cows also had more cells positive for CD14 postpartum compared with prepartum. Moreover, RUB cows showed upregulation of MMP13 and TAC1 compared with CON. These genes are associated with lameness and pain detection respectively. Greater neutrophil to lymphocyte ratios and CD14 expression are associated with physiological stress or with activated immunity. Rubber flooring is associated with an increase in activity and standing. This may have resulted in indications of physiological stress and upregulation of genes associated with lameness and pain for RUB cows. However, this study did

not take into account the long-term effects of concrete or rubber flooring; for instance, occurrence of lameness or survivability within the herd.

Odumeru, J., et al. (2001). "Use of the bead beater for preparation of Mycobacterium paratuberculosis template DNA in milk." Canadian Journal of Veterinary Research **65**(4): 201-205.

Mycobacterium paratuberculosis is a recognized chronic enteric pathogen that can affect many different species of animals, including primates. It has been suggested that this organism is associated with Crohn's disease in humans, and that milk is a potential source of human exposure to this organism. The limit of the detection of M. paratuberculosis in milk samples by direct PCR was 10(5) cfu/mL if the traditional boiling method was used for template DNA preparation. In this study, an improved method for template DNA preparation was examined. The method involves the use of a bead beater, which breaks up bacterial cell wall mechanically by vibrating bacteria with microbeads at high speed. The effectiveness of this method for lysing M. paratuberculosis cells was compared to that of the freeze-thaw method, and use of commercial kits such as the InstaGene Matrix and the QIAamp Tissue Kit. The bead beater procedure was tested in combination with various cell lysis and template DNA preparation procedures to determine which of these steps improved the limit of detection of PCR assay that amplifies a 413 bp fragment of the IS900 gene.

Odun-Ayo, F., et al. (2015). "Chemoprevention of azoxymethane-induced colonic carcinogenesis in Balb/c mice using a modified pectin alginate probiotic." Anticancer Research **35**(9): 4765-4775.

Background: Increased intake of probiotic dietary fibre reduces colonic cancer risk. Modified citrus pectin (MCP) requires optimal bioactivity to inhibit galectin-3 (GAL-3) and vascular endothelial growth factor (VEGF). This study evaluated the preventative effect of modified pectin alginate (MCPA) probiotic microbeads on azoxymethane (AOM)-induced colonic carcinogenesis in Balb/c mice. Materials and Methods: Optimization of AOM dose duration: 10-15 mg/kg was administered for 2-4 weeks. The optimal AOM dose was initiated prior to intake of MCPA, alginate probiotic (AP) microbeads and MCP in Balb/c mice for 16 weeks; samples were analyzed for colonic histopathology and immunohistochemistry.

Odun-Ayo, F., et al. (2016). "Improving the survival of probiotic in simulated conditions and azoxymethane-induced colon tumour bearing mice using modified citrus pectin-alginate microencapsulation." African Journal of Traditional, Complementary and Alternative Medicines **13**(2): 101-109.

Background: For a probiotic to be viable it needs to be preserved at a recommended minimum level of 6-7 log₁₀ cfu/g in the product being consumed, as suggested by the International Dairy Federation. Different biopolymer matrices have been used for encapsulation of probiotic; however, loss of viability is still a challenge. Materials and Methods: Modified citrus pectin-alginate microbeads containing Lactobacillus acidophilus ATCC 4356 was developed. Efficiency of the microbeads was evaluated in simulated conditions of the gastrointestinal tract and in Balb/c mice induced with colon tumor. Genomic identification of faecal lactobacilli samples from treated mice was also performed.

Oertel, M., et al. (2007). "Comparison of hepatic properties and transplantation of Thy-1⁺ and Thy-1⁻ cells isolated from embryonic day 14 rat fetal liver." Hepatology **46**(4): 1236-1245.

Thy-1, a marker of hematopoietic progenitor cells, is also expressed in activated oval cells of rat liver. Thy-1⁺ cells are also in rat fetal liver and exhibit properties of bipotent

hepatic epithelial progenitor cells in culture. However, no information is available concerning liver repopulation by Thy-1⁺ fetal liver cells. Therefore, we isolated Thy-1⁺ and Thy-1⁻ cells from embryonic day (ED) 14 fetal liver and compared their gene expression characteristics in vitro and proliferative and differentiation potential after transplantation into adult rat liver. Fetal liver cells selected for Thy-1 expression using immunomagnetic microbeads were enriched from 5.2%-87.2% Thy-1⁺. The vast majority of alpha fetoprotein⁺, albumin⁺, cytokine-19⁺, and E-cadherin⁺ cells were found in cultured Thy-1⁻ cells, whereas nearly all CD45⁺ cells were in the Thy-1⁺ fraction. In normal rat liver, transplanted Thy-1⁺ cells produced only rare, small DPPIV⁺ cell clusters, very few of which exhibited a hepatocytic phenotype. In retrorsine-treated liver, transplanted Thy-1 ⁺ fetal liver cells achieved a 4.6%-23.5% repopulation. In contrast, Thy-1⁻ fetal liver cells substantially repopulated normal adult liver and totally repopulated retrorsine-treated liver. Regarding the stromal cell-derived factor (SDF)-1/chemokine (C-X-C motif) receptor 4 (CXCR4) axis for stem cell homing, Thy-1⁺ and Thy-1⁻ fetal hepatic epithelial cells equally expressed CXCR4. However, SDF-1alpha expression was augmented in bile ducts and oval cells in retrorsine/partial hepatectomy-treated liver, and this correlated with liver repopulation by Thy-1⁺ cells. Conclusion(s): Highly enriched Thy-1⁺ ED14 fetal liver cells proliferate and repopulate the liver only after extensive liver injury and represent a fetal hepatic progenitor cell population distinct from Thy-1⁻ stem/progenitor cells, which repopulate the normal adult liver. Ogonowski, M., et al. (2018). "Evidence for selective bacterial community structuring on microplastics." Environmental Microbiology **20**(8): 2796-2808.

In aquatic ecosystems, microplastics are a relatively new anthropogenic substrate that can readily be colonized by biofilm-forming organisms. To examine the effects of substrate type on microbial community assembly, we exposed ambient Baltic bacterioplankton to plastic substrates commonly found in marine environments (polyethylene, polypropylene and polystyrene) as well as native (cellulose) and inert (glass beads) particles for 2 weeks under controlled conditions. The source microbial communities and those of the biofilms were analyzed by Illumina sequencing of the 16S rRNA gene libraries. All biofilm communities displayed lower diversity and evenness compared with the source community, suggesting substrate-driven selection. Moreover, the plastics-associated communities were distinctly different from those on the non-plastic substrates. Whereas plastics hosted greater than twofold higher abundance of Burkholderiales, the non-plastic substrates had a significantly higher proportion of Actinobacteria and Cytophagia. Variation in the community structure, but not the cell abundance, across the treatments was strongly linked to the substrate hydrophobicity. Thus, microplastics host distinct bacterial communities, at least during early successional stages.

Ogonowski, M., et al. (2016). "The Effects of Natural and Anthropogenic Microparticles on Individual Fitness in Daphnia magna." PLoS ONE **11**(5).

Concerns are being raised that microplastic pollution can have detrimental effects on the feeding of aquatic invertebrates, including zooplankton. Both small plastic fragments (microplastics, MPs) produced by degradation of larger plastic waste (secondary MPs; SMPs) and microscopic plastic spheres used in cosmetic products and industry (primary MPs; PMPs) are ubiquitously present in the environment. However, despite the fact that most environmental MPs consist of weathered plastic debris with irregular shape and broad size distribution, experimental studies of organism responses to MP exposure have largely used uniformly sized spherical PMPs. Therefore, effects observed for PMPs in such experiments may not be representative for MP-effects in situ. Moreover, invertebrate filter-feeders are generally well adapted to the presence of refractory material in seston, which questions the potential of MPs at environmentally relevant concentrations to measurably affect digestion in these organisms. Here, we compared responses to MPs (PMPs and SMPs) and naturally occurring particles (kaolin clay) using the cladoceran Daphnia magna as a model organism. We manipulated food levels (0.4 and 9 µg C mL-1) and MP or kaolin contribution to the feeding suspension (<1 to 74%) and evaluated effects of MPs and kaolin on food uptake, growth, reproductive capacity of the daphnids, and maternal effects on offspring survival and feeding. Exposure to SMPs caused elevated mortality, increased inter-brood period and decreased reproduction albeit only at high MP levels in the feeding suspension (74% by particle count). No such effects were observed in either PMP or kaolin treatments. In daphnids exposed to any particle type at the low algal concentration, individual growth decreased by ~15%. By contrast, positive growth response to all particle types was observed at the high algal concentration with 17%, 54% and 40% increase for kaolin, PMP and SMP, respectively. When test particles comprised 22% in the feeding suspension, both MP types decreased food intake by 30%, while kaolin had no effect. Moreover, SMPs were found to homoaggregate in a concentration-dependent manner, which resulted in a 77% decrease of the ingested SMPs compared to PMPs. To better understand MP-processing in the gut, gut passage time (GPT) and evacuation rate of MPs were also assayed. SMPs and PMPs differed in their effects on daphnids; moreover, the particle effects were dependent on the MP: algae ratio in the suspension. When the MP contribution to the particle abundance in the medium changed from 1 to 4%, GPT for daphnids exposed to SMPs increased 2-fold. Our results suggest that MPs and, in particular, SMPs, have a greater capacity to negatively affect feeding in D. magna compared to naturally occurring mineral particles of similar size. Moreover, grazer responses observed in experiments with PMPs cannot be extrapolated to the field where SMPs dominate, because of the greater effects caused by the latter.

Ogonowski, M., et al. (2019). "Microplastic Intake, Its Biotic Drivers, and Hydrophobic Organic Contaminant Levels in the Baltic Herring." Frontiers in Environmental Science.

It is commonly accepted that microplastic (MP) ingestion can lead to lower food intake and bioaccumulation of hydrophobic organic contaminants (HOCs) in aquatic organisms. However, causal links between MP and contaminant levels in biota are poorly understood and in situ data are very limited. Here, we investigated whether HOC concentrations in herring muscle tissue (Clupea harengus membras) are related to MP ingestion using fish caught along the West coast of the Baltic Sea. The MP occurrence exhibited a large geographic variability, with MP found in 22.3% of the fish examined, and the population average being 0.9 MP ind-1. However, when only individuals containing MP were considered, the average MP burden was 3.9 MP ind-1. We also found that MP burden decreased with reproductive stage of the fish but increased with its body size. To predict MP abundance in fish guts, we constructed a mass-balance model using literature data on MP in the water column and physiological rates on ingestion and gut evacuation for clupeids of a similar size. The model output was in agreement with the observed values, thus supporting the validity of the results. Contaminant concentrations in the muscle tissue varied substantially across the study area but were unrelated to the MP levels in fish, suggesting a lack of direct links between the levels of HOCs and MP ingestion. Thus, despite

their ubiquity, MP are unlikely to have a measurable impact on food intake or the total body burden of hydrophobic contaminants in Baltic herring.

Ogret, Y., et al. (2014). "Investigation of lineage-specific and peripheral blood chimerism analysis in post-stem cell transplant patients." Tissue Antigens **84 (1)**: 55-56.

Monitoring engraftment is a key part of post-transplant treatment. Post-transplant chimerism may predict graft versus host disease (GVHD) but not relapse in patients undergoing allogeneic transplantation. Monitoring chimerism after transplant consecutively can also early document unstable mixed chimerism and rejection, which provide the basis for donor lymphocyte infusion (DLI). In the early post-transplant period, co-existence of host and donor cells can develop, especially in case of a reduced intensity conditioning (RIC) regimen. This status is referred to as mixed chimerism, whereas complete donor chimerism denotes the situation where all cell lineages are reconstituted by donor-derived cells. In this study, we analyzed the chimerism status of T cells and B cells allo-SCT patients by using multiplex STR-PCR and determined the correlation between these results and the clinical outcome, including cumulative incidence of GVHD and relapse. Our current method of chimerism analysis is based on analysis of polymorphic short tandem repeats (STRs) to uniquely define the source of DNA extracted from the buffy coat layer. 69 peripheral blood (PB) samples were collected from 9 patients at 30th, 90th and 180th day after allogeneic transplantation. Lineage-specific cell enrichment was performed by using CD3 and CD19 "Whole Blood Micro Beads", yielding T cells, B cells respectively. PCR amplifications of theDNAsamples were obtained by using Applied Biosystems Identifier STR kit. Mean age was 35.6 year, 4 of patients were female and 5 were male. Among the patients, nine achieved engraftment and nine patients achieved complete chimerism (CC) at 30th day after allogeneic transplantation. Peripheral blood chimerism was analyzed more than 4 times in all patients but, lineage-specific chimerism analysis was performed according to the clinician request for four patients who had relapse development. Peripheral blood chimerism analyses were as a CC, although T or B cells chimerism analyses were observed with mix or recipient-derived cells. Thus, the clinical relapse of patients was considered from the whole blood chimerism analysis, a more distinctive lineage-specific chimerism analysis on the prognosis of patients with early relapse and was able to provide access to important information.

Ogunola, O. S., et al. (2018). "Mitigation measures to avert the impacts of plastics and microplastics in the marine environment (a review)." Environmental Science & Pollution Research **25**(10): 9293-9310.

The increasing demand for and reliance on plastics as an everyday item, and rapid rise in their production and subsequent indiscriminate disposal, rise in human population and industrial growth, have made the material an important environmental concern and focus of interest of many research. Historically, plastic production has increased tremendously to over 250 million tonnes by 2009 with an annual increased rate of 9%. In 2015, the global consumption of plastic materials was reported to be > 300 million tonnes and is expected to surge exponentially. Because plastic polymers are ubiquitous, highly resistant to degradation, the influx of these persistent, complex materials is a risk to human and environmental health. Because microplastics are principally generated from the weathering or breakdown of larger plastics (macroplastics), it is noteworthy and expedient to discuss in detail, expatiate, and tackle this main source. Macro- and microplastic pollution has been reported on a global scale from the poles to the equator. The major problem of concern is that they strangulate and are ingested by a number of aquatic biota especially the filter feeders, such as molluscs, mussels, oysters, from where it enters the food chain and consequently could lead to physical and toxicological effects on aquatic organisms and human being as final consumers. To this end, in order to minimise the negative impacts posed by plastic pollution (macro- and microplastics), a plethora of strategies have been developed at various levels to reduce and manage the plastic wastes. The objective of this paper is to review some published literature on management measures of plastic wastes to curb occurrence and incidents of large- and microplastics pollution in the marine environments.

O'Hanlon, N. J., et al. (2017). "Seabirds and marine plastic debris in the northeastern Atlantic: A synthesis and recommendations for monitoring and research." Environmental Pollution **Part 2. 231**: 1291-1301.

Marine plastic pollution is an increasing, and global, environmental issue. Numerous marine species are affected by plastic debris through entanglement, nest incorporation, and ingestion, which can lead to lethal and sub-lethal impacts. However, in the northeastern Atlantic Ocean, an area of international importance for seabirds, there has been little effort to date to assess information from studies of wildlife and plastic to better understand the spatiotemporal variation of how marine plastic affects different seabird species. To improve our understanding of seabirds and marine plastic in this region, we completed a synthesis of the published and grey literature to obtain information on all known documented cases of plastic ingestion and nest incorporation by this group. We found that of 69 seabird species that commonly occur in the northeastern Atlantic, 25 had evidence of ingesting plastic. However, data on plastic ingestion was available for only 49% of all species, with 74% of investigated species recorded ingesting plastic. We found only three published studies on nest incorporation, for the Northern Gannet (Morus bassanus) and Black-legged Kittiwake (Rissa tridactyla). For many species, sample sizes were small or not reported, and only 39% of studies were from the 21st century, whilst information from multiple countries and years was only available for 11 species. This indicates that we actually know very little about the current prevalence of plastic ingestion and nest incorporation for many species, several of them globally threatened. Furthermore, in the majority of studies, the metrics reported were inadequate to carry out robust comparisons among locations and species or perform meta-analyses. We recommend multi-jurisdictional collaboration to obtain a more comprehensive and current understanding of how marine plastic is affecting seabirds in the northeastern Atlantic Ocean. Only 49% of commonly occurring northeastern Atlantic seabird species have been investigated for active interactions with marine plastic pollution, with 74% of these found to ingest plastic or incorporate it into their nests. O'Hara, P. D., et al. (2019). "Seasonal variability in vulnerability for Cassin's Auklets (Ptychoramphus aleuticus) exposed to microplastic pollution in the Canadian Pacific region." Science of the Total Environment **649**: 50-60.

Marine plastic pollution is an emerging global conservation challenge, potentially impacting organisms at all trophic levels. However, currently it is unclear to what extent plastic pollution is impacting marine organisms at the population, species or multispecies level. In this study, we explore seasonal exposure (i.e., vulnerability) of Cassin's Auklet (Ptychoramphus aleuticus) to plastic pollution with exposure models during boreal summer and winter seasons. Based on these models, we infer exposure at the population level for this species, in the Canadian Pacific region where approximately 75% of the global population of this species breeds. The models quantify plastic exposure by determining seasonal core foraging areas and plastic concentrations found in those same areas. Core foraging areas were determined using a Generalized Additive Model based on at-sea observation data (collected year round: 1990-2010) and 50% Home Range Kernels based on aerial telemetry data (May and June 1999-2001). Plastic concentrations within these core areas were interpolated based on seawater microplastic concentrations from the summer of 2012. We found that during the boreal summer, Cassin's Auklets were exposed to relatively low concentrations of plastics. During the winter, auklet distribution shifted towards the coast where plastic concentrations are considerably higher. Model derived seasonal variability in exposure was consistent with necropsy results from bird carcasses recovered during the winter of 2014, and from a multiyear study on chick provisioning during the summer. Local oceanography likely plays a role in determining seasonal shifts in both marine bird as well microplastic concentrations, and hence exposure. As well, individual sensitivity (i.e., dose-dependent effect) may vary with annual cycles. Currently, research is focusing on determining how sensitive individual birds are to microplastic concentrations, and our models will help translate sensitivity found at the individual level to potential impacts at population or species level.

Ohashi, T., et al. (2010). "On-chip antibody immobilization for on-demand and rapid immunoassay on a microfluidic chip." Biomicrofluidics **4**(3): 32207.

Immunoassay is one of the important applications of microfluidic chips and many methodologies were reported for decreasing sample/reagent volume, shortening assay time, and so on. Micro-enzyme-linked immunosorbent assay (micro-ELISA) is our method that utilizes packed microbeads in the microfluidic channel and the immunoreactions are induced on the beads surface. Due to the large surface-to-volume ratio and small analytical volume, excellent performances have been verified in assay time and sample/reagent volume. In order to realize the micro-ELISA, one of the important processes is the immobilization of antibody on the beads surface. Previously, the immobilization process was performed in a macroscale tube by physisorption of antibody, and long time (2 h) and large amount of antibody (or high concentration) were required for the immobilization. In addition, the processes including the reaction and washing were laborious, and changing the analyte was not easy. In this research, we integrated the immobilization process into a microfluidic chip by applying the avidin-biotin surface chemistry. The integration enabled very fast (1 min) immobilization with very small amount of precious antibody consumption (100 ng) for one assay. Because the laborious immobilization process can be automatically performed on the microfluidic chip, ELISA method became very easy. On-demand immunoassay was also possible just by changing the antibodies without using large amount of precious antibodies. Finally, the analytical performance was investigated by measuring C-reactive protein and good performance (limit of detection <20 ng/ml) was verified.

Ohiwa, N., et al. (2008). "An Investigation on Thermal Recycling of Recycled Plastic Resin (Numerical Prediction of Unburnt Rate in PET-Resin Powder Combustion)." Journal of Environment and Engineering **3**(1): 158-169.

To burn PET-resin powder as an alternative or additional fuel and to realize effective thermal recycling of a great deal of wasted and recycled PET-resin, some practical studies have been made on the physical aspects of PET-powder combustion in the industrial burner. The results showed that a large amount of PET-powder up to about 80 % is exhausted without burn-up in the open atmospheric operation, whereas PET-powder is perfectly consumed in the high temperature in-furnace operation. Understanding of the relationship between the heating time and the unburnt rate of PET-powder is therefore necessary to get an important knowledge to reduce the amount of unburnt PET-powder. In this paper, the behavior of particle diameter is first modeled according to those experimentally measured, a particle-size histogram of

PET-powder is then transformed into a particle-number profile by stepping the particle diameter at 0.01 mu m intervals, and simple numerical prediction of the unburnt rate in the PET-powder combustion is finally attempted by introducing the parcel approximation. The results give good quantitative agreement between the unburnt rates of PET-powder measured experimentally and those predicted.

Ohta, K. and K. Tanaka (1999). "Simultaneous determination of common mono- and divalent cations in natural water samples by conductimetric detection ion chromatography with an unmodified silica gel column and oxalic acid /18-crown-6 as eluent." Analytica Chimica Acta **381**(2/3): 265-273.
An unmodified silica gel (Super Micro Beads Silica Gel B-5) was used as a cation-exchange stationary phase in the ion chromatographic (IC) determination of lithium(I), sodium(I), ammonium(I), potassium(I), magnesium(II) and calcium(II) cations in natural water samples using strongly acidic eluents; the method employed conductimetric detection. Excellent simultaneous separation of these cations was achieved in 15 minutes using a 15 cm SMBSG B-5 column and 1 mM oxalic acid/3 mM 18-crown 6 as the eluent. Calibration graphs were linear in the concentration ranges 0.005 to 1.0 mM, and detection limits ranged from 0.63 ug per litre for lithium(I) to 28 ug per litre for potassium(I). The proposed method was applied to the analysis of the 6 cations in various rain and river water samples. The results were in good agreement with those obtained by a conventional IC method using a TSK gel IC-CationI/II column and 2 mM nitric acid as the eluent.

Oi, K., et al. (2017). "CTLA4-IG directly inhibits osteoclast generation from human peripheral monocytes and tumor necrosis factor alpha-treated inflammatory monocytes." Arthritis and Rheumatology. Conference: American College of Rheumatology/Association of Rheumatology Health Professionals Annual Scientific Meeting, ACR/ARHP **69**(Supplement 10).
Background/Purpose: CTLA-4 is a surface protein on T lymphocytes, which negatively regulates the co-stimulation process between antigen-presenting cells and T cells. CTLA-4 binds to monocytes via CD80/CD86, which are precursor of osteoclast. In addition, CTLA-4 has been shown to directly inhibit osteoclast formation. However, little is known about the effect of CTLA-4 on osteoclast generation from human monocytes and monocytes exposed to inflammatory cytokines. The aim of this study was to evaluate the effect of a CTLA4-Ig (Abatacept) on osteoclastogenesis in human peripheral monocytes and TNFalpha-treated inflammatory monocytes. Method(s): Peripheral blood mononuclear cells are separated by Ficoll-Paque gradient centrifugation. Highly purified monocytes are prepared from prepared mononuclear cells using MACS microbeads (Pan Monocyte Isolation kit). In this study, more than 92 % of obtained cells are CD14-positive, as determined by flow cytometric analysis. Cultures were maintained in alpha-minimal essential medium for 7-14 days with both or either of M-CSF, RANKL and/or TNFalpha in the presence or absence of CTLA4-Ig. Osteoclasts were identified by TRAP staining and bone resorptive activity using the osteo assay surface multiwell plate. The expressions of CD80/CD86 on resting and TNFalpha-pretreated monocyte were determined by flow cytometric analysis. Result(s): Peripheral monocytes from healthy donors were incubated with M-CSF (50 ng/ml) and RANKL (100 ng/ml) in the presence of increasing doses of CTLA4-Ig for 5~7 days. After the culture, generated osteoclasts were determined by TRAP staining and bone resorptive activity. CTLA-4 inhibited the osteoclast generation in a dose-dependent manner (in the range of 0 to 500 mug/ml). To examine the effect of CTLA4-Ig on monocytes exposed to inflammatory cytokines, peripheral monocytes were preincubated with TNFalpha for 48 hours, and then cultured with RANKL. When the expression of CD80/CD86 antigens on peripheral monocytes was analysed, CD86 was only expressed on resting monocytes.

Interestingly, TNFalpha pretreatment potently induced the expression of CD80, suggesting modification of action of CTLA-4. CTLA4-Ig more potently inhibited osteoclast generation from TNFalpha-treated monocytes than those from resting monocytes. Conclusion(s): CTLA4-Ig directly inhibits osteoclast generation from human peripheral monocytes. In addition, the inhibitory effect of CTLA4-Ig is more potent in TNFalpha-treated inflammatory monocytes than resting monocytes, suggesting that CTLA4-Ig could inhibit osteoclast generation in inflammatory monocytes at inflamed joints of RA.

Ojha, N. K., et al. (2019). "Membrane potential manipulation with visible flash lamp illumination of targeted microbeads." Biochemical & Biophysical Research Communications **517**(2): 297-302.

The electrical membrane potential (V_m) is a key dynamical variable of excitable membranes. Despite the tremendous success of optogenetic methods to modulate V_m with light, there are some shortcomings, such as the need of genetic manipulation and limited time resolution. Direct optical stimulation of gold nanoparticles targeted to cells is an attractive alternative because the absorbed energy heats the membrane and, thus, generates capacitive current sufficient to trigger action potentials [1, Carvalho-de-Souza et al., 2015]. However, focused laser light is required and precise location and binding of the nanoparticles cannot be assessed with a conventional microscope. We therefore examined a complementary method to manipulate V_m in a spatio-temporal fashion by non-focused visible flashlight stimulation (Xenon discharge lamp, 385-485nm, ~500mus) of superparamagnetic microbeads. Flashlight stimulation of single beads targeted to cells resulted in transient inward currents under whole-cell patch-clamp control. The waveform of the current reflected the first time derivative of the local temperature induced by the absorbed light and subsequent heat dissipation. The maximal peak current as well as the temperature excursion scaled with the proximity to the plasma membrane. Transient illumination of light-absorbing beads, targeted to specific cellular sites via protein-protein interaction or direct micromanipulation, may provide means of rapid and spatially confined heating and electrical cell stimulation.

Oka, A., et al. (2010). "Decreased production of IL-10 in TLR9-activated peripheral blood B cells in inflammatory bowel disease." Gastroenterology **1)**: S740.

(Background & Aim) A regulatory B cell subset expressing interleukin (IL)-10 plays essential roles to maintain innate immunity and autoimmunity in various organs. Lack or loss of this subset exacerbated symptoms in experimental mice models with immune-mediated disorders. However, its role in the pathogenesis of human diseases, including inflammatory bowel disease (IBD), is largely unknown. We examined TLR-mediated production of IL-10 in human peripheral blood B cells and investigated its role in the pathogenesis of IBD. (Materials and Methods) We studied 35 patients with ulcerative colitis (UC), 30 with Crohn's disease (CD), and 45 healthy subjects. The expressions of CD19, CD1d, CD5, TLR4, RP105, and TLR9 in peripheral blood B cells were analyzed by flow cytometry. In Vitro, B cells were separated from isolated mononuclear cells magnetically by positive selection with CD19 microbeads, and purified B cells were cultured in 96-well plates (4 x 105/well) and stimulated with LPS or CpG DNA for 3 days, then IL-10 contents in culture media were measured using enzyme immunoassays. Also, the intracellular contents of IL-10 in TLR ligand-stimulated B cells were analyzed by flow cytometry, after staining with CD5 and CD1d. Further, multiple regression analysis was used to determine significant factors affecting TLR-mediated production of IL-10 in TLR-mediated B cells of IBD patients in relation to clinical parameters. (Results) Expression patterns of several cellular markers evaluated by flow cytometry in B cells isolated from IBD patients were similar to those of the healthy controls. Although IL- 10 production was induced in TLR ligand-mediated B cells, the level in CpG-DNA-stimulated cells was significantly higher than that in LPS-stimulated cells. B cells expressing IL-10 were mainly located in a population characterized by the cell surface markers CD19^{high} and CD1d^{high}. Interestingly, the production of IL-10 stimulated by CpG DNA was significantly lower in B cells separated from the IBD patients than from the control subjects (mean values: control; 503 pg/ml, CD; 196 pg/ml, UC; 276 pg/ml). Multiple regression analysis showed that disease severity had a significant effect to decrease TLR9-mediated IL-10 production in the IBD patients. (Conclusion) We found decreased production of IL-10 in TLR9-activated intestinal B cells in both CD and UC patients, suggesting that the function of this regulatory subset of B cells may associated with the pathogenesis of IBD.

Okada, A. (1973). "Plastic wastes hazards and development of degradable plastics." Technocrat **6**(5): 56-59.

This paper describes some technically and economically feasible methods for disposing of plastic waste materials, discusses the role of degradable plastics and their present level of development, and outlines some considerations for the practical application of degradable plastics.

Okajima, I., et al. (2012). "Production of Composite Fuel with High Heating Value from Waste Mixture of Food and Plastic Using Subcritical Water." Journal of the Japan Institute of Energy **91**(10): 998-1006.

Waste mixture of food and plastics is one of the most refractory wastes, because conventional recycling techniques require the separation of the waste into each group before treatment. In this work, new recycling technique was developed to produce an excellent composite fuel using subcritical water. The waste mixture was agitated with sawdust as a plastic dispersed material in subcritical water at 200 degree C and 1.6 MPa for 30 min, and the composite fuel particles with less than 20 mm in size were produced. The fuel had a high heating value close to that of coal and the fixed carbon ratio was 93 %. The fuel was dried in a short time of one third of conventional drying period. This was because a part of the surface tissue and cell wall of the biomass was decomposed by subcritical water and water inside the biomass was evaporated easily. The roles of subcritical water were the stabilization of the dispersed melting plastic particles, the removal of toxic elements such as chlorine and sulfur, and the saving of drying energy and the realization of high energy efficiency more than 4.When the composite fuel was pressed into pellet, the pellet fuel ignited easily and burned in a biomass stove stably for long time. The concentrations of the toxic compounds in the combustion gas were far below the emission standard of small boiler. The composite fuel was demonstrated to be safe and clean.

Okamoto, Y., et al. (2013). "Identification of autoantibodies to tyrosyl-transfer RNA synthetase associated with anti-synthetase syndrome." Arthritis and Rheumatism **10)**: S880.

Background/Purpose: Autoantibodies directed against the aminoacyl transfer RNA (tRNA) synthetases are associated with myositis, arthritis, Raynaud's phenomenon, mechanic's hands, fever, and interstitial lung disease, clinically referred to as the anti-synthetase syndrome. A preliminary report has described the detection of an autoantibody to tyrosyl- tRNA synthetase (TyrRS) in only one patient with features of anti- synthetase syndrome. In addition, it has also been reported that TyrRS can be split into two fragments with distinct cytokine activities. We aimed to identify further patients with anti-TyrRS autoantibodies using other assays than previously reported methods and elucidate their clinical significance. Method(s): Multiple assays were performed to detect anti-TyrRS antibodies in the sera of patients with active polymyositis/dermatomyositis patients. First, recombinant human TyrRS protein coupled with a His-tag was expressed in Escherichia coli. Autoantibodies against the recombinant human TyrRS in sera of patients with polymyositis/dermatomyositis were quantified by employing solid phase direct enzyme-linked immunosorbent assay (ELISA). Second, the recombinant human TyrRS was electrophoresed and transferred to PVDF membranes. Western blot was performed with the serum samples and anti-human IgG secondary antibodies. Third, TyrRS-transfected HeLaS3 cells were immunoprecipitated with sample serum. Then, the antibody-protein complex captured with muMACSTM Protein G MicroBeads was loaded onto a muColumn. The eluted immunoprecipitates were subjected to the SDS-polyaclylamidegel electrophoresis, and western blotted with rabbit anti-TyrRS polyclonal antibodies. In addition, the titer of anti-TyrRS antibodies was evaluated by ELISA before and after treatment among the patients with positive anti-TyrRS antibodies at the initial evaluation. Control sera were obtained from normal healthy control subjects. The clinical features of the patients with positive anti-TyrRS antibodies were analyzed. This study was approved by the ethics committee of our institution, and the principles of the Helsinki Declaration were followed throughout the study. Result(s): Sera from three patients with polymyositis/dermatomyositis showed significantly high O.D. values in ELISA, significant bands of 59 kDa protein of TyrRS at the same place as anti-His tag antibody in Western blot, and significant bands at the same place as the recombinant human TyrRS in immunoprecipitation assay. These data strongly suggest that these sera had autoantibodies to TyrRS. These patients had myositis, interstitial lung disease, arthritis, Raynaud's phenomenon, and fever. In two of the three patients, anti-TyrRS antibody titers decreased as clinical diseases were ameliorated following treatment. Conclusion(s): This study reconfirmed the presence of anti-TyrRS antibody in the setting of the anti-synthetase syndrome and strengthens the association of anti-synthetases with these conditions.

Okan, M., et al. (2019). "Current approaches to waste polymer utilization and minimization: a review." Journal of Chemical Technology and Biotechnology **94**(1): 8-21.

The mass production of polymer products, in particular plastics, and their widespread use depending on the inherent advantages they have, make these materials ironically a threat to life on Earth. Polymer recycling is being considered as one of the most widely accepted remedies to the threat of growing amounts of plastic waste by both the public and scientists. In practice, recycling is associated with many difficulties, such as problems related to separation, sorting and cleaning operations, lack of fiscal subsidies, instability of selective garbage separation programs, high transport and electricity costs, etc. Still, a large section of society and the authorities agree on the necessity and importance of recycling to protect the environment, and natural habitats and resources for future generations in a balanced manner to conserve raw materials, and to reduce energy consumption, municipal solid waste production and greenhouse gas emission. The recycling effort is almost endless in itself and includes a variety of approaches such as refurbishing, mechanically reshaping, chemically treating, thermally utilizing, etc. Some novel approaches such as application in carbon capture or synthesis of carbon nanostructures from the plastic waste are among the new process technologies of recycling. From traditional and promising polymer waste utilization approaches, this review will highlight sustainable methods to reduce impacts of plastic waste on the environment. © 2018 Society of Chemical Industry.

O'Kane, D. J. and J. Lee (1990). "Encapsulated radiophosphorescent standards for day-to-day photometer calibration." Photochemistry & Photobiology **52**(4): 723-734.

Solid, unquenched, radiophosphorescent standards for use in the day-to-day calibration of bottom viewing photometers (luminometers) were prepared by encapsulating

commercially-available phosphor powders that are excited to phosphoresce by the beta- decay of 63Ni (t0.5 = 96 yr) or 14C (t0.5 = 5730 yr). The radionuclides are physically adsorbed on the phosphors by precipitation either as a "basic nickel carbonate" or as barium carbonate. The radioactive phosphors are then deposited by centrifugation as a thin layer at the bottom of the vials or tubes that are normally used in the photometer. The phosphor layer is infiltrated with a plastic resin and embedded. A light absorbing layer is subsequently cast over the phosphor layer to prevent stray light excitation of phosphorescence. The encapsulated photometer standards have remained mechanically and photometrically stable since their fabrication, which in some cases is 3 years ago. An equivalent level of visible luminescence emitted from the standards of up to 2.3 x 10(10) photons.s-1 was achieved by using an appropriate amount of radioactivity and the proper phosphor. The phosphor used in the standards could be chosen such that the radiophosphorescence emission spectrum corresponded approximately to the chemiluminescence or bioluminescence spectrum under investigation.

Okano, T., et al. (2011). "Appropriate Unit of Measurement to Quantify the Contamination of Beaches by Synthetic Marine Debris." Journal of Environmental Chemistry **21**(1): 69-74.

Serious pollution of the beach environment by plastic marine debris (litter) has been reported around the world. However, these reports are recorded in two types of measurement units: /m and /m super(2). Therefore, we investigated which measurement is the more appropriate unit to measure beach debris. Our analysis is based on our 146 surveys of anthropogenic debris larger than or almost equal to plastic resin pellets from November 2004 to November 2009 at five relatively deserted beaches in Tottori, Japan. A total of 173, 981 fragments and items with a total weight of 433kg were collected. Surprisingly, about ten percent were thermal-fused plastic lumps, presumably due to incomplete burning. The floating marine debris washed up on the beaches normally forms a wrack belt, and the debris in the belt is over half of the total number and weight of the debris from shoreline to upper wrack limit. Since the wrack belts are narrow, the depth of sandy beaches affects neither the wash-up of floating debris nor the formation of debris belts. In fact, the correlation coefficients between the depth of beach and the number and weight of debris are very low (r sub(n)=0.20 and r sub(w)=0.19). The quantity of beach debris is significantly correlated with the length of the beach line because the wrack belt is usually parallel to the shoreline. Since the floating debris is ideally washed up on a one-dimensional intersection between beach and water surfaces,the unit of measure to quantify beach debris ought to be defined by the length of the beach line.

Okazaki, Y., et al. (2010). "Quantification of circulating endothelial progenitor cells: Verification of the Eustar recommendations." Clinical and Experimental Rheumatology **58)**: S169-S170.

Objective: It has been proposed that defective vasculogenesis with reduced and/ or dysfunctional endothelial progenitor cells (EPCs) plays a role in the pathogenic process of vasculopathy in patients with systemic sclerosis (SSc). However, whether the number of circulating EPCs is reduced in SSc patients is a matter of debate. The working group of EUSTAR recently proposed the recommendations for evaluation of EPCs. In this study, we evaluated these recommendations by comparing two different methods. Method(s): Peripheral blood samples were obtained from 10 SSc (5 diffuse and 5 limited cutaneous SSc) and 10 healthy controls (HC), divided into two tubes, and simultaneously subjected to flow cytometry (FCM)-based procedures to quantify EPCs after different enrichment techniques: immunomagnetic enrichment of CD34+ cells (Kuwana, Lancet 2004;364:603) and rosette-based enrichment of lineage-negative (Lin-) cells (Allanore, Ann Rheum Dis 2008;67:1455). After incubation with Fc-receptor blocking reagent, the enriched fractions were subjected to triple

labeling with anti-CD34, anti-CD133, and anti-VEGFR2 antibodies in conjunction with or without a viability maker 7-AAD. Finally, EPCs defined as 7-AAD-CD34+CD133+VEGFR2+ cells were detected by FCM, and their absolute number was determined by its ratio to the Flow-countTM microbeads. Result(s): The EPC numbers determined by the CD34+ cell-enriched protocol without 7-AAD staining (original method by Kuwana) and the Lin-cell-enriched protocol without microbead quantification (original method by Allanore) were not correlated at all (r=0.12, p=0.6). However, the numbers were correlated when 7-AAD staining and microbead quantification were applied to both procedures (r=0.65,p=0.002). In the Lin-cell-enriched protocol, the correlation between EPC numbers obtained with and without microbead quantification was not statistically significant (r=0.41), probably due to contamination of erythrocytes and platelets in the Lin-cell fraction, which constituted >90% of cell counts. The EPC count was significantly reduced in SSc than HC by CD34+ cell-enriched protocol with 7-AAD (2.7 +/- 1.4 versus 6.4 +/- 3.5/ml, p=0.01) and by Lin-cell-enriched protocol combined with microbeads (2.1 +/- 2.2 versus 6.7 +/- 2.9/ml, p=0.001). However, the count measured by the Lin-cell-enriched protocol without microbeads was similar (61.0 +/- 60.4 for SSc versus 76.9 +/- 52.3/106 Lin-cells for HC, p=0.5). Conclusion(s): The EUSTAR recommendations are valid when they are combined with the FCM procedure to count the absolute number of antibody-labeled cells. Two different protocols that met the revised recommendations consistency showed reduced circulating EPC count in SSc patients.

Okkenhaug, G., et al. (2015). "The presence and leachability of antimony in different wastes and waste handling facilities in Norway." Environmental Science. Processes & Impacts **17**(11): 1880-1891.

The environmental behaviour of antimony (Sb) is gathering attention due to its increasingly extensive use in various products, particularly in plastics. Because of this it may be expected that plastic waste is an emission source for Sb in the environment. This study presents a comprehensive field investigation of Sb concentrations in diverse types of waste from waste handling facilities in Norway. The wastes included waste electrical and electronic equipment (WEEE), glass, vehicle fluff, combustibles, bottom ash, fly ash and digested sludge. The highest solid Sb concentrations were found in WEEE and vehicle plastic (from 1238 to 1715 mg kg(-1)) and vehicle fluff (from 34 to 4565 mg kg(-1)). The type of acid used to digest the diverse solid waste materials was also tested. It was found that HNO3:HCl extraction gave substantially lower, non-quantitative yields compared to HNO3:HF. The highest water-leachable concentration for wastes when mixed with water at a 1 : 10 ratio were observed for plastic (from 0.6 to 2.0 mg kg(-1)) and bottom ash (from 0.4 to 0.8 mg kg(-1)). For all of the considered waste fractions, Sb(v) was the dominant species in the leachates, even though Sb(iii) as Sb2O3 is mainly used in plastics and other products, indicating rapid oxidation in water. This study also presents for the first time a comparison of Sb concentrations in leachate at waste handling facilities using both active grab samples and DGT passive samples. Grab samples target the total suspended Sb, whereas DGT targets the sum of free- and other chemically labile species. The grab sample concentrations (from 0.5 to 50 mug L(-1)) were lower than the predicted no-effect concentration (PNEC) of 113 mug L(-1). The DGT concentrations were substantially lower (from 0.05 to 9.93 mug L(-1)) than the grab samples, indicating much of the Sb is present in a non-available colloidal form. In addition, air samples were taken from the chimney and areas within combustible waste incinerators, as well as from the vent of WEEE sorting facility. The WEEE vent had the highest Sb concentration (from <100 to 2200 ng m(-3)), which were orders of magnitude higher than the air surrounding the combustible shredder (from 25 to 217 ng m(-3)), and the incinerator chimney (from <30 to 100 ng m(-3)). From these results, it seems evident that Sb from waste is not an environmental concern in Norway, and that Sb is mostly readily

recovered from plastic and bottom ash.

Okoffo, E. D., et al. (2019). "Wastewater treatment plants as a source of plastics in the environment: a review of occurrence, methods for identification, quantification and fate (Electronic supplementary information (ESI) available. See DOI: 10.1039/c9ew00428a)." Environmental Science. Water Research & Technology **5**(11): 1908-1931.

Plastics accumulate in the natural environment due to their durability and low recycling volumes. Wastewater treatments plants (WWTPs) have been identified as important sources for the release of plastics into aquatic and terrestrial environments that may lead to further contamination. This review provides a comprehensive summary of current knowledge on plastic pollution from WWTPs. Specifically, this article presents the current status on the sources of plastics entering WWTPs via influent, the occurrence of plastics in WWTP influent, treated effluent and sewage sludge as well as the techniques used for sampling and analysing plastics in WWTP derived samples. The fate and transfer of plastics from WWTPs to aquatic and terrestrial ecosystems is also discussed. While various studies have reported the presence of plastics in WWTP samples, which have certainly improved our level of understanding on the fate of plastics within the WWTP treatment chain, many unanswered questions still remain. A major gap is the lack of standardized methods and robust analytical techniques for the sampling, identification and quantification of plastics including nano-sized plastics in WWTP derived samples, leading to the potential underestimation of total plastics. To aid comparison of data generated by different researchers, we advocate for the harmonisation of sampling approaches, extraction methods, analytical techniques and reporting units for plastics abundance. Future studies should focus on enhanced methods that can also include estimates of nano-sized plastics.

Okudan, A., et al. (2019). "Cu(II) Sorption Performance of Novel Chitosan/Ter-(vinyl pivalate-maleic anhydride-N-tert-butylacrylamide) Microcapsules." Journal of Polymers & the Environment **27**(11): 2454-2463.

In this study, first, the ter-polymerization reaction between vinyl pivalate (VP), maleic anhydride (MA), and N-tert-butylacrylamide (NTBA) was done in inert atmosphere (N2). FT-IR and 1HNMR spectroscopy was applied to study the chemical composition of the obtained ter-polymers. MA content of the ter-polymers was determined by following the chemical titration method. Second, novel chitosan/ter-(vinyl-pivalate-maleic-anhydride-N-tert-butylacrylamide) microcapsules were synthesized. In microcapsule production, chitosan polymer served as a matrix for acrylamide ter-polymers with four different molar ratios. The microcapsules were characterized by FT-IR and SEM analyses. Cu(II) sorption efficiency of the microcapsules were tested at different pH levels, temperature, sorbent dosage, and metal ion concentration. Comparison with blank chitosan microbeads revealed that incorporation of acrylamide ter-polymers into the cross-linked chitosan matrix increased the metal sorption. Sorption capacities of the sorbents were recorded; blank chitosan microbeads: 67.03 mg g−1, and chitosan/acrylamide ter-polymer microcapsules: in range of 75.39–98.64 mg g−1. The findings demonstrated chitosan/acrylamide ter-polymer microcapsules can be utilized in sorption of Cu(II) ions in water treatment [ABSTRACT FROM AUTHOR]

Okunlola, A., et al. (2015). "Design of cissus-alginate microbeads revealing mucoprotection properties in anti-inflammatory therapy." International Journal of Biological Macromolecules **79**: 226-234s.

Cissus gum was used as polymer with sodium alginate in the formulation of diclofenac microbeads and the in vivo mucoprotective properties of the polymer in anti-inflammatory therapy was assessed in rats with carrageenan-induced paw oedema in comparison to diclofenac powder and commercial diclofenac tablet. A full 2³ factorial experimental design has been used to investigate the influence of concentration of cissus gum, concentration of calcium acetate and stirring speed on properties of the microbeads. Optimized small discrete microbeads with size of 1.22+or-0.10 mm, entrapment efficiency of 84.6% and t₈₀ of 15.2+or-3.5 h were obtained at ratio of cissus gum:alginate (1:1), low concentration of calcium acetate (5%, w/v) and high stirring speed (400 rpm). The in vivo studies showed that the ranking of percentage inhibition of inflammation after 3 h was diclofenac powder > commercial tablet=cissus > alginate. Histological damage score and parietal cell density were lower while crypt depth and mucosal width were significantly higher (P <0.05) in the groups administered with the diclofenac microbeads than those administered with diclofenac powder and commercial tablet, suggesting the mucoprotective property of the gum. Thus, cissus gum could be suitable as polymer in the formulation of non-steroidal anti-inflammatory drugs ensuring sustained release while reducing gastric side effects.

Okunlola, A., et al. (2012). "Formulation optimization of floating microbeads containing modified Chinese yam starch using factorial design." Journal of Excipients and Food Chemicals **3**(1): 17-25.

Controlled release floating metformin hydrochloride microbeads were prepared and optimized using a blend of varying concentrations of freeze-dried pregelatinized Chinese yam starch (Dioscorea oppositifolia L) and sodium alginate. Floating microbeads were prepared by the ionotropic gelation method using 10% w/v calcium chloride as the cross-linking agent and sodium bicarbonate as the gas releasing agent. A full 3² factorial design was used to investigate the influence of two variables: concentrations of starch (X<inf>1</inf>) and sodium bicarbonate (X<inf>2</inf>) on the swelling, floating lag time and amount of drug released after 1 hour (Q<inf>1</inf>) and 10 hours (Q<inf>10</inf>). Potential variables such as the concentrations of drug and total polymer were kept constant. The results showed that the properties of the floating microbeads were significantly (p<0.01) affected by the concentration of the modified Chinese yam starch. Buoyancy and drug release appeared to be facilitated by increased concentrations of both starch and sodium bicarbonate in the formulation. The results also show that an optimized formulation of metformin hydrochloride could be obtained with the potential for gastroretentive controlled drug delivery using a blend of freeze-dried pregelatinized Chinese yam starch and sodium alginate. © IPEC-Americas Inc.

Oleinikov, V. A. (2011). "[Semiconductor fluorescent nanocrystals (quantum dots) in biological biochips]." Bioorganicheskaia Khimiia **37**(2): 171-189.

Comprehension of biological processes in cells, tissues and organisms requires identification and analysis of numerous biological objects, mechanisms of their action and regulation. Microarray (biochips) technology is a rare tool to solve this problem. It is based on high-throughput recognition of a target to the probe and has the potential to measure simultaneously the presence of numerous molecules in multiplexed testes, all contained in a small drop of test fluid. Biochips allow the parallel analysis of genomic or proteomic content in healthy versus disease-affected or altered tissues or cells. The signals read-out from the biochips is done with organic dyes which often suffer from photobleaching, low brightness and background

fluorescence. Recent data show that the use of fluorescent nanocrystals "quantum dots" (QDs) allows push away these restrictions. The QDs are sufficiently bright to be detected as individual particles, extremely resistant to photobleaching and provide unique possibilities for multiplexing thus supplying the microarray technology with the novel read-out option enabling the sensitivity of detection reaching the single molecule level. This paper is aimed at the development of the approaches to the QDs application in microarray-based detection. Possibilities of QDs application both in solid state (planar) biochips as well as intensively developing technique of suspension biochips (bead-based assays or liquid biochips) are demonstrated. The latter are more and more applied for simultaneous identification of very large numbers of molecules in proteomics, genomics, drug screening and clinical diagnostics. This assays base on spectral encoded elements (as a rule polymer microbeads). The benefits of using optically encoded microbeads (instead of the solid-state two-dimensional arrays) are derived from the freedom of bead to move in three dimensions. Polymeric beads optically encoded with organic dyes allow for a limited number of unique codes, whereas the use of semiconductor nanocrystals as fluorescent tags improves the beads multiplexed imaging capabilities, photostability and sensitivity of the biological objects detection. Additionally, an employment in suspension biochips of Frster resonance energy transfer (FRET) allows improving detection specificity. The absence of fluorescent background from non-interacting with the beads dye-labelled antibodies additionally increases the sensitivity of detection and further facilitates the multiplexing capabilities of nanocrystals-based detection and diagnostics. So the combination of the biochips and QDs techniques allow increasing detection sensitivity and significantly raising the number of detected objects (multiplexing capacities). Such combination should provide the breakthrough in proteomics, particularly in new drugs development, clinical diagnostics, new disease markers identification, better understanding of intracellular mechanisms.

Olgasi, C., et al. (2015). "Correcting the bleeding phenotype in hemophilia A using lentivirally FVIII-corrected endothelial cells differentiated from hemophilic induced Pluripotent Stem Cells (iPSCs)." Human Gene Therapy **26 (10)**: A29-A30.

Hemophilia A (HA) is an X-linked bleeding disorder caused by factor VIII (FVIII) deficiency. Somatic cells can be reprogrammed generating autologous, disease-free iPSCs, differentiated into targets cells relevant for gene and cell therapy. We generated FVIII-corrected patient-specific iPSCs from peripheral blood cells and differentiated into functional endothelial cells (ECs), secreting FVIII after transplantation in HA mouse model. CD34 + cells were isolated from peripheral blood of healthy and hemophilic donors and reprogrammed with a Cre- Lox LV carrying OCT4, SOX2 and KLF4. Reprogrammed CD34 + cells originated ESC-like-iPSCs + colonies for AP staining and stem cell markers. EBs expressed germ layers specific markers and differentiated in osteogenic, chondrogenic and adipose tissues. iPSCs showed increased telomeres length and normal karyotype. FVIII-corrected HA-iPSCs expressed hBDD-FVIII by lentiviral vectors under the control of an ECspecific promoter (VEC). iPSCs differentiated into ECs, acquired endothelial-like morphology, expressed ECs markers and formed tubules when cultured in matrigel. VEC-GFP-LV transduced ECs were transplanted intraportal in NOD/ SCID(NS)-gammaNull mice engrafted and proliferated in the livers up to 12 weeks later. Finally, healthy and FVIII-corrected ECiPSC- derived linked to Cytodex microbeads were transplanted in NS hemophilic mice. aPTT was performed 3 and 7 days later and FVIII activity was 2% in mice transplanted with healthy cells and 5% in mice received FVIII-corrected HA cells. Immunofluorescent staining showed the presence of transplanted EC associated with beads recovered from injected mice. In conclusion, our cells engrafted, proliferated and expressed FVIII from differentiated, gene corrected and reprogrammed factor-free iPSCs confirming the

suitability of this approach for HA gene-cell-therapy.

Olivatto, G. P., et al. (2019). "Microplastic contamination in surface waters in Guanabara Bay, Rio de Janeiro, Brazil." Marine Pollution Bulletin **139**: 157-162.

Microplastics (MPs) are contaminants of environmental concern that represent a threat to marine systems. Here we report data on the abundance and characteristics of MPs collected from surface waters of the urban Guanabara Bay. Samples were collected, by horizontal trawling of a plankton net on two occasions (summer of 2016). The MPs were obtained from samples by sieving and particles were manually sorted with microscope. Characterization of MPs was accomplished by gravimetry and digital image processing (for quantification and morphology categorization), and chemical composition identified by infrared spectroscopy and elemental analyses. Total MPs ranged from 1.40 to 21.3particles/m³, which places Guanabara Bay amongst the most contaminated coastal systems worldwide by microplastics. Polyethylene and polypropylene polymers <=1mm were the most abundant particles. Therefore, the occurrence of MPs in Guanabara Bay is relevant to understand ecological hazards of exposition to marine biota and merits further investigation.

Oliveira, M. and M. Almeida (2019). "The why and how of micro(nano)plastic research." TrAC - Trends in Analytical Chemistry **114**: 196-201.

The presence of small plastic particles in the environment, reported for the first time in the 1970's, has only recently been recognized as a global issue. Although environmental awareness continues to grow, so does its consumption and associated risks. The number of studies reporting the presence of microplastics, has grown exponentially as did the concern over plastic degradation into smaller particles like nanoplastics, a potentially more pernicious form of plastic pollution. The reported effects of micro(nano)plastics on biota range from depletion of energy reserves and altered metabolism to immunological, neurotoxic effects and behavioral effects. This paper presents a critical review of current scientific knowledge in terms of reasons to study the effects of small plastics present in the environment, what has been assessed so far; most common methodologies. Research and technical developments requirements are also presented. Overall, it is clear the need for standardization of procedures and communication of results. Copyright © 2019 Elsevier B.V.

Oliveira, M., et al. (2019). "A micro(nano)plastic boomerang tale: A never ending story?" TrAC - Trends in Analytical Chemistry **112**: 196-200.

Plastics are an integral but largely inconspicuous part of human daily routines. Associated with a high production and single use nature of several products, small plastic particles became ubiquitous. Due to processes like water currents and winds, plastics may occur far from their place of origin and affect biota at different environmental compartments. In the environment plastics can degrade into increasingly smaller particles, reaching a nanometer size which increases their potential to be incorporated by organisms. Currently it is recognized that the plastics in the environment are reaching humans via contaminated food, drinks, and air but their effects on humans are largely unknown. In this paper, the potential exposure routes and effects to humans are discussed and approaches to decrease impact of microplastics to humans presented. Copyright © 2019 Elsevier B.V.

Oliveira, M., et al. (2019). "Are ecosystem services provided by insects "bugged" by micro (nano)plastics?" TrAC - Trends in Analytical Chemistry **113**: 317-320.

Although the study of the effects of microplastics increased in the last years, terrestrial

ecosystems remain less studied. In fact, the effects of microplastics in insects, the most abundant group of animals and major providers of key Ecosystem Services, are not well known despite the potential cascading negative effects on the ecosystems functioning in the habitats where they occur. In this paper, a revision on available studies on microplastics contamination is provided and potential consequences to major Ecosystem Services provided by insects are discussed, using the Common International Classification of Ecosystem Services (CICES) methodology. The revision underpinned probable and potential impacts for all tree CICES divisions, i.e.: Provision, Regulation and Maintenance and Cultural Services. The available studies seem to show that different groups react differently to microplastics contamination, which clearly indicates that the effects in Ecosystem Services provided by insects need a more empirical and targeted approach. Oliveira, M., et al. (2013). "Single and combined effects of microplastics and pyrene on juveniles (0+ group) of the common goby Pomatoschistus microps (Teleostei, Gobiidae)." Ecological Indicators **34**: 641-647.

Microplastic particles have increasingly been detected in aquatic biota, from zooplankton to fish, raising concern for potential effects on aquatic organisms. In addition, they may potentially influence the toxicity of other contaminants in the marine environment. The aim of this study was to clarify whether polyethylene microspheres (1-5 micro m) modulate short-term toxicity of the polycyclic aromatic hydrocarbon pyrene to juveniles (0+ group) of the common goby (Pomatoschistus microps). Fish were exposed for 96 h to pyrene (20 and 200 micro g L⁻¹) in the absence and presence of microplastics (0, 18.4 and 184 micro g L⁻¹). Mortality, bile pyrene metabolites, and biomarkers involved in neurotransmission, aerobic energy production, biotransformation and oxidative stress were quantified. Microplastics delayed pyrene-induced fish mortality and increased the concentration of bile pyrene metabolites. Microplastics, alone or in combination with pyrene, significantly reduced acetylcholinesterase (AChE) activity, an effect also observed for pyrene alone. The mixture also decreased isocitrate dehydrogenase (IDH) activity. No significant effects were found for glutathione S-transferase activity or lipid peroxidation. Overall, results show that: (i) microplastics modulate either the bioavailability or biotransformation of pyrene; (ii) simultaneous exposure to microplastics and pyrene decrease the energy available through the aerobic pathway of energy production; and (iii) microplastics inhibit AChE activity. The mechanism for AChE inhibition appeared to be different for pyrene and microplastics, since simultaneous exposure to both did not increase significantly the inhibitory effect. The observed neurotoxic effects of microplastics per se and the effects on IDH activity of the two stressors combined are of concern because they may increase mortality in natural fish populations. More studies need to be carried out on possible combined effects of microplastics and polycyclic aromatic hydrocarbons on fish, particularly juveniles.

Oliveira, P., et al. (2018). "Effects of microplastics and mercury in the freshwater bivalve Corbicula fluminea (Muller, 1774): Filtration rate, biochemical biomarkers and mercury bioconcentration." Ecotoxicology and Environmental Safety **164**: 155-163.

The main objectives of this study were to investigate the effects of a mixture of microplastics and mercury on Corbicula fluminea, the post-exposure recovery, and the potential of microplastics to influence the bioconcentration of mercury by this species. Bivalves were collected in the field and acclimated to laboratory conditions for 14 days. Then, a 14-day bioassay was carried out. Bivalves were exposed for 8 days to clean medium (control), microplastics (0.13 mg/L), mercury (30 micro g/L) and to a mixture (same concentrations) of

both substances. The post-exposure recovery was investigated through 6 additional days in clean medium. After 8 and 14 days, the following endpoints were analysed: the post-exposure filtration rate (FR); the activity of cholinesterase enzymes (ChE), NADP-dependent isocitrate dehydrogenase (IDH), octopine dehydrogenase, catalase, glutathione reductase, glutathione peroxidase and glutathione S-transferases (GST), and the levels of lipid peroxidation (LPO). After 8 days of exposure to mercury, the bioconcentration factors (BCF) were 55 in bivalves exposed to the metal alone and 25 in bivalves exposed to the mixture. Thus, microplastics reduced the bioconcentration of mercury by C. fluminea. Bivalves exposed to microplastics, mercury or to the mixture had significantly ($p <= 0.05$) decreased FR and increased LPO levels, indicating fitness reduction and lipid oxidative damage. In addition, bivalves exposed to microplastics alone had significant ($p <= 0.05$) reduction of adductor muscle ChE activity, indicating neurotoxicity. Moreover, bivalves exposed to mercury alone had significantly ($p <= 0.05$) inhibited IDH activity, suggesting alterations in cellular energy production. Antagonism between microplastics and mercury in FR, ChE activity, GST activity and LPO levels was found. Six days of post-exposure recovery in clean medium was not enough to totally reverse the toxic effects induced by the substances nor to eliminate completely the mercury from the bivalve's body. These findings have implications to animal, ecosystem and human health. Copyright © 2018 The Authors

Oliviero, M., et al. (2019). "Leachates of micronized plastic toys provoke embryotoxic effects upon sea urchin Paracentrotus lividus." Environmental Pollution **247**: 706-715.

Microplastics are defined as plastic fragments <5 mm, and they are found in the ocean where they can impact on the ecosystem. Once released in seawater, microplastics can be internalized by organisms due to their small size, moreover they can also leach out several additives used in plastic manufacturing, such as plasticizers, flame retardants, etc., resulting toxic for biota. The aim of this study was to test the toxicity of micronized PVC products with three different colors, upon Paracentrotus lividus embryos. In particular, we assessed the effects of micronized plastics and microplastic leachates. Results showed a decrease of larval length in plutei exposed to low concentrations of micronized plastics, and a block of larval development in sea urchin embryos exposed to the highest dose. Virgin PVC polymer did not result toxic on P. lividus embryos, while an evident toxic effect due to leached substances in the medium was observed. In particular, the exposure to leachates induced a development arrest immediately after fertilization or morphological alterations in plutei. Finally, PVC products with different colors showed different toxicity, probably due to a different content and/or combination of heavy metals present in coloring agents.

Oltean, S., et al. (2014). "Platelet refractoriness management on the basis of HLA antibody specificity." Tissue Antigens **84 (1)**: 119.

Platelet refractoriness (PR) is defined as a posttransfusion platelet increment less than expected. It occurs due to non-immune causes and/or immunological mechanisms such as alloimmunization to HLA and/or platelet-specific antigens. For patients who are refractory to platelet transfusion as a result of HLA alloimmunization there are three strategies for identifying compatible platelet units: HLA-matching, crossmatching and antibody specificity prediction. HLA typing by sequence specific oligonucleotide-PCR, detection of anti-HLA antibodies by a Luminex-based microbead assay and identification of their specificity on the Luminex platform utilizing microbeads coated with individual HLA are performed in our transfusion service in cases of PR. In 18 of 29 patients (62%) investigated over 1 year (Jan 2013 - Jan 2014) for PR we detected anti-HLA class I antibodies and identified their specificity. The gender ratio (F/M) was

12/6 in the anti-HLA class I positive group as compared to 4/7 in the negative group. Ten (5F/5M) of 18 patients were transfused with leucocyte-depleted blood components before the occurrence of PR (in 8 the transfusion history was not available). Among the positive patients, the highest MFI (mean fluorescence intensity) in the antibody identification assay varied between 1731 and 15436 (median 10400) and the most frequent specificity for the highest MFI was anti-A2 (30%). Sixteen (89%) of the positive patients had a haematological disease that had required subsequent multiple platelet transfusions. HLA antibody identification proved to be a very valuable tool in providing platelets selected according to the patient's antibody specificity in those cases when they could not benefit of HLA-mached platelets.

Omar, H., et al. (2004). "Techno-Economic Feasibility Study of Manufacturing Yarn from Recycled Plastics." Polymer-Plastics Technology & Engineering **43**(6): 1687-1693.

Solid waste management is becoming a problem that demands a timely solution. Those people concerned with municipal solid waste (MSW), are faced with the problem of disposing of significant volumes of potentially hazardous waste materials. There are many sectors which can make use of this MSW. One such sector in Oman is plastic manufacturing that uses polyethylene yarn from which they make net bags for the fruit and vegetable market. The yarn is produced from 75 wt.% high-density polyethylene (HDPE), 12 wt.% polyethylene (PE), and 13 wt.% MB for color. The HDPE comes from Asian countries and constitutes about 35% of the total production cost. Replacement of HDPE with 35 wt.% Recycled Product is estimated to reduce production costs by 10%. Such a reduction in production costs will give these local Plastic manufacturers a competitive edge. On the other hand, the reduction of plastic waste reduces the environmental effects, creates different groups of buyers, receivers, dealers and recycling enterprises, and therefore new jobs. [ABSTRACT FROM AUTHOR]

Omer, A. M., et al. (2016). "Development of amphoteric alginate/aminated chitosan coated microbeads for oral protein delivery." International Journal of Biological Macromolecules **92**: 362-370.

A new amphoteric biopolymer carrier based on alginate and aminated chitosan coated microbeads (Alg/AmCS) was developed and characterized for bovine serum albumin (BSA) protein delivery. The amphoteric character was investigated through studying the swelling and in vitro BSA release behaviors of the developed microbeads in simulated gastric (SGF; pH1.2), intestinal (SIF; pH6.8), and colonic (SCF; pH7.4) fluids. The pH sensitivity was found to depend on the amount of AmCS in the coating medium. The results were interpreted from the view of the individual pH sensitivity of alginate and aminated chitosan in addition to the ionic interaction between them under the studied pHs. Besides; it was found that the BSA loading efficiency (LE) exceeded 82% regardless of the initial concentration of BSA. The released amount of BSA reached approximately 63% and 86% in SIF and SCF, respectively, using 0.25% AmCS. The stability of alginate microbeads in SCF was improved with increasing AmCS concentration in the coating medium up to 2%. Furthermore, the developed microbeads demonstrated their ability for biodegradation in addition to their antibacterial activities against selected bacterial strains. The results clearly suggested that Alg/AmCS coated microbeads could be suitable carriers for site-specific protein delivery in the intestinal and colon tracts. Copyright © 2016 Elsevier B.V.

Onay, H. and G. Dalgic (2019). "SEASONAL CHANGES IN THE FOOD SPECTRUM AND DAY-TIME RHYTHM OF FEEDING IN RED MULLET MULLUS BARBATUS (LINNAEUS, 1758) IN THE SOUTHEAST BLACK SEA." Fresenius Environmental Bulletin **28**(4): 2671-2268.

The diet of the red mullet Mullus barbatus was studied in the southeast Black Sea region of Turkey during the autumn, winter, summer and spring. In one year, the stomach contents of 760 individuals of M. barbatus, a confirmed omnivorous fish species, were examined (April 2017-March 2018), in addition to those of 180 additional individuals examined within a 24-h period (28 April 2018). Among the 14 prey groups identified in the stomachs of red mullet, the predominant one was Bivalvia, followed by Nematoda, Polychaeta, Brachyura and Cumacea. Data analysis revealed significant differences in prey species composition between seasons (ANOSIM, $R = 0.089$, $p < 0.001$). Moreover, the prey groups that constituted the majority of the diet changed significantly with a season. SIMPER analysis revealed that the prey item contributing the most to the differences between seasons was Bivalvia. Microplastic was also found in the samples. Analysis of the daily rhythm diet variation in stomach contents allowed the identification of 8 prey groups, namely Bivalvia, Amphipoda and Cumacea. In 24-hour examinations, feeding began in the first hours of the day, then showed an increase in the following hours and decreased after the evening. The results of this study could be used to describe the diversity of prey species and intraspecific food competition in the Black Sea. [ABSTRACT FROM AUTHOR]

O'Neill, G. J., et al. (2015). "Kinetics of immobilisation and release of tryptophan, riboflavin and peptides from whey protein microbeads." Food Chemistry **180**: 150-155.

This study investigated the kinetics of immobilisation and release of riboflavin, amino acids and peptides from whey microbeads. Blank whey microbeads were placed in solutions of the compounds. As the volume of microbeads added to the solution was increased, the uptake of the compounds increased, to a maximum of 95% for the pentapeptide and 56%, 57% and 45% for the dipeptide, riboflavin and tryptophan respectively, however, the rate of uptake remained constant. The rate of uptake increased with increasing molecule hydrophobicity. The opposite was observed in the release studies, the more hydrophobic compounds had lower release rate constants (kr). When whey microbeads are used as sorbents, they show excellent potential to immobilise small hydrophobic molecules and minimise subsequent diffusion, even in high moisture environments.

O'Neill, G. J., et al. (2015). "In vitro and in vivo evaluation of whey protein hydrogels for oral delivery of riboflavin." Journal of Functional Foods **19**(Part A): 512-521.

The release of riboflavin from whey microbeads under in vitro and in vivo gastrointestinal conditions was evaluated. Release of riboflavin from whey protein microbeads subjected to in vitro gastric digestion was rapid. To limit the release of riboflavin the microbeads were convection dried at 30 degrees C. Effects of temperature, pH and simulated gastric salts on the release of riboflavin from dried beads were examined. Dried microbeads underwent swelling at gastric and intestinal pH resulting in the release of 58 and 34% of riboflavin respectively in the

first hour. Drying significantly decreased the riboflavin release rate constant (k_r) from 0.1 to 0.016/min. Microbeads fed to piglets via oral gavage showed good resistance to gastrointestinal degradation as microbeads recovered from the colon 8.5 hours after ingestion were only partially degraded. This study showed that dried whey microbeads have potential as an encapsulation system for oral delivery of bioactives to the intestine.

Ongen, A. (2016). "Methane-rich syngas production by gasification of thermoset waste plastics." Clean Technologies & Environmental Policy **18**(3): 915-924.

Thermoset waste plastics from a cable materials company have been processed using pyrolysis/gasification in a fixed-bed steel reactor with cyclone separation unit to produce fuel gas mixture consisting primarily of H, CH, and CO. Initially, samples were pyrolysed at 600 °C and processed for gasification through 0.05 L min dry air at 750 °C. Following samples were conducted under direct gasification conditions at dry air flows varying 0.05, 0.1, and 0.2 L min at 750 °C. Transformation of solid residual, and liquid and gas products which were obtained at the end of the thermal processes conducted under varying conditions was monitored. Volume percentages of H, CH, and CO gases within the produced gas were instantly measured via continuous gas analyser. It was determined that thermoset plastic waste which can remain in the environment without disintegration decreases in mass by 94 % and solid forms being easy to control occur at the end of heat treatment. Within the scope of waste-to-energy, 3100 kcal m medium calorific value gas was produced through direct gasification 750 °C and optimum air volume was 0.05 L min. Data management and statistical analysis were carried out with SPSS software. Thermochemical processing of waste plastic from waste wire and cable materials in a fixed-bed steel reactor with a cyclone separator achieved promising results to produce synthetic fuel gas. Onink, V., et al. (2019). "The Role of Ekman Currents, Geostrophy, and Stokes Drift in the Accumulation of Floating Microplastic." Journal of Geophysical Research. Oceans **124**(3): 1474-1490.

Floating microplastic in the oceans is known to accumulate in the subtropical ocean gyres, but unclear is still what causes that accumulation. We investigate the role of various physical processes, such as surface Ekman and geostrophic currents, surface Stokes drift, and mesoscale eddy activity, on the global surface distribution of floating microplastic with Lagrangian particle tracking using GlobCurrent and WaveWatch III reanalysis products. Globally, the locations of microplastic accumulation (accumulation zones) are largely determined by the Ekman currents. Simulations of the North Pacific and North Atlantic show that the locations of the modeled accumulation zones using GlobCurrent Total (Ekman+Geostrophic) currents generally agree with observed microplastic distributions in the North Pacific and with the zonal distribution in the North Atlantic. Geostrophic currents and Stokes drift do not contribute to large-scale microplastic accumulation in the subtropics, but Stokes drift leads to increased microplastic transport to Arctic regions. Since the WaveWatch III Stokes drift and GlobCurrent Ekman current data sets are not independent, combining Stokes drift with the other current components leads to an overestimation of Stokes drift effects and there is therefore a need for independent measurements of the different ocean circulation components. We investigate whether windage

would be appropriate as a proxy for Stokes drift but find discrepancies in the modeled direction and magnitude. In the North Pacific, we find that microplastic tends to accumulate in regions of relatively low eddy kinetic energy, indicating low mesoscale eddy activity, but we do not see similar trends in the North Atlantic. Plain Language Summary: Microplastic is a common form of pollution in the oceans, and high floating microplastic concentrations tend to be observed at the surface in the subtropical ocean gyres. These regions are commonly referred to as garbage patches. However, the physical processes that control the buildup in these regions are not yet fully understood. Therefore, we model microplastic transport with various surface current components that correspond to different physical processes. We do this with Lagrangian modeling, where microplastic is represented by virtual particles that are transported by ocean currents. We find good agreement between the modeled distribution with the full surface currents with observations in the North Pacific and North Atlantic and find that the microplastic accumulation is mainly due to the wind-driven Ekman currents. Meanwhile, wave-driven Stokes drift results in microplastic transport to Arctic regions. Since Stokes drift has not consistently been included in microplastic transport modeling, microplastic contamination of Arctic regions might be more severe than currently expected. Key Points: Ekman currents are the main process behind microplastic accumulation in the subtropical ocean gyresStokes drift contributes to microplastic transport to Arctic regionsWindage is, on a global scale, not an accurate proxy to model Stokes drift dynamics [ABSTRACT FROM AUTHOR]

Onwudili, J. A. and P. T. Williams (2016). "Catalytic supercritical water gasification of plastics with supported RuO2: A potential solution to hydrocarbons-water pollution problem." Process Safety & Environmental Protection: Transactions of the Institution of Chemical Engineers Part B **102**(Part B): 140-149.

Here we report on a potential catalytic process for efficient clean-up of plastic pollution in waters, such as the Great Pacific Garbage Patch (GPGP). Detailed catalytic mechanisms of RuO2 during supercritical water gasification of common polyolefin plastics including low-density polyethylene (LDPE), high-density polyethylene (HDPE), polypropylene (PP) and polystyrene (PP) have been investigated in a batch reactor at 450 °C for 60 min. All four plastics gave very high carbon gasification efficiencies (CGE) and hydrogen gasification efficiencies (HGE). Methane was the highest gas component, with a yield of up to 37 mol kg-1 LDPE using the 20 wt% RuO2 catalyst. Evaluation of the gas yields, CGE and HGE revealed that the conversion of PS involved thermal degradation, steam reforming and methanation; whereas hydrogenolysis was a possible additional mechanism during the conversion of aliphatic plastics. The process has the benefits of producing a clean-pressurized methanerich fuel gas as well as cleaning up hydrocarbons-polluted waters. [ABSTRACT FROM AUTHOR]

Opitz, S., et al. (2015). "The removal of Triton X-100 by dialysis is feasible!" Analytical and bioanalytical chemistry **407**(4): 1107-1118.

Issue Title: A different way of looking at vibrational hyperspectral data/Micellar extraction for the analysis of Alzheimer's disease brain proteome/Quantification of polyolefin microplastics in personal-care products/Removal of Triton X-100 by microdialysis Triton X-100 has been widely used in many analytical and preparative protocols for a long time. Nevertheless, mass spectrometry, chromatographic separation, and spectrophotometric readout may be considerably hampered by this detergent due to signal suppression, complex formation, and high blank values, respectively. Additionally, Triton X-100 is not safe to remove prior to analytics. Here, microdialysis is introduced as a parallelizable, high-throughput method to clean samples from Triton X-100 with high efficacy and precision. To achieve this, we exploit the potential to considerably increase the critical micellar concentration of Triton X-100 by alteration of matrix properties. To that end, addition of several chaotropic compounds and organic solvents has been shown to increase the critical micellar concentration as well as the removal rate of the detergent. For application, matrix additives can be selected for analyte stability requirements out of a variety of compounds. Conveniently, all these additives are removable subsequently using the same microdialysis tool for downstream analytics requirements. Applicability and protocols are shown with proteomic sample preparation of purified proteins and complex protein mixtures prior to matrix-assisted laser desorption ionization (MALDI) mass spectrometry.

Oppenheimer, H., et al. (2012). "SET7/9 and SIRT1 induce promoter-driven collagen 2ALPHA1 expression in 3D cultured human chodrocytes." Annals of the Rheumatic Disease. Conference: Annual European Congress of Rheumatology of the European League Against Rheumatism, EULAR **71**(SUPPL. 3).

Background Osteoarthritis (OA) is characterized by disrupted balance between extracellular matrix (ECM) synthesis and breakdown, leading to loss of articular cartilage (AC) and severe joint pain-dysfunction. Collagen type IIalpha1 (Col2alpha1) is a predominant cartilage-type ECM component that forms densely packed fibers which provide tensile force to the tissue, enabling it to withstand mechanical compression. Previous published findings establish that the protein deacetylase SirT1 is a positive regulator of Col2alpha1 expression. SirT1 achieves this by recruiting PGC1a and Sox9 to the enhancer region of Col2alpha1. Additional data in SirT1 overexpressing chondrocytes show that SirT1 is enriched on the promoter region of actively transcribed Col2alpha1 and reduced during OA development. Objectives Here we propose to explore the SirT1-mediated promoter-driven mechanism of Col2alpha1 expression in human chondrocytes. Methods Isolated human OA-derived (passage 2) chondrocytes were encapsulated in three dimensional (3D) alginate hydrogel microbeads and systematically compared to their equivalent monolayer (2D) cultures. Col2alpha1 expression was examined via confocal microscopy immunofluorescence, quantitative PCR (qPCR) and immunoblot analyses. SirT1 protein and RNA levels were analyzed via immunoblot and qPCR analyses, respectively. Chromatin immunoprecipitation (ChIP) for SirT1, SirT1-associated chromatin modifying enzymes (CMEs) and histone modifications were carried out on the Col2alpha1 promoter site. Sequential ChIP was executed to characterize SirT1 complex formation with CMEs on the Col2alpha1-promoter of actively transcribed Col2alpha1. Results 3D-cultured human chondrocytes possessed augmented expression of Col2alpha1 as compared to their equivalent 2D cultures. ChIP analyses for the promoter of Col2alpha1 exhibited enrichment for SirT1 and the histone methyl transferase SET7/9 in 3D cultured chondrocytes vs. 2D cultures. Sequential-ChIP assays revealed that SirT1 and SET7/9 form a protein complex on the promoter

region of Col2alpha1 and show elevated marks of Histone 3 Lysine 4 trimethylation (3MeH3K4), where Col2a1 is actively transcribed. Contrary to the enrichment SirT1 on the Col2a1 promoter site, ChIP assays revealed enhanced acetylation of its histone target H4K16 during Col2a1 expression. Conclusions (i) 3D/2D experimental platforms provide a valuable tool for deciphering epigenetic mechanisms of gene regulation towards a better understanding of processes leading to tissue degeneration and disease, as in OA. (ii) Our preliminary data show that SirT1 and SET7/9 co-regulate COL2alpha1 expression through their enhanced association on its promoter region. Increased marks of histone acetylation especially in known SirT1 deacetylation targets (i.e. H4K16) may be a result the inhibitory effect of SET7/9 on the SirT1 deacetylase activity, consistent with previous reports. Expectedly, these investigations will provide mechanistic insight of cartilage ECM production, towards identifying novel epigenetic drug targets for the treatment of OA in susceptible individuals.

Oppenheimer, H., et al. (2013). "SET7/9 represses sirt1 to induce collagen type ii expression in3D cultured human chodrocytes." Osteoarthritis and Cartilage **1)**: S170.

Objective: Collagen type II (Col-II) plays a significant role in skeletal development and cartilage homeostasis and its loss with age is associated with degenerative joint diseases such as osteoarthritis (OA). Previously findings establish that the protein deacetylase SirT1 is required for enhanced expression of Col-IIa1, a major cartilage structural component of Col-II. Here we profile the mechanism by which SirT1 activates promoter-driven Col-IIa1 expression. Method(s): Chondrocytes derived from human osteoarthritic knee joints were encapsulated in three-dimensional alginate hydrogel microbeads (3D) and compared to paired monolayer (2D, passage 2) cultures derived from the same donor tissue. 3D-cultured cells displayed augmented expression of Col-IIa1 and were subject to serial chromatin immunoprecipitation (ChIP) and ChIP reChIP analyses to characterize epigenetic variations as compared to 2D cultures. Result(s): ChIP analyses exhibited enrichment for SirT1 and the histone methyl transferase Set7/9, which formed a complex in 3D cultures wherein Col-IIa1 was augmented in expression. Consistent with enriched Set7/9 levels on the Col-IIa1 promoter, ChIP data revealed enriched levels of trimethylation on histone 3 lysine 4 (3MeH3K4). Acetylated H3K9/14 and H4K16 on Col-IIa1 promoters of 3D-cultured chondrocytes were also elevated indicating that SirT1 is enzymatically repressed by Set7/9 on the transactivated Col-IIa1 promoter. Elevated marks of the Histone acetyl transferases GCN5 and P300 also supported the local enrichment of their acetylated histone marks (i.e. H3K9/ 14,H4K5 and H4K16). Conclusion(s): The data support that Set7/9 is capable of locally repressing SirT1 enzymatic activity on the promoter of Col-IIa1, resulting in its augmented expression dependent on cell morphology.

Oren, A., et al. (2005). "A comparative study of immunomagnetic methods used for separation of human natural killer cells from peripheral blood." Journal of Immunological Methods **303**(1-2): 1-10.

Immunomagnetic sorting of natural killer (NK) cells from the peripheral blood of healthy donors has been evaluated in a comparative study of composition, yield and activation of target cells obtained by positive (Dynabeads, Microbeads) and negative (Microbeads) sorting procedures. Positively sorted target cells were selected by expression of the NK cell marker CD56, whereas NK cells obtained by negative sorting were those remaining after steps to remove all non-NK cell leukocyte populations were accomplished. In positive sorting, both CD56+CD3- NK cells and CD56+CD3+ natural killer T (NKT) cells were included. The NKT cell fraction differed between individuals, but not between the positive sorting methods. Whereas 20-30% of positively sorted target cells were NKT cells, only approximately 3% of negatively sorted cells were CD3+. Contamination with monocytes and B cells was low (1-3%) in all methods studied. Sorting with

Microbeads (both positive and negative) gave higher cell yields than those obtained with Dynabeads (14% vs. 5% of total leukocyte numbers). A higher CD56 fluorescence intensity of NK cells and a better discrimination between the CD56bright and CD56dim NK cell subpopulations was obtained after negative sorting. Dynabeads-separated cells had, shortly after separation, a significantly higher expression (approximately 30%) of the early activation marker CD69 than cells either positively or negatively separated by Microbeads (approximately 8%). CD56+ cells positively sorted by Microbeads demonstrated a significantly higher production of TNF-alpha and IFN-gamma after IL-2 stimulation than Dynabeads-sorted cells. However, the cytotoxicity of cells obtained by the two positive sorting procedures did not differ. In conclusion, positive selection of CD56+ cells by Microbeads is better than Dynabeads, as determined from cell yield and procedure-associated cell activation and should be chosen for in vitro studies of NK/NKT cells. However, when pure NK cells and phenotypic subtypes are to be studied, negative sorting seems most appropriate.

Orhan, Y. and H. Bueyuekguengoer (2000). "Enhancement of biodegradability of disposable polyethylene in controlled biological soil." International Biodeterioration & Biodegradation **45**(1-2): 49-55.

Plastics as polyethylene are widely used in packaging and other agricultural applications. They accumulate in the environment at a rate of 25 million tons per year. Thus, the development and use of degradable plastics was proposed as a solution for plastic waste problem. Because of the ever-increasing use of plastic films, nowadays, biodegradability has become a useful characteristic for plastics. Conversely, the introduction of biodegradable plastics has generated a need for methods to evaluate the biodegradation of these polymers in landfills and solid waste treatment systems such as composting or anaerobic digestion treatment plants. The purpose of this study was to investigate the biodegradation of disposable low-density polyethylene bags containing starch (12%), autoxidizable fatty acid ester and catalytic agents in soil. Structurally this work intended to evaluate the capacity of Phanerochaete chrysosporium (ATCC 34541) to enhance polyethylene film biodegradation in soil microcosms. Soil samples inoculated with P. chrysosporium were mixed with LDPE/starch blend films and biological changes of the films and soil were monitored for 6 months. The biodegradation of polyethylene starch blend film has been determined by the physical, chemical and biological properties of the samples such as pH, biomass, CO sub(2) formation, percentage elongation, relative viscosity and FTIR spectrum.

Oriekhova, O. and S. Stoll (2018). "Heteroaggregation of nanoplastic particles in the presence of inorganic colloids and natural organic matter." Environmental Science: Nano **5**(3): 792-799.

The presence and accumulation of micro- and nanoplastics in marine and fresh waters represent a huge environmental concern. Due to the complexity of nanoplastic surface chemistry and impact of the surrounding aquatic environment, the fate of nanoplastics is still difficult to evaluate. Our study aims to explore the effect of different water components such as natural organic matter and inorganic colloids as well as water composition on the stability of polystyrene nanoplastics. Heteroaggregation experiments are performed under contrasting conditions by considering mixtures of three components: nanoplastics, Fe_2O_3 and alginate and at different concentration ratios. It is found that the charge neutralization mechanism in most cases is responsible for the formation of large heteroaggregates. A shift in the optimal heteroaggregation concentration is observed in the presence of alginate indicating competitive effects between alginate and Fe_2O_3. The formation of primary heteroaggregates is found to be a requisite before the formation of large structures. The behavior of polystyrene nanoplastics is also studied here in natural water from the Rhône river. Nanoplastic particles are found to

rapidly change their surface charge from positive to negative and form small heteroaggregates at low concentration. Increasing the nanoplastic particle concentration is found to result in the formation of large heteroaggregates when the isoelectric point is achieved indicating the importance of nanoplastic surface charge neutralization.

Orte, M. R. d., et al. (2019). "Response of bleached and symbiotic sea anemones to plastic microfiber exposure." Environmental Pollution **249**: 512-517.

Microplastics are emerging contaminants in the marine environment. They enter the ocean in a variety of sizes and shapes, with plastic microfiber being the prevalent form in seawater and in the guts of biota. Most of the laboratory experiments on microplastics has been performed with spheres, so knowledge on the interactions of microfibers and marine organisms is limited. In this study we examined the ingestion of microfibers by the sea anemone Aiptasia pallida using three different types of polymers: nylon, polyester and polypropylene. The polymers were offered to both symbiotic (with algal symbionts) and bleached (without algal symbionts) anemones. The polymers were introduced either alone or mixed with brine shrimp homogenate. We observed a higher percentage of nylon ingestion compared to the other polymers when plastic was offered in the absence of shrimp. In contrast, we observed over 80% of the anemones taking up all types of polymers when the plastics were offered in the presence of shrimp. Retention time differed significantly between symbiotic and bleached anemones with faster egestion in symbiotic anemones. Our results suggest that ingestion of microfibers by sea anemones is dependent both on the type of polymers and on the presence of chemical cues of prey in seawater. The decreased ability of bleached anemones to reject plastic microfiber indicates that the susceptibility of anthozoans to plastic pollution is exacerbated by previous exposure to other stressors. This is particularly concerning given that coral reef ecosystems are facing increases in the frequency and intensity of bleaching events due to ocean warming.

Ortega Lopez, J., et al. (1993). "Lactose hydrolysis by immobilized beta -galactosidase on nylon-6: a novel spin-basket reactor." Biotechnology Techniques **7**(11): 775-780.

beta -D-Galactosidase from Kluyveromyces marxianus var. lactis immobilized on nylon-6 microbeads was used to hydrolyse lactose in skim milk (28.6% TS) using a novel spin-basket reactor. >75% of lactose was hydrolysed at 34 degrees C and a flow rate of 1.5 litres/h within a short time period (<7 min). The spin-basket reactor configuration had the kinetic advantage of a packed-bed reactor, and none of the plugging typically seen in packed column methods was experienced. The activity of the immobilized enzyme remained virtually unchanged after 52 days of alternate use and storage at 4 degrees C; after 29 months 53% of the original enzyme activity remained. It is suggested that a short washing cycle could be introduced to reduce the loss of enzyme activity caused by microbial contamination and to increase the operational life of the enzyme. This system satisfied requirements for industrial application in that it demonstrated high efficiency and stability and had a reactor configuration which was appropriate for continuous operation.

Ortiz, N. (2018). Eps antibiotics: photodecomposition and biocarbon adsorption. London, Emerging pollutants
Intech**:** 79-97 27 ref.

The emerging pollutants (EPs) are considered a global monitoring challenge, present in the environment in very reduced concentrations, and the proper methods for sampling and analysis are still in development. Many published types of research considering the EPs identification only depend on the analytical methodology and a more efficient higher number of EPs. The quantitative determination of the prioritized EPs in water needs advanced and ultra-sensitive instrumental techniques applied in water, water-suspended mater, soil, and biota. The regulatory framework of the water-quality parameters does not often include the microplastics, EPs, and their metabolites; especially, the groundwater water-quality monitoring and control are urgent but not yet achieved. The EPs sources in water are the sewage, industrial, and agricultural waste discard, and the UN estimated that the wastewater produced annually is about 1500 km³, about six times more water than existing in all rivers of the word. In 2015, in China, which has a fast-growing economy, the water is a scarce resource with just 8% of the world's fresh water to meet the water needs of the 22% of the world's population.

Ory, N., et al. (2018). "Low prevalence of microplastic contamination in planktivorous fish species from the southeast Pacific Ocean." Marine Pollution Bulletin **127**: 211-216.

The gut contents of 292 planktivorous fish, from four families (Atherinopsidae, Clupeidae, Engraulidae and Scombridae) and seven species, captured along the coast of the southeast Pacific, were examined for microplastic contamination. Only a small fraction of all studied fish (2.1%; 6 individuals) contained microplastic particles in their digestive tract. Microplastics found were degraded hard fragments and threads, ranging from 1.1 to 4.9 (3.8 +/- SD 2.4) mm in length, and of various colours, which suggests that the planktivorous fish species examined herein did not capture microplastics on the basis of their colour. The low prevalence of microplastic contamination in planktivorous fishes found in this study suggests that the risk of accidental ingestion by these species might be limited in the coastal upwelled waters of the southeast Pacific, perhaps due to small human population and highly dynamic oceanographic processes. Copyright © 2017 Elsevier Ltd

Ory, N. C., et al. (2018). "Capture, swallowing, and egestion of microplastics by a planktivorous juvenile fish." Environmental Pollution **240**: 566-573.

Microplastics (<5 mm) have been found in many fish species, from most marine environments. However, the mechanisms underlying microplastic ingestion by fish are still unclear, although they are important to determine the pathway of microplastics along marine food webs. Here we conducted experiments in the laboratory to examine microplastic ingestion (capture and swallowing) and egestion by juveniles of the planktivorous palm ruff, Seriolella violacea (Centrolophidae). As expected, fish captured preferentially black microplastics, similar to food pellets, whereas microplastics of other colours (blue, translucent, and yellow) were mostly co-captured when floating close to food pellets. Microplastics captured without food were almost always spit out, and were only swallowed when they were mixed with food in the fish's mouth. Food probably produced a 'gustatory trap' that impeded the fish to discriminate and reject the microplastics. Most fish (93% of total) egested all the microplastics after 7 days, on average, and 49 days at most, substantially longer than food pellets (<2 days). No acute detrimental effects of microplastics on fish were observable, but potential sublethal effects of microplastics on the fish physiological and behavioural responses still need to be tested. This study highlights that visually-oriented planktivorous fish, many species of which are of commercial value and ecological importance within marine food webs, are susceptible to ingest microplastics resembling or floating close to their planktonic prey.

Ory, N. C., et al. (2017). "Amberstripe scad Decapterus muroadsi (Carangidae) fish ingest blue microplastics resembling their copepod prey along the coast of Rapa Nui (Easter Island) in the South Pacific subtropical gyre." Science of the Total Environment **586**: 430-437.

An increasing number of studies have described the presence of microplastics (<=5 mm) in many

different fish species, raising ecological concerns. The factors influencing the ingestion of microplastics by fish remain unclear despite their importance to a better understanding of the routes of microplastics through marine food webs. Here, we compare microplastics and planktonic organisms in surface waters and as food items of 20 Amberstripe scads (Decapterus muroadsi) captured along the coast of Rapa Nui (Easter Island) to assess the hypothesis that fish ingest microplastics resembling their natural prey. Sixteen (80%) of the scad had ingested one to five microplastics, mainly blue polyethylene fragments that were similar in colour and size to blue copepod species consumed by the same fish. These results suggest that planktivorous fish, as a consequence of their feeding behaviour as visual predators, are directly exposed to floating microplastics. This threat may be exacerbated in the clear oceanic waters of the subtropical gyres, where anthropogenic litter accumulates in great quantity. Our study highlights the menace of microplastic contamination on the integrity of fragile remote ecosystems and the urgent need for efficient plastic waste management.

Osama, A. M., et al. (1999). "Construction and characterization of bacterial artificial chromosome library of Egyptian cotton (Gossypium barbadense L.)." Egyptian Journal of Agricultural Research **77**(4): 1769-1787.

Bacterial artificial chromosome (BAC) libraries for the Gossypium barbadense cultivars Giza 70, Giza 86, and Giza 75 were constructed and characterized. The isolation and purification of high molecular weight DNA from nuclei embedded in agarose microbeads was an essential part of this work. Several experimental parameters were investigated, including optimization of megabase-size DNA restriction enzyme digest and CHEF gel conditions to achieve the highest resolution and separation of such DNA. Fragments ranging in size from 200 to 500 kb were size selected and recovered from agarose gel to be used in BAC library construction. BAC vector pBeloBAC II, derived from endogenous Escherichia coli F-factor plasmid, was used in library construction. Different insert : vector ligation ratios examined indicated 15:1 to be the optimum. The maximum construct-host transformation efficiency was calculated at 1.8 kV electroporation voltage. Purification and isolation of BAC clones was followed by restriction enzyme digestion using NotI to characterize insert sizes. Characterization of insert sizes and integrity was achieved by using CHEF gel electrophoresis conditions at 6V/cm, 5 and 15 sec initial and final switch times, respectively, and 12 degrees C temperature for 12 h. BAC libraries for Giza 70, Giza 86 and Giza 75 contained 45 237, 45 742 and 46 531 clones, respectively, with an average insert size of 100 kb. Considering the haploid genome size for cotton to be 2118 Mb, the BAC libraries contain 2.12 haploid genome equivalents. The BAC libraries constructed for Giza 70, Giza 86 and Giza 75 provide 88% probability of isolating a specific genomic region and are optimized for future gene identification, isolation, target gene mapping and chromosome walking.

Osborn, S. L., et al. (2015). "Inosculation of Blood Vessels Allows Early Perfusion and Vitality of Bladder Grafts-Implications for Bioengineered Bladder Wall." Tissue Engineering, Part A: Tissue Engineering **21**(11-12): 1906-1915.

Bioengineered bladder tissue is needed for patients with neurogenic bladder disease as well as for cancer. Current technologies in bladder tissue engineering have been hampered by an inability to efficiently initiate blood supply to the graft, ultimately leading to complications that include graft contraction, ischemia, and perforation. To date, the biological mechanisms of vascularization on transplant have not been suitably investigated for urologic tissues. To better understand the mechanisms of neovascularization on bladder wall transplant, a chimeric mouse model was generated such that angiogenesis and vasculogenesis could be independently assessed in vivo. Green fluorescence protein (GFP) transgenic mice received bone marrow transplants from beta -galactosidase (LacZ) transgenic animals and then subsequent bladder wall transplants from wild-type donor mice. Before euthanization, the aorta was infused with fluorescent microbeads (fluorospheres) to identify perfused vessels. The contributions of GFP (angiogenesis) and LacZ (vasculogenesis) to the formation of CD31-expressing blood vessels within the wild-type graft were evaluated by immunohistochemistry at different time points and locations within the graft (proximal, middle, and distal) to provide a spatiotemporal analysis of neovascularization. The GFP index, a measure of angiogenic host ingrowth, was significantly higher at proximal versus mid or distal regions in animals 2-16 weeks post-transplant. However, GFP index did not increase over time in any area. Within 7 days post-transplant, perfusion of primarily wild-type, donor blood vessels in the most distal areas of the graft was observed by intraluminal fluorospheres. In addition, chimeric host-donor (GFP-wild type) blood vessels were evident in proximal areas. The contribution of vasculogenesis to vascularization of the graft was limited, as LacZ cells were not specifically associated with the endothelial cells of blood vessels, but rather found primarily in areas of inflammation. The data suggest that angiogenesis of host blood vessels into the proximal region leads to inosculation between host and donor vessels and subsequent perfusion of the graft via pre-existing graft vessels within the first week after transplant. As such, the engineering of graft blood vessels and the promotion of inosculation might prevent graft contraction, thereby potentiating the use of bioengineered bladder tissue for transplantation.

Osborne, L. D., et al. (2012). "12-Channel high-throughput microscope for cancer cell mechanics." Molecular Biology of the Cell. Conference: Annual Meeting of the American Society for Cell Biology, ASCB **23**(24).

Understanding how cell behavior and function relates to physical structure is a major goal of current cell mechanics studies. Elucidating this relationship is especially important in the study of cancer biology related to dramatic phenotypic changes as seen in epithelial to mesenchymal transitions. Although much interest is given to studying the signaling pathways that govern how normal cell function and structure become abnormal during cancer progression, these changes convolute already difficult and highly variable mechanical measurements of single cells. To address the need of minimizing single measurement variability as well as the desire to explore the large signaling-protein parameter spaces of cancer biology, we have developed an automated high throughput microscope system that utilizes passive microbead diffusion to characterize cell mechanics. Here, we report on the instrumentation advances of our system, including 12 independently controllable optical paths - each of which is capable of video rate image acquisition in brightfield and two-channel fluorescence, and is equipped with electronically tunable autofocus. In all, video data collection across a 96-well plate takes as little as 10 minutes. A data analysis pipeline then identifies and tracks microbeads, filters and applies statistical analysis to mechanical measurements, and occurs completely unsupervised. We show that the thermal diffusion of micron-sized beads connected to integrin surface receptors via fibronectin can distinguish ovarian, pancreatic and skin cancers with varying metastatic potentials. With sampling sizes in the thousands, we report elastic moduli differences between cancer cell types as well as the effect of pharmaceutical treatments aimed to alter actin cytoskeletal structures. Our results support previously published work describing the inverse relationship between mechanical stiffness and invasion behavior, and ultimately, demonstrate the value of our high throughput instrument and passive rheology assay as a screening tool for studying relevant signaling pathways involved in cancer cell mechanics.

Oskin, B. (2011). "The road less traveled." New Scientist **211**(2827): 54-55.

The article looks at sources of funding for scientific research other than grants from the U.S. National Institutes of Health (NIH) or the National Science Foundation (NSF). Renee Reijo Pera of Stanford University does research on human embryonic stem cells which is funded by the university, nonprofit organizations, and private donors. Environmentalist Mary Maxwell used crowdfunding to study plastic pollution, while the biomedical research institution Stowers Institute fully funds scientists.

Osmann, B., et al. (2019). "Comment on "exposure to microplastics (<10 mum) associated to plastic bottles mineral water consumption: The first quantitative study by Zuccarello et al." Water Research **162**: 516-517.

Microplastics in food is a relatively new research field with only few studies available so far. Scientists have been pointing out that some of these studies apply questionable analytical methods. Nevertheless, media often use such results to gain attention of the readers. It is therefore of particular significance, that only those scientific studies are published, clearly presenting valid data on the content of microplastics in food. Unfortunately, the study by Zuccarello et al. shows very critical aspects regarding analytical methods used and conclusions made. The applied procedure is not described and, therefore, does not allow any assessment by other groups, which is indispensable prerequisite of any scientific publication. Moreover, the analytical method used for the identification and quantification of microplastic particles - SEM-EDX - is not sound and not validated. Therefore, in our opinion the results on the contamination of bottled mineral water with microplastics published by Zuccarello et al. are more than questionable.

Osmann, B. E., et al. (2018). "Small-sized microplastics and pigmented particles in bottled mineral water." Water Research **141**: 307-316.

Up to now, only a few studies about microparticle contamination of bottled mineral water have been published. The smallest analysed particle size was 5mum. However, due to toxicological reasons, especially microparticles smaller than 1.5mum are critically discussed. Therefore, in the present study, 32 samples of bottled mineral water were investigated for contamination by microplastics, pigment and additive particles. Due to the application of aluminium coated polycarbonate membrane filters and micro-Raman spectroscopy, a lowest analysed particle size of 1mum was achieved. Microplastics were found in water from all bottle types: in single use and reusable bottles made of poly(ethylene terephthalate) (PET) as well as in glass bottles. The amount of microplastics in mineral water varied from 2649+/-2857 per litre in single use PET bottles up to 6292+/-10521 per litre in glass bottles. While in plastic bottles, the predominant polymer type was PET; in glass bottles various polymers such as polyethylene or styrene-butadiene-copolymer were found. Hence, besides the packaging itself, other contamination sources have to be considered. Pigment particles were detected in high amounts in reusable, paper labelled bottles (195047+/-330810 pigment particles per litre in glass and 23594+/-25518 pigment particles per litre in reusable paper labelled PET bottles). Pigment types found in water samples were the same as used for label printing, indicating the bottle cleaning process as possible contamination route. Furthermore, on average 708+/-1024 particles per litre of the additive Tris(2,4-di-tert-butylphenyl)phosphite were found in reusable PET bottles. This additive might be leached out from the bottle material itself. Over 90% of the detected microplastics and pigment particles were smaller than 5mum and thus not covered by previous studies. In summary, this is the first study reporting about microplastics, pigment and additive particles found in bottled mineral water samples with a smallest analysed particle size of 1mum.

Osmann, B. E., et al. (2017). "Development of an optimal filter substrate for the identification of small microplastic particles in food by micro-Raman spectroscopy." Analytical & Bioanalytical Chemistry **409**(16): 4099-4109.

When analysing microplastics in food, due to toxicological reasons it is important to achieve clear identification of particles down to a size of at least 1 mum. One reliable, optical analytical technique allowing this is micro-Raman spectroscopy. After isolation of particles via filtration, analysis is typically performed directly on the filter surface. In order to obtain high qualitative Raman spectra, the material of the membrane filters should not show any interference in terms of background and Raman signals during spectrum acquisition. To facilitate the usage of automatic particle detection, membrane filters should also show specific optical properties. In this work, beside eight different, commercially available membrane filters, three newly designed metal-coated polycarbonate membrane filters were tested to fulfil these requirements. We found that aluminium-coated polycarbonate membrane filters had ideal characteristics as a substrate for micro-Raman spectroscopy. Its spectrum shows no or minimal interference with particle spectra, depending on the laser wavelength. Furthermore, automatic particle detection can be applied when analysing the filter surface under dark-field illumination. With this new membrane filter, analytics free of interference of microplastics down to a size of 1 mum becomes possible. Thus, an important size class of these contaminants can now be visualized and spectrally identified. Graphical abstract A newly developed aluminium coated polycarbonate membrane filter enables automatic particle detection and generation of high qualitative Raman spectra allowing identification of small microplastics.

Ostendorff, H. P., et al. (2013). "Multiplexed VeraCode bead-based serological immunoassay for colorectal cancer." Journal of Immunological Methods **400-401**: 58-69.

Colorectal cancer (CRC) is the second leading cause of cancer deaths in the US and Western world. Despite increased screening and advances in treatment, the mortality rate (ca. 50,000/year) and high national health-care burden for CRC are likely to remain high unless an effective non-invasive screening test for CRC is instituted for a large segment of the population. Blood-based protein biomarkers hold great promise for early disease diagnosis and personalized medicine; yet robust and reproducible multiplexing platforms and methodologies have lagged behind their genomic counterparts. Here, we report the development of a novel, multiplexed, hybrid immunoassay for CRC that is formatted on barcoded VeraCodeTM micro-beads, which

have until now only been used for genomic assays. The method combines a sandwich immunoassay format for detection of serum protein biomarkers with an antigen assay for autoantibody detection. The serum protein biomarkers CEA and GDF15 as well as autoantibodies to the p53 tumor associated antigen (TAA) were used to exemplify the method. This multiplex biomarker panel was configured to run on Illumina's holographically barcoded VeraCodeTM micro-bead platform, which is capable of measuring hundreds of analytes simultaneously in a single well from small volumes of blood (<50 muL) using a 96-well industry standard microtiter plate. This novel use of the VeraCodeTM micro-bead platform translates into a potentially low volume, high throughput, multiplexed assay for CRC, for the purposes of biomarker validation, as well as patient screening, diagnostics and prognostics. In an evaluation of a 186 patient sera training set (CRC and normal), we obtained a diagnostic sensitivity of 54% and a specificity of 98%. We anticipate that by expanding and refining the biomarkers in this initial panel, and performing more extensive clinical validations, such an assay could ultimately provide a basis for CRC population screening to complement the more invasive, expensive and low throughput (but highly sensitive and specific) colonoscopy.

Ostrowski, L. E., et al. (2019). "Mucociliary transport in vitro: Effect of mucin concentration, reducing agents, and DNA on rheological properties and transport rate." American Journal of Respiratory and Critical Care Medicine. Conference **199**(9).

Rationale: Mucus obstruction is a common feature of many airway diseases, including chronic obstructive pulmonary disease (COPD), cystic fibrosis (CF), primary ciliary dyskinesia (PCD), and asthma. Improved treatments for these diseases require a thorough understanding of how changes in mucus composition affect mucociliary clearance (MCC) and how different therapeutics affect mucus rheology and mucociliary transport. We have developed an in vitro system in which well-differentiated cultures of primary human airway epithelial cells continuously transport mucus, allowing carefully controlled investigations of a wide-range of experimental and therapeutic manipulations. METHOD(S): Early passage human bronchial epithelial (HBE) cells were cultured at the air/liquid interface in modified culture inserts as previously published (Sears, Yin, Ostrowski; Am J Physiol Lung Cell Mol Physiol. 2015). In these modified inserts, the presence of a central ring encourages the development of circular mucociliary transport (MCT) that is maintained for extended periods. For these studies, cultures demonstrating circular transport were washed to remove endogenous mucus. To provide a standard mucus for comparisons, bovine submaxillary mucus (BSM) was used. BSM at different concentrations that simulate healthy and disease states, as well as mucus treated with therapeutic agents, was labeled with fluorescent microbeads and added to the washed cultures and the rate of MCT was determined. In parallel, mucus rheology (viscosity, elasticity) was measured in the same BSM preparations. Controls typically included measuring MCT in the same culture using BSM with and without the experimental treatment, and studies were performed using cultured cells from multiple different donors. RESULT(S): Mucociliary transport was reduced when higher concentrations of BSM that mimic pathological mucus (50 mg/ml) were compared to lower concentrations that mimic healthy mucus (20 mg/ml). Treatment of the high concentration BSM with the reducing agent tris(2-carboxyethyl)phosphine (TCEP) reduced viscosity and increased the rate of MCT by ~2-fold. Addition of a small amount of high molecular weight DNA (0.02%) increased mucus viscosity and significantly reduced MCT. CONCLUSION(S): Our data show that well-differentiated cultures of HBE cells grown under conditions that promote MCT provide a useful system to investigate MCC in vitro. Further, these cultures can be utilized to investigate the effect of potential therapeutic agents under carefully controlled conditions. Interestingly, these data show that a relatively small amount of high

molecular weight DNA has a significant effect on the rate of MCT. Future studies will compare the effectiveness of different therapeutic approaches, alone and in combination, to improve the treatment of muco-obstructive diseases.

Otsyina, H. R., et al. (2018). "Knowledge, attitude, and practices on usage, disposal, and effect of plastic bags on sheep and goats." Tropical Animal Health & Production **50**(5): 997-1003.

The objective of this study was to evaluate knowledge, attitudes, and practices of people in the Nairobi and Kajiado Counties, Kenya, on the usage, disposal, and effect of plastic waste on sheep and goats (shoats). A semi-structured questionnaire was used to collect data from 384 respondents in four communities in the two counties. Most of the people irrespective of their age, occupation, and educational status used plastic bags of some type on a daily basis. A high proportion of the respondents (37.0%, 142) used plastic bags because of the low cost. Approximately, 79.1% (304) disposed used plastic bags in open dumps. A total of 147 (38.3%) households kept shoats. Out of these, 38.1% (56) purchased feed and also allowed their animals to roam. Most of them (45.3%, 174) thought that lack of feed for the animals was the main reason why shoats roam and scavenge at refuse dump sites and road sides. A large proportion of the respondents (44.5%, 143) mentioned death of animals as the ultimate consequence of ingestion of waste plastic bags. Though, the respondents were aware that indiscriminate disposal of used plastic bags could result in death of the animals from which they derive their livelihoods, they nevertheless continued with the practice. There is a need for a paradigm shift in the way and manner plastic bags are used and disposed.

Ott, D. E. (2009). "Chapter 2: Purification of HIV-1 Virions by Subtilisin Digestion or CD45 Immunoaffimty Depletion for Biochemical Studies." Methods in Molecular Biology **485**: 15-25.

The presence of cellular proteins outside and inside retroviruses can indicate the roles they play in viral biology. However, experiments examining retroviruses can be complicated by the contamination of even highly purified virion preparations with nonvinal particles (either microvesicles or exosomes). Two useful methods have been developed that can remove contaminating particles from virus stocks to produce highly pure virus preparations. One approach, the subtilisin digestion procedure, enzymatically removes the proteins outside the virions. While this method is well suited for the analysis of the interior proteins in the virions, it removes the extracellular domains of the integral membrane proteins on the virion. To preserve the proteins on the exterior of the virion for biochemical studies, a CD45 immunoaffinity depletion procedure that removes vesicles by capture with antibody-linked microbeads is employed. These methods allow for the isolation of highly purified virion preparations that are suitable for a wide variety of experiments, including the biochemical characterization of cellular proteins both on and in HIV virions, examination of virion/cell interactions, and imaging of virions.

Ottaviani, M., et al. (2019). "Remote sensing of the ocean surface refractive index via short-wave infrared polarimetry." Remote Sensing of Environment **221**: 14.

The linear polarization of sunlight reflected by ocean surfaces in the short-wave infrared (SWIR), at geometries where specular reflection dominates the signal, is a direct function of the refractive index of the surface microlayer (SML). This simple physical concept is at the base of a novel technique presented in this study. We invert observations obtained by the airborne Research Scanning Polarimeter (RSP) in the sunglint region, where each pixel's radiance is dominated by the signal originating from the wave slopes oriented precisely to cause specular reflection. The SWIR wavelength ensures minimization of aerosol interference when radiance travels through the atmosphere; strong absorption by the water body then limits the penetration depth to the first micrometer or so, effectively probing the SML. The resulting Degree of Linear Polarization (DoLP) is then governed by the refractive index via the Fresnel law for the specific pixel geometry, independently of the windspeed. The selected dataset concerns several field deployments from both low- and high-altitude aircraft, including total reflectance measurements with the sole purpose of accounting for the residual aerosol effect. Stable retrievals from transects above pure seawater yielded values of refractive index that match the values published in the literature within an accuracy of 5×10^{-4}. Flying over the oil spill caused by the explosion of the Deepwater Horizon platform, detected variations were found compatible with the presence of an oil slick. The robustness of the results, guaranteed by the high RSP polarimetric accuracy (≤ 0.2%), opens the possibility for remote-sensing detection of other entities that similarly affect the refractive index including whitecaps, microplastics, biological gels, seaweed and grass mats.

Otto, G., et al. (2016). "A flow-cytometry-based method for detecting simultaneously five allergens in a complex food matrix." Journal of Food Science & Technology-Mysore **53**(12): 4179-4186.

To avoid carry-over contamination with allergens, food manufacturers implement quality control strategies relying primarily on detection of allergenic proteins by ELISA. Although sensitive and specific, this method allowed detection of only one allergen per analysis and effective control policies were thus based on multiplying the number of tests done in order to cover the whole range of allergens. We present in this work an immunoassay for the simultaneous detection of milk, egg, peanut, mustard and crustaceans in cookies samples. The method was based on a combination of flow cytometry with competitive ELISA where microbeads were used as sorbent surface. The test was able to detect the presence of the five allergens with median inhibitory concentrations (IC_{50}) ranging from 2.5 to 15 mg/kg according to the allergen to be detected. The lowest concentrations of contaminants inducing a significant difference of signal between non-contaminated controls and test samples were 2 mg/kg of peanut, 5 mg/kg of crustaceans, 5 mg/kg of milk, 5 mg/kg of mustard and 10 mg/kg of egg. Assay sensitivity was influenced by the concentration of primary antibodies added to the sample extract for the competition and by the concentration of allergenic proteins bound to the surface of the microbeads.

Ou, L. J., et al. (2009). "DNA encapsulating liposome based rolling circle amplification immunoassay as a versatile platform for ultrasensitive detection of protein." Analytical Chemistry **81**(23): 9664-9673.

A novel rolling circle amplification (RCA) immunoassay based on DNA-encapsulating liposomes, liposome-RCA immunoassay, was developed for ultrasensitive protein detection. This technique utilized antibody-modified liposomes with DNA prime probes encapsulated as the detection reagent in the sandwiched immunoassays. The DNA prime probes were released from liposomes and then initiated a linear RCA reaction, generating a long tandem repeated sequences that could be selectively and sensitively detected by a microbead-based fluorescence assay. The developed technique offered very high sensitivity due to primary amplification via releasing numerous DNA primers from a liposome followed by a secondary RCA amplification. A biobarcode design was incorporated in the technique, which allowed the strategy to be directly implemented for multiplex assay of multiple proteins. Also, the technique allowed easy preparation of the DNA-carrying antibody reagent and the implementation with simple instrumentation. The technique was demonstrated for the determination of prostate-specific antigen (PSA), a highly selective biomarker associated with prostate cancer. The results revealed that the technique exhibited a dynamic response to PSA over a 6-decade concentration range from 0.1 fg mL(-1) to 0.1 ng mL(-1) with a limit of detection as low as 0.08 fg mL(-1) and a high dose-response sensitivity. The liposome-RCA immunoassay holds great promise as a versatile, sensitive, and robust platform to combine the nucleic acid amplification with immunoassay for ultrasensitive protein detection.

Ou, L. T. and M. Alexander (1974). "Influence of glass microbeads on growth, activity and morphological changes of Bacillus megaterium." Archives of Microbiology **101**(1): 35-44.

Oudshoorn, M., et al. (2013). "Improving the biocompatibilty of alginate/poly-lornithine capsules through the masking of amines and pegylation." Cytotherapy **1)**: S44.

Living Cell Technologies (LCT) Ltd uses encapsulation to isolate porcine pancreatic islets from the recepient's immune system to prevent rejection in xenotransplantation. This capsule is composed of an alginate bead coated with poly-L-orithine (PLO) and alginate (APA). One of the main problems with this capsule is the exposure of PLO which has a net positive charge and exposed amine groups. Here we present the approach LCT is using to modify the surface of PLO by masking exposed amine groups and the positive charge, using Sulfo-NHS-acetate and PEGylated compounds. Sulfo-NHS-acetate is commonly used to block amine groups on proteins by capping amino groups with a more favourable acyl group. PEGylated compounds covalently attach through amine esters, shielding the surface of the microcapsule with a nonionic water-soluble polymer. Both approaches aim to reduce protein adsorption and and the onset of the immune response. In vitro experiments have investigated modifications to the encapsulation procedure using the following coating scheme: AlginatePLO/PLO/x, where x is sulfo-NHS-acetate, BS (PEG) 9 or MS (PEG) 12 at concentrations over the range of 1-10 mM. Micro-beads are formed by pumping the alginate, porcine islet mix through a needle supplied with a coaxial airflow into a CaCl2 bath, PLO is used to coat the external surface of the bead, followed by the amine masking reagent. Capsules are then treated with sodium citrate to remove the alginate core. Capsules were characterised using light and fluorescent microscopy, flourescent imaging and Transmission electron microscopy (TEM). Capsule size, uniformity and defects were also assessed. Islet viability and insulin release were monitored over the course of a month. All conditions tested showed excellent islet viabilty and no reduction in insulin release when compared to the control.

Owens, E. L., et al. (2011). "Material Flow Analysis Applied to Household Solid Waste and Marine Litter on a Small Island Developing State." Journal of Environmental Engineering **137**(10): 937-944.

Small island developing states (SIDS) have limited access to imported goods, and their associated patterns of consumption and waste generation are affected by space limitations. They are also impacted by the global presence of marine litter that reaches their shores from the ocean. A material flow analysis (MFA) was applied to household solid waste and marine litter collected from Kayangel Island in the Republic of Palau to provide a comprehensive characterization and spatial accounting of the inflow of nonputrescible materials that become solid waste. Approximately 15,100 kg of nonputrescible solid waste are generated annually on Kayangel Island (0.42 kg per capita per day), with 57% being marine litter derived from the ocean and 43% derived from household activities. Household generation of nonputrescible solid waste (that ignores inputs of marine litter) ranged from 0.14-0.18 kg/capita-day for the school in session and nonschool periods, respectively. The most significant waste categories (by mass) include mixed material and nonrecyclable plastic wastes from both household sources and ocean-derived marine litter. Once nonputrescible solid waste is introduced, 0.39 kg per capita per day accumulates, 0.02 kg per capita per day is removed from the island via shipping, and 0.01 kg per capita per day is processed by open pit burning. Applying an MFA to solid waste on a SIDS links local and global solid waste generation with material fates, and may assist solid waste management practices. [ABSTRACT FROM AUTHOR]

Owolodun, O. A., et al. (2013). "Development of a fluorescent microbead-based immunoassay for the detection of hepatitis E virus IgG antibodies in pigs and comparison to an enzyme-linked immunoassay." Journal of Virological Methods **193**(2): 278-283.

Swine hepatitis E virus (HEV) is a zoonotic virus and pigs are considered as an important reservoir. Swine HEV infection is widespread and most pig herds are infected. Humans can be infected with swine HEV via consumption of undercooked pork or through direct contact with infected pigs. To minimize the risk of zoonotic transmission, sensitive tools to assess the HEV infection status of pigs and pork products are needed. The objective of this study was to develop a fluorescent microbead-based immunoassay (FMIA) for the detection of IgG antibodies against swine HEV and compare it to an in-house enzyme-linked immunoassay (ELISA). Three sets of samples were utilized: (A) samples from pigs infected experimentally with different strains of HEV (positive controls, n= 72), (B) samples from known HEV-negative pigs (negative controls, n= 62) and (C) samples from pigs of unknown HEV infection status (n= 182). All samples were tested by both ELISA and FMIA. The results on the experimental samples with known HEV exposure indicate that both assays have a specificity of 100% while the sensitivity ranges from 84.6% (ELISA) to 92.3% (FMIA). The overall prevalence of HEV IgG antibodies in field samples from pigs with unknown HEV exposure was 21.9% (40/182) for the ELISA and 21.4% (39/182) for the FMIA. The two assays had an almost perfect overall agreement (Kappa= 0.92). © 2013 Elsevier B.V.

Oz, N., et al. (2019). "Investigation of heavy metal adsorption on microplastics." Applied Ecology and Environmental Research **17**(4): 7301-7310.

Microplastics and heavy metals represent two pollutant classes which have adverse impacts on aquatic ecosystems. This study has investigated the adsorption of two heavy metals [Lead (Pb)II and Aluminum (Al)III] on three different types of microplastics [polyethylene terephthalate (PET), polyamide (PA), ethylene vinyl acetate (EVA)]. The Scanning Electron Microscope (SEM) analysis has shown that microplastics have different surface characteristics. The effects of parameters such as the pH of solution, duration of contact, initial concentration and temperature on adsorption capacity have been examined. Experimental results have been applied to the adsorption isotherm models of Langmuir and Freundlich and it has been seen that the Freundlich model has been seen as more suitable than the Langmuir model. Moreover, the pseudo-second kinetic has been found to be more appropriate than the pseudo-first kinetic model. Adsorption percentages have changed according to the type of microplastic and working conditions. Finally, the study has investigated the potential of microplastics to act as an instrument of transport for heavy metals to the food chain and for their bioaccumulation.

Ozawa, M. and P. J. Hansen (2010). "A novel method for purification of inner cell mass and trophectoderm cells from bovine blastocysts using magnetic activated cell sorting." Reproduction, Fertility and Development **23 (1)**: 174-175.

The first distinct lineage differentiation in the mammalian embryo occurs at the blastocyst stage when blastomeres are segregated into inner cell mass (ICM) or trophectoderm (TE). Obtaining purified TE or ICM can be useful for understanding regulation of early development and differentiation. Although several methods have been reported to separate TE and ICM (e.g. immunosurgery, mechanical dissection using a micromanipulator, or manual selection following trypsinization), limitations exist with these methods. Here, we describe a simple and effective method to sort cells of the blastocyst using magnetic activated cell sorting (MACS) following disaggregation of the blastocyst into single cells using trypsin. Bovine blastocysts were produced in vitro and the zona pellucida removed with a short exposure to acidic Tyrode's solution. Zona-free blastocysts were incubated with concanavalin A conjugated to fluorescein isothiocyanate (FITC) to label the outer layer of the blastocyst. The blastocysts were then exposed to Hoechst 33342 to label nuclei of all blastomeres. The blastocysts were treated with 0.05% (wt/vol) trypsin, and then disaggregated into single blastomeres by repeating pipetting using a finely drawn, flame-polished mouth micropipette. Single blastomeres were incubated with magnetic microbeads conjugated to anti-FITC and subjected to MACS separation. A fraction of sorted cells was observed under a fluorescence microscope. The remainder were subjected tomRNAextraction, and NANOG (ICM marker) and CDX2 (TE marker)mRNA were quantified by quantitative PCR. After disaggregation of the blastocyst, 2 types of single blastomeres were observed: cells that were positive for both FITC and Hoechst 33342 (TE cells) and cells that were negative for FITC but positive for Hoechst 33342 (ICM cells). Before MACS, about two-thirds of the disaggregated blastomeres labelled with Hoechst 33342 were also labelled with FITC, while one-third were FITC negative. After MACS, the percent of dual-labelled cells in the FITC positive fraction was 91.2%, whereas the incidence of dual-labelled cells in the FITC negative fraction was only 7.8+/-3.0%. A total of 11.5 mug of RNA per blastocyst was recovered from cells isolated by MACS. This represents 80% of the RNA present in intact blastocysts and suggests a high rate of recovery of blastomeres during the purification process. Furthermore, relative expression level of NANOG was lower in the FITC-positive fraction than in the FITC-negative fraction (0.30+/-0.05 v. 3.1+/-0.6, respectively, relative to gene expression level in whole blastocysts). Conversely, the relative expression level of CDX2 was higher in the FITC-positive fraction than in the FITC-negative fraction (3.2+/-0.09 v. 0.30+/-0.9, respectively). Results indicate that highly purified TE cells or ICM cells can be collected using MACS. This simple method can be used to

study differentiation of the mammalian embryo as well as to prepare embryonic cells of specific lineages for cell therapy.

Ozawa, M., et al. (2009). "Human neutrophil antigen (HNA)-specific antibodies are associated with renal allograft loss." Human Immunology **1)**: S163.

Aim: Antibodies to human neutrophil antigens (HNA) and HLA antibodies are the two known causes of transfusion-related acute lung injury (TRALI). To date, no reported studies have evaluated the impact of HNA antibodies on transplantation, perhaps due to lack of readily available detection assay for HNA antibodies. Here we report on the detection of HNA antibodies in renal transplant recipients using the newly developed microbead HNA assay. Method(s): Soluble HNA-1a, HNA-1b, HNA-1c, HNA-2, HNA-4, and HNA-5 antigens purified from recombinant cell lines or human granulocytes were coated onto microbeads. A total of 158 post-transplant sera from renal recipients from 14 transplant centers who had lost graft with no detectable HLA or MICA antibodies were tested for HNA antibodies using these single antigen beads. Additional 90 patients from the same cohort, who still had functioning graft, were tested as the control. Result(s): HNA antibodies were found in 10 (6%) of the 158 patients who had graft loss, while only one (1%) of the 90 patients with functioning graft had HNA antibodies (p=0.05). The most frequent specificity was anti-HNA-1b, followed by HNA-1a and HNA-2. Interestingly, half of the patients who had HNA antibodies were male, and half were female, however, there were marked differences in the strength of antibodies between the males and females; the mean MFI of HNA antibodies in males was 1941, while the mean MFI among the females was 12221. Conclusion(s): HNA antibodies have been associated with kidney graft failure for the first time in this study. 6% of patients, who had graft failure without HLA or MICA antibodies, had HNA antibodies, compared to 1% of patients with good function.

Ozdemir, F. T., et al. (2016). "Immune and inflammatory gene expressions are different in Behcet's disease compared to those in Familial Mediterranean Fever." Europan Journal of Rheumatology **3**(4): 146-152.

OBJECTIVE: The immune classification of Behcet's disease (BD) is still controversial. In this study, we aimed to compare the immune/inflammatory gene expressions in BD with those in familial Mediterranean fever (FMF), an autoinflammatory disorder with innate immune activation.

MATERIAL AND METHODS: CD4+ T cells and CD14+ monocytes were isolated from the peripheral blood mononuclear cells of Behcet's disease patients (n=10), FMF (n=6) patients, and healthy controls (n=4) with microbeads, and then, the mRNA was isolated. The expressions of 440 genes associated with immune and inflammatory responses were studied with a focused DNA microarray using a chemiluminescent tagging system. Changes above 1.5-fold and below 0.8-fold were accepted to be significant.

RESULTS: In BD patients, in the CD4+ T-lymphocyte subset, interleukin 18 receptor accessory protein (1.7-fold), IL-7 receptor (1.9-fold), and prokineticin 2 (2.5-fold) were all increased compared to those in FMF patients, whereas chemokine (C-X3-C motif) receptor-1 (CX3CR1) (0.7-fold) and endothelial cell growth factor-1 (0.6-fold) were decreased. In the CD14+ monocyte population, the V-fos FBJ murine osteosarcoma viral oncogene homolog (1.5-fold), Interleukin-8 (IL-8) (2.1-fold), and Tumor Necrosis Factor alpha (TNF-alpha) (1.8-fold) were all increased, whereas the chemokine (C-C motif) ligand 5 (CCL5) (0.6-fold), C-C chemokine receptor type 7 (0.6-fold), and CX3CR1 (0.7-fold) were decreased, again when compared to those in FMF. Compared to healthy controls in the CD4+ T-lymphocyte population, in both BD and FMF patients, pro-platelet basic protein and CD27 had elevated expression. In BD and FMF patients, 24 and 19 genes, respectively, were downregulated, with 15 overlapping genes between both disorders. In the CD14+ monocytes population, chemokine (C-C motif) receptor-1 (CCR1) was upregulated both in BD and FMF patients compared to that in the controls, whereas CCL5 was downregulated.

CONCLUSION: Immune and inflammatory gene expressions seem to be variable in both the innate (CD14+) and adaptive (CD4+) immune responses in BD and FMF patients compared to those in controls, suggesting differences in immune regulation between the two disorders.

Ozer, E. T., et al. (2017). "Dummy molecularly imprinted microbeads as solid-phase extraction material for selective determination of phthalate esters in water." Journal of Chromatography. A **1500**: 53-60.

The aim of this study was to investigate the usability of newly synthesized dummy molecularly imprinted microbeads (DMIMs) as a solid phase extraction (SPE) material to determine six phthalate esters (PEs) in water by GC-MS analysis. Diethyl phthalate (DEP) was used as a dummy template to prepare poly(ethylene glycol dimethacrylate N-methacryloyl-l-tryptophan methyl ester) [PEMATrp)] DMIMs by using suspension polymerization. The PEMATrp DMIMs were characterized by using Fourier transform infrared spectroscopy (FTIR), X-ray photoelectron spectroscopy (XPS) and scanning electron microscopy (SEM). Firstly, the adsorption capacities of the DMIMs prepared in different template molecule (DEP) to functional monomer (MATrp) ratios were investigated by using DEP solutions in the concentration range of 1-500mg/L at pH 3.0. Styrene and vanillic acid were used to evaluate the selectivity of the prepared DMIMs towards the template molecule (DEP). Then, the best analytical conditions were investigated for the simultaneous determination of dimethyl phthalate (DMP), diethyl phthalate (DEP), di-n-butyl phthalate (DBP), benzylbutyl phthalate (BBP), di-(2-ethylhexyl) phthalate (DEHP) and di-n-octyl phthalate (DnOP) in aqueous media by using the PEMATrp DMIMs as SPE material. Validation experiments showed that the PEMATrp DMIMs-SPE method had good linearity at 12.5-250.0mug/L (0.988-0.999), good precision (1.2-5.9%), and limits of detection in a range of 0.31-0.41mug/L.

Özsin, G. and A. E. Pütün (2019). "TGA/MS/FT-IR study for kinetic evaluation and evolved gas analysis of a biomass/PVC co-pyrolysis process." Energy Conversion and Management **182**: 143.

This study aims to investigate the thermal behaviours of a specific biomass and a polymer sample through co-pyrolytic degradation. Therefore, a non-edible food processing waste (cherry seed: CS) and a typical plastic waste (polyvinyl chloride (PVC)) were selected and their interaction was studied using a combined TGA/MS/FT-IR system. By the help of TGA data, the non-isothermal kinetic analysis was performed using four different kinetic methods [Friedman, Flynn-Wall-Ozawa (FWO), Vyazovkin and distributed activation energy (DAEM)]. The kinetic results showed that the activation energy values were in agreement over the conversion degree values between 0.1 and 0.9. For determination of the synergistic or inhibitive interactions, theoretical and experimental thermogravimetry values were also compared. Moreover, in situ determination of the main pyrolytic and co-pyrolytic degradation compounds such as methyl, water, methoxy, hydrogen chloride, carbon dioxide and benzene with respect to temperature and time was studied for the first time. By this way, primary and secondary reactions related to methylation, dehydration, aromatization, fragmentation, dehydrochlorination were interpreted. Consequently, PVC was found to change pyrolytic degradation behaviour of lignocellulosic biomass by changing reactivity, activation energy and reaction mechanisms.

P, R. (2010). "UP TO SPEED: TWO MONTHS, ONE PAGE." Sierra **95**(4): 19-19.

The article offers anecdotal information about the environment. The Atlantic and Indian Oceans are said to contain as much floating plastic waste materials as the Pacific Ocean. With causes

unknown, more than 300 right whales largely constituted by calves have died near the coast of Argentina. The U.S. Environmental Protection Agency (EPA) finalized regulations that require a 42-percent increase in automobile gas mileage by 2016.

Paasch, U., et al. (2003). "Transduction of apoptotic signals in ejaculated spermatozoa after cryopreservation via activation of caspases. [German]." Journal fur Fertilitat und Reproduktion **13**(2): 22-31.

Objective: To study the relation between disintegration of plasma membrane and the activation of caspases, the transducers of apoptotic signals for programmed cell death in ejaculated spermatozoa. The spermatozoa were subpopulated by magnetic activated cell sorting (MACS) in dependence on sperm binding to superparamagnetic annexin V-conjugated microbeads (ANMB). The binding indicates an exposure of phosphatidylserine to the outer membrane (EPS) as an early event of apoptosis or a disturbance of membrane integrity. The resulting two populations were investigated for active caspases (aCP) 8, 9, 1 and 3, which mediate the main pathways of apoptosis. Method(s): Twenty semen samples of 10 healthy volunteers were splitted to get two aliquots, which were examined before and after cryopreservation. The fresh or cryopreserved semen samples were further aliquoted into two by MACS getting ANMB-negative- and ANMB-positive-subpopulations in dependence on the sperm membrane integrity. Afterwards, the aCP 8, 9, 1 and 3 were detected in both subpopulations. Result(s): The aCPs were localized predominantly in the postacrosmal region except aCP9 which was found in the midpiece. The cryopreservation led to a significantly increased number of sperm showing an activation of all caspases investigated (15.7 % in native vs. 40.8 % in cryopreserved spermatozoa, $p < 0.01$). The MACS separation in dependence on binding of ANMB to PS resulted in a significant depletion ($p < 0.01$) of sperm with aCP within the ANMB-negative spermatozoa with intact membranes. The percentage of sperm with aCP within the ANMB-negative fraction was not significantly influenced by cryopreservation. The cryopreservation increased the probability that spermatozoa with aCP8, aCP9, aCP1 and aCP3 may also develop a disintegration of plasma membrane and appear in the ANMB-positive fraction. Conclusion(s): For the first time it is reported that initiator and effector caspases of the main pathways of apoptosis are present and ready to be coordinately activated in ejaculated spermatozoa. Activated caspases were found especially in spermatozoa with disturbed membranes, but spermatozoa with intact membranes do also house a small amount of aCP. The annexin V-MACS separation resulted in a significant depletion of spermatozoa having aCP within the ANMB-negative fraction. Hence a wide spectrum of cell cytosceletal proteins and membrane components are targets of caspases, they very likely contribute to a decrease in the fertilization capacity.

Paben, J. (2017). "China announces 'Sword' crackdown on illegal material imports." Resource Recycling **36**(3): 8-9.

The article reports on the plan of China's General Administration of Customs (GAC) to launch an initiative to curtail foreign waste such as plastics, industrial waste, electronics and other household waste materials. Topics include the initiative as part of a larger plan known as National Sword 2017 that targets the smuggling of agricultural and resource products, drugs, and guns, the role of the Institute of Scrap Recycling Industries (ISRI), and details on the measures announced by GAC.

Pace, G. S., et al. (2012). Development of the heat melt compactor for waste management during long duration human space missions. 42nd International Conference on Environmental Systems 2012, ICES 2012.

Solid Waste handling and management in space habitats poses serious challenges for long duration human space missions. These wastes typically contain a high quantity of plastic from packaging as well as personal hygiene wastes, wet and dry wipes, gloves, duct tape, and unused food items. The unused food and personal hygiene wastes present substrates for growth of microorganisms that can seriously affect astronaut health and consequently mission success. The heat melt compaction process uses heat to sterilize and dry the waste, and the plastic content to bond and encapsulate the various waste items into a hard tile. The tile that is produced in the heat melt compaction process is tough, extremely compact, and has a predictable shape that allows the efficient use of very limited spacecraft storage volume. The encapsulation of the waste in the melted plastic isolates the growth substrate from spacecraft cabin air to prevent reinoculation of the waste. Plastic wastes contain a high percentage of hydrogen which is considered a desirable material for radiation shielding because it does not produce secondary radiation. Collaborative work with MSFC personnel on evaluating the effectiveness of tiles produced in the Heat Melt Compactor as a shielding material against radiation is in progress. Progress on the development of the next generation Heat Melt Compactor hardware is also presented.

Pacheco, A., et al. (2018). "Toxicological interactions induced by chronic exposure to gold nanoparticles and microplastics mixtures in Daphnia magna." Science of the Total Environment **628**(629): 474-483.

The effects of emerging environmental contaminants on human and environmental health is of high concern, especially those potentially induced by mixtures. The main goal of the present study was to assess the chronic effects of mixtures of citrate stabilized ~5 nm gold nanoparticles (AuNP) and 1-5 micro m microplastics (MP) on Daphnia magna. A 21-day bioassay was carried out. The effect criteria were parental mortality, somatic growth and several reproductive parameters. AuNP induced parental mortality, reduced the total offspring and caused immobile juveniles and aborted eggs. MP induced parental mortality, delayed the first brood release, decreased the number of broods released, the total offspring, and caused immobile juveniles. All the mixtures caused higher toxicity than AuNP and MP alone. Based on parental mortality, evidences of antagonism between AuNP and MP were observed at low concentrations of both mixture components, whereas evidences of synergism at high concentrations were found. Chronic (21-day) exposure of D. magna to AuNPs, MP, and their mixtures can impair development, reproduction, ultimately leading to death.

Paciorek-Sadowska, J., et al. (2019). "New Poly(lactide-urethane-isocyanurate) Foams Based on Bio-Polylactide Waste." Polymers **11**(3): 12.

The article presents the results of research on the synthesis of a new eco-polyol based on polylactide (PLA) waste and its use for the production of rigid polyurethane-polyisocyanurate (RPU/PIR) foams. The obtained recycling-based polyol was subjected to analytical, physicochemical and spectroscopic tests (FTIR, 1H NMR, ¹³C NMR) to confirm its suitability for the synthesis of polyurethane materials. Then, it was used to partially replace petrochemical polyol in polyurethane formulation. The obtained RPU/PIR foams were characterized by lower apparent density, brittleness, and water absorption. In addition, foams modified by eco-polyol had higher flame retardancy, as compared to reference foam. The results of the research show that the use of PLA polyol based on plastic waste may be an alternative to petrochemical polyols. This research matches with the current trends of sustainable development and green chemistry.

Packialakshmi, N. and N. R. Badhru (2015). "Screening and identification of efficient

polyhydroxybutyrate producing bacteria from plastic wastes dumped soil samples." World Journal of Pharmaceutical Research **4**(10): 1785-1794.

The soil samples were collected from the polythene and plastic waste dumped site area of Sankarapuram. The collected samples were subjected to serial dilution and plating technique. The isolated microbial strains were identified based on their cultural morphological and biochemical study. To identify the PHB producers from nonproducers Carbol fuchsin staining was carried, for this staining Bacillus species found to have dark colored granules within their cells. For further confirmation PHB producers were stained with Sudan black, the results observed as dark black to purple granules against pink back ground when counter stained with Safranin. Polythene bag degradation (broth and tray method) by Bacillus species were observed for one month. After the incubation color changes softness of plastics were observed due to the degrading action of microbes. The green gram seeds were inoculated in 3 pots each pot treated with Bacillus strain I, II, III, the growth rate were analyzed. Compared with other two strain the Bacillus megaterium gave the maximum growth. The FT-IR analysis identified the functional groups.

Paco, A., et al. (2017). "Biodegradation of polyethylene microplastics by the marine fungus Zalerion maritimum." Science of the Total Environment **586**: 10-15.

Plastic yearly production has surpassed the 300milliontons mark and recycling has all but failed in constituting a viable solution for the disposal of plastic waste. As these materials continue to accumulate in the environment, namely, in rivers and oceans, in the form of macro-, meso-, micro- and nanoplastics, it becomes of the utmost urgency to find new ways to curtail this environmental threat. Multiple efforts have been made to identify and isolate microorganisms capable of utilizing synthetic polymers and recent results point towards the viability of a solution for this problem based on the biodegradation of plastics resorting to selected microbial strains. Herein, the response of the fungus Zalerion maritimum to different times of exposition to polyethylene (PE) pellets, in a minimum growth medium, was evaluated, based on the quantified mass differences in both the fungus and the microplastic pellets used. Additionally, molecular changes were assessed through attenuated total reflectance Fourier transform Infrared Spectroscopy (FTIR-ATR) and Nuclear Magnetic Resonance (NMR).

Padet, L. and R. Bazin (2013). "IVIg prevents the in vitro activation of T cells by neutralizing the T cell activators." Immunology Letters **150**(1-2): 54-60.

Clinical observations in patients treated with IVIg revealed significant modulations in T cell populations and functions. However, it is unclear whether IVIg acts directly on activated T cells to suppress their functions. To clarify the exact mechanism of IVIg action, we studied its effect on T cells activated using anti-CD3/CD28 microbeads to mimic stimulatory signals provided by accessory cells. We report here that IVIg reduces T cell proliferation and cytokine secretion by interfering with the ability of anti-CD3/CD28 microbeads to deliver activating signals to T cells. We further show that the interference occurs between IVIg and anti-CD3/CD28 microbeads and does not involve T cells. In conclusion, our work suggests that T cells are not a direct target of IVIg and that the modulation of T cell populations and functions observed in treated patients is the indirect consequence of a direct effect of IVIg on accessory cells. © 2013 Elsevier B.V.

Padgelwar, S., et al. (2019). "Plastic waste management and current scenario in India: a review."

India has the second largest population in the world after China with 1.324 billion of people which become significant for industrialisation and rapid urbanisation. Since India is a developing country, people from villages started migrating to cities which creates the large amount of solid waste daily, resulting inenvironmental problem for cities. Among all solid waste, 14% of waste is coming from plastic waste, out of which most plastic generates from household use, industrial product, food packaging and water bottles. Also, a few states in India have a coastal region which generates plastic waste from recreational activities on the seashore. Inappropriate dumping of such waste collected outside the villages and cities which creates unhealthy and chaotic conditions which not only affect the health of the people staying around it but also create landfill problems results in major environmental implications contributing to pollution of ground water. To minimise the consumption of plastic, efforts have to be taken considering the use of renewable raw material to innovative products through recent development in technology. Also, daily use of plastic should be avoided which helps to improve healthy environmental conditions. The present study focusses on the rate of plastic being used in all the states of India, which is being segregated from solid waste coming from municipal waste and other sources. The review also includes the comparison of consumption of plastic in various states across India. A sustainable solution to recycle the plastic waste towards reducing environmental losses. 2019, 2019 Informa UK Limited, trading as Taylor & Francis Group.

Paffenhofer, G. A. and M. Koster (2020). "The Effects of Microplastics on Dolioletta gegenbauri (Tunicata, Thaliacea)." Archives of Environmental Contamination & Toxicology **78**(1): 94-105.

Oceanographic studies revealed the abundance of minute plastic particles in coastal regions. Such particles, called microplastics, are abundant in sizes smaller than 100 micro m ESD (Equivalent Spherical Diameter) and can be collected and ingested by planktonic copepods. Those animals are the most abundant metazoans on our planet. Abundantly co-occurring with planktonic copepods in subtropical and temperate neritic waters are doliolids (Tunicata, Thaliacea), which can dominate subtropical shelves because of their high asexual reproductive performance. Our studies were designed to examine the effects of polystyrene beads at low abundance, compared with phytoplankton, on abundantly occurring gonozooids of Dolioletta gegenbauri. Our findings reveal that such abundance of microplastic particles, in the presence of environmental concentrations of phytoplankton, reduces rates of feeding, growth, and oxygen consumption of this tunicate. Feeding rates on phytoplankton in the presence of beads were reduced by up to 58%, growth rates by up to 85%, and oxygen consumption rates by up to 33%. We conclude that such microplastic particles could limit the often in situ encountered pronounced proliferation of this tunicate species (Deibel in: Bone (ed) The biology of pelagic tunicates, Oxford University Press, Oxford, 1998).

Paget, R. J. (1974). "The treatment of plastic waste." Polymers Paint Colour J **164**(3876): 652-653.

This article develops the various courses of action or paths the treatment of plastic waste will follow and highlights some of the main difficulties. After briefly defining the general problem, the author discusses the three main methods of treating plastic wastes; recycling, reclaiming, and pyrolysis. It is shown that the necessity to recycle must become a fundamental part of society's future due to rapid and irreplaceable demand upon fossil fuels.

Pagter, E., et al. (2018). "Microplastics in Galway Bay: A comparison of sampling and separation methods." Marine Pollution Bulletin **135**: 932-940.

Microplastics, an emerging pollutant, are recognised as having a ubiquitous distribution in the environment. Currently several benthic sampling tools are being employed to collect subtidal marine sediment, however, there are no comparative studies on the efficiency of these tools to sample for microplastics or the subsequent extraction methods of microplastics from these marine sediments. This study addresses these knowledge gaps by comparing commonly applied benthic sampling tools (Van Veen grab, box corer, gravity corer) and a variety of density separation methods (elutriation column, sodium chloride solution, sodium tungstate dihydrate solution) for microplastic collection and processing. Each sampling tool was tested at the same station and the collected sediment was used to assess the extraction performance for the different density separation techniques. No statistically significant differences were found between the concentrations of microplastics extracted for any of the sampling tools. However, there were significant differences between the density separation methods using sodium tungstate dihydrate and sodium chloride solution and the elutriation method. This preliminary study provides evidence that the sampling tools tested are both suitable and proficient at determining the abundance of microplastics in sediments. Sodium tungstate dihydrate proved to be a novel and feasible option for dense liquid separation of microplastics in subtidal marine sediments. These results will allow for more confidence in data quality when comparing future surveys applying different benthic sampling tools. Copyright © 2018 Elsevier Ltd

Pajic-Lijakovic, I. (2013). "Micro-environmentally restricted hybridoma cell growth within polysaccharide hydrogel microbeads." Bio-Medical Materials & Engineering **23**(5): 361-371.

The mechanism of micro-environmentally restricted hybridoma cell growth caused by action of local mechanical compression stress generated within various polysaccharide hydrogel matrixes is estimated by comparing the growth of hybridoma cells within (1) 1.5% Ca-alginate microbeads from Bugarski et al. [in: Fundamentals of Animal Cells Immobilization and Microencapsulation, M.F.A. Goosen, ed., CRC Press, Boca Raton, FL, 1993, p. 267] and (2) 1.3% alginate-agarose microbeads from Shen et al. [Animal Cell Technology: Basic & Applied Aspects, H. Murakami ed., Kluwer Academic Publishers, The Netherlands, 1992, p. 173].Consideration of restricted cell growth dynamics based on developed kinetic model and kinetic 3D Monte Carlo simulation include: (1) changes the fraction of active proliferating cells in the exponential phase and (2) changes of non-proliferating cell concentration in the plateau phase.Higher value of the specific decrease of active fraction of proliferating cells kappa is obtained for 1.3% alginate-agarose compared to 1.5% alginate microbeads. It corresponds to higher compression stress generated within hydrogel matrix during cell growth obtained for 1.3% alginate-agarose microbeads.

Pajic-Lijakovic, I., et al. (2007). "Ca-alginate hydrogel mechanical transformations--the influence on yeast cell growth dynamics." Journal of Biotechnology **129**(3): 446-452.

A mathematical model was formulated to describe yeast cell growth within the Ca-alginate microbead during air-lift bioreactor cultivation. Model development was based on experimentally obtained data for the intra-bead cell concentration profile, after reached the equilibrium state, as well as, total yeast cell concentration per microbed and microbead volume as function of time. Relatively uniform cell concentration in the carrier matrix indicated that no internal nutrient diffusion limitations, but microenvironmental restriction, affected dominantly the dynamics of cell growth. Also interesting phenomenon of very different rates of cell number growth during cultivation is observed. After some critical time, the growth rate of cell colonies decreased drastically, but than suddenly increased again under all other experimental condition been the same. It is interpreted as disintegration of gel network and opening new free space for growth of cell clusters. These complex phenomena are modeled using the thermodynamical, free energy formalism. The particular form of free energy functional is proposed to describe various kinds of interactions, which affected the dynamics of cell growth and cause pseudo-phase transition of hydrogel. The good agreement of experimentally obtained data and model predictions are obtained. In that way the model provides both, the quantitative tools for further technological optimization of the process and deeper insight into dynamics of cell growth mechanism.

Pajic-Lijakovic, I., et al. (2007). "Investigation of Ca-alginate hydrogel rheological behaviour in conjunction with immobilized yeast cell growth dynamics." Journal of Microencapsulation **24**(5): 420-429.

The rheological model is developed to elucidate the mechanism of Ca-alginate microbead deformation in the course of cell growth within. It is a complex process influenced by relaxation of the expanded polymer network inside a bead, and forces generated by cell growth inside the bead and interactions between solvent, network parts and cells as well. The resulting effects are measured experimentally by estimating isotropic volumetric deformations of beads with yeast cells as function of time and cell concentration per bead. The mathematical model of the process is developed based on a modified general Zener model with fractional derivatives. It is particularly suitable for incorporating effects of different nature also during different stages of such complex process development. The results of theoretical analyses using the model developed and comparison with experimental values obtained, indicate a high impact of partial decomposition, i.e. plastic response of polymer network inside a bead due to cell growth, on bead deformation. For comparison, corresponding deformation measurements and modelling were performed on the same network system exposed to swelling in the solvent, but without the cells. In this case elastic forces are dominant, indicating different mechanism of relaxation without the influence of cells, in agreement with previous conclusions.

Pajic-Lijakovic, I., et al. (2008). "Modeling of microenvironmetal restricted yeast cell growth within Ca-alginate microbead." Minerva Biotecnologica **20**(2): 99-102.

Aim. A phase-field mathematical model was formulated to describe yeast cell growth within the Ca-alginate microbead during air-lift bioreactor cultivation. Model development was based on experimentally obtained data for the intra-bead yeast cell volume fraction profile within the microbead after reaching the equilibrium state for cells (150 h), as well as, total yeast cell volume fraction per microbead and microbead volume as functions time. Microbead with growing yeast cells is treated as a two-phase system. One phase represents the cell agglomerates, while the other is the alginate hydrogel matrices. The interactions between phases are simulated using the Langevin class, non-conservative phase-field model based on the reduction of the modeling resolution. The model considered the growth of small domains of one phase (cell agglomerates) as nucleation. Methods. Total yeast cell volume fraction in the beads was estimated by using Thoma counting chamber after dissolution of beads. Local cell volume fraction per microbead layers is calculated from experimentally determined surface fraction of cells for various micro-bead cross sections by image analysis. Microbead volume is estimated by measuring the microbead diameter. Diameters of microbeads were measured using the optical microscope equipped with a micrometric device. Results. The proposed model offered the only one model parameter, which represents the specific measure of microenvironmental restrictive action to die cell growth dynamics. The optimal value of this model parameter is obtained by comparison analysis between experimental data and model predictions. Conclusion. Besides giving useful insights into the dynamics of restrictive cell growth within the Ca-alginate microbead, the model can be used as a tool to design/optimize the performance of microbead and studying the microenvironmental restrictive mechanism action of the cell growth.

Pakes, S. P., et al. (1984). "Comparison of tests for the diagnosis of spontaneous encephalitozoonosis in rabbits." Laboratory Animal Science **34**(4): 356-359.

The immunofluorescence, complement fixation, microagglutination serological tests, intradermal skin test, and detection of histological lesions were compared in the diagnosis of encephalitozoonosis in rabbits. The India ink and microbead agglutination reactions were compared with immunofluorescence and complement fixation by testing 11 single or pooled serum samples. Serological tests correlated best with each other and less well with intradermal tests or presence of lesions. Immunofluorescence, India ink reaction and microbead agglutination were equally useful in detecting antibodies to Encephalitozoon cuniculi. The intradermal test correlated best with the presence of detectable lesions.

Pal, R., et al. (2011). "Preparation and characterization of sodium alginate-carbopol-934P based mucoadhesive microbeads." Der Pharmacia Lettre **3**(5): 1-11.

The purpose of the research work was to formulate and evaluate oral sustained release microspheres of clarithromycin for the treatment of Helicobacter pylori. The stomach specific alginate carbopol microbeads were selected in order to improve patient compliance by simplifying its administration, improving its therapeutic effect and reducing its dose related side effects. To eradicate the H. pylori, stomach specific alginate carbopol microbeads were prepared, by orifice ion-gelation process using different ratio of polymers. The microbeads were characterized by particle size, percentage drug entrapment efficiency, % adhering, antibacterial activity in terms of % Growth Inhibition [GI] and stability study. Sizes of microbeads were found in the range of 800-980 mum, SEM photomicrograph showed microbeads with smooth surface and spherical shapes. The percentage drug entrapment was up to 80 %. In vitro drug release studies were performed in phosphate buffer saline [PBS, pH 7.4] and simulated gastric fluid [SGF, pH 1.2] at 37+/-2degreeC. In vitro and in vivo mucoadhesive study was performed on albino rats, which showed that microbeads were remained adhered to mucus membrane of stomach for longer period of time. The efficacy of formulation was determined in term of its percentage growth of inhibition on H. pylori. The Stability studies were performed at different storage conditions. The site specific as well as sustained release of antibiotic could decrease the likelihood of significant systemic toxicity and may provide selective delivery of biologically active molecules on the site of action. The developed systems could possibly improve site specific release of drug at bacterial site and selectively kill the micro organism.

Palanisamy, R., et al. (2011). "Epiallele quantification using molecular inversion probes." Analytical Chemistry **83**(7): 2631-2637.

The location and level of DNA methylation within a genome is emerging as an important biomarker for cancer diagnosis. Despite its potential, it is difficult to comprehensively analyze the epialleles that are often found in a biological sample. Therefore, an assay utilizing molecular inversion probes was designed and used to expose and quantify epialleles in heterogeneously methylated bisulphite treated genomic DNA. Different CpG dinucleotides were able to be rapidly quantified with high resolution, sensitivity and specificity over a large dynamic range using rapid flow cytometric readout of multiplexable microbead DNA biosensors.

Palatinus, A., et al. (2019). "Marine litter in the Croatian part of the middle Adriatic Sea: Simultaneous assessment of floating and seabed macro and micro litter abundance and composition." Marine Pollution Bulletin **139**: 427-439.

In this study, abundance, distribution and composition of floating and seabed macro and micro litter in the Central Adriatic Sea were assessed. Floating macro litter observations were made. Floating and seabed micro litter were sampled with manta net and Van Veen grab, respectively. Micro litter particles visually found under the microscope were chemically analyzed with Fourier Transform Infrared microscope. Average calculated concentrations of floating macro (175

items/km²), floating micro (127 thousand particles/km²) and seabed micro litter (36 particles/100 g dry weight) show similar values as other published studies from the Mediterranean Sea. A statistically significant ($p < 0.01$) correlation between the floating micro and macro litter concentrations was found for the sites located in the channel waters. Disagreement between model and observations revealed gaps in our knowledge concerning the sea circulation and litter sources. Simultaneous samplings and observations of marine litter in different marine compartments proved possible, efficient and informative. Copyright © 2019 Elsevier Ltd

Paler, M. K. O., et al. (2019). "Plastic waste occurrence on a beach off southwestern Luzon, Philippines." Marine Pollution Bulletin **141**: 416-419.

The Philippines is one of the countries with the highest plastic waste inputs into the ocean yet there is dearth of information on the level of contamination by plastic wastes in local marine ecosystems. This study aims to provide a plastic litter profile in a local beach as an initial report on plastic waste contamination in a typical coast. Likewise, microplastic (MP) occurrence is measured to establish baseline data on MP level.

Palmer, C. S., et al. (2012). "Glut1: Establishing a new paradigm for HIV-1 infection by regulating glucose metabolism and activation in CD4+ T cells in HIV-1-positive subjects." Journal of the International AIDS Society **3)**: 9.

Background: A characteristic feature of the early phase of mammalian cells to metabolic stress is an increase in the rate of glucose uptake and metabolism. Glucose transporter 1 (Glut1) is the major glucose transporter in T cells and its expression is increased on CD4+T cells during chronic HIV-1 infection in vivo (Palmer et al., Abstract 1, IAS, 2012).We therefore seek to determine the impact of increased Glut1 expression on glucose metabolism in CD4+T cells from HIV-1-infected subjects. Method(s): The cell surface expression of Glut1 and glucose uptake (2- NBDG) was monitored in CD4+T cells from HIV-1 infected treatment naive or HIV- controls subjects by flow cytometry. Hexokinase and glycolytic activity was measured by the intracellular concentrations of Glucose-6-phosphate (G-6-P) and L-lactate, respectively. Intracellular PTEN, pAkt (T308) and pAkt (S473) levels determined PI3KmTOR activity. In vitro HIV-1 infection was performed on PBMCs activated with anti-CD3/CD28 microbeads and IL-7 and incubated with the CXCR4-using NL4.3-GFP virus. Result(s): Basal glucose uptake, G-6-P, L-lactate, intracellular p-Akt (T308) and p-Akt (S473) were significantly higher in CD4+Glut1+ vs CD4+Glut1- cells. This corresponded with an overall increased glucose uptake and glycolysis and lower levels of PTEN expression in CD4+T cells from HIV-1+subject vs seronegative individuals. Anti-CD3/CD28-induced Glut1 expression on CD4+ T cells was sensitive to specific inhibition of the Class1B PI3K-y and mTORC1 pathways which also blocked HIV-1 infection of CD4+T cells in vitro. Conclusion(s): CD4+T cells from HIV-1 infected patients have increased glucose uptake and glycolytic activity mediated at least in part by the PI3k-y-mTORC1 pathway. Increased Glut1 cell surface expression and glycolysis in CD4+T cells may increase their susceptibility to HIV-1 infection and foster their depletion due to hypermetabolism. Approaches to normalize Glut1 expression or glycolysis in CD4+T cells may offer a platform for interventions to slow HIV-1 disease progression.

Palmon, A., et al. "High-efficiency immunomagnetic isolation of solid tissue-originated integrin-expressing adult stem cells." Methods.

Isolation of highly pure specific cell types is crucial for successful adult stem cell-based therapy. As the number of such cells in adult tissue is low, an extremely efficient method is needed for their isolation. Here, we describe cell-separation methodologies based on magnetic-affinity cell

sorting (MACS) MicroBeads with monoclonal antibodies against specific membrane proteins conjugated to superparamagnetic particles. Cells labeled with MACS MicroBeads are retained in a magnetic field within a MACS column placed in a MACS separator, allowing fast and efficient separation. Both positively labeled and non-labeled fractions can be used directly for downstream applications as the separated cell fractions remain viable with no functional impairment. As immunomagnetic separation depends on the interaction between a cell's membrane and the magnetically labeled antibody, separation of specific cells originating from solid tissues is more complex and demands a cell-dissociating pretreatment. In this paper, we detail the use of immunomagnetic separation for the purpose of regenerating damaged salivary gland (SG) function in animal and human models of irradiated head and neck cancer. Each year 500,000 new cases of head and neck cancer occur worldwide. Most of these patients lose SG function following irradiation therapy. SGs contain integrin alpha6beta1-expressing epithelial stem cells. We hypothesized that these cells can be isolated, multiplied in culture and auto-implanted into the irradiated SGs to regenerate damaged SG function. © 2011 Elsevier Inc. All rights reserved.

Palombini, F. L., et al. (2018). "Occurrence and recovery of small-sized plastic debris from a Brazilian beach: characterization, recycling, and mechanical analysis." Environmental Science & Pollution Research **25**(26): 26218-26227.

Small-sized plastic debris are an increasing global concern, particularly in environmental protected areas. Consequently, tourism-based economy of poor coastal regions is also impaired. Nevertheless, little interest has been shown about recycling approaches of such materials, mostly because of the natural degradation of polymers on these conditions. This research presents the report of the occurrence of plastic debris nearby Lencois Maranhenses National Park, on the northeast Brazilian coast, aiming to provide a feasible method for recycling. We collected more than 80 samples from the sediment and classified them via FT-IR. Degraded polypropylene samples were selected for blending with virgin material using different concentration rates, and were mechanically tested. Tensile testing results suggest that 5% recycled material concentration mixture has suitable mechanical properties on the elastic regime for applications on new parts. Our findings show that particular interest should be addressed on the recovery of commodity plastic debris from environmental protected areas.

Paltiel, O., et al. (2000). "Translocation t(14;18) in healthy individuals: preliminary study of its association with family history and agricultural exposure." Annals of Oncology **11 Suppl 1**: 75-80.

BACKGROUND: The t(14;18) translocation, present in 90% of follicular non-Hodgkin's lymphomas (NHL), has been found to exist in low levels in healthy persons. Its clinical/prognostic significance in healthy populations is unknown, and risk factors for its development have not been determined. Our objectives were to assess the prevalence of t(14;18) in individuals without NHL, comparing residents of agricultural settlements (kibbutzim) with city dwellers, as well as first degree relatives of NHL cases.

PATIENTS AND METHODS: Residents of kibbutzim and members of two control groups: 1) Jerusalem residents--randomly selected hospital administrative workers and 2) first degree family members of lymphoma patients were interviewed extensively regarding exposures and had blood drawn for t(14;18) determination. The translocation was detected after B-cell purification of blood samples with CD-19 microbeads (Mini-Macs) using nested PCR. The method detects the translocation in a BCL2 positive cell line after dilutions of up to 1:10(5) with normal peripheral blood lymphocytes.

RESULTS: Nineteen of two hundred thirty healthy individuals (8.3%) tested were found to be positive for

t(14;18). No statistically significant differences in the prevalence of t(14;18) were detected among the rural and urban populations. Five of thirty-four (11.9%) family members tested positive for t(14;18). No age or sex differences between t(14;18) positive and negative individuals were found. No significant association with exposure to specific agricultural or other chemicals was found.

CONCLUSIONS: The presence of the t(14;18) translocation in healthy individuals was not associated with agricultural residence in this preliminary study. Whether relatives of patients with NHL are at increased risk will require further study in larger populations. Specific exposures affecting the onset of this translocation have not been ruled out. The significance of this translocation in healthy individuals remains unknown.

Pan, C., et al. (2015). "Neuroprotective effect of AAV-mediated cell-specific expression of GDNF in Muller glial cells versus retinal ganglion cells in a murine model of glaucoma." Investigative Ophthalmology and Visual Science **56 (7)**: 2421.

Purpose: To compare the neuroprotective effects of intravitreal AAV vectormediated expression of GDNF in Muller glial cells (ShH10.GDNF) versus retinal ganglion cells (RGC) (AAV2.GDNF) in the murine model of microbead-induced ocular hypertension. Method(s): Polystyrene microbeads were injected into the anterior chamber of adult mice to elevate intraocular pressure (IOP) and induce glaucoma. An intravitreal injection containing 1x10¹⁰ vector genomes of either ShH10.GDNF or AAV2.GDNF was administered concomitantly. IOP was measured by TonoLab tonometry at weekly intervals. Mice were sacrificed at four weeks and RGC loss and optic nerve axon (ONA) loss was quantified. Enzyme-linked immunosorbent assay (ELISA) was performed to determine GDNF expression in the retina and optic nerve. Result(s): Increased IOP was confirmed in microbead-injected eyes by tonometer. Neither Sh10.GDNF nor AAV2.GDNF had any effect on IOP. At four weeks, uninjected control eyes and microbead-injected eyes had a mean RGC count of 3065 +/- 410 cells/mm² (n=15) and 1573 +/- 75 cells/mm² (n=12). Microbead-injected eyes that received either ShH10.GDNF or AAV2.GDNF demonstrated 2185 +/- 78 cells/mm² (n=13) and 1689+/- 77 cells/mm² (n=12) respectively. At four weeks, uninjected control eyes and microbead-injected eyes had a mean ONA count of 538842 +/- 88924 axons/mm² (n=15) and 220716 +/- 76253 axons/mm² (n=15). Microbead-injected eyes that received either ShH10.GDNF or AAV2.GDNF demonstrated 367415 +/- 19701 axons/mm² (n=8) and 281800 +/- 16044 axons/mm (n=12) respectively. Thus, microbead-injected eyes treated with ShH10.GDNF contained ~130% increase in viable RGCs and axons at four weeks compared to eyes treated with AAV2.GDNF (p<0.05). Intravitreous ShH10.GDNF and AAV2.GDNF resulted in increased GDNF levels (pg GDNF/mg total protein) in the retina compared to uninjected eyes (5433 and 10874 vs 5.5) and optic nerve (2474 and 4310 vs 40) (n=10). Conclusion(s): Intravitreal ShH10.GDNF and AAV2.GDNF result in GDNF expression in the retina and optic nerve with no effect on IOP. Although ELISA results showed relatively higher expression in retina and optic nerve tissues with AAV2 compared to ShH10, the ShH10 vector had a stronger neuroprotective effect on RGC and axon survival indicating that specific cellular targeting or indirect pathways may be an important consideration in the treatment of glaucoma.

Pan, Z., et al. (2019). "Microplastics in the Northwestern Pacific: Abundance, distribution, and characteristics." Science of the Total Environment **Part 2. 650**: 1913-1922.

Prevalence of microplastics (MPs) throughout the world's oceans has raised growing concerns due to its detrimental effects on the environment and living organisms. Most recent studies of

MPs, however, have focused on the estuaries and coastal regions. There is a lack of study of MPs pollution in the open ocean. In the present study, we conducted field observations to investigate the abundance, spatial distribution, and characteristics (composite, size, color, shape and surface morphology) of MPs at the surface of the Northwestern Pacific Ocean. Samples of MPs were collected at 18 field stations in the Northwestern Pacific Ocean using a surface manta trawl with a mesh size of ~330 mum and width of 1 m from August 25 to September 26, 2017. The MPs were characterized using light microscopy, Micro-Raman spectroscopy, and scanning electron microscopy (SEM). Our field survey results indicate the ubiquity of MPs at all stations with an abundance from 6.4 x 10² items km⁻² to 4.2 x 10⁴ items km⁻² and an average abundance of 1.0 x 10⁴ items km⁻². The Micro-Raman spectroscopic analysis of the MPs samples collected during our field survey indicates that the dominant MPs is polyethylene (57.8%), followed by polypropylene (36.0%) and nylon (3.4%). The individual chemical compositions of MPs from the stations within the latitude range 123-146degreeE are comparable with each other, with PE being the dominating composition. Similar chemical fingerprints were observed at these field stations, suggesting that the MPs originated from similar sources. In contrast, the major MPs at the field stations adjacent to Japan is polypropylene, which may originate from the nearby land along the coast of Japan. Physical oceanography parameters were also collected at these stations. The spatial distribution of MPs is largely attributed to the combined effects of flow pattern, adjacent ocean circulation eddies, the Kuroshio and Kuroshio Extension system. Pan, Z., et al. (2019). "Environmental implications of microplastic pollution in the Northwestern Pacific Ocean." Marine Pollution Bulletin **146**: 215-224.

Microplastics (MPs) contamination has been recognized as one of major threats to coastal marine environments. Although studies evidenced severe MPs contaminations to the Pacific Ocean, environmental implications of MPs concentrations, distributions, and characteristics have not been evaluated in sufficient detail. Here, we report on the distribution, abundance, and characteristics of MPs at the surface of the Northwestern Pacific Ocean, from which environmental implications are assessed. A manta trawl with a mesh size of ~330mum and a rectangular net opening of 0.45x1m was used to collect MPs samples on May 11-June 3, 2018. The MPs samples were sequentially isolated, digested, filtered, and characterized using an optical microscope, micro-Raman spectroscopy, and scanning electron microscopy. The results indicate the heterogeneity in abundance, shapes, color, and sizes of MPs. The study provides strong environmental implications such as sources, environmental degradation, residence time, transportation routes, and biological interactions.

Pan, Z., et al. (2019). "Prevalence of microplastic pollution in the Northwestern Pacific Ocean." Chemosphere **225**: 735-744.

People are increasingly aware of ubiquitous microplastic (MP) pollution in the world's ocean due to its far-reaching harmful impacts on marine ecosystem and potential hazards to human health, yet surprisingly comparatively limited studies about the abundance, source, transport, and fate of MPs in the Northwestern Pacific Ocean are available. We conducted the field survey of MPs pollution at the surface of the Northwestern Pacific Ocean between August 25 and September 26, 2017. MPs were collected from 18 sampling stations in the Northwestern Pacific Ocean using a manta trawl net with a mesh size of ~330mum and a rectangular net opening of 0.45x1m. The abundance, shape, color, size, chemical composition, and surface morphology were characterized using light microscopy, mu-Raman spectroscopy, and scanning electron

microscopy (SEM). The results show surface MPs at concentrations ranging over two orders of magnitude (6.4x10² to 4.2x10⁴ particles km⁻²) and a mean abundance of 1.0x10⁴ particles km⁻². The most concentrated MPs were found at XTJ3-9, which may be associated with the convergence of surface currents collectively affected by the Kuroshio and its extension, adjacent eddies, and flow regimes. Polyethylene accounts for 57.8% of enumerated MPs, followed by polypropylene (36.0%) and nylon (3.4%). Pellets, sheets, lines, and films are major forms which may be linked to the breakdown of larger particles, aging processes, and movement over long distances by prevailing currents. Four possible MPs migration pathways were proposed based on the source-specific distribution, chemical fingerprints, size distribution patterns, and the observed physical oceanographic parameters.

Panda, A. K., et al. (2010). "Thermolysis of waste plastics to liquid fuel: A suitable method for plastic waste management and manufacture of value added products - A world prospective." Renewable & Sustainable Energy Reviews **14**(1): 233-248.

The present rate of economic growth is unsustainable without saving of fossil energy like crude oil, natural gas or coal. Thus mankind has to rely on the alternate/renewable energy sources like biomass, hydropower, geothermal energy, wind energy, solar energy, nuclear energy, etc. On the other hand, suitable waste management strategy is another important aspect of sustainable development. The growth of welfare levels in modern society during the past decades has brought about a huge increase in the production of all kinds of commodities, which indirectly generate waste. Plastics have been one of the materials with the fastest growth because of their wide range of applications due to versatility and relatively low cost. Since the duration of life of plastic products is relatively small, there is a vast plastics waste stream that reaches each year to the final recipients creating a serious environmental problem. Again, because disposal of post consumer plastics is increasingly being constrained by legislation and escalating costs, there is considerable demand for alternatives to disposal or land filling. Advanced research in the field of green chemistry could yield biodegradable/green polymers but is too limited at this point of time to substitute the non-biodegradable plastics in different applications. Once standards are developed for degradable plastics they can be used to evaluate the specific formulations of materials which will find best application in this state as regards their performance and use characteristics. Among the alternatives available are source reduction, reuse, recycling, and recovery of the inherent energy value through waste- to-energy incineration and processed fuel applications. Production of liquid fuel would be a better alternative as the calorific value of the plastics is comparable to that of fuels, around 40 MJ/kg. Each of these options potentially reduces waste and conserves natural resources. Plastics recycling, continues to progress with a wide range of old and new technologies. Many research projects have been undertaken on chemical recycling of waste plastics to fuel and monomer. This is also reflected by a number of pilot, demonstration, and commercial plants processing various types of plastic wastes in Germany, Japan, USA, India, and elsewhere. Further investigations are required to enhance the generation of value added products (fuel) with low investments without affecting the environment. The paper reviews the available literature in this field of active research and identifies the gaps that need further attention.

Pandey, A. K., et al. (2012). "Fabrication and evaluation of tinidazole microbeads for colon targeting." Asian Pacific Journal of Tropical Disease **1**(20).

Objective: The purpose of present investigation was to develop and evaluate multiparticulate system exploiting pH-sensitive property and specific biodegradability of calcium alginate microbeads, for colon-targeted delivery of Tinidazole for the treatment of amoebic colitis.

Panebianco, A., et al. (2019). "First discoveries of microplastics in terrestrial snails." Food Control **106**(106722).

Microplastics (MPs) are widely recognized as pollutants of the marine environment, while their presence, diffusion and distribution in the terrestrial ecosystem have been investigated so far. The aim of this study is to evaluate, for the first time, the presence of microplastics in three different species of edible snails belonging to the genus Helix (H. aperta, H. aspersa and H. pomatia) in order to improve the knowledge about the distribution of MPs in the terrestrial ecosystem, and the consequent MPs human exposure deriving from their consumption. Their breeding techniques, the frequent response in rural areas close to agricultural activities and their food behavior, suggest us that they can be exposed to the main contamination sources of MPs in terrestrial ecosystem. A total of 425 specimens were collected in nature or in breeding and divided in 85 samples (5 snails for each sample). All the specimens belonging to the H. aspersa (44 samples) and H. pomatia (4 samples) were in active life phase, while those belonging to the H. aperta (37 samples) species were in resting phase. The digestion of the samples was carried out through the nitric acid and a stereomicroscope was used for the physical identification of MPs. Out of 85 samples of snails examined, 44 (51.75%) presented MPs. A total of 78 MPs were isolated, ranging from 1 to 3 in each sample, with a mean value of 0.92+or-1.21 particles/sample and an amount of 0.07+or-0.01 MPs/g. Among these 78 MPs, 43 were plastic line with variable length between 200 micro m and 2500 micro m and the remaining 35 plastic fragments, whose longest lengths varied between 200 micro m and 1000 micro m. Although the quantity of MPs/g found is relatively low, in any case their presence in terrestrial snails contributes to the risk assessment of human exposure deriving from their consumption.

Panicker, P. K. and A. Magid (2016). Microwave plasma gasification for the restoration of urban rivers and lakes, and the elimination of oceanic garbage patches. ASME 2016 10th International Conference on Energy Sustainability, ES 2016, collocated with the ASME 2016 Power Conference and the ASME 2016 14th International Conference on Fuel Cell Science, Engineering and Technology, June 26, 2016 - June 30, 2016, Charlotte, NC, United states, American Society of Mechanical Engineers.

This review paper describes techniques proposed for applying microwave-induced plasma gasification (MIPG) for cleaning rivers, lakes and oceans of synthetic and organic waste pollutants by converting the waste materials into energy and useful raw materials. Rivers close to urban centers tend to get filled with manmade waste materials, such as plastics and paper, gradually forming floating masses that further trap biological materials and animals. In addition, sewage from residences and industries, as well as rainwater runoff pour into rivers and lakes carrying solid wastes into the water bodies. As a result, the water surfaces get covered with a stagnant, thick layer of synthetic and biological refuse which kill the fish, harm animals and birds, and breed disease-carrying vectors. Such destruction of water bodies is especially common in developing countries which lack the technology or the means to clean up the rivers. A terrible consequence of plastic and synthetic waste being dumped irresponsibly into the oceans is the presence of several large floating masses of garbage in the worlds' oceans, formed by the action of gyres, or circulating ocean currents. In the Pacific Ocean, there are numerous debris fields that have been labeled the Great Pacific Garbage Patch. These patches contain whole plastic litters as well as smaller pieces of plastic, called microplastics, which are tiny fragments that were broken down by the action of waves. These waste products are ingested by animals, birds and fishes, causing death or harm. Some of the waste get washed ashore on beaches along with dead marine life. The best solution for eliminating all of the above waste management problems is by the application of MIPG systems to convert solid waste materials and contaminated water into syngas, organic fuels and raw materials. MIPG is the most efficient form of plasma gasification, which is able to process the most widest range of waste materials, while consuming only about a quarter of the energy released from the feedstock. MIPG systems can be scaled in size, power rating and wastetreatment capacity to match financial needs and waste processing requirements. MIPG systems can be set up in urban locations and on the shores of the waterbody, to filter and remove debris and contaminants and clean the water, while generating electric power to feed into the grid, and fuel or raw materials for industrial use. For eliminating the pelagic debris fields, the proposed design is to have ships fitted with waste collector and filtration systems that feeds the collected waste materials into a MIPG reactor, which converts the carbonaceous materials into syngas (H2 + CO). Some of the syngas made will be used to produce the electric power needed for running the plasma generator and onboard systems, while the remainder can be converted into methanol and other useful products through the Fischer-Tropsch process. This paper qualitatively describes the implementation schemes for the above processes, wherein MIPG technology will be used to clean up major waste problems affecting the earth's water bodies and to convert the waste into energy and raw materials in a sustainable and environmentally friendly manner, while reducing the dependence on fossil fuels and the release of carbon dioxide and methane into the atmosphere. Panizon, E., et al. (2015). "MARTINI Coarse-Grained Models of Polyethylene and Polypropylene." Journal of Physical Chemistry. B, Condensed Matter, Materials, Surfaces, Interfaces & Biophysical **119**(25): 8209-8216.

The understanding of the interaction of nanoplastics with living organisms is crucial both to assess the health hazards of degraded plastics and to design functional polymer nanoparticles with biomedical applications. In this paper, we develop two coarse-grained models of everyday use polymers, polyethylene (PE) and polypropylene (PP), aimed at the study of the interaction of hydrophobic plastics with lipid membranes. The models are compatible with the popular MARTINI force field for lipids, and they are developed using both structural and thermodynamic properties as targets in the parametrization. The models are then validated by showing their reliability at reproducing structural properties of the polymers, both linear and branched, in dilute conditions, in the melt, and in a PE-PP blend. PE and PP radius of gyration is correctly reproduced in all conditions, while PE-PP interactions in the blend are slightly overestimated. Partitioning of PP and PE oligomers in phosphatidylcholine membranes as obtained at CG level reproduces well atomistic data.

Pankaj, V. P. (2015). "Sustainable model of plastic waste management." International Journal of ChemTech Research **7**(1): 440-458.

In India, Plastic waste rising rapidly day by day due to increasing the living standards of human beings by leaps & bounds and due to increasing population.The plastic waste management is not developing in India however, India having Plastic Waste (Management and Handling) Rules, 2011. The collection, transportation and process of plastic waste management are unscientific and chaotic. Uncontrolled dumping of wastes on outskirts of towns and cities has created abundantlandfills, which are not only impossible to reclaim because of the haphazard manner of dumping, but also have serious environmental implications in terms of ground water pollution and contribution to global warming. Burning of plastic waste leads to air pollution, which is equivalent to vehicular emissions at times.In the absence of plastic waste segregation practices,

recycling has remained to be an informalsector working on outdated technology, but nevertheless flourishing owing to waste material availability and market demand of cheaper recycled products. Plastic recycling have been especially growing due to continuously increasing consumption levels of both the commodities. In this paper, I developa model of plastic waste management under the rule and regulation which has been given by CPCB, Ministry of Environment and etc. in India to maintain the balance of the ecosystem by proper managing the plastic wastes. Pannetier, P., et al. (2019). "Toxicity assessment of pollutants sorbed on environmental sample microplastics collected on beaches: Part I - Adverse effects on fish cell line." Environmental Pollution **248**: 1088-1097.

Microplastics (MPs), are tiny plastic fragments from 1 micro m to 5 mm generally found in the aquatic environment which can be easily ingested by organisms and may cause chronic physical but also toxicological effects. Toxicological assays on fish cell lines are commonly used as an alternative tool to provide fast and reliable assessment of the toxic and ecotoxic properties of chemicals or mixtures. Rainbow trout liver cell line (RTLW-1) was used to evaluate the toxicity of pollutants sorbed to MPs sampled in sandy beaches from different islands around the world during the first Race for Water Odyssey in 2015. The collected MPs were analyzed for polymer composition and associated persistent organic pollutants: polycyclic aromatic hydrocarbons (PAHs), polychlorobiphenyls (PCBs) and dichlorodiphenyltrichloroethane (DDT). In addition, DMSO-extracts from virgin MPs, MPs artificially coated with B[a]P and environmental MPs were analyzed with different bioassays: MTT reduction assay (MTT), ethoxyresorufin-O-deethylase (EROD) assay and comet assay. Microplastics from sand beaches were dominated by polyethylene, followed by polypropylene fragments with variable proportions. Organic pollutants found on plastic from beach sampling was PAHs (2-71 ng g⁻¹). Samples from Bermuda (Somerset Long Bay) and Hawaii (Makapu'u) showed the highest concentration of PAHs and DDT respectively. No toxicity was observed for virgin microplastics. No cytotoxicity was observed on cells exposed to MP extract. However, EROD activity was induced and differently modulated depending on the MPs locations suggesting presence of different pollutants or additives in extract. DNA damage was observed after exposure to four microplastics samples on the six tested. Modification of EROD activity level and DNA damage rate highlight MPs extract toxicity on fish cell line.

Pannetier, P., et al. (2019). "Toxicity assessment of pollutants sorbed on environmental microplastics collected on beaches: Part II - Adverse effects on Japanese medaka early life stages." Environmental Pollution **248**: 1098-1107.

While microplastics are present in great abundance across all seas and oceans, little is known about their effects on marine life. In the aquatic environment, they can accumulate a variety of chemicals and can be ingested by many marine organisms including fish, with chronic physical and chemical effects. The purpose of this paper is to evaluate the toxic effects of pollutants sorbed at the surface of environmental microplastics (MPs), collected on various beaches from three islands of the Pacific Ocean. Developmental toxicity of virgin MPs or artificially coated with B[a]P and environmental MPs from Easter Island, Guam and Hawaii was evaluated on embryos and prolarvae of Japanese medaka. Mortality, hatching success, biometry, malformations, EROD activity and DNA damage were analyzed after exposure to DMSO extracts. No toxicity was observed for extracts of virgin MPs whatever the endpoint considered. Extracts of virgin MPs coated with 250 micro g.g⁻¹ of B(a)P induced lethal effects with high embryo mortality (+81%) and low hatching rate (-28%) and sublethal effects including biometry and

swimming behavior changes, increase of EROD activity (+94%) and DNA damage (+60%). Environmental MPs collected on the three selected islands exhibited different polymer, pollutant and toxicity patterns. The highest toxicity was detected for MPs extract from Hawai with head/body length and swimming speed decreases and induction of EROD activity and DNA stand breaks. This study reports the possible sublethal toxicity of organic pollutants sorbed on MPs to fish early life stages.

Pannetier, P., et al. (2020). "Environmental samples of microplastics induce significant toxic effects in fish larvae." Environment International **134**: 105047.

Microplastics (MPs) are present throughout aquatic ecosystems, and can be ingested by a wide variety of organisms. At present, the physical and chemical effects of environmental MPs on aquatic organisms are poorly documented. This study aims to examine the physiological and behavioral effects caused by fish consuming environmental microplastics at different life stages. MP samples were collected from beaches on three islands (Easter Island, Guam and Hawaii) located near the North and South gyres of the Pacific Ocean. Larvae and juveniles of Japanese Medaka were fed for 30days with three doses of MPs (0.01, 0.1 and 1% w/w in fish food) approximate to the concentrations measured in moderately and heavily contaminated ocean areas. Ingestion of MPs by medaka larvae caused (variously) death, decreased head/body ratios, increased EROD activity and DNA breaks and, alterations to swimming behavior. A diet of 0.1% MPs was the most toxic. Two-month-old juveniles fed with 0.01% MPs did not exhibit any symptoms except an increase in DNA breaks. Our results demonstrate ingestion and mainly sublethal effects of environmental MPs in early life stages of fish at realistic MP concentrations. The toxicity of microplastics varies from one sample to another, depending on polymer composition, weathering and pollutant content. This study examines the ecological consequences microplastic build-up in aquatic ecosystems, more particularly in coastal marine areas, which serve as breeding and growing grounds for a number of aquatic species.

Panno, S. V., et al. (2019). "Microplastic Contamination in Karst Groundwater Systems." Ground Water **57**(2): 189-196.

Groundwater in karst aquifers constitutes about 25% of drinking water sources globally. Karst aquifers are open systems, susceptible to contamination by surface-borne pollutants. In this study, springs and wells from two karst aquifers in Illinois, USA, were found to contain microplastics and other anthropogenic contaminants. All microplastics were fibers, with a maximum concentration of 15.2 particles/L. The presence of microplastic was consistent with other parameters, including phosphate, chloride and triclosan, suggesting septic effluent as a source. More studies are needed on microplastic sources, abundance, and impacts on karst ecosystems.

Panti, C., et al. (2019). "Marine litter: One of the major threats for marine mammals. Outcomes from the European Cetacean Society workshop." Environmental Pollution **247**: 72-79.

Marine litter is a pollution problem affecting thousands of marine species in all the world's seas and oceans. Marine litter, in particular plastic, has negative impacts on marine wildlife primarily due to ingestion and entanglement. Since most marine mammal species negatively interact with marine litter, a first workshop under the framework of the European Cetacean Society Conference, was held in 2017 to bring together the main experts on the topic of marine mammals and marine litter from academic and research institutes, non-governmental organisations, foundations and International Agreements. The workshop was devoted to defining the impact of marine litter on marine mammals by reviewing current knowledge, methodological advances and new data available on this emerging issue. Some case studies were also presented from European waters, such as seals and cetaceans in the North, Baltic, and Mediterranean Seas. Here, we report the main findings of the workshop, including a discussion on the research needs, the main methodological gaps, an overview of new techniques for detecting the effects of marine litter (including microplastics) on marine mammals and, also, the use of citizen science to drive awareness. The final recommendations aim to establish priority research, to define harmonised methods to detect marine litter and microplastics, enforce networking among institutions and support data sharing. The information gathered will enhance awareness and communication between scientists, young people, citizens, other stakeholders and policy makers, and thereby facilitate better implementation of international directives (e.g., the Marine Strategy Framework Directive) in order to answer the question about the actual status of our oceans and finding solutions. To understand the sources, the transfer and the effects of marine litter, and therefore their impacts on marine mammal researchers need to apply a multidisciplinary standardized protocols. Panti, C., et al. (2015). "Occurrence, relative abundance and spatial distribution of microplastics and zooplankton NW of Sardinia in the Pelagos Sanctuary Protected Area, Mediterranean Sea." Environmental Chemistry **12**(5): 618-626.

Floating plastic debris tends to fragment into smaller pieces, termed microplastics, which may increase the likelihood of ingestion of plastics by marine organisms entering the food web. This study analyses the amount and spatial distribution of microplastics and zooplankton in an area near Asinara National Park (NW Sardinia) and overlapping the Pelagos Sanctuary (Mediterranean Sea). Analysis showed microplastics in 81 % of the 27 samples analysed, with a mean value of 0.17 plus or minus 0.32 items m-3. From geographic information system processing of the data, microplastics appeared more abundant (by a factor of four) in the pelagic than in the neritic environment, and showed a size range of the same order as major zooplanktonic taxa determined in the area. These findings suggest a potential risk of mesozooplankton and species preying on plankton mistaking microplastics for food. Further functional and toxicological studies are therefore necessary to assess the hazard associated with microplastics in the marine food web.

Panyachanakul, T., et al. (2019). "Development of biodegradation process for Poly(DL-lactic acid)degradation by crude enzyme produced by Actinomadura keratinilytica strain T16-1." Electronic Journal of Biotechnology **40**: 52-57.

Background: Plastic waste is a serious problem because it is difficult to degrade, thereby leading to global environment problems. Poly(lactic acid)(PLA)is a biodegradable aliphatic polyester derived from renewable resources, and it can be degraded by various enzymes produced by microorganisms. This study focused on the scale-up and evaluated the bioprocess of PLA degradation by a crude microbial enzyme produced by Actinomadura keratinilytica strain T16-1 in a 5 L stirred tank bioreactor. Result(s): PLA degradation after 72 h in a 5 L bioreactor by using the enzyme of the strain T16-1 under controlled pH conditions resulted in lactic acid titers (mg/L)of 16,651 mg/L and a conversion efficiency of 89% at a controlled pH of 8.0. However, the PLA degradation process inadvertently produced lactic acid as a potential inhibitor, as shown in our experiments at various concentrations of lactic acid. Therefore, the dialysis method was performed to reduce the concentration of lactic acid. The experiment with a dialysis bag achieved PLA degradation by weight loss of 99.93%, whereas the one without dialysis achieved a degradation of less than approximately 14.75%. Therefore, the dialysis method was applied to degrade a commercial PLA material (tray)with a conversion efficiency of 32%, which was 6-fold more than that without dialysis. Conclusion(s): This is the first report demonstrating the scale-up of PLA degradation in a 5 L bioreactor and evaluating a potential method for enhancing PLA degradation efficiency. Papadopoulou, A., et al. (2019). "Enzymatic PET Degradation." Chimia **73**(9): 743-749.

Plastic, in the form of packaging material, disposables, clothing and other articles with a short lifespan, has become an indispensable part of our everyday life. The increased production and use of plastic, however, accelerates the accumulation of plastic waste and poses an increasing burden on the environment with negative effects on biodiversity and human health. PET, a common thermoplastic, is recycled in many countries via thermal, mechanical and chemical means. Recently, several enzymes have been identified capable of degrading this recalcitrant plastic, opening possibilities for the biological recycling of the omnipresent material. In this review, we analyze the current knowledge of enzymatic PET degradation and discuss advances in improving the involved enzymes via protein engineering. Looking forward, the use of plastic degrading enzymes may facilitate sustainable plastic waste management and become an important tool for the realization of a circular plastic economy.

Paraboschi, E. M., et al. (2011). "Genetic association and altered gene expression of mir-155 in multiple sclerosis patients." International Journal of Molecular Sciences **12**(12): 8695-8712.

Multiple sclerosis (MS) is a complex autoimmune disease of the central nervous system characterized by chronic inflammation, demyelination, and axonal damage. As microRNA (miRNA)-dependent alterations in gene expression in hematopoietic cells are critical for mounting an appropriate immune response, miRNA deregulation may result in defects in immune tolerance. In this frame, we sought to explore the possible involvement of miRNAs in MS pathogenesis by monitoring the differential expression of 22 immunity-related miRNAs in peripheral blood mononuclear cells of MS patients and healthy controls, by using a microbead-based technology. Three miRNAs resulted >2 folds up-regulated in MS vs controls, whereas none resulted down-regulated. Interestingly, the most up-regulated miRNA (mir-155; fold change = 3.30; P = 0.013) was previously reported to be up-regulated also in MS brain lesions. Mir-155 up-regulation was confirmed by qPCR experiments. The role of mir-155 in MS susceptibility was also investigated by genotyping four single nucleotide polymorphisms (SNPs) mapping in the mir-155 genomic region. A haplotype of three SNPs, corresponding to a 12-kb region encompassing the last exon of BIC (the B-cell Integration Cluster non-coding RNA, from which mir-155 is processed), resulted associated with the disease status (P = 0.035; OR = 1.36, 95% CI = 1.05-1.77), suggesting that this locus strongly deserves further investigations.

Parenti, C. C., et al. (2019). "Evaluation of the infiltration of polystyrene nanobeads in zebrafish embryo tissues after short-term exposure and the related biochemical and behavioural effects." Environmental Pollution **254**(Part A).

One of the current main challenges faced by the scientific community is concerning the fate and toxicity of plastics, due to both the well-known threats made by larger plastic items spreading in ecosystems and their fragmentation into micro- and nanoparticles. Since the chemical and physical characteristics of these smaller plastic fragments are markedly different with respect to their bulk product, the potential toxicological effects in the environment need to be deeply investigated. To partially fill this gap of knowledge, the aim of this study was to evaluate the polystyrene nanobead intake in the tissues of zebrafish (Danio rerio) embryos and their related toxicity. Embryos at 72 h post fertilization (hpf) were exposed for 48 h to 0.5 micro m fluorescent polystyrene nanobeads at a concentration of 1 mg L⁻¹. Confocal microscopy was employed to investigate nanoplastic ingestion and tissue infiltration, while potential sub-lethal effects were evaluated by measuring several endpoints, which covered the adverse effects at the molecular (protein carbonylation), cellular (P-glycoprotein, activity of several antioxidant/detoxifying enzymes) and organism levels by evaluating of possible changes in the embryos' swimming behaviour. Imaging observations clearly highlighted the nanoplastics' uptake, showing nanobeads not only in the digestive tract, but also migrating to other tissues through the gut epithelium. Biomarker analyses revealed a significant decrease in cyclooxygenase activity and an induction of superoxide dismutase. The behavioural test highlighted a significant ($p<0.05$) variation in the turn angle between the control and exposed embryos. This study points out the capability of nanoplastics to infiltrate zebrafish embryo tissues, even after a short exposure, thus suggesting the need for deeper investigations following longer exposure times, and highlighting the potential of nanoplastics to cause toxicological effects on freshwater organisms, at the organism level.

Park, B. H., et al. (2017). "An integrated rotary microfluidic system with DNA extraction, loop-mediated isothermal amplification, and lateral flow strip based detection for point-of-care pathogen diagnostics." Biosensors & Bioelectronics **91**: 334-340.

Point-of-care (POC) molecular diagnostics plays a pivotal role for the prevention and treatment of infectious diseases. In spite of recent advancement in microfluidic based POC devices, there are still rooms for development to realize rapid, automatic and cost-effective sample-to-result genetic analysis. In this study, we propose an integrated rotary microfluidic system that is capable of performing glass microbead based DNA extraction, loop mediated isothermal amplification (LAMP), and colorimetric lateral flow strip based detection in a sequential manner with an optimized microfluidic design and a rotational speed control. Rotation direction-dependent coriolis force and siphon valving structures enable us to perform the fluidic control and metering, and the use of the lateral flow strip as a detection method renders all the analytical processes for nucleic acid test simplified and integrated without the need of expensive instruments or human intervention. As a proof of concept for point-of-care DNA diagnostics, we identified the food-borne bacterial pathogen which was contaminated in water or milk. Not only monoplex Salmonella Typhimurium but also multiplex Salmonella Typhimurium and Vibrio parahaemolyticus were analysed on the integrated rotary genetic analysis microsystem with a limit of detection of 50 CFU in 80min. In addition, three multiple samples were simultaneously analysed on a single device. The sample-to-result capability of the proposed microdevice provides great usefulness in the fields of clinical diagnostics, food safety and environment monitoring.

Park, B. L., et al. (2013). "Genome-wide association study of aspirin-exacerbated respiratory disease in a Korean population." Human Genetics **132**(3): 313-321.

Aspirin-exacerbated respiratory disease (AERD) is a nonallergic clinical syndrome characterized by a severe decline in forced expiratory volume in one second (FEV1) following the ingestion of non-steroidal anti-inflammatory drugs (NSAIDs) such as aspirin. The effects of genetic variants have not fully explained all of the observed individual differences to an aspirin challenge despite previous attempts to identify AERD-related genes. In the present study, we performed genome-wide association study (GWAS) and targeted association study in Korean asthmatics to identify new genetic factors associated with AERD. A total of 685 asthmatic patients without

AERD and 117 subjects with AERD were used for the GWAS of the first stage, and 996 asthmatics without AERD and 142 subjects with AERD were used for a follow-up study. A total of 702 SNPs were genotyped using the GoldenGate assay with the VeraCode microbead. GWAS revealed the top-ranked variants in 3' regions of the HLA-DPB1 gene. To investigate the detailed genetic effects of an associated region with the risk of AERD, a follow-up targeted association study with the 702 single nucleotide polymorphisms (SNPs) of 14 genes was performed on 802 Korean subjects. In a case-control analysis, HLA-DPB1 rs1042151 (Met105Val) shows the most significant association with the susceptibility of AERD (p = 5.11 x 10(-7); OR = 2.40). Moreover, rs1042151 also shows a gene dose for the percent decline of FEV1 after an aspirin challenge (p = 2.82 x 10(-7)). Our findings show that the HLA-DPB1 gene polymorphism may be the most susceptible genetic factor for the risk of AERD in Korean asthmatics and confirm the importance of HLA-DPB1 in the genetic etiology of AERD.

Park, D., et al. (2014). "Motility analysis of bacteria-based microrobot (bacteriobot) using chemical gradient microchamber." Biotechnology & Bioengineering **111**(1): 134-143.

A bacteria-based microrobot (bacteriobot) was proposed and investigated as a new type of active drug delivery system because of its useful advantages, such as active tumor targeting, bacteria-mediated tumor diagnosis, and therapy. In this study, we fabricated a bacteriobot with enhanced motility by selective attachment of flagellar bacteria (Salmonella typhimurium). Through selective bovine serum albumin (BSA) pattering on hydrophobic polystyrene (PS) microbeads, many S. typhimurium could be selectively attached only on the unpatterned surface of PS microbead. For the evaluation of the chemotactic motility of the bacteriobot, we developed a microfluidic chamber which can generate a stable concentration gradient of bacterial chemotactic chemicals. Prior to the evaluation of the bacteriobot, we first evaluated the directional chemotactic motility of S. typhimurium using the proposed microfluidic chamber, which contained a bacterial chemo-attractant (L-aspartic acid) and a chemo-repellent (NiSO4), respectively. Compared to density of the control group in the microfluidic chamber without any chemical gradient, S. typhimurium increased by about 16% in the L-aspartic acid gradient region and decreased by about 22% in the NiSO4 gradient region. Second, we evaluated the bacteriobot's directional motility by using this microfluidic chamber. The chemotactic directional motility of the bacteriobot increased by 14% and decreased by 13% in the concentration gradients of L-aspartic acid and NiSO4 , respectively. These results confirm that the bacteriobot with selectively patterned S. typhimurium shows chemotaxis motility very similar to that of S. typhimurium. Moreover, the directional motilities of the bacteria and bacteriobot could be demonstrated quantitatively through the proposed microfluidic chamber.

Park, E. J., et al. (2020). "Repeated-oral dose toxicity of polyethylene microplastics and the possible implications on reproduction and development of the next generation." Toxicology Letters **16**: 16.

With the increased distribution of microplastics in the environment, the potential for harmful effects on human health and ecosystems have become a global concern. Considering that polyethylene microplastics (PE-MPs) are among the most produced plastics worldwide, we administered PE-MPs (0.125, 0.5, 2 mg/day/mouse) by gavage to mice (10 mice/sex/dose) for 90 days. Compared to control, the body weight gain was significantly reduced in the male mice, and the proportion of neutrophils in the blood stream clearly increased in both sexes of mice. Persistence of a PE-MPs-like material and migration of granules to the mast cell membrane and accumulation of damaged organelles were observed in the stomachs and the spleens from the treated dams, respectively. Additionally, the IgA level in the blood stream was significantly elevated in the dams administered with PE-MPs compared to control, and the subpopulation of lymphocytes within the spleen was altered. Following, we performed an additional study to screen the effects of PE-MPs on reproduction and development (5 mice/sex/dose). Importantly, number of live births per dam, the sex ratio of pups, and body weight of pups was notably altered in groups treated with PE-MPs compared to the control group. Additionally, PE-MPs affected the subpopulation of lymphocytes within the spleen of the offspring, as did in the dams. Therefore, we propose that reproductive and developmental toxicity testing is warranted to evaluate the safety of microplastics. Additionally, we suggest that the IgA level may be used as a biomarker for harmful effects following exposure on microplastics.

Park, H. J. and Y. H. Khang (1995). "Production of cephalosporin C by immobilized Cephalosporium acremonium in polyethyleneimine-modified barium alginate." Enzyme and Microbial Technology **17**(5): 408-412.

Calcium, barium, and strontium alginates were studied to develop a suitable gel matrix for the immobilization of Cephalosporium acremonium. Barium alginate gave better results in both gel stability and cell activity than Ca- and Sr-alginates. The mechanical stability of Ba-alginate was greatly enhanced by use of polyethyleneimine (PEI). According to quantitative studies of two factors, PEI concentration and Ba-alginate bead size, cephalosporin C (CPC) production was predominantly influenced by the bead size alone. Thus, C. acremonium cells were immobilized in microbeads of PEI-modified Ba-alginate. Minimal production media, which increased CPC productivity 3.4-fold compared with chemically defined media, were used in fed-batch fermentations. Cephalosporin C was produced continuously for 30 days and CPC yields of immobilized cells in fed-batch fermentation increased about sevenfold as compared with those of free cells in batch fermentation. Immobilized cells in PEI-modified Ba-alginate were reusable for more than 30 days.

Park, H. J., et al. (2020). "National Reconnaissance Survey of Microplastics in Municipal Wastewater Treatment Plants in Korea." Environmental Science & Technology **14**: 14.

Large quantities of microplastics are thought to be emitted to freshwater environments via wastewater treatment plants (WWTPs). To evaluate the occurrence of microplastics in Korean WWTPs, a nationwide study was conducted for the first time in 50 representative WWTPs with large treatment capacities. Grab sampling and laboratory filtration were used for influents, whereas in situ filtration using a custom-made sampling device was used for effluents. The filtrates were pretreated using wet peroxidation and density separation prior to the identification of microplastics with a dissection microscope and Fourier-transform infrared spectroscopy. Pooled analyses of the microplastics revealed that they were predominantly fragment-shaped, and thermoplastics and synthetic fibers were the dominant microplastic materials in WWTPs. The concentration ranged from 10 to 470 L⁻¹ in influents and 0.004 to 0.51 L⁻¹ in effluents. The removal efficiency of microplastics during wastewater treatment was calculated to be 98.7-99.99% in 31 WWTPs. Additionally, WWTPs using advanced phosphorus removal processes exhibited higher removal efficiency than those not implementing such processes. Power-law distribution was successful in describing microplastic particle sizes down to 100 mum, although it was not applicable for smaller particles. This comprehensive monitoring study provides information on the current level and characteristics of microplastics in WWTPs in Korea.

Park, H. R., et al. (2005). "Factors effecting the Th2-like immune response after gamma-irradiation: low production of IL-12 heterodimer in antigen-presenting cells and small expression of the IL-12 receptor in T cells." International Journal of Radiation Biology **81**(3): 221-231.

Ionizing radiation is known to reduce the helper T (Th) 1-like function, but not the Th2-like function, resulting in a Th1/Th2 imbalance. While this has been known for some time, the mechanism behind the preferential suppression of the Th1?cell activation has not yet been explained. The aim is to elucidate the mechanism in the Th cell imbalance after ionizing irradiation. C57BL/6 mice, 7 weeks old, received whole-body?-irradiation (WBI) of 5?Gy. In all instances, the spleen and peritoneal cells were obtained from mice 7 weeks after irradiation. To distinguish Th1 and Th2?cell function, interferon (IFN)-? and interleukin (IL)-4 produced by these cells were analysed by an enzyme-linked immunosorbent assay (ELISA). To isolate the primary T cells, the anti-CD90.2 microbead-conjugated antibody was used and the labelled cells were separated by magnetic cell sorting (MACS). To investigate the influence of the IL-12p70 secreted by the antigen-presenting cells, ovalbumin (OVA)-primed peritoneal adherent cells (PAC) were fixed by 1% paraformaldehyde and co-cultured with OVA-specific Th cells in the presence of supernatant of PAC culture with OVA for 16?h. IL-12 receptor, signal transducers and activators of transcription 4 (STAT4) and IFN-? expression in the T cells of the WBI mice were detected by reverse transcriptase-polymerase chain reaction (RT-PCR). The spleen lymphocytes of WBI mice showed a depression of IFN-? production against OVA, although the total IL-12 was highly secreted. However, the heterodimer IL-12, biologically active protein, was induced less in WBI mice. Although the OVA-specific Th cells were co-cultured with fixed OVA-primed PAC obtained from normal mice, the OVA-specific Th cells showed a decreased IFN-? secretion in the presence of the culture supernatant of the activated PAC from the WBI mice. In addition, recombinant IL-12p70 restored the cytokine balance of the OVA-specific Th cells. However the cytokine balance of primary T cells from WBI mice was not completely restored by the normal antigen-presenting cells that abundantly secrete IL-12p70. It was assumed that after WBI, the regenerated T cells also have some problems. It was then observed that the IL-12 receptor expression and intracellular levels of the STAT4 were much lower in the T cells of the WBI mice. The results suggest that the shifted response of the helper T cells after WBI exposure is due not only due to a significant suppression of the secretion of the IL-12p70 in the antigen-presenting cells, but also to the lower expression of the IL-12 receptor on T cells.

Park, I. U., et al. (2019). "Performance of Treponemal Tests for the Diagnosis of Syphilis." Clinical Infectious Diseases **68**(6): 913-918.

BACKGROUND: Treponemal immunoassays are increasingly used for syphilis screening with the reverse sequence algorithm. There are few data describing performance of treponemal immunoassays compared to traditional treponemal tests in patients with and without syphilis.

METHODS: We calculated sensitivity and specificity of 7 treponemal assays: (1) ADVIA Centaur (chemiluminescence immunoassay [CIA]); (2) Bioplex 2200 (microbead immunoassay); (3) fluorescent treponemal antibody absorption test (FTA-ABS); (4) INNO-LIA (line immunoassay); (5) LIAISON CIA; (6) Treponema pallidum particle agglutination assay (TPPA); and (7) Trep-Sure (enzyme immunoassay [EIA]), using a reference standard combining clinical diagnosis and serology results. Sera were collected between May 2012-January 2013. Cases were characterized as: (1) current clinical diagnosis of syphilis: primary, secondary, early latent, late latent; (2) prior treated syphilis only; (3) no evidence of current syphilis, no prior history of syphilis, and at least 4 of 7 treponemal tests negative.

RESULTS: Among 959 participants, 262 had current syphilis, 294 had prior syphilis, and 403 did not have syphilis. FTA-ABS was less sensitive for primary syphilis (78.2%) than the immunoassays or TPPA (94.5%-96.4%) (all P <= .01). All immunoassays were 100% sensitive for secondary syphilis, 95.2%-100% sensitive for early latent disease, and 86.8%-98.5% sensitive in late latent disease. TPPA had 100% specificity.

CONCLUSIONS: Treponemal immunoassays demonstrated excellent sensitivity for secondary, early latent, and seropositive primary syphilis. Sensitivity of FTA-ABS in primary syphilis was poor. Given its high specificity and superior sensitivity, TPPA is preferred to adjudicate discordant results with the reverse sequence algorithm over the FTA-ABS.

Park, J., et al. (2019). "Assessment of endocrine-disrupting activities of alternative chemicals for bis(2-ethylhexyl)phthalate." Environmental Research **172**: 10-17.

Plastic products are closely intertwined with modern life. Some plasticizers used in making plastics, such as phthalates, are reported to be endocrine-disrupting chemicals. Plasticizers can be released into the environment, and health risks related to plasticizer exposure have been reported. In addition, due to plastic waste that flows into the ocean, microplastics have been found in marine products, including non-biological seawater products such as sea salt. Plastics can affect the body via a variety of pathways, and therefore safer alternative chemicals are needed. Three chemicals were evaluated: acetyl tributyl citrate (ATBC), triethyl 2-acetylcitrate (ATEC), and trihexyl O-acetylacitrate (ATHC), replacing bis(2-ethylhexyl)phthalate (DEHP), a typical plasticizer. The endocrine-disrupting activities of each chemical, including estrogenic or anti-estrogenic activity (test guideline (TG) No. 455), androgenic or anti-androgenic activity (TG No. 458), steroidogenesis (TG No. 456), and estrogenic properties via a short-term screening test using the uterotrophic assay (TG No. 440), were assessed in accordance with the Organisation for Economic Co-operation and Development guidelines for chemical testing. Our results showed that DEHP, ATBC, ATEC, ATHC possess no estrogenic activity, whereas DEHP, ATBC and ATHC demonstrate anti-estrogenic activity and ATBC anti-androgenic activity. DEHP and ATHC exhibited a disruption in steroidogenesis activities. Additional tests are necessary, but our results suggest that ATEC is a good candidate plasticizer providing a suitable alternative to DEHP.

Park, J. M., et al. (2014). "Fully automated circulating tumor cell isolation platform with large-volume capacity based on lab-on-a-disc." Analytical Chemistry **86**(8): 3735-3742.

Full automation with high purity for circulating tumor cell (CTC) isolation has been regarded as a key goal to make CTC analysis a "bench-to-bedside" technology. Here, we have developed a novel centrifugal microfluidic platform that can isolate the rare cells from a large volume of whole blood. To isolate CTCs from whole blood, we introduce a disc device having the biggest sample capacity as well as manipulating blood cells for the first time. The fully automated disc platform could handle 5 mL of blood by designing the blood chamber having a triangular obstacle structure (TOS) with lateral direction. To guarantee high purity that enables molecular analysis with the rare cells, CTCs were bound to the microbeads covered with anti-EpCAM to discriminate density between CTCs and blood cells and the CTCs being heavier than blood cells were only settled under a density gradient medium (DGM) layer. To understand the movement of CTCs under centrifugal force, we performed computational fluid dynamics simulation and found that their major trajectories were the boundary walls of the DGM chamber, thereby optimizing the chamber design. After whole blood was inserted into the blood chamber of the disc platform, size- and density-amplified cancer cells were isolated within 78 min, with minimal contamination as much as approximately 12 leukocytes per milliliter. As a model of molecular analysis toward personalized cancer treatment, we performed epidermal growth factor receptor (EGFR) mutation analysis with HCC827 lung cancer cells and the isolated cells were then successfully detected for the mutation by PCR clamping and direct sequencing.

Park, J. M., et al. (2012). "Highly efficient assay of circulating tumor cells by selective sedimentation with a density gradient medium and microfiltration from whole blood." Analytical Chemistry **84**(17):

7400-7407.

Isolation of circulating tumor cells (CTCs) by size exclusion can yield poor purity and low recovery rates, due to large variations in size of CTCs, which may overlap with leukocytes and render size-based filtration methods unreliable. This report presents a very sensitive, selective, fast, and novel method for isolation and detection of CTCs. Our assay platform consists of three steps: (i) capturing CTCs with anti-EpCAM conjugated microbeads, (ii) removal of unwanted hematologic cells (e.g., leukocytes, erythrocytes, etc.) by selective sedimentation of CTCs within a density gradient medium, and (iii) simple microfiltration to collect these cells. To demonstrate the efficacy of this assay, MCF-7 breast cancer cells (average diameter, 24 mum) and DMS-79 small cell lung cancer cells (average diameter, 10 mum) were used to model CTCs. We investigated the relative sedimentation rates for various cells and/or particles, such as CTCs conjugated with different types of microbeads, leukocytes, and erythrocytes, in order to maximize differences in the physical properties. We observed that greater than 99% of leukocytes in whole blood were effectively removed at an optimal centrifugal force, due to differences in their sedimentation rates, yielding a much purer sample compared to other filter-based methods. We also investigated not only the effect of filtration conditions on recovery rates and sample purity but also the sensitivity of our assay platform. Our results showed a near perfect recovery rate (~99%) for MCF-7 cells and very high recovery rate (~89%) for DMS-79 cells, with minimal amounts of leukocytes present.

Park, J. W. (2018). "Ecotoxicological effects of microplastics and the importance of multidisciplinary endeavors for risk assessment." Toxicology and Environmental Health Sciences **10 (4)**: S23.

Due to the economical and convenient use of plastics, global plastics production is rapidly increasing. The fact that half of the plastics produced so far have been produced in the last 13 years shows how fast the production and consumption of plastics have grown. Microplastics is fine plastic pieces less than 5 mm in size and is categorized as primary microplastics produced for a specific purpose and secondary microplastics which are naturally broken or worn from large plastics in the environment. In environment, microplastics can be worn to ultra-fine plastics of the nanometer level (nanoplastics) due to ultraviolet rays etc. Microplastics are found in sea, river and river around the world including Korea, and it is known that the level of microplastic pollution in Korea is higher than that of other countries. Important features of microplastics found in the environment are the wide variety of polymer types, sizes and shapes of microplastics. And these various physicochemical properties can cause various effects of microplastics on organisms and human body. In order to protect the environment and human from the risk of microplastics, it is necessary to accurately evaluate and predict the risk of microplastics. However, the research data are not sufficient yet. And it is unlikely that any conclusions about the risk of microplastics will be reached in the near future. This presentation will present the effects of (nano) microplastics on the environment and human which were investigated so far, and introduce the necessary research areas for future risk assessment studies.

Park, J. Y. and C. Gupta (2015). "Evaluating localism in the management of post-consumer plastic bottles in Honolulu, Hawai'i: perspectives from industrial ecology and political ecology." Journal of Environmental Management **154**: 299-306.

Localism or regionalization has become a popular topic in urban design, but recent critics raise the question of whether the local or regional scale is most desirable for industrial ecosystems. As a way to explore the claim that localized metabolism is more sustainable, this study examines the costs and benefits of two differentially scaled strategies for the management of post-consumer polyethylene terephthalate (PET) bottles originating in the city of Honolulu, Hawai'i: local incineration and trans-continental recycling. We first estimate total environmental impacts of two options using life cycle assessment, and then disaggregate them into local versus non-local impacts to examine the spatial distribution of costs and benefits. We further assess the environmental justification for localized waste management in relation to the broader socio-economic motivations that underlie the way that plastics are managed in Honolulu. In doing so we assess the scale at which waste management is optimized from an environmental standpoint as well as the non-environmental considerations such as security and safety that influence the politics of scale involved in urban metabolic design. By illustrating the trade-offs between a local versus global metabolic pathway for plastic waste, the results from our Honolulu case study are globally relevant for communities interested in sustainable urban design and in particular urban waste management.

Park, J. Y., et al. (2009). "Study of cellular behaviors on concave and convex microstructures fabricated from elastic PDMS membranes." Lab on a Chip **9**(14): 2043-2049.

Cells respond to geometrical cues, as well as to biochemical and mechanical stimuli. Recent progress in micro- and nano-technology has allowed researchers to create microbeads, micro-circular islands, and microposts, that can be used to examine the effect of geometrical cues on cellular behavior. Knowledge of changes in cell mechanics and morphology in response to geometric cues is important for understanding the basic behavior of cells during development and pathological processes. Most previous research in this area has focused on cell responses to two-dimensional planar or rectilinear structures. Very few studies have examined cell responses to three-dimensional curved structures because of the difficulty of fabricating such microstructures. Here we describe a novel method for the fabrication of convex and concave microstructures by use of a thin poly(dimethylsiloxane) (PDMS) membrane, SU-8 shadow mask, and negative air pressure without using any complicated silicon processes. We successfully fabricated concave and convex microstructures, with base diameters of 200-300 microm and depth (or height) of 50-150 microm (aspect ratios up to 1 : 0.5), and used these microstructures to study the responses of cultured L929 mouse fibroblast cells and human mesenchymal stem cells. These cells clearly sensed the three-dimensional microscale curvature and actively "escaped" from concave patterns, but not from those which were convex. Thus, it appears that microscale concave structures suppress cell adhesion and proliferation. We hypothesized that this might relate to deformation of the plasma membrane and subsequent opening of membrane channels. We anticipate that our system will be useful for various bio-MEMS (micro electro mechanical system) applications, including formation of uniformly-sized embryoid bodies, embryonic stem cell differentiation, and the fabrication of cell docking devices, microbioreactors, and microlenses as well as cell mechanics study.

Park, S.-H., et al. (2012). Comparing of various collagens for application of cartilage tissue engineering. 2012 2nd IEEE-EMBS Conference on Biomedical Engineering and Sciences, IECBES 2012, December 17, 2012 - December 19, 2012, Langkawi, Malaysia, IEEE Computer Society.

Mammalian collagens have been used as a base material for collagen matrices in tissue engineering applications. However, collagens of aquatic animals and human sources can potentially be utilized as a safe and viable substitute, because collagen products of bovine origin have been shown to be contaminated with some diseases. In the present study, we prepared and investigated collagen materials from several sources (bovine skin, porcine skin, amniotic membrane and starfish) as matrix biomaterials. Detailed investigations on their physicochemical and biological properties, such as amino acid composition, thermal transition temperature, molar mass, IR spectra, and cell response, suggested strong relations between their amino acid composition and intermolecular structure, thermal property, and cell response. Selectively, an amniotic membrane collagen scaffold was evaluated for cartilage tissue engineering in three types of three-dimensional 3D culture (sponge, gel and micro bead forms) and compared with a bovine matrix. Results showed that amniotic membrane collagen has a potential as an alternative source of collagen for use in tissue engineering. 2012 IEEE.

Park, S. J., et al. (2013). "Selective bacterial patterning using the submerged properties of microbeads on agarose gel." Biomedical Microdevices **15**(5): 793-799.

We proposed a new bacteria patterning method on the restricted region of microbeads, using the submerged property of polystyrene microbeads on various concentrations of agarose gel. Moreover, we fabricated a bacterial microrobot using attenuated Salmonella typhimurium through the new patterning methods. We controlled the submerged degree of polystyrene microbeads through the regulation of the hardness of the agarose gel. The polystyrene microbeads on agarose gel were transferred onto a poly-dimethylsiloxane (PDMS) surface for easy manipulation of the microbeads. Then, we treated the polystyrene microbeads on the PDMS surface with antibacterial adherent factors, such as O sub(2) plasma and bovine serum albumin (BSA). The Salmonella typhimurium was attached to the entire surface of the untreated polystyrene microbeads, whereas Salmonella typhimurium were only attached to the restricted surface region of the treated polystyrene microbeads through the proposed patterning method. The bacteria-attached microbeads gain motility by the propulsion of the attached bacteria, and the selective-bacteria-attached microbeads showed enhanced motility. Compared with whole-bacteria-attached polystyrene microbeads (1.74 plus or minus 1.62 mu m/s), the selective bacteria-attached polystyrene microbeads, using O sub(2) plasma and BSA, showed 9.18 plus or minus 1.88 mu m/s and 14.65 plus or minus 8.66 mu m/s faster moving velocities, respectively. Through the results, we expected that the proposed patterning methodology of microbeads could contribute to the development of biomedical bacterial microrobots.

Park, S. J., et al. (2014). "Monocyte-based microrobot with chemotactic motility for tumor theragnosis." Biotechnology & Bioengineering **111**(10): 2132-2138.

Biocompatibility, sensing, and self-actuation are very important features for a therapeutic biomedical microrobot. As a new concept for tumor theragnosis, this paper proposes a monocyte-based microrobots, which are combining the phagocytosis and engulfment activities containing human acute monocytic leukemia cell line (THP-1) with various sized polystyrene microbeads are engulfed instead of a therapeutic drug. For the validation of the blood vessel barrier-penetrating activity of the monocyte-based microrobot, we fabricate a new cell migration assay with monolayer-cultured endothelial cell (HUVEC), similar with the blood vessels. We perform the penetrating chemotactic motility of the monocyte-based microrobot using various types of the chemo-attractants, such as monocyte chemotactic protein (MCP)-1, human breast cancer cell lines (MCF7)-cell lysates, and -contained alginate spheroids. The monocyte-based microrobot show chemotactic transmigrating motilities similar with what an actual monocyte does. This new paradigm of a monocyte-based microrobot having various useful properties such as biocompatibility, sensing, and self-actuation can become the basis of a biomedical microrobot using monocytes for diagnosis and therapy of various diseases.

Park, S. Y. and C. G. Kim (2019). "Biodegradation of micro-polyethylene particles by bacterial colonization of a mixed microbial consortium isolated from a landfill site." Chemosphere **222**: 527-533.

In this study, we investigated the decomposition of micro-sized polyethylene (PE) by mesophilic

mixed bacterial culture isolates obtained from a municipal landfill sediment. Among these, Bacillus sp. and Paenibacillus sp. were more specifically enriched in the non-carbonaceous nutrient medium (i.e., Basal medium) as they were the most dominant species when they were exposed to PE microplastics. They reduced the dry weight of particles (14.7% after 60d) and the mean particle diameter (22.8% after 60d; obtained by field-emission scanning electron microscopy analysis). In the gas chromatography-mass spectrometer analysis of biologically aged particles, the amount and types of organic contents eluted from the PE microplastics were far lower in the early decomposition phase; however, they increased in the later phase. Thermal gravimetric analysis showed that the aged particles had higher thermal stability at temperatures greater than 570degreeC compared to the control, thereby suggesting that microplastics were degraded by enzymatic chain scission, which could in turn be ascribed to the greater refractory fractions of aged particles remaining at a high combustion temperature. It was further verified that PE particles could be biologically utilized as a sole carbon source and broken down during the test period.

Park, T. J., et al. (2020). "Occurrence of microplastics in the Han River and riverine fish in South Korea." Science of the Total Environment **708**: 134535.

Microplastic pollution has been paid attention due to the possibly global threat to human health and ecosystem in recent years. In this study, we investigated the distribution of microplastics in the Han River and its tributaries, South Korea, and in six species of inhabiting fish, namely carp (C. carpio), crucian carp (C. cuvieri), bluegill (L. macrochirus), bass (M. salmoides), catfish (S. asotus), and snakehead (C. argus). We found that the concentration of microplastics in the surface waters (0 m) was 0-42.9 particles/m³ (mean: 7.0 +/- 12.9 particles/m³) compared to 20.0-180.0 particles/m³ (mean: 102.0 +/- 50.3 particles/m³) at a depth of 2 m. Concentrations in the river tributaries ranged from 1.2 to 234.5 particles/m³ (mean: 91.1 +/- 72.3 particles/m³). The most common types the plastic identified were polyethylene (PE), silicone, and polystyrene, while polytetrafluoroethylene (PTFE), polyethylene, and polyester dominated in the tributaries. With respect to shape, >73% of the recovered microplastics were fragments and the rest were fibers in the water. We also measured the concentration of microplastics in the intestines of fish, which ranged from 4 to 48 particles/fish (mean: 22.0 +/- 16.0 particles/fish). The most common types of plastic found in the sampled fish were polytetrafluoroethylene (PFTE), polyethylene (PE), and rayon, and >94% of all the microplastic found in fish was in the form of fragments with the remainder being fibers. The concentrations of microplastic in the gills of fish ranged from 1 to 16 particles/fish (mean: 8.3 +/- 6.0 particles/fish). In contrast, no microplastic was found in the flesh of the sampled fish. Our results imply that the ingestion of microplastics by fish is more closely related to habitat rather than feeding habits.

Park, Y. H., et al. (2019). "Transcriptomic profiles of retinal ganglion cells are defined by the magnitude of intraocular pressure elevation in adult mice." Scientific Reports **9**(1): 2594.

Elevated intraocular pressure (IOP) is the major risk factor for glaucoma, a sight threatening disease of retinal ganglion cells (RGCs) and their axons. Despite the central importance of IOP, details of the impact of IOP elevation on RGC gene expression remain elusive. We developed a 4-step immunopanning protocol to extract adult mouse RGCs with high fidelity and used it to isolate RGCs from wild type mice exposed to 2 weeks of IOP elevation generated by the microbead model. IOP was elevated to 2 distinct levels which were defined as Mild (IOP increase >1 mmHg and <4 mmHg) and Moderate (IOP increase >=4 mmHg). RNA sequencing was used to compare the transcriptional environment at each IOP level. Differentially expressed genes were

markedly different between the 2 groups, and pathway analysis revealed frequently opposed responses between the IOP levels. These results suggest that the magnitude of IOP elevation has a critical impact on RGC transcriptional changes. Furthermore, it is possible that IOP-based set points exist within RGCs to impact the direction of transcriptional change. It is possible that this improved understanding of changes in RGC gene expression can ultimately lead to novel diagnostics and therapeutics for glaucoma.

Park, Y. M., et al. (2015). "Detection of CTX-II in serum and urine to diagnose osteoarthritis by using a fluoro-microbeads guiding chip." Biosensors & Bioelectronics **67**: 192-199.

This study reports a new strategy for simultaneous detection of the C-telopeptide fragments of type II collagen (CTX-II) as a biomarker of osteoarthritis (OA) using a fluoro-microbeads guiding chip. As osteoarthritis progresses, the joint components including matrix and cartilage are degraded by proteases. The degraded products such as CTX-II are released into the serum and urine, and the CTX-II concentration in body fluids reflects OA progression. Because the CTX-II has heterogeneous epitope structure in serum (sCTX-II; homodimers) and urine (uCTX-II; monomers or variant monomers), a multiple-sensing device enabling both sandwich and competitive-type immunoassays is required. For multiple assessments of serum and urinary CTX-II, we designed a fluoro-microbeads guiding chip (FMGC) containing multiple sensing areas and connecting channels. Using the approach, the sandwich (sCTX-II) and competition (uCTX-II) assays could be simultaneously performed on a single chip. We designed a fluidic control device enabling selective control of the open-close function of FMGC channels. The immune-specific signal was quantitatively analyzed by counting the number of fluorescent microbeads from the registered images. The results from the developed FMGC assay showed high correlation with those obtained in ELISA. The completion time of the FMGC assay was 24-fold and 3.5-fold shorter than the ELISA for urinary and serum CTX-II. Taken together, it enabled the simultaneous detection of both sCTX-II and uCTX-II. This FMGC-based assay would be a promising tool for monitoring of osteoarthritis.

Parkin, B., et al. (2012). "Clonal evolution and devolution following chemotherapy in adult acute myelogenous leukemia." Blood. Conference: 54th Annual Meeting of the American Society of Hematology, ASH **120**(21).

Introduction: Despite significant advances in the understanding of the biology of adult acute myelogenous leukemia (AML), overall survival remains poor due chiefly to the high rate of relapse after achieving complete remission as well as primary failure of induction chemotherapy. Efforts to further unravel the mechanisms leading to relapse and primary refractory disease are critical in order to guide the development of effective and durable treatment strategies for AML. To that end, this study seeks to elucidate the clonal relationship of AML in various disease phases. Method(s): We employed SNP 6.0 array-based genomic profiling of acquired copy number aberrations (aCNA) and copy neutral LOH (cnLOH) together with sequence analysis of recurrently mutated genes to characterize paired AML genomes. We analyzed 28 AML sample pairs from patients that achieved complete remission with chemotherapy and subsequently relapsed (median remission duration 272 days [range 25 - 1249 days]) and 11 sample pairs from patients with persistent disease following induction chemotherapy. AML cell samples were isolated with a Ficoll gradient, negatively selected using Miltenyi microbead columns, and then further purified with flow cytometric cell sorting. Processed DNA isolated from highly purified AML blasts and paired buccal DNA was hybridized to Affymetrix SNP 6.0 arrays. aCNA were visually identified using the dChip program in paired data displays and corroborated by algorithmic lesion scoring, and cnLOH was detected using internally developed software. In addition, 11 genes known to be recurrently mutated in AML (CEBPA, DNMT3A, IDH1, IDH2, RUNX1, BCORL1, NPM1, NRAS, KRAS, FLT3 and TP53) were resequenced in all 39 presentation samples to identify somatically acquired mutations. Genes found mutated in individual AML cases were subsequently tested for the persistence of the mutation in paired samples. Result(s): For the 28 paired specimens in the relapsed cohort, comparison of aCNA and cnLOH occurrences, gene mutation patterns and karyotypes revealed 6 cases that carried no aCNA/cnLOH at either presentation or relapse, but at presentation carried at least 1 gene mutation, all of which but one were stable in relapse (1 case lost a RUNX1 mutation but carried a t(8;21) in both disease stages); 11 cases that were characterized by the presence of aCNA/cnLOH at presentation, of which 55% (6 of 11) gained additional aCNA/cnLOH at relapse; 6 cases without aCNA/cnLOH at presentation that gained aCNA/cnLOH at relapse, of which 2 concurrently lost a FLT3-ITD or CEPBA mutation; and 5 cases that carried no informative genomic events. For the 11 paired specimens in the persistent AML cohort, the same comparison revealed 2 cases without aCNA/cnLOH before or after chemotherapy and stable gene mutations; 5 cases with aCNA/cnLOH at presentation that carried the same genomic lesions and gene mutations before and after chemotherapy; 3 cases with aCNA/cnLOH present at enrollment that lost some but not all of these aCNA/cnLOH and gained none after initial induction therapy; and 1 additional case that lost a FLT3-ITD. Comparative analysis of these patterns demonstrates that relapsed AML invariably represents reemergence or evolution of an antecedent clone. Furthermore, all individual aCNA or cnLOH detected at presentation persisted at relapse indicating that this lesion type is proximally involved in AML evolution. Analysis of informative paired persistent AML disease samples uncovered at least two coexisting dominant clones of which at least one was chemotherapy sensitive and one resistant. Conclusion(s): This detailed genomic analysis supports the conclusion that incomplete eradication of AML founder clones rather than stochastic emergence of fully unrelated novel clones underlies AML relapse and persistence with direct implications for clinical AML research.

Parks, J. W., et al. (2014). "Integration of programmable microfluidics and on-chip fluorescence detection for biosensing applications." Biomicrofluidics **8**(5): 054111.

We describe the integration of an actively controlled programmable microfluidic sample processor with on-chip optical fluorescence detection to create a single, hybrid sensor system. An array of lifting gate microvalves (automaton) is fabricated with soft lithography, which is reconfigurably joined to a liquid-core, anti-resonant reflecting optical waveguide (ARROW) silicon chip fabricated with conventional microfabrication. In the automaton, various sample handling steps such as mixing, transporting, splitting, isolating, and storing are achieved rapidly and precisely to detect viral nucleic acid targets, while the optofluidic chip provides single particle detection sensitivity using integrated optics. Specifically, an assay for detection of viral nucleic acid targets is implemented. Labeled target nucleic acids are first captured and isolated on magnetic microbeads in the automaton, followed by optical detection of single beads on the ARROW chip. The combination of automated microfluidic sample preparation and highly sensitive optical detection opens possibilities for portable instruments for point-of-use analysis of minute, low concentration biological samples.

Parks, M. S. (2002). "Practical considerations in converting to Renalin 100 for dialyzer reprocessing." Nephrology News & Issues **16**(12): 55, 59-62, 64.

It is clear from our findings (shown in Figs. 2, 3) that the cost of Renalin 100 is equal to or less than the cost of Renalin on a liter-to-liter basis. The decreased cost may be due to the elimination of the need to discard expired, diluted Renalin and the ability to use the small amount of Renalin 100 remaining in the container for making disinfectant solutions for disinfecting caps. The use of Renalin 100 leads to a 65% reduction in case count and storage space, as well as a 21% decrease in product weight. This means decreased costs in shipping and worker exertion to move this product. It is interesting that the 65% determination is virtually identical to the theoretical value advertised. The decreased waste generated was substantial. Cardboard waste was reduced by 78% and plastic waste was decreased by 72%. Even in this moderately sized facility this meant a decrease in waste generation of 780 lbs. annually. Extrapolation of this number across reprocessing centers in the United States would suggest that the widespread use of Renalin 100 would produce great domestic environmental gains. Because there is no diluting and mixing of Renalin 100, there is a substantial savings of time for personnel. The 95% time saving in this facility accounts for over two full weeks of technician time. In addition, the elimination of mixing and diluting decreases technician exposure to the sterilant. Finally, automated mixing and diluting eliminates the possibility of human error in preparing the sterilant and adds to the consistency of the reprocessing procedure.

Parr, J. F., et al. (1963). "A Glass Micro-Bead System for the Investigation of Soil Micro-Organisms." Nature **200**: 1227-1228.

Parsa, S. F., et al. (2018). "Early diagnosis of disease using microbead array technology: A review." Analytica Chimica Acta **1032**: 1-17.

Early diagnosis of diseases (before they become advanced and incurable) is essential to reduce morbidity and mortality rates. With the advent of novel technologies in clinical laboratory diagnosis, microbead-based arrays have come to be recognized as an efficient approach, that demonstrates useful advantages over traditional assay methods for multiple disease-related biomarkers. Multiplexed microbead assays provide a robust, rapid, specific, and cost-effective approach for high-throughput and simultaneous screening of many different targets. Biomolecular binding interactions occur after applying a biological sample (such as blood plasma, saliva, cerebrospinal fluid etc.) containing the target analyte(s) to a set of microbeads with different ligand-specificities that have been coded in planar or suspension arrays. The ligand-receptor binding activity is tracked by optical signals generated by means of flow cytometry analysis in the case of suspension arrays, or by image processing devices in the case of planar arrays. In this review paper, we discuss diagnosis of cancer, neurological and infectious diseases by using optically-encoded microbead-based arrays (both multiplexed and single-analyte assays) as a reliable tool for detection and quantification of various analytes.

Partovinia, A. and E. Vatankhah (2019). "Experimental investigation into size and sphericity of alginate micro-beads produced by electrospraying technique: Operational condition optimization." Carbohydrate Polymers **209**: 389-399.

Alginate spherical hydrogel beads have several applications in biomedical and biological processes in which the bead size and sphericity are critical factors affecting mass transfer phenomena. Electrospraying technology facilitates generation of small and almost uniform beads with higher diffusion rate resulting in process performance improvement. There are several key factors affecting particle size and shape behavior of electrosprayed alginate beads meanwhile interactions between these factors introduce complexity in determining appropriate conditions to produce spherical beads with the size of interest. Thus, the need to achieve reliable products has put growing emphasis on the use of modeling methodology to establish correlations between particle size and affecting variables as well as sphericity coefficient and meaningful factors. Obviously, a more applicable model based on intentionally manipulatable factors would spark a great deal of interest for practical engineering applications. In this regard we employed a central composite design (CCD) and response surface methodology (RSM) to model the diameter and sphericity coefficient of electrosprayed alginate beads for the first time. Two quadratic models were obtained in which the effectiveness order of the variables were found. We could benefit from this RSM-based empirical model not only for better understanding the complex physics of the electrospraying process, but also for selection of factors and their levels to produce alginate micro-beads with appropriate size and sphericity. The results indicate that the alginate concentration, voltage and needle size have the strongest influence on both response variables. The quite spherical beads with a minimum size of 130 mum can be obtained at alginate concentration of 1.5%, voltage of 11 kV, and needle size of 26 G.

Pate, J. A. and E. E. McKinnon (2016). "A citizen engagement approach to water advocacy: experiences from "eXXpedition Great Lakes"." Maritime Affairs: Journal of the National Maritime Foundation of India **12**(2): 99-108.

The Great Lakes are a group of interconnected lakes located on the Canada-United States border. Lake Superior, Michigan, Huron, Erie and Ontario form the largest group of freshwater lakes on Earth, and contain around 21% of the world's surface fresh water by volume. These lakes suffer from considerable microplastic contamination. Despite this awareness, citizens around the lakes struggle to take action. With over 80% of plastic debris in the world's water bodies being contributed from land, the solutions for eliminating microplastics have to come from changes in consumer behaviour and by stopping contamination at the source. "eXXpedition Great Lakes 2016" was designed as a one-day mass engagement event to bring the science of microplastics to citizens across the region, allowing them to experience first hand the presence and impact of this pollution. Volunteers collected water samples and conducted shoreline clean-ups on the Great Lakes and connecting waterways. Sailing vessels led by female scientists specialising in plastic pollution, human and environmental health were also launched from key cities in both Canada and the United States. The approach was to utilise the power of citizen engagement to promote clean-water advocacy and action in North America. By experiencing the issue of microplastics pollution first hand, it was hoped that participants would feel an increased sense of responsibility and consider protection of the environment as their duty, which would hopefully lead to changes in consumer behaviour. This paper shares the experiences during the event.

Patel, H. and D. Davidson (2014). "Control of pro-inflammatory cytokine release from human monocytes with the use of an interleukin-10 monoclonal antibody." Methods in Molecular Biology **1172**: 99-106.

The monocytes (MONOs) can be considered as "double-edge swords"; they have both important pro- inflammatory and anti-inflammatory functions manifested in part by cytokine production and release. Although MONOs are circulating cells, they are the major precursors of a variety of tissue-specific immune cells such as the alveolar macrophage, dendritic cells, microglial cells, and Kupffer cells. Unlike the polymorphonuclear leukocyte, which produces no or very little interleukin-10 (IL-10), the monocyte can produce this potent anti-inflammatory cytokine to control inflammation. IL-10, on an equimolar basis, is a more potent inhibitor of pro-inflammatory cytokines produced by monocytes than many antiinflammatory glucocorticoids which are used clinically. This chapter describes how to isolate monocytes from human blood and the use of IL-10 monoclonal antibody to determine the effect and timing of endogenous IL-10 release on the production and release of pro-inflammatory cytokines. Copyright © Springer Science+Business Media New York 2014.

Patel, H., et al. (2014). "External Cross-linked Mucoadhesive Microbeads for Prolonged Drug Release: Development and In vitro Characterization." Indian Journal of Pharmaceutical Sciences **76**(5): 437-444.

Mucoadhesive microbeads of low methoxyl pectin were prepared, either alone or in combinations with hydroxypropyl methyl cellulose, sodium carboxymethyl cellulose, methyl cellulose and carbopol 934P, by ionotropic gelation. The influence of copolymers on mucoadhesivity, microbeads characteristics and in vitro drug release was investigated. Spherical microbeads with 78.69+/-0.59 to 85.84+/-0.78% drug entrapment and of a size of 791.90+/-4.58 to 960.88+/-4.61 mum were prepared. The concentration of cross linking agent affects the encapsulation efficiency of microbeads. Mucoadhesiveness of microbeads was dependent on the concentration of copolymers. The formulations exhibiteda pH-dependent release and followed diffusion-controlled first-order kinetics.

Patel, J. K. and J. A. Kobashigawa (2013). "Thoracic organ transplantation: laboratory methods." Methods in Molecular Biology **1034**: 127-143.

Although great progress has been achieved in thoracic organ transplantation through the development of effective immunosuppression, there is still significant risk of rejection during the early post-transplant period, creating a need for routine monitoring for both acute antibody and cellular mediated rejection. The currently available multiplexed, microbead assays utilizing solubilized HLA antigens afford the capability of sensitive detection and identification of HLA and non-HLA specific antibodies. These assays are being used to assess the relative strength of donor specific antibodies; to permit performance of virtual crossmatches which can reduce the waiting time to transplantation; to monitor antibody levels during desensitization; and for heart transplants to monitor antibodies post-transplant. For cell mediated immune responses, the recent development of gene expression profiling has allowed noninvasive monitoring of heart transplant recipients yielding predictive values for acute cellular rejection. T cell immune monitoring in heart and lung transplant recipients has allowed individual tailoring of immunosuppression, particularly to minimize risk of infection. While the current antibody and cellular laboratory techniques have enhanced the ability to manage thoracic organ transplant recipients, future developments from improved understanding of microchimerism and graft tolerance may allow more refined allograft monitoring techniques.

Patel, P., et al. (2015). "Fully automated ultrasensitive digital immunoassay for troponin using single molecule array technology." Clinical Chemistry **1)**: S128.

Background: Ultra-sensitive cardiac troponin measurement offers a promising new tool for early detection and monitoring of cardiovascular disease. With growing interest in exploring as an early indicator of adverse heart health trends, the ability to quantitate troponin in healthy control populations is emerging as a highly desirable assay capability. We report analytical data from a fully automated digital immunoassay for cardiac troponin I (cTnI) based on single molecule array (Simoa) technology with a limit of detection 2 logs lower than contemporary high sensitivity troponin assays. Method(s): Reagents were developed for a paramagnetic bead-based ELISA for use in the Simoa HD-1 Analyzer. Anti-cTnI capture beads were prepared by covalent coupling of antibody to carboxy paramagnetic microbeads, detector antibody was biotinylated by standard methods, and an enzyme conjugate was prepared by covalent coupling of streptavidin and [[Unsupported Character - Symbol Font]]-galactosidase. The HD-1 Analyzer

first performs a 2-step sandwich immunoassay using 42 muL of serum or plasma sample, then transfers washed and labeled capture beads to a Simoa disc where the beads are singulated in 50-femtoliter microwells, sealed in the presence of substrate, and interrogated for presence of enzyme label. A single labeled cTnI molecule provides sufficient fluorescent signal in 30 seconds to be counted by the HD-1 optical system. At low cTnI concentration, the percentage of bead-containing wells in the array with a positive signal is proportional to the amount of cTnI present in the sample. At higher cTnI concentration, the total fluorescence signal is proportional to the cTnI in the sample. The concentration of cTnI is then interpolated from a standard curve (range to 300 pg/mL). Time to first result is 45 minutes. The assay was evaluated for sensitivity, recovery, linearity precision and normal range. Discrimination of healthy subjects from those with mild to moderate heart failure was also preliminarily assessed. Result(s): Limit of detection (2.5 SD) was 0.010 pg/mL across 26 runs. Limit of quantification (20% dose CV from diluted serum samples) was 0.079 pg/mL across 16 runs and 144 determinations. Recovery of cTnI spiked into normal serum averaged 80.5%. Mean linearity was 89.5%. Precision per EP5-A guideline included two serum-based panels, 1 plasma-based panel and two cTnI controls assayed in replicates of three twice per day for five days using a single calibration curve. ANOVA gave CV's <10% for all levels. Serum cTnI values from 97 healthy control samples ranged from 0.072 to 8.40 pg/mL, with a mean and 99th percentile of 1.01 and 8.40 pg/mL. Serum cTnI values from 375 patients with mild to moderate heart failure (NYHA classification II and III) ranged from 0.440 to 1770 pg/mL, with a median of 15.1 pg/mL. The heart failure samples had significantly higher cTnI concentrations than the healthy subjects (p=0.0002). Evaluation of the predictive value of the cTnI concentrations is ongoing. Conclusion(s): The results show the digital Simoa cTnI assay exhibited good general analytical properties and cTnI levels from healthy subjects were above the sensitivity limits. The assay represents a new enabling tool for ultra-sensitive cTnI measurement.

Patrick, S. M., et al. (2001). "Controlled Cell Deformation Produces Defined Areas of Contact between Cells and Ligand-Coated Surfaces." Annals of Biomedical Engineering **29**(1): 1-8.

A method which allows precise control of the time of initiation and the area of contact of T cells with immobilized ligands has been developed. Cells are trapped in an asymmetric film that can be quantitatively thinned by reducing the film's capillary pressure. Ligands adsorbed to the base of the apparatus are forced into close contact with the cells as the air-liquid interface is drawn down. Using interference microscopy and microbeads to indicate the film height, the amount of thinning can be controlled to within 1 µm. In this study, this system was used to produce contact areas of 182 and 356 µm^sup 2^ between T cells and anti-CD3 coated surfaces. These contact areas were measured using fluorescent dye exclusion microscopy. This apparatus can be used for quantitative studies of T cell activation, as is reported in Patrick et al., J. Immunol. Method. 24:97-108, 2000. © 2001 Biomedical Engineering Society. PAC01: 8717-d, 8764Rr[PUBLICATION ABSTRACT]

Pattanapanyasat, K., et al. (2010). "The use of glutaraldehyde-fixed chicken red blood cells as counting beads for performing affordable single-platform CD4(+) T-lymphocyte count in HIV-1-infected patients." Journal of Acquired Immune Deficiency Syndromes: JAIDS **53**(1): 47-54.

CD4(+) T-lymphocyte count is an important marker in management of HIV-1-infected patients. The standard single-platform (SP) flow cytometric (FCM) CD4(+) testing that uses the known reference microbeads is expensive; more affordable alternatives are therefore needed. We evaluated the use of glutaraldehyde-fixed chicken red blood cells (CRBCs) as counting beads as an alternative for enumerating CD4(+) T-lymphocyte counts in 87 HIV-1-infected patients. Linear regression analyses revealed an excellent correlation of the SP FCM using CRBCs with the standard SP bead-based FCM method (percentages, r(2) > 0.99; absolute counts, r(2) > 0.98) over the entire range including the clinically relevant range. Mean percent bias for the CRBC method was +0.35% [limits of agreement (LOA): -1.86% to +2.57%]. For absolute CD4(+) T-lymphocytes, the mean biases was -47.76 cells per microliter (LOA: -191.34 to +98.81 cells/microL) with much lower bias for CD4 T-lymphocyte counts <200 cells per microliter (LOA: -31.92 to +22.95 cells/microL). The use of CRBCs is comparable with the use of commercial microbeads. This has resulted in major cost savings to resource-limited countries where the health care system is under increasing pressure to operate cost effectively. This can greatly facilitate and ensure the success of the ongoing antiretroviral therapy program in these countries.

Pattanapanyasat, K., et al. (2007). "Evaluation of a single-platform microcapillary flow cytometer for enumeration of absolute CD4+ T-lymphocyte counts in HIV-1 infected Thai patients." Cytometry Part B - Clinical Cytometry **72**(5): 387-396.

Background: Various assays are used to enumerate peripheral blood absolute CD4+ T-lymphocytes. Flow cytometry is considered the gold standard for this purpose. However, the high cost of available flow cytometers and monoclonal antibody reagents make it difficult to implement such methods in the resource-poor settings. In this study, we evaluated a cheaper, recently developed single-platform microcapillary cytometer for CD4+ T-lymphocyte enumeration, the personal cell analyzer (PCA), from Guava Technologies. Method(s): CD4+ and CD8+ T-lymphocyte counts in whole blood samples from 250 HIV-1 infected Thais were determined, using a two-color reagent kit and the Guava PCA, and compared with the results obtained with two reference microbead-based methods from Becton Dickinson Biosciences: the three-color TruCOUNTTM tube method and the two-color FACSCountTM method. Statistical correlations and agreements were determined using linear correlation and Bland-Altman analysis. Result(s): Absolute CD4+ T-lymphocyte counts obtained using the Guava PCA method highly correlated with those obtained using TruCOUNT method (R² = 0.95, mean bias +13.1 cells/mul, limit of agreement [LOA] -117.9 to +144.1 cells/mul) and the FACSCount method (R² = 0.94, mean bias = +33.2 cells/mul, LOA -101.8 to +168.3 cells/mul). Absolute CD8+ T-lymphocyte counts obtained using the Guava PCA method also highly correlated with those obtained with the two reference methods (R² = 0.92 and 0.88, respectively). Conclusion(s): This study shows that the enumeration of CD4+ T-lymphocytes using the Guava microcapillary cytometer PCA method performed well when compared with the two reference bead-based methods. However, like the two reference methods, this new method needs substantial technical expertise. © 2007 Clinical Cytometry Society.

Pattarayingsakul, W., et al. (2019). "The gastric sieve of penaeid shrimp species is a sub-micrometer nutrient filter." Journal of Experimental Biology **222**(Pt 10): 17.

Unlike that of vertebrates, the penaeid shrimp stomach is of ectodermic origin and is thus covered by a cuticle that is sloughed upon molting. It is composed of two chambers, here called the anterior and posterior stomach chambers, ASC and PSC, respectively. The PSC contains a filtration structure variously called a pyloric filter, filter press, gastric filter or gastric sieve (GS), and the last of these will be used here. The GS resembles an elongated, inverted-V, dome-like, chitinous structure with a midline ridge that is integral to the ventral base of the PSC. The dome surface is covered with a carpet-like layer of minute, comb-like setae bearing laterally branching setulae. This carpet serves as a selective filter that excludes large partially digested food particles but allows smaller particles and soluble materials to enter hepatopancreatic ducts that conduct them into the shrimp hepatopancreas (HP), where further digestion and absorption of nutrients takes place. Although the GS function is well known, its exclusion limit for particulate material has not been clearly defined. Using histological and ultra-structure analysis, we show that the GS sieve pore diameter is approximately 0.2-0.7 micro m in size, indicating a size exclusion limit of substantially less than 1 micro m. Using fluorescent microbeads, we show that particles of 1 micro m diameter could not pass through the GS but that particles of 0.1 micro m diameter did pass through to accumulate in longitudinal grooves and move on to the HP, where some were internalized by tubule epithelial cells. We found no significant difference in these sizes between the species Penaeus monodon and Penaeus vannamei or between juveniles and adults in P. vannamei This information will be of value for the design of particulate feed ingredients such as nutrients, therapeutic drugs and toxin-absorbing materials that may selectively target the stomach, intestine or HP of cultivated shrimp.

Patterson, J., et al. (2019). "Profiling microplastics in the Indian edible oyster, Magallana bilineata collected from the Tuticorin coast, Gulf of Mannar, Southeastern India." Science of the Total Environment **691**: 727-735.

The objective of this study is to quantify the extent of microplastic (MP) contamination in the Indian edible oyster (Magallana bilineata) and to understand how this relates to the MP contamination in its surrounding marine environment. Samples of water, sediment and oysters of different sizes were collected from three sites along Tuticorin coast in Gulf of Mannar in Southeast India. The mean abundance of MP in oysters was found to be 6.9 ± 3.84 items/individual and the mean concentration to be 0.81 ± 0.45 items/g of tissue. Polyethylene (PE) and polypropylene (PP) fibers were the dominant MP types in oysters (92% and 4%, respectively) and in seawater (75% and 25%, respectively), with PE fibers, ranging from 0.25 to 0.5 mm, being the most common. Both PE and PP are low-density polymers which are slow to sediment to the seafloor. This increases the potential of their availability in the environment and ingestion by the oysters. The largest oysters (14–16 cm) contained the highest abundance and

concentrations of MP, suggesting a greater proportion of MP in the water column is ingested with increasing size. The calculated microplastic index (0.02 to 0.99) also indicates that MP bioavailability increases with increasing size of oysters. The distribution patterns of MP abundance, shape and size in oysters more closely resemble those in water than in sediment. The surface morphology of the MPs reveals the characteristic pits and cracks which result from partial degradation through the weathering processes. Energy-dispersive X-ray spectroscopy analysis shows the presence of Ni and Fe in association with MP, and this probably indicates the fly-ash pollution and the petroleum-related activities in the surrounding area. Being sessile animals the oysters are good candidates for use as sentinel organisms for monitoring MP in specific marine environments. Unlabelled Image • MP distributions in oysters closely reflected those in surrounding seawater. • Mean abundance of 6.9 MP/individual and concentration of 0.81MP/g detected (ww). • MP abundance and concentration increases with increasing size of oysters. • PE fibers ranging from 0.25 to 0.5 mm were the most common MP in oysters. • Sediments contained a broader range of MP than seawater or oysters. [ABSTRACT FROM AUTHOR]

Paul, A., et al. (2019). "High-throughput NIR spectroscopic (NIRS) detection of microplastics in soil." Environmental Science & Pollution Research **26**(8): 7364-7374.

The increasing pollution of terrestrial and aquatic ecosystems with plastic debris leads to the accumulation of microscopic plastic particles of still unknown amount. To monitor the degree of contamination, analytical methods are urgently needed, which help to quantify microplastics (MP). Currently, time-costly purified materials enriched on filters are investigated both by micro-infrared spectroscopy and/or micro-Raman. Although yielding precise results, these techniques are time consuming, and are restricted to the analysis of a small part of the sample in the order of few micrograms. To overcome these problems, we tested a macroscopic dimensioned near-infrared (NIR) process-spectroscopic method in combination with chemometrics. For calibration, artificial MP/ soil mixtures containing defined ratios of polyethylene, polyethylene terephthalate, polypropylene, and polystyrene with diameters < 125 mum were prepared and measured by a process FT-NIR spectrometer equipped with a fiber-optic reflection probe. The resulting spectra were processed by chemometric models including support vector machine regression (SVR), and partial least squares discriminant analysis (PLS-DA). Validation of models by MP mixtures, MP-free soils, and real-world samples, e.g., fermenter residue, suggests a reliable detection and a possible classification of MP at levels above 0.5 to 1.0 mass% depending on the polymer. The benefit of the combined NIRS chemometric approach lies in the rapid assessment whether soil contains MP, without any chemical pretreatment. The method can be used with larger sample volumes and even allows for an online prediction and thus meets the demand of a high-throughput method.

Paul-Pont, I., et al. (2016). "Exposure of marine mussels Mytilus spp. to polystyrene microplastics: toxicity and influence on fluoranthene bioaccumulation." Environmental Pollution **216**: 724-737.

The effects of polystyrene microbeads (micro-PS; mix of 2 and 6 micro m; final concentration: 32 micro g L⁻¹) alone or in combination with fluoranthene (30 micro g

L⁻¹) on marine mussels Mytilus spp. were investigated after 7 days of exposure and 7 days of depuration under controlled laboratory conditions. Overall, fluoranthene was mostly associated to algae Chaetoceros muelleri (partition coefficient Log Kp=4.8) used as a food source for mussels during the experiment. When micro-PS were added in the system, a fraction of FLU transferred from the algae to the microbeads as suggested by the higher partition coefficient of micro-PS (Log Kp=6.6), which confirmed a high affinity of fluoranthene for polystyrene microparticles. However, this did not lead to a modification of fluoranthene bioaccumulation in exposed individuals, suggesting that micro-PS had a minor role in transferring fluoranthene to mussels tissues in comparison with waterborne and foodborne exposures. After depuration, a higher fluoranthene concentration was detected in mussels exposed to micro-PS and fluoranthene, as compared to mussels exposed to fluoranthene alone. This may be related to direct effect of micro-PS on detoxification mechanisms, as suggested by a down regulation of a P-glycoprotein involved in pollutant excretion, but other factors such as an impairment of the filtration activity or presence of remaining beads in the gut cannot be excluded. Micro-PS alone led to an increase in hemocyte mortality and triggered substantial modulation of cellular oxidative balance: increase in reactive oxygen species production in hemocytes and enhancement of anti-oxidant and glutathione-related enzymes in mussel tissues. Highest histopathological damages and levels of anti-oxidant markers were observed in mussels exposed to micro-PS together with fluoranthene. Overall these results suggest that under the experimental conditions of our study micro-PS led to direct toxic effects at tissue, cellular and molecular levels, and modulated fluoranthene kinetics and toxicity in marine mussels.

Pauly, D., et al. (2009). "Simultaneous quantification of five bacterial and plant toxins from complex matrices using a multiplexed fluorescent magnetic suspension assay." Analyst **134**(10): 2028-2039.

Proteotoxins such as ricin, abrin, botulinum neurotoxins type A and B (BoNT/A, BoNT/B) and staphylococcal enterotoxin B (SEB) are regarded as potential biological warfare agents which could be used for bioterrorism attacks on the food chain. In this study we used a novel immunisation strategy to generate high-affinity monoclonal and polyclonal antibodies against native ricin, BoNT/A, and BoNT/B. The antibodies were used along with antibodies against SEB and abrin to establish a highly sensitive magnetic and fluorescent multiplex bead array with excellent sensitivities between 2 ng/L and 546 ng/L from a minimal sample volume of 50 micro L. The assay was validated using 20 different related analytes and the assay precision was determined. Advancing the existing bead array technology, the novel magnetic and fluorescent microbeads proved amenable to enrichment procedures, by further increasing sensitivity to 0.3-85 ng/L, starting from a sample volume of 500 micro L. Furthermore, the method was successfully applied for the simultaneous identification of the target toxins spiked into complex food matrices like milk, baby food and yoghurt. On the basis of our results, the assay appears to be a good tool for large-scale screening of samples from the food supply chain.

Pauna, V. H., et al. (2019). "The issue of microplastics in marine ecosystems: A bibliometric network analysis." Marine Pollution Bulletin **149 (no pagination)**(110612).

Human activities lead to several impacts on marine ecosystems, among which a massive input of plastic entering the marine environment. This scenario has the potential to threaten ecosystem health and integrity, also reducing the ability of marine ecosystems to provide good and services on which human well-being relies. In this study, the global scientific literature on marine microplastics was explored by combining social network analysis and bibliometrics. Network maps displayed the relationships among keywords, authors, countries, and journals dealing with the issue of microplastics in marine ecosystems. The citation analysis of journals showed that

"Marine Pollution Bulletin" resulted the first among the scientific journals publishing articles on this subject. The results also highlighted that most research on the subject is focused on toxicology and environmental chemistry, while ecological studies focusing on the impact of microplastics at ecosystem level are still limited. Pavlík, Z. P., et al. (2017). EXPERIMENTAL ANALYSIS OF LIGHT-WEIGHT CONCRETE INCORPORATING REGRANULATED WASTE POLYPROPYLENE. Sofia, Surveying Geology & Mining Ecology Management (SGEM). **17:** 155-162.

Concrete production has high adverse effect on the quality of environment, and its sustainability is open question for material researchers and producers. In addressing the environmental concerns of concrete manufacturing and problems relating to the disposal of wastes and industrial by-product and also economic advantages, application of secondary raw materials in composition of concrete mix is of the particular importance both from the environmental and financial point of view. A substantial growth in the consumption of plastics is observed all over the world in recent years, which has led to huge quantities of plastic-related waste. Recycling of plastic waste to produce new materials like concrete or mortar appears as one of the best solution for disposing of plastic waste, due to its economic and ecological advantages. In this paper, light-weight concrete incorporating high volume of waste polypropylene was developed and experimentally tested. Regranulated polypropylene, a by-product of polypropylene tubes production, partially substituted fine natural silica aggregate in 10, 20, 30, 40 and 50 mass %. First, characterization of waste plastic was done. Specific attention was paid to thermal properties of regranulated polypropylene that were examined in dependence on compaction time. For the developed light-weight concrete, basic physical, mechanical and hygric properties were accessed. Since the thermal properties were of the particular importance, they were measured using transient impulse technique in dependence on moisture content, from the dry state to fully water saturated state. The tested light-weight concrete was found to be prospective construction material having improved thermal insulation function and acceptable mechanical strength. From the environmental and financial point of view, the reuse of waste polypropylene in concrete composition was beneficial taking into account plastics low biodegradability and safe disposal.

Pawar, C. T. and M. V. Joshi (2003). "Solid waste and its environmental impact in Ichalikaranji City, Maharashtra." Nature, Environment and Pollution Technology **2**(2): 237-240.

In the present investigation an attempt is made to analyze the impact of the solid waste on the environment and health of the people of Ichalkaranji city through the method of Leopold Matrix. The sources of data used for this paper are the empirical facts collected by circulating questionnaire among residents residing near waste depots. The waste constituents are referred from environmental status report of Ichalkaranji (2001-2002) prepared by Textile and Engineering Institute, Ichalkaranji. The solid waste details were collected through Municipal Health Department, Ichalkaranji. The analysis reveals that the worst impact maker factor is the mutton market waste followed by plastic waste, cotton waste, vegetable remains and so on. The people are aware of the cleanliness, decency and aesthetics of the city. The presence of uncontrolled dogs, pigs and cows also add to the problems of the people. The biodegradable waste can be converted into manure and can become a source of revenue. Structural demolitions may become useful landfills in marshy low lying areas. With regular, prompt transportation of solid waste much impact can be controlled. Metal scrap, glass and plastics can be assorted and resold. To conduct awareness programmes and demonstrations on minimization of refuse generation at source and that on avoiding the use of plastic bags is necessary.

Payne, R. (2019). "The environmental impact of prescribing." Prescriber **30**(6): 4.

Pazienza, P. and C. De Lucia (2020). "For a new plastics economy in agriculture: Policy reflections on the EU strategy from a local perspective." Journal of Cleaner Production **253**.

Plastic production and consumption around the world have seen a rapid increase since the end of World War II, with an expected peak in the next 20 years. Agriculture is among the causes of this due to its intensive farming practices and the use of various plastic materials. This produces both advantages (e.g. yield increase, early harvest, reduced use of chemicals) and disadvantages. The disadvantages are particularly related to a plastic waste management problem, from which the contamination of terrestrial, marine and air environments with severe consequences on food security and human health also derive. With the 2018 European Strategy for Plastics in a Circular Economy, the European Commission (EC) identifies a set of actions to reduce plastic pollution in the decades ahead. For the actual implementation of this strategic vision, however, innovative investment and appropriate policy tools need to be identified. This paper attempts to understand the acceptability of some ad-hoc policy tools among farmers by investigating their attitudes towards the application of subsidies, tax-credits and pay-back (this latter under an Extended Producer Responsibility (EPR) scheme) to abate agricultural plastic pollution with the aim of making this sector cleaner and more oriented to the implementation of the sustainability principles. While referring to the territory of the province of Foggia in southern Italy as a case study, we analyse the preferences expressed by 1,783 farmers by using a multinomial logistic regression. Key results suggest that large agricultural farms would favour the adoption of tax-credits. In contrast, small farms would consider more favourable the introduction of a pay-back tool to incentivize their contribution to plastic pollution abatement. The significance of the obtained results is twofold. First, farm size is a key element towards a differentiation of policy tools to adopt for plastic waste management in agriculture. Second, the differentiation of the above policy tools according to the farm dimension would lead to a cost-effectiveness management of agricultural plastic waste. 2020 Elsevier Ltd

Pazos, R. S., et al. (2018). "Microplastics integrating the coastal planktonic community in the inner zone of the Rio de la Plata estuary (South America)." Environmental Pollution **Part A. 243**: 134-142.

This study explores in plankton samples the abundance, distribution, size, types (fibres and fragments), colours of the microplastics (MPs) and its relation with the characteristics of the plankton (size and morphology) of the Rio de la Plata estuary. Water samples were collected in triplicate in freshwater-mixohaline tidal zone of the estuary, in ten sampling sites located along 150 km of coast, in two periods (September-November 2016 and April-June 2017). The results revealed the presence of MPs in all the samples analysed, with a dominance of fibres and sizes >500 <= 1000 mum, and blue colour being more frequent. The MPs distribution was significantly different among sampling sites, being more abundant in the most urbanized sites, sewage discharges and near the maximum turbidity front. The mean density, in the two samplings analysed, were 164 and 114 MPs m⁻³. The fibres amount was significantly different among sites. The MPs integrated a planktonic community dominated by pico-microphytoplankton, mainly conformed by filaments/chains and solitary forms and by micro-mesozooplankton. The comparative analysis of plankton and MPs demonstrated that a fraction of the latter showed a frequency range of size that coincides with the most common sizes of plankton (<=500 mum). The mean percentage of MPs items in relation to zooplankton was 0.36% (sampling 1) and 1.20% (sampling 2) and for phytoplankton was 0.0002% (sampling

1) and 0.0005% (sampling 2). The correlations between the MPs concentration and habitat quality (IHRPlata index) were statistically significant, on the contrary correlations between the MPs concentration and measured environmental variables were not found. The findings of this study emphasises the need for a better treatment of urban waste, which would contribute to reducing the entry of this pollutant into the ecosystem. The presence of microplastics in plankton samples on the coast of the Rio de la Plata estuary. Copyright © 2018 Elsevier Ltd

Peda, C., et al. (2016). "Intestinal alterations in European sea bass Dicentrarchus labrax (Linnaeus, 1758) exposed to microplastics: preliminary results." Environmental Pollution **212**: 251-256.

This study investigates, for the first time, the intestinal responses of European sea bass Dicentrarchus labrax chronically exposed to microplastics through ingestion. Fish (n=162) were fed with 3 different treatment diets for 90 days: control, native polyvinyl chloride (PVC) and polluted polyvinyl chloride (PVC) pellets. Intestines were fixed and processed for histological analysis using standard techniques. Histopathological alterations were examined using a score value (from 0 to 4). The distal part of intestine in all samples proved to be the most affected by pathological alterations, showing a gradual change varying from moderate to severe related to exposure times. The histological picture that characterizes both groups especially after 90 days of exposure, suggests that the intestinal functions can be in some cases totally compromised. The worst condition is increasingly evident in the distal intestine of fish fed with polluted PVC pellets respect to control groups ($p<0.05$) to different exposure times. These first results underline the need to assess the impact of increasing microplastics pollution on the marine trophic web.

Pedrotti, M. L., et al. (2016). "Changes in the Floating Plastic Pollution of the Mediterranean Sea in Relation to the Distance to Land." PLoS ONE [Electronic Resource] **11**(8): e0161581.

The composition, size distribution, and abundance of floating plastic debris in surface waters of the Mediterranean Sea were analyzed in relation to distance to land. We combined data from previously published reports with an intensive sampling in inshore waters of the Northwestern Mediterranean. The highest plastic concentrations were found in regions distant from from land as well as in the first kilometer adjacent to the coastline. In this nearshore water strip, plastic concentrations were significantly correlated with the nearness to a coastal human population, with local areas close to large human settlements showing hundreds of thousands of plastic pieces per km2. The ratio of plastic to plankton abundance reached particularly high values for the coastal surface waters. Polyethylene, polypropylene and polyamides were the predominant plastic polymers at all distances from coast (86 to 97% of total items), although the diversity of polymers was higher in the 1-km coastal water strip due to a higher frequency of polystyrene or polyacrylic fibers. The plastic size distributions showed a gradual increase in abundance toward small sizes indicating an efficient removal of small plastics from the surface. Nevertheless, the relative abundance of small fragments (< 2 mm) was higher within the 1-km coastal water strip, suggesting a rapid fragmentation down along the shoreline, likely related with the washing ashore on the beaches. This study constitutes a first attempt to determine the impact of plastic debris in areas closest to Mediterranean coast. The presence of a high concentration of plastic including tiny plastic items could have significant environmental, health and economic impacts.

Peeken, I., et al. (2018). "Arctic sea ice is an important temporal sink and means of transport for microplastic." Nature communications **9**: 1-12.

Microplastics (MP) are recognized as a growing environmental hazard and have been identified as far as the remote Polar Regions, with particularly high concentrations of microplastics in sea ice. Little is known regarding the horizontal variability of MP within sea ice and how the underlying water body affects MP composition during sea ice growth. Here we show that sea ice MP has no uniform polymer composition and that, depending on the growth region and drift paths of the sea ice, unique MP patterns can be observed in different sea ice horizons. Thus even in remote regions such as the Arctic Ocean, certain MP indicate the presence of localized sources. Increasing exploitation of Arctic resources will likely lead to a higher MP load in the Arctic sea ice and will enhance the release of MP in the areas of strong seasonal sea ice melt and the outflow gateways.

Peeters, J. R., et al. (2015). "Forecasting waste compositions: A case study on plastic waste of electronic display housings." Waste Management **46**: 28-39.

Because of the rapid succession of technological developments, the architecture and material

composition of many products used in daily life have drastically changed over the last decades. As a result, well-adjusted recycling technologies need to be developed and installed to cope with these evolutions. This is essential to guarantee continued access to materials and to reduce the ecological impact of our material consumption. However, limited information is currently available on the material composition of arising waste streams and even less on how these waste streams will evolve. Therefore, this paper presents a methodology to forecast trends in the material composition of waste streams. To demonstrate the applicability and value of the proposed methodology, it is applied to forecast the evolution of plastic housing waste from flat panel display (FPD) TVs, FPD monitors, cathode ray tube (CRT) TVs and CRT monitors. The results of the presented forecasts indicate that a wide variety of plastic types and additives, such as flame retardants, are found in housings of similar products. The presented case study demonstrates that the proposed methodology allows the identification of trends in the evolution of the material composition of waste streams. In addition, it is demonstrated that the recycling sector will need to adapt its processes to deal with the increasing complexity of plastics of end-of-life electronic displays while respecting relevant directives.

Peez, N., et al. (2019). "Quantitative analysis of PET microplastics in environmental model samples using quantitative ¹H-NMR spectroscopy: validation of an optimized and consistent sample clean-up method." Analytical & Bioanalytical Chemistry **411**(28): 7409-7418.

Identification and quantification of microplastics (MP) in environmental samples is crucial for understanding the risk and distribution of MP in the environment. Currently, quantification of MP particles in environmental samples and the comparability of different matrices is a major research topic. Research also focusses on sample preparation, since environmental samples must be free of inorganic and organic matrix components for the MP analysis. Therefore, we would like to propose a new method that allows the comparison of the results of MP analysis from different environmental matrices and gives a MP concentration in mass of MP particles per gram of environmental sample. This is possible by developing and validating an optimized and consistent sample preparation scheme for quantitative analysis of MP particles in environmental model samples in conjunction with quantitative ¹H-NMR spectroscopy (qNMR). We evaluated for the first time the effects of different environmental matrices on identification and quantification of polyethylene terephthalate (PET) fibers using the qNMR method. Furthermore, high recovery rates were obtained from spiked environmental model samples (without matrix ~ 90%, sediment ~ 97%, freshwater ~ 94%, aquatic biofilm ~ 95%, and invertebrate matrix ~ 72%), demonstrating the high analytical potential of the method. Graphical abstract.

Peh, G. S., et al. (2012). "Optimization of human corneal endothelial cells for culture: the removal of corneal stromal fibroblast contamination using magnetic cell separation." International Journal of Biomaterials Print **2012**: 601302.

The culture of human corneal endothelial cells (CECs) is critical for the development of suitable graft alternative on biodegradable material, specifically for endothelial keratoplasty, which can potentially alleviate the global shortage of transplant-grade donor corneas available. However, the propagation of slow proliferative CECs in vitro can be hindered by rapid growing stromal corneal fibroblasts (CSFs) that may be coisolated in some cases. The purpose of this study was to evaluate a strategy using magnetic cell separation (MACS) technique to deplete the contaminating CSFs from CEC cultures using antifibroblast magnetic microbeads. Separated "labeled" and "flow-through" cell fractions were collected separately, cultured, and morphologically assessed. Cells from the "flow-through" fraction displayed compact polygonal morphology and expressed Na(+)/K(+)ATPase indicative of corneal endothelial cells, whilst cells from the "labeled" fraction were mostly elongated and fibroblastic. A separation efficacy of 96.88% was observed. Hence, MACS technique can be useful in the depletion of contaminating CSFs from within a culture of CECs.

Peiponen, K. E., et al. (2019). "Outlook on optical identification of micro- and nanoplastics in aquatic environments." Chemosphere **214**: 424-429.

Plastic pollution in natural water bodies is an emerging problem that requires quick actions. Recently, the role of micro- and nanoplastics in pollution and health issues has been realized and taken seriously. In this paper, we have studied optical properties, such as NIR spectra and refractive index, of some common plastic materials and present a method and data to screen especially problematic transparent plastics with rough surface in aquatic environments. We also give an outlook of possible optical measurement methods that could be used for detection of micro- and nanoplastics.

Peisino, L. E., et al. (2019). "Metal leaching analysis from a core-shell WEEE plastic synthetic aggregate." Sustainable Chemistry and Pharmacy **12 (no pagination)**(100134).

Plastic wastes from electrical and electronic equipment (WEEEP) contain an important amount of metals and brominated flame retardants. These contaminants are hazardous for human and environment, therefore the WEEE are considered dangerous wastes by the law. In order to revalue this waste, we developed a cement based stabilization strategy for these contaminants. The WEEEP was covered with a mixture of cement and a very fine aggregate. This strategy takes a core-shell concept to obtain a synthetic aggregate with potential use in the construction industry. To evaluate the concentration of metals in the waste, extractions with hot water followed by acid digestion were carried out in samples of WEEEP, and then we compared these values with the leached of metals from the synthetic aggregate. The quantification was made by atomic absorption technique. The most of the studied metals did not leached in hot water, except for the antimony, which leached in hot water from WEEEP but showed an important decrease in its concentration in the leached of the synthetic arid. Peixoto, D., et al. (2019). "Uptake and effects of different concentrations of spherical polymer microparticles on Artemia franciscana." Ecotoxicology and Environmental Safety **176**: 211-218.

Artemia cysts have a huge economic importance for the aquaculture sector due to the fact that they are used as live feed for larviculture. Microplastics (MPs) are common and emergent pollutants in the aquatic environments, with unknown and potential long-term effects on planktonic species such as Artemia spp. When used as live feed, Artemia could transfer contaminants to fish along the food chain, with possible adverse effects on human health through their consumption. This study aims to assess the uptake of different concentrations of spherical polymer microparticles (FRM) (1-5 micro m diameter) and their associated chronic effects on feeding, growth, mortality, and reproductive success from juvenile to adult stage of brine shrimp Artemia franciscana. Individuals were exposed for 44 days to 0.4, 0.8 and 1.6 mg.L⁻¹ of FRM. No significant detrimental effects on growth, ingestion and mortality rates of A. franciscana were observed in all tested conditions. However, reproductive success was strongly affected by the increase of MP concentrations. The results of the present study showed that A. franciscana juveniles and adults were able to survive different experimental MP concentrations, but their reproductive success and progeny were significantly impacted by exposure to FRM particles.

Peixoto, D., et al. (2019). "Microplastic pollution in commercial salt for human consumption: A review."

Estuarine, Coastal and Shelf Science **219**: 161-168.

Microplastics (MPs) are plastic particles with less than 5 mm in size that are considered global environmental pollutants. The MPs present in the environment result from the successive breakdown of larger plastic pieces or from the direct input of micro- and nano-sized particles used in various industries and products available to consumers. Such MPs have been found in several wild species and other natural resources, including some consumed as food by humans, with possible adverse effects on ecosystem and human health. The central aim of this work was to review the published literature regarding the contamination of sea commercial salts (sea and terrestrial origins) and its possible impacts on human health. Moreover, to lead to a comprehensive understanding of the paradigm, a short introduction and revision of the environmental contamination by MPs and its effects are included. MPs have been found in commercial salts from 128 brands, from 38 different countries spanning over five continents. The concentration of MPs found in the samples analysed is lower than the concentrations of MPs reported in other resources, such as blue mussels. However, as commercial salts are used every day and by all humans, they constitute a long-term exposure route for the general population in addition to others (e.g., animals consumed as food by humans, water, air). Therefore, commercial salts contaminated with MPs may contribute to the potential long-term adverse effects resulting from human exposure to these particles. © 2019

Peller, J. R., et al. (2019). "Tracking the distribution of microfiber pollution in a southern Lake Michigan watershed through the analysis of water, sediment and air." Environmental Science. Processes & Impacts **21**(9): 1549-1559.

Microplastic waste is a worldwide problem, heavily afflicting marine and freshwater environments; the loading of this pollution in water, sediment and living organisms continues to escalate. Synthetic microfibers, resulting from the release of microscopic fibers from synthetic textiles, constitute the most prevalent type of microplastics pollution in aquatic environments. This study investigated the origin and distribution of synthetic microfibers in a representative Lake Michigan watershed in Indiana (USA) by analyzing water, sediment and air samples above and below wastewater treatment plant discharges, downstream in the watershed and water from the Lake Michigan shoreline. Synthetic microfibers were also quantified in wastewater from a local wastewater treatment plant (WWTP) and in laundry effluent. Laboratory testing of numerous fabrics suggests that Fenton oxidation, used to break down natural fibers, effectively eliminates non-polluting, natural fibers from the samples. However, the hydroxyl radical-mediated oxidation bleaches the dye from certain synthetic microfibers, which likely leads to under-reported values for these microplastics in natural samples. The data collected from the watershed samples indicate that approximately 4 billion synthetic microfibers are transported daily through the Lake Michigan tributary. Wastewater effluent is not the only source of synthetic microfibers, since surface water samples above the WWTP contained a similar load to downstream samples. Repeated sampling exhibited variability in the number of microfibers detected, substantiating the heterogeneous distribution of these pollutants and the requirement for multiple samples for a given site. The average load of synthetic microfibers from water sampled at the Lake Michigan shoreline was higher than the tributary water, suggesting the shoreline functions as a repository for the microfibers. Given the extent and potential consequences of this pollution, quantification of the ubiquitous plastic fibers can be instituted as part of the traditional total suspended solids (TSS) water quality monitoring parameter.

Pellini, G., et al. (2018). "Characterization of microplastic litter in the gastrointestinal tract of Solea solea

from the Adriatic Sea." Environmental Pollution **234**: 943-952.

Micro-plastic particles in the world's oceans represent a serious threat to both human health and marine ecosystems. Once released into the aquatic environment plastic litter is broken down to smaller pieces through photo-degradation and the physical actions of waves, wind, etc. The resulting particles may become so small that they are readily taken up by fish, crustaceans and mollusks. There is mounting evidence for the uptake of plastic particles by marine organisms that form part of the human food chain and this is driving urgent calls for further and deeper investigations into this pollution issue. The present study aimed at investigating for the first time the occurrence, amount, typology of microplastic litter in the gastrointestinal tract of Solea solea and its spatial distribution in the northern and central Adriatic Sea. This benthic flatfish was selected as it is a species of high commercial interest within the FAO GFCM (General Fisheries Commission for the Mediterranean) area 37 (Mediterranean and Black Sea) where around 15% of the overall global Solea solea production originates. The digestive tract contents of 533 individuals collected in fall during 2014 and 2015 from 60 sampling sites were examined for microplastics. These were recorded in 95% of sampled fish, with more than one microplastic item found in around 80% of the examined specimens. The most commonly found polymers were polyvinyl chloride, polypropylene, polyethylene, polyester, and polyamide, 72% as fragments and 28% as fibers. The mean number of ingested microplastics was 1.73 ± 0.05 items per fish in 2014 and 1.64 ± 0.1 in 2015. PVC and PA showed the highest densities in the northern Adriatic Sea, both inshore and off-shore while PE, PP and PET were more concentrated in coastal areas with the highest values offshore from the port of Rimini. [ABSTRACT FROM AUTHOR]

Pellis, A., et al. (2019). "Enzymatic synthesis of lignin derivable pyridine based polyesters for the substitution of petroleum derived plastics." Nature communications **10**(1): 1762.

Following concerns over increasing global plastic pollution, interest in the production and characterization of bio-based and biodegradable alternatives is rising. In the present work, the synthesis of a series of fully bio-based alternatives based on 2,4-, 2,5-, and 2,6-pyridinedicarboxylic acid-derived polymers produced via enzymatic catalysis are reported. A similar series of aromatic-aliphatic polyesters based on diethyl-2,5-furandicarboxylate and of the petroleum-based diethyl terephthalate and diethyl isophthalate were also synthesized. Here we show that the enzymatic synthesis starting from 2,4-diethyl pyridinedicarboxylate leads to the best polymers in terms of molecular weights (M_n = 14.3 and M_w of 32.1 kDa when combined with 1,8-octanediol) when polymerized in diphenyl ether. Polymerization in solventless conditions were also successful leading to the synthesis of bio-based oligoesters that can be further functionalized. DSC analysis show a clear similarity in the thermal behavior between 2,4-diethyl pyridinedicarboxylate and diethyl isophthalate (amorphous polymers) and between 2,5-diethyl pyridinedicarboxylate and diethyl terephthalate (crystalline polymers).

Peltomaa, R., et al. (2016). "Species-specific optical genosensors for the detection of mycotoxigenic Fusarium fungi in food samples." Analytica Chimica Acta **935**: 231-238.

Plant-pathogenic Fusarium species, Fusarium verticillioides and Fusarium proliferatum, are the major producers of fumonisins which are one of the most common mycotoxins found in maize. Herein, we report the development of specific and sensitive genosensors for detecting these two closely related Fusarium species in food samples. The sensors are based on species-specific capture and detection probes, which bind to the intergenic spacer region of rDNA (IGS). Oligonucleotide functionalized magnetic microbeads are used to capture the target DNA which is then detected using biotinylated detection probes and a streptavidin-coupled label. The developed genosensors had detection limits of 1.8 pM and 3.0 pM for F. proliferatum and F. verticillioides, respectively, using synthetic DNA targets. Furthermore, the biosensors were used to analyze natural fungal contamination of commercial maize samples. After amplification of the genomic DNA the sensors detected the presence of the fungi, in accordance with previous results obtained with PCR. No cross-reactivity between F. verticillioides and F. proliferatum, or other fungi species tested, was observed. The developed biosensors can provide a valuable tool to evaluate the potential for mycotoxin contamination in conditions where detection of mycotoxins directly is challenging.

Pelucchi, S., et al. (2011). "Genetic modifiers in HFE-hemochromatosis: Analysis of 355 TAG SNPs in an Italian population of C282Y homozygotes." American Journal of Hematology **86 (9)**: E45-E46.

Hemochromatosis (HH) may lead to tissue iron accumulation and iron-related complications. Penetrance and expression of HH largely differs among C282Y homozygotes and genetic components affecting the development of clinical manifestations are largely unknown. The main objectives of this study is to identify potential modifiers of iron accumulation in HFE-HH. We analysed 420 subjects including 308 unrelated C282Y homozygotes and 110 healthy controls selected from Units' databases and DNA banks. Serum ferritin (SF) levels, total iron removed (IR) and % of transferrin saturation (TS), as markers of HH expression, were normalized using a log transformation before testing for association. A linear regression model was implemented to evaluate the effect on these three phenotypes of covariates as age, sex and alcohol consumption. Age, sex and gender covariates were all significantly associated with SF and IR ($p<0.001$). SNPs were tested for genetic association by using a linear regression model adjusted for age, sex and alcohol consumption. For each phenotype we assumed an additive genetic model. The false discovery rate (FDR) method of Benjamini and Hochberg (J R Stat Soc B 1995) was applied to the minP test results to account for multiple comparisons. We considered FDR <0.1 as being noteworthy. The genetic analyses were performed using R (R Foundation for Statistical Computing, Vienna, Austria) and the library GenABEL (genome-wide SNP association analysis. R package version 1.6-4). Overall we selected 355 tagSNPs of whom 211 are located in 53 candidate genes and 144 in two regions of chromosome 19q (34.5-46Mb and 51-56.5Mb) previously identified as candidate region of variability in HFE-ko animal model (Bensaid M et al, 2004). SNPs were typed using the GoldenGate Assay on VeraCode microbeads supported by the BeadXpress Reader platform. After imposing the quality control measures, 22 subjects and 14 markers were excluded from the analysis. None of the remaining SNPs deviated from Hardy-Weinberg Equilibrium. 341 markers and 398 subjects (296 patients and 102 controls) were finally considered. SF associated ($p<0.05$) with several SNPs (rs12467409, rs13541, rs2662255, rs9325886 and rs17804636) belonging to candidate genes (BMPR2, RGMB, GDF2 and SMAD9) and with 7 SNPs located on chromosome 19q. IR associated with rs11684885, rs12467409, rs4678013, rs1800702, rs2794719, rs3780474, rs11204215, rs149411, rs762642, rs918587 belonging to candidate genes (EPAS1, BMPR2, CASR, HFE, ACO1, GDF2, SLC11A2, BMP4, CCN1) and with 6 SNPs located on chromosome 19q. Considering that HAMP is located on chromosome 19q we constructed an haplotype including 3 SNPs of HAMP (rs8101606, rs7251432 and rs12971321) and two SNPs in UBA2 and SARS2 genes (rs1559196 and

rs10412886) significantly associated with phenotype expression located at 5' and 3' from HAMP, respectively. The haplotype GAAGA was slightly associated with SF (frequency 0.055, p=0.033) and IR (frequency 0.56, p=0.049), haplotype AAGCA was more markedly associated with IR (frequency 0.12, p=0.0015), and haplotype GAAGG with TS (frequency 0.11, p=0.016). Besides age, gender and alcohol intake, phenotype expression in HFE-HH might be influenced by SNPs variation in genes involved in iron metabolisms. The observed association between phenotype variability and chromosome 19q regions needs to be further explored to understand whether it is related to HAMP locus or to other unknown modifier(s).

Penalver, R., et al. (2020). "An overview of microplastics characterization by thermal analysis." Chemosphere **242**: 125170.

Microplastics may be present in the environment as primary microplastics (manufactured) or secondary microplastics (result of the continuous degradation of larger plastic pieces into smaller fragments due to environmental, physicochemical and biotic factors). To fully understand the dynamics of microplastic particles and their environmental effects, harmonized, automated, cheap, rapid and reliable methodologies for sampling, extraction and characterization of microplastic need to be developed. This review focuses on the potential of thermal analytical techniques for microplastics characterization and highlights some of the new trends in this area.

Peng, B.-Y., et al. (2019). "Biodegradation of Polystyrene by Dark (Tenebrio obscurus) and Yellow (Tenebrio molitor) Mealworms (Coleoptera: Tenebrionidae)." Environmental Science & Technology **53**(9): 5256.

Yellow mealworms (larvae of Tenebrio molitor, Coleoptera: Tenebrionidae) have been proven to be capable of biodegrading polystyrene (PS) products. Using four geographic sources, we found that dark mealworms (larvae of Tenebrio obscurus) ate PS as well. We subsequently tested T. obscurus from Shandong, China for PS degradation capability. Our results demonstrated the ability for PS degradation within the gut of T. obscurus at greater rates than T. molitor. With expanded PS foam as the sole diet, the specific PS consumption rates for T. obscurus and T. molitor at similar sizes (2.0 cm, 62–64 mg per larva) were 32.44 ± 0.51 and 24.30 ± 1.34 mg 100 larvae–1 d–1, respectively. After 31 days, the molecular weight (Mn) of residual PS in frass (excrement) of T. obscurus decreased by 26.03%, remarkably higher than that of T. molitor (11.67%). Fourier transform infrared spectroscopy (FTIR) indicated formation of functional groups of intermediates and chemical modification. Thermo gravimetric analysis (TGA) suggested that T. obscurus larvae degraded PS effectively based on the proportion of PS residue. Co-fed corn flour to T. obscurus and wheat bran to T. molitor increased total PS consumption by 11.6% and 15.2%, respectively. Antibiotic gentamicin almost completely inhibited PS depolymerization. High-throughput sequencing revealed significant shifts in the gut microbial community in both Tenebrio species that were associated with the PS diet and PS biodegradation, with changes in three predominant families (Enterobacteriaceae, Spiroplasmataceae, and Enterococcaceae). The results indicate that PS biodegradability may be ubiquitous within the Tenebrio genus which could provide a bioresource for plastic waste biodegradation.

Peng, G., et al. (2020). "The ocean's ultimate trashcan: Hadal trenches as major depositories for plastic pollution." Water Research **168**: 115121.

Plastic debris and marine microplastics are being discharged into the ocean at an alarming scale and have been observed throughout the marine environment. Here we report microplastic in sediments of the Challenger Deep, the deepest known region on the planet, abyssal plains and hadal trenches located in the Pacific Ocean (4900 m-10,890 m). Microplastic abundance reached 71.1 items per kg dry weight sediment. That high concentrations are found at such remote depths, knowing the very slow sinking speed of microplastics, suggests that supporting mechanisms must be at-play. We discuss cascading processes that transport microplastics on their journey from land and oceanic gyres through intermediate waters to the deepest corners of the ocean. We propose that hadal trenches will be the ultimate sink for a significant proportion of the microplastics disposed in the ocean. The build-up of microplastics in hadal trenches could have large consequences for fragile deep-sea ecosystems.

Peng, G., et al. (2018). "Microplastics in freshwater river sediments in Shanghai, China: A case study of risk assessment in mega-cities." Environmental Pollution **234**: 448-456.

Microplastics, which are plastic debris with a particle diameter of less than 5 mm, have attracted growing attention in recent years. Its widespread distributions in a variety of habitats have urged scientists to understand deeper regarding their potential impact on the marine living resources. Most studies on microplastics hitherto are focused on the marine environment, and research on risk assessment methodology is still limited. To understand the distribution of microplastics in urban rivers, this study investigated river sediments in Shanghai, the largest urban area in China. Seven sites were sampled to ensure maximum coverage of the city's central districts, and a tidal flat was also included to compare with river samples. Density separation, microscopic inspection and mu-FT-IR analysis were conducted to analyze the characteristics of microplastics and the type of polymers. The average abundance of microplastics in six river sediment samples was 802 items per kilogram of dry weight. The abundance in rivers was one to two orders of magnitude higher than in the tidal flat. White microplastic spheres were most commonly distributed in river sediments. Seven types of microplastics were identified, of which polypropylene was the most prevailing polymers presented. The study then conducted risk assessment of microplastics in sediments based on the observed results, and proposed a framework of environmental risk assessment. After reviewing waste disposal related legislation and regulations in China, this study conclude that in situ data and legitimate estimations should be incorporated as part of the practice when developing environmental policies aiming to tackle microplastic pollution. Microplastic abundance in rivers was one to two orders of magnitude higher than in the tidal flat, and a framework of risk assessment was proposed. Copyright © 2017

Peng, G., et al. (2017). "Microplastics in sediments of the Changjiang Estuary, China." Environmental Pollution **225**: 283-290.

Microplastics are plastics that measure less than 5 mm in diameter. They enter the marine environment as primary sources directly from industrial uses, as well as secondary sources resulting from the degradation of large plastic debris. To improve the knowledge of microplastic pollution in China, we investigated samples from 53 estuarine sediment locations collected with a box corer within the Changjiang Estuary. Microplastics (<5 mm) were extracted from sediments by density separation, after which they were observed under a microscope and categorized according to shape, color and size. Identification was carried out using Micro-Fourier-Transform Infrared Spectroscopy (mu-FT-IR). The abundance of microplastics in the Changjiang Estuary was mapped. The mean concentration was 121 +/- 9 items per kg of dry weight, varying from 20 to 340 items per kg of dry weight. It was found that the concentration of microplastics was the highest on the southeast coast of Shanghai. The distribution pattern of microplastics may be affected by the Changjiang diluted water in summer. All of the microplastics collected were categorized according to shape, color and size. Among which fiber (93%), transparent (42%) and small microplastics (<1 mm) (58%) were the most abundant types. No clear correlation between microplastics and the finer sediment fraction was found. Rayon, polyester, and acrylic were the most abundant types of microplastics identified, indicating that the main source of microplastics in the Changjiang Estuary was from washing clothes (the primary source). It is possible to compare microplastic abundance in this study with the results of other related studies using the same quantification method. The identification of microplastics raises the awareness of microplastic pollution from drainage systems. The prevalence of microplastic pollution calls for monitoring microplastics at a national scale on a regular basis.

Peng, J., et al. (2017). "Current understanding of microplastics in the environment: Occurrence, fate, risks, and what we should do." Integrated Environmental Assessment & Management **13**(3): 476-482.

Microplastics pollution has been documented in the global environment, including at sea, in freshwater and in atmospheric fallout. Ingestion of microplastics by multiple kinds of organisms has been reported and has received increasing attention, because microplastics not only act as a source of toxic chemicals but also a sink for toxic chemicals. To better understand the great concerns about microplastics and associated toxic chemicals potential exposed to the organisms ingesting the debris, we should know more about the occurrence, fate, and risks of microplastics in the environment. What we should do depends on this better understanding. Integr Environ Assess Manag 2017;13:476-482. © 2017 SETAC.

Peng, L., et al. (2020). "Micro- and nano-plastics in marine environment: Source, distribution and threats - A review." Science of the Total Environment **698**: 134254.

Plastic litters have become the predominant components of marine debris due to extensive consumption plastics and mismanagement of plastic wastes. As part of the problem, microplastics (MPs) and nanoplastics (NPs) have generated special concerns due to their unique features that make them easy to transfer among oceans in the marine ecosystem, across different trophic levels inside the food web, and even across different tissues inside contaminated animals. Studies have demonstrated the almost omnipresence of MPs in the marine ecosystem, which present serious threats to the health of marine animals, causing symptoms such as malnutrition, inflammation, chemical poisoning, growth thwarting, decrease of fecundity, and death due to damages at individual, organ, tissue, cell, and molecule levels. The information on NPs in the marine ecosystem has been scarce due to the challenges in sampling and detecting these nano-scaled entities. In vitro and in vivo experiments have demonstrated that NPs have the potential to penetrate different biological barriers including the gastrointestinal barrier and the brain blood barrier and have been detected in many important organs such as brains, the circulation system and livers of sampled animals.

Peng, W., et al. (2014). "Surface evaluation and evolution during hydrodynamic effect polishing for quartz glass." Applied Optics **53**(29): 6913-6919.

Hydrodynamic effect polishing (HEP), a noncontact machining process, can realize the processed surface roughness as small as atomic level. To investigate the subsurface structure, the HEP processed quartz glass surface was etched by the hydrofluoric acid solution. It has been proved that HEP is a polishing method with the ability to process the surface with atomic-level flatness and damage-free surface/subsurface. It has been found that the microplastic scratches on the lap prepolished glass were obviously exposed when the thin redeposition layer was removed. Then the scratches were gradually removed and surface roughness decreased quickly as the removal depth increased. The surface becomes very smooth and the surface roughness maintains at an atomic level when the subsurface damage is removed clearly. The experimental results demonstrated that the defects such as the scratches parallel to the rotational axis of the wheel were firstly removed during the polishing process, and then the defects vertical to the wheel rotational axis were removed.

Pentecost, A., et al. (2010). "Deaggregation of nanodiamond powders using salt- and sugar-assisted milling." Acs Applied Materials & Interfaces **2**(11): 3289-3294.
Diamond particles of 5-10 nm in size can be produced in large quantities by denonating oxygen-lean explosives in a closed chamber. They have numerous useful properties and are used in applications ranging from lubricants to drug delivery. Aggregation of diamond nanoparticles is limiting wider use of this important carbon nanomaterial because most applications require single separated particles. We demonstrate that dry media assisted attrition milling is a simple, inexpensive, and efficient alternative to the current ways of deaggregating of nanodiamond. This technique uses water-soluble nontoxic and noncontaminating crystalline compounds, such as sodium chloride or sucrose. When milling is complete, the media can be easily removed from the product by water rinsing, which provides an advantage when compared to milling with ceramic microbeads. Using the dry media assisted milling with subsequent pH adjustment, it is possible to produce stable aqueous nanodiamond colloidal solutions with particles <10 nm in diameter, which corresponds to 1-2 primary nanodiamond particles. The study of milling kinetics and the characterization of the produced nanodiamond colloids led us to conclude that aggregates of less than 200 nm in diameter, observed at the tail of the pore size distribution of milled nanodiamond, are loosely bonded and rather dynamic in nature. Color change observed in ND colloids upon shifting their pH toward the basic end allowed us to demonstrate that the coloration comes from the light interaction with colloidal particles and not from an increase in nondiamond carbon content.

Percopo, C. M., et al. (2010). "Isolation of human eosinophils: microbead method has no impact on IL-5 sustained viability." Experimental Dermatology **19**(5): 467-469.
BACKGROUND/PURPOSE: In a recent issue of Experimental Dermatology (18, 2009, 654), Schefzyk et al. concluded that multi-antibody eosinophil isolation (Miltenyi) should be abandoned, as differential purity was minimal, and eosinophils underwent accelerated apoptosis when compared with those isolated with traditional anti-CD16 microbeads. Our intent was to investigate the universality of these findings.
METHODS: We isolated eosinophils from normal donor granulocyte packs using two methods, and evaluated purity, viability and annexin-V/propidium-iodide staining.
RESULTS: Purity was substantially greater when multi-antibody isolation was used for eosinophil isolation from granulocyte packs (98% vs 69%). No differential survival was detected when eosinophils were maintained in culture with or without interleukin-5.
CONCLUSIONS: Multi-antibody eosinophil isolation represents a substantial advantage over anti-CD-16 microbeads when isolating large numbers of eosinophils from concentrated leucocyte preparations. No differential survival was observed. While appropriate consideration of methods is always crucial, multi-antibody eosinophil isolation should not be abandoned completely.

Pereira, F. M., et al. (2016). "Hybrid Microfluidic Platform for Multifactorial Analysis Based on Electrical Impedance, Refractometry, Optical Absorption and Fluorescence." Micromachines **7**(10): 07.
This paper describes the development of a novel microfluidic platform for multifactorial analysis

integrating four label-free detection methods: electrical impedance, refractometry, optical absorption and fluorescence. We present the rationale for the design and the details of the microfabrication of this multifactorial hybrid microfluidic chip. The structure of the platform consists of a three-dimensionally patterned polydimethylsiloxane top part attached to a bottom SU-8 epoxy-based negative photoresist part, where microelectrodes and optical fibers are incorporated to enable impedance and optical analysis. As a proof of concept, the chip functions have been tested and explored, enabling a diversity of applications: (i) impedance-based identification of the size of micro beads, as well as counting and distinguishing of erythrocytes by their volume or membrane properties; (ii) simultaneous determination of the refractive index and optical absorption properties of solutions; and (iii) fluorescence-based bead counting.

Perez, A. A., et al. (2012). "Foaming characteristics of beta -lactoglobulin as affected by enzymatic hydrolysis and polysaccharide addition: relationships with the bulk and interfacial properties." Journal of Food Engineering **113**(1): 53-60.

The objective of this work was to study the effect of enzymatic hydrolysis and polysaccharide addition on the foaming characteristics of beta -lactoglobulin (beta -LG). Enzymatic treatment was performed in the hydrolysis degree (HD) range of 0.0-5.0% using bovine alpha -chymotrypsin II immobilized on agarose microbeads. Anionic non-surface active polysaccharides (PS), sodium alginate (SA) and lambda -carrageenan (lambda -C) were studied in the concentration range of 0.0-0.5 wt.%. Foaming characteristics were determined by conductimetric and optical methods and were linked to protein diffusion kinetics, film mechanical properties and biopolymer molecular dynamics in solution. Experiments were performed at constant temperature (20 degrees C), pH 7 and ionic strength 0.05 M. Limited hydrolysis improved the formation and stability of beta -LG foam possibly due to an increased protein diffusion rate and film dilatational elasticity. Furthermore, PS addition caused different effects on beta -LG foaming characteristics depending on the PS type, their relative concentration and extent of enzymatic treatment (HD). Diffusion rate and interfacial rheological behavior of mixed systems could exert a decisive role in foaming characteristics of beta -LG and its hydrolysates in close connection with biopolymer interactions in solution, e.g., macromolecule repulsion, protein segregation/aggregation and soluble complexes formation.

Perez-Martinez, A. (2019). Transfusion Clinique et Biologique **26 (3 Supplement)**: S25-S26.

Background: NKG2D is a C-type lectin-like transmembrane activating receptor present on the surface of natural killer (NK) cells, NKT cells, CD8 + gammadelta T cells and certain subsets of CD4 + T cells. In humans, there are two families of NKG2D ligands (NKG2DL): the MHC class I chain-related protein A (MICA) and B (MICB) family, and the UL16-binding proteins (ULBPs) family, also known as retinoic acid early transcript 1 (RAET1) proteins, which comprises six members (ULBP1 - 6). NKG2DL biogenesis is stimulated in cells under stress conditions as viral infection, cellular senescence and tumorigenesis. However, NKG2DL expression on healthy and unstressed cells has also been reported as dendritic cells, activated T cells, normal myelomonocytic cells and epithelial cells of gastric mucosa. NKG2DL are expressed on various tumor types including different pediatric solid and hematological malignancies, providing suitable targets for cancer therapy. Ligand engagement of human NKG2D triggers the phosphorylation of the signaling adaptor protein DNAX-activating protein of 10 kDa (DAP10) and the recruitment of either phosphatidylinositol-3-kinase (PI3 K) or a Grb2-Vav1 complex, both of which are required for full activation. NKG2D activation on NK cells results in cytokine secretion (including IFN-gamma, GM-CSF and MIP-1b) and exocytosis of cytotoxic granules. NKG2D expression can be modulated by different regulatory mechanisms. For instance, IL-4 and

TGF-beta decrease NKG2D surface expression and, thereby, NKG2D-mediated cytotoxic function. However, several cytokines as IL-2, IL-7 and IL-15 induce NKG2D expression. The activating receptor NKG2D is particularly relevant for cancer immunosurveillance. For instance, interaction between NKG2DL and NKG2D receptor is essential for NK-cell elimination of osteosarcoma tumor-initiating cells. However, tumor cells may develop immune scape strategies like ligand release (NKG2DLs) mediated by distinct matrix metalloproteinases, which reduces NKG2DL expression and may cause NKG2D receptor downregulation, thus limiting their clinical efficacy. In addition, chronic exposure of NKG2D receptor with membrane-bound ligand reduces NKG2D-mediated cytotoxic activity upon a trogocytosis process which produce induced-self recognition named fratricide. The use of NKG2D-CAR on memory (45RA-) T cells may overcome these limitations. In our experience, we have observed preclinical evidence of the efficacy of a NKG2D-CAR expressed on memory (45RA-) T cell based therapy as treatment for different pediatric cancers. In addition, we have developed a protocol to expand clinical grade NKG2D-CAR on memory (45RA-) T cells in a fully automated closed system, CliniMACS Prodigy. Finally, we report the safety of NKG2D-CAR on memory (45RA-) T cells infusions in two pediatric patients suffering from refractory acute leukemia. Patients and Methods: CD45RA+ cells were depleted from non-mobilized apheresis by using CD45RA microbeads and CliniMACS device. NKG2D-CAR T cells were obtained by lentiviral (NKG2D-41BB-CD3z) transduction of CD45RA-T cells (MOI = 2). The expression of NKG2DL was analyzed in primary samples of osteosarcoma (22 patients), as well as in the peripheral blood or bone marrow samples from 97 leukemia patients (AML = 13, B-ALL = 52 and T-ALL = 19), at different status of the disease (Diagnosis, Remission, Relapse/refractory). Three osteosarcoma and ten leukemia cell lines were also analyzed for NKG2DL expression by flow cytometry (FCM). Cytotoxicity of NKG2D-CAR on memory (45RA-) T cells against pediatric cancer cells was evaluated in vitro by performing 4-hours Europium-TDA assays. For the in vivo orthotopic model, 531MII YFP-luc human osteosarcoma cells were used as targets in NOD-scid IL2Rgnull mice. The effect of sNKG2DL on NKG2D-CAR T cells was explored by culturing with different concentrations of sNKG2DL for 7 days. Cell proliferation and CAR downregulation were measured by FCM. The production of IFN-gamma and TNF-alpha was measured in the supernatants by ELISA. The effect on cytotoxicity was evaluated in a 2 hours-degranulation assay by co-culturing sNKG2DL pretreated NKG2D-CAR T cells against K562 cell line. An automated manufacturing protocol to obtain clinical-grade NKG2D-CAR memory (45RA-) T cells were developed using CliniMACS Prodigy instrument. NKG2D-CAR memory (45RA-) T cells were infused into two patients. Patient #1 suffered from r/r biphenotypic ALL. She received two cycles of NKG2D CAR memory T cells infusions. In the first cycle, a total of 3 x 107 cells/kg were infused into three doses with no conditioning. In the second cycle, a total of 4 x 107 cells/kg were administered into two doses after lymphodepleting conditioning with Cy/Flu and low dose bortezomib. Patient#2 suffered from r/r B-ALL. She received a single dose of 1 x 107 cells/kg after lymphodepleting conditioning and low dose bortezomib. Result(s): NKG2DL were expressed in pediatric primary tumor cells and cell lines. We observed that NKG2DL expression changed with disease status. In osteosarcoma samples, metastatic tumors showed significantly higher expression of MICA, MICB and ULBP1. In leukemia samples, we found a trend of NKG2DL to decrease at diagnosis and relapse/refractory compared to remission. NKG2D-CAR on memory (45RA-) T cells were cytotoxic against 3 osteosarcoma cell lines and 8/10 leukemia cell lines with specific lysis over 50%. Myeloid and T-ALL cell lines were more susceptible to NKG2D-CAR T cells (specific lysis ranging from 50-78%) compared to B-ALL cell lines (19-52%). NKG2D-CAR memory (45RA-) T cells had considerable antitumor activity in a mouse model of human osteosarcoma, whereas untransduced T cells were ineffective. Physiological concentrations of sNKG2DL increased

NKG2D-CAR expression. However, supra-physiological levels of sNKG2DL decreased NKG2D-CAR expression up to 5 times and increased cell proliferation up to 4 times. The effects of sNKG2DL were dose-dependent and attenuated by IL-2. NKG2D-CAR memory (45RA-) T cells manufactured at CliniMACS Prodigy expanded up to 2076 +/- 697 million with 77,8 +/- 20% NKG2D-CAR expression and 76 +/- 10% viability. Harvested CAR T cells showed 90 +/- 14% of specific lysis against Jurkat cells and 31 +/- 16% against 531MII osteosarcoma cell line. Vector copy number was <= 5 in all validations except for one. CGH and karyotype showed no genetic alterations. Free viral particles were undetectable in the supernatants. No overexpression of myc/tert was found except for one validation. Endotoxins were <= 0.25 EU/ml. NKG2D CAR memory T cells infusions were well tolerated by patients, although a therapeutic effect was only observed in Patient#2. Conclusion(s): NKG2D-CAR expression on memory (CD45RA-) T cells are cytotoxic against pediatric tumor cells in vitro and in vivo, and thus could be a novel therapeutic approach for children suffering from cancer. Supraphysiological levels of sNKG2DL may downregulate NKG2D-CAR expression, that is softened by IL-2. The changes observed in NKG2DL surface expression at the different stages of the disease could be related to ligands shedding and immune escape. Automated manufacturing of clinical-grade NKG2D-CAR on memory (CD45RA-) T cells using CliniMACS Prodigy is feasible and reproducible. NKG2D CAR memory (CD45RA-) T cells infusions are essentially safe and therapeutic effect mainly relies on lymphodepleting conditioning, NKG2DL expression on tumor cells and sNKG2DL. Copyright © 2019

Perez-Pi, I., et al. (2019). "alpha-Synuclein-Confocal Nanoscanning (ASYN-CONA), a Bead-Based Assay for Detecting Early-Stage alpha-Synuclein Aggregation." Analytical Chemistry **91**(9): 5582-5590.

alpha-Synuclein fibrils are considered a hallmark of Parkinson's disease and other synucleinopathies. However, small oligomers that formed during the early stages of alpha-synuclein aggregation are thought to be the main toxic species causing disease. The formation of alpha-synuclein oligomers has proven difficult to follow, because of the heterogeneity and transient nature of the species formed. Here, a novel bead-based aggregation assay for monitoring the earliest stages of alpha-synuclein oligomerization, alpha-Synuclein-Confocal Nanoscanning (ASYN-CONA), is presented. The alpha-synuclein A91C single cysteine mutant is modified with a trifunctional chemical tag, which allows simultaneous fluorescent labeling with a green dye (tetramethylrhodamine, TMR) and attachment to microbeads. Beads with bound TMR-labeled alpha-synuclein are then incubated with a red dye (Cy5)-labeled variant of alpha-synuclein A91C, and EtOH (20%) to induce aggregation. Aggregation is detected by confocal scanning imaging, below the equatorial plane of the beads, which is known as the CONA technique. On-bead TMR-labeled alpha-synuclein and aggregated Cy5-labeled alpha-synuclein from the solution are quantitatively monitored in parallel by detection of fluorescent halos or "rings". alpha-Synuclein on-bead oligomerization results in a linear increase of red bead ring fluorescence intensity over a period of 5 h. Total internal reflection fluorescence microscopy was performed on oligomers cleaved from the beads, and it revealed that (i) oligomers are sufficiently stable in solution to investigate their composition, consisting of 6 +/- 1 monomer units, and (ii) oligomers containing a mean of 15 monomers bind Thioflavin-T. Various known inhibitors of alpha-synuclein aggregation were used to validate the ASYN-CONA assay for drug screening. Baicalein, curcumin, and rifampicin showed concentration-dependent inhibition of the alpha-synuclein aggregation and the IC₅₀ (the concentration of the compound at which the maxiumum intensity was reduced by one-half) were calculated.

Periyasamy-Thandavan, S., et al. (2012). "Differential expression of micrornas in human mesenchymal stem cells with age may be related to musculoskeletal disorders." Journal of Bone and Mineral Research. Conference **27**(SUPPL. 1).

Age-associated osteoporosis is one of the most common and debilitating types of bone disease. Although the mechanisms involved remain poorly defined, recent studies suggest that age-associated osteoporosis is a stem cell disease. Human mesenchymal stromal/stem cells (hMSCs) are multipotent stem cells that can differentiate into osteoblasts. MicroRNAs (miRNAs), a class of short single-stranded noncoding RNAs are post-transcriptional regulators that can modulate the homeostasis of multiple genes and associated pathways simultaneously. Changes in miRNA expression have been linked to the development of numerous disorders, including musculoskeletal disorders. While miRNAs are emerging as critical modulators of cell function and phenotype development little work has been done to determine their role in hMSC differentiation or in the regulation of bone metabolism with aging. Here, we directly isolated hMSC CD271 cells by using a kit (CD271 (APC) MicroBead Kit, Miltenyi Biotec Inc. CA.) from surgical bone marrow specimens of three young (under 40 yrs old) and three old (over 75 yrs old) patients, without plastic adhesion or culturing that might alter miRNA and gene expression. Total RNA was isolated from the hMSC CD271 cells and microarrays were performed using an Affymetrix GeneChip miRNA 2.0 Array, normalized using robust multichip average (RMA), and assessed by 2-way ANOVA analysis of young vs old hMSCs (with sex and age as the variables) using the Partek Genomics Suite. This genome-wide assessment of miRNA expression revealed multiple miRNAs whose expressions were altered with age. We identified six miRNAs (miR-579,-1244,-374ab,-671-5p,-370,-29abcd) that were significantly up-regulated in aged hMSCs. Predicted bone homeostasis targets of these miRNAs include SDF-1, BMP2, beta arrestin, SOX4, Leptin, IGF-1, VEGF, Collagen type 1 alpha1 and alpha2. Similarly, we identified 11 miRNAs including miR- 1231,-517-ac,-3180-5p that were significantly reduced in aged hMSCs. Predicted targets of these miRNAs included adipogenic genes such as PPAR-gamma or-alpha, AP2-alpha, and CD36. These results suggest that the differential miRNA expression in hMSCs with age may regulate age-associated changes that reduce osteogenic capacity and increase the adipogenic fate of these stem cells, and may help drive the development of osteoporosis. Targeting these miRNAs may be a potential therapeutic strategy to treat age-related musculoskeletal disorders.

Peronaci, M., et al. (2012). "Trascriptome analysis of bone marrow CD14+ monocytes revealed differential expression profiles in symptomatic multiple myeloma (MM) compared to smoldering MM and monoclonal gammopathy of undetermined significance." Blood. Conference: 54th Annual Meeting of the American Society of Hematology, ASH **120**(21).

Symptomatic multiple myeloma (MM), smoldering MM (SMM) and monoclonal gammopathy of uncertain significance (MGUS) are well known different pathological and clinical entities of plasma cell (PC) disorders. Nevertheless molecular studies performed on clonal CD138⁺ PC do not clear distinguished these disorders that share common alterations. Studies focusing on the presence of potential molecular alterations in the microenvironment cells are ongoing. Because monocytes are the cells primarily involved in osteoclastogenesis, angiogenesis and immune system disfuction, that are the hallmark of symptomatic MM compared to SMM and MGUS, in this study we have analyzed the transcriptional profile of the bone marrow (BM) CD14⁺ cells in these settings of patients. BM CD14⁺ monocytes were purified from a total cohort of 36 patients with PC disorders including 21 patients with symptomatic MM, 8 patients with SMM and 7 patients with MGUS. CD14⁺ cells were isolated from the CD138 negative fraction of BM samples of patients by immunomagnetic method with anti-CD14 monoclonal antibody conjugated with microbeads. The presence of potential haemopoietic and CD138⁺ contaminating cells was excluded by FACS analysis. Only samples with CD14 purity greater than 95% were analyzed by microarrays by GeneChip HG-U133Plus 2.0 arrays (Affymetrix) (13 MM, 8 SMM and 7 MGUS). Data obtained were then validated on selected genes by Real-Time quantitative PCR. A multiclass analysis identified 14 differentially expressed genes, which characterized MGUS vs SMM vs symptomatic MM. A supervised analysis between symptomatic MM vs. SMM and MGUS samples identified 101 genes differentially expressed in CD14⁺ (58 genes up-regulated in MM vs SMM and MGUS and 43 genes donwregulated). Interestingly, among the differentially expressed genes we found that cytokines and cytokine receptors (IL21, IL21R, IL15, IL15R), chemokines (CXCL10, CXCL11) and interferon-inducible proteins (IFI27, IFI44) were up-regulated in CD14⁺ of MM patients as compared to SMM and MGUS. A supervised analysis between MM and MGUS identified 6 differentially expressed genes in CD14⁺ whereas 37 genes distinguished MM and SMM patients. Notably the SLAMF7 (CS1) gene recently indentified as a therapeutic target in CD138⁺ MM cells was up-regulated in CD14⁺ monocytes of MM patients as compared either to MGUS alone or to MGUS plus SMM could be a potential candidate gene. Overall our preliminary results indicate that a different transcriptional fingerprint may be identified in BM CD14⁺ cells of patients with symptomatic MM as compared to those with indolent PC disorders such as SMM and MGUS with a greater number of differentially expressed genes between symptomatic MM and SMM patient rather than between MM and MGUS.

Perrechil, F. A., et al. (2012). "Development of Na-CN--[kappa]-carrageenan Microbeads for the Encapsulation of Lipophilic Compounds." Food Biophysics **7**(3): 264-275.

The ionotropic gelation of double-layered emulsions composed of sodium caseinate and κ-carrageenan at pH values of 7 and 3.5 was evaluated, in order to obtain potential encapsulation matrices for hydrophobic compounds. The influence of some of the extrusion process variables (nozzle diameter at fluid exit and collecting distance) on the microbead production was studied, as well as the stability of the microbeads. The fluid nozzle diameter showed little influence on the shape of the microbeads, with a slight tendency for a decrease in microbead diameter with increase in fluid nozzle diameter. On the other hand, the collecting distance strongly influenced the microbead shape and they became more spherical (aspect ratio was reduced from ~2.0 to ~1.4) as the collecting distance was increased from 10 cm to 50 cm. The emulsion pH did not affect the aspect ratio of the microbeads, but the diameter was greater for microbeads produced at pH 3.5. This difference was attributed to the kind of interactions occurring between the κ-carrageenan and sodium caseinate at these distinct pH values. The microbeads were highly unstable when dispersed in deionized water, sugar solutions and low salt concentrations, releasing the encapsulated oil. However, no release of oil from the microbeads was observed when they were dispersed in ethanol or potassium chloride solutions with concentrations above 0.75 %, although their shape was modified when dispersed in ethanol. In general, the results obtained demonstrated the viability of the extrusion process to produce biopolymer-based microbeads and the potential application of these systems.[PUBLICATION ABSTRACT]

Perrechil, F. A., et al. (2012). "Development of Na-CN - kappa -carrageenan microbeads for the encapsulation of lipophilic compounds." Food Biophysics **7**(3): 264-275.

The ionotropic gelation of double-layered emulsions composed of sodium caseinate and kappa -carrageenan at pH values of 7 and 3.5 was evaluated, in order to obtain potential encapsulation matrices for hydrophobic compounds. The influence of some of the extrusion process variables (nozzle diameter at fluid exit and collecting distance) on the microbead production was studied, as well as the stability of the microbeads. The fluid nozzle diameter showed little influence on the shape of the microbeads, with a slight tendency for a decrease in microbead diameter with increase in fluid nozzle diameter. On the other hand, the collecting distance strongly influenced the microbead shape and they became more spherical (aspect ratio was reduced from ~2.0 to ~1.4) as the collecting distance was increased from 10 cm to 50 cm. The emulsion pH did not affect the aspect ratio of the microbeads, but the diameter was greater for microbeads produced at pH 3.5. This difference was attributed to the kind of interactions occurring between the kappa -carrageenan and sodium caseinate at these distinct pH values. The microbeads were highly unstable when dispersed in deionized water, sugar solutions and low salt concentrations, releasing the encapsulated oil. However, no release of oil from the microbeads was observed when they were dispersed in ethanol or potassium chloride solutions with concentrations above 0.75%, although their shape was modified when dispersed in ethanol. In general, the results obtained demonstrated the viability of the extrusion process to produce biopolymer-based microbeads and the potential application of these systems.

Perren, W., et al. (2018). "Removal of Microbeads from Wastewater Using Electrocoagulation." ACS Omega **3**(3): 3357-3364.

The need for better microplastic removal from wastewater streams is clear, to prevent potential harm the microplastic may cause to the marine life. This paper aims to investigate the efficacy of electrocoagulation (EC), a well-known and established process, in the unexplored context of microplastic removal from wastewater streams. This premise was investigated using artificial wastewater containing polyethylene microbeads of different concentrations. The wastewater was then tested in a 1 L stirred-tank batch reactor. The effects of the wastewater characteristics (initial pH, NaCl concentration, and current density) on removal efficiency were studied. Microbead removal efficiencies in excess of 90% were observed in all experiments, thus suggesting that EC is an effective method of removing microplastic contaminants from wastewater streams. Electrocoagulation was found to be effective with removal efficiencies in excess of 90%, over pH values ranging from 3 to 10. The optimum removal efficiency of 99.24% was found at a pH of 7.5. An economic evaluation of the reactor operating costs revealed that the optimum NaCl concentration in the reactor is between 0 and 2 g/L, mainly due to the reduced energy requirements linked to higher water conductivity. In regard to the current density, the specific mass removal rate (kg/kWh) was the highest for the lowest tested current density of 11 A/m², indicating that low current density is more energy efficient for microbead removal.

Perugini, F., et al. (2005). "A Life Cycle Assessment of Mechanical and Feedstock Recycling Options for Management of Plastic Packaging Wastes." Environmental Progress **24**(2): 137-154.

Life cycle assessment (LCA) methodology is generally considered one of the best environmental management tools that can be used to compare alternative eco-performances of recycling or disposal systems. It considers the environment as a whole, including indirect releases, energy and material consumption, emissions in the environment, and waste disposal and follows each activity from the extraction of raw materials to the return of wastes to the ground (cradle-to-grave approach). The study refers to the whole Italian system for recycling of household plastic packaging wastes. The aim was to quantify the overall environmental performances of mechanical recycling of plastic containers in Italy and to compare them with those of conventional options of landfilling or incineration and of a couple of innovative processes of feedstock recycling, low-temperature fluidized bed pyrolysis, and high-pressure hydrogenation. The results confirm that recycling scenarios are always preferable to those of nonrecycling. They also highlight the good environmental performance of new plastic waste management schemes that couple feedstock and mechanical recycling processes.

Pessoni, L., et al. (2019). "Soap- and metal-free polystyrene latex particles as a nanoplastic model (Electronic supplementary information (ESI) available. See DOI: 10.1039/c9en00384c)." Environmental Science: Nano **6**(7): 2253-2258.

The ability of nanoplastics (NPTs) to bioaccumulate and cotransport pollutants in the whole organism is one of the most dangerous aspects of this form of plastic debris, defining a new class of emerging pollutants that is still largely unknown. In this context, it is essential to have accurate and representative models of nanoplastics to better understand their toxic effects. Models reported in the literature and commercial standards are far from mimicking the relevant properties for transporting pollutants, such as the size, shape, composition, purity, functionalization and surface morphology of nanoplastics sampled in the environment. Due to the lack of such nanoparticle models, we proposed an alternative nanoplastic model challenging three of the key properties affecting interactions with trace metals: purity, morphology and surface functionalization. NPTs with different surface functionalities (6–7 and 43–45 carboxylic groups per nm2), with smooth or raspberry-like surface morphologies, and that were monodisperse in size (PDI < 0.05) were synthesized using soap free emulsion polymerization. NPTs were stable over time as a function of the salinity and pH (potential zeta < −33 mV, pH = 4–6, salinities < 500 mM). These nanoplastics were free of additives such as surfactants and stabilizers, and their metal content was measured to be less than 100 ppt (Cr, Fe, Ni, Co, Zn, As, Se, Ag, Cd, Au, Gg, Ce and Pb). Their metal absorption capacity was evaluated on lead(ii) using AF4-ICPMS and electrochemistry and was characterized by a partition coefficient of lead between that of NPT and water, of approximately 105.

Peters, C. A. and S. P. Bratton (2016). "Urbanization is a major influence on microplastic ingestion by sunfish in the Brazos River Basin, Central Texas, USA." Environmental Pollution **210**: 380-387.

Microplastics, degraded and weathered polymer-based particles, and manufactured products ranging between 50 and 5000 micro m in size, are found within marine, freshwater, and estuarine environments. While numerous peer-reviewed papers have quantified the ingestion of microplastics by marine vertebrates, relatively few studies have focused on microplastic ingestion by freshwater organisms. This study documents microplastic and manufactured fiber ingestion by bluegill (Lepomis macrochirus) and longear (Lepomis megalotis) sunfish (Centrarchidae) from the Brazos River Basin, between Lake Whitney and Marlin, Texas, USA. Fourteen sample sites were studied and categorized into urban, downstream, and upstream areas. A total of 436 sunfish were collected, and 196 (45%) stomachs contained microplastics. Four percent (4%) of items sampled were debris on the macro size scale (i.e. >5 mm) and consisted of masses of plastic, metal, Styrofoam, or fishing material, while 96% of items sampled were in the form of microplastic threads. Fish length was statistically correlated to the number of microplastics detected (p=0.019). Fish collected from urban sites displayed the highest mean number of microplastics ingested, followed by downstream and upstream sites. Microplastics were associated with the ingestion of other debris items (e.g. sand and wood) and correlated to the ingestion of fish eggs, earthworms, and mollusks, suggesting that sunfish incidentally ingest microplastics during their normal feeding methods. The high frequency of microplastic ingestion suggest that further research is needed to determine the residence time of microplastics within the stomach and gut, potential for food web transfer, and adverse effects on wildlife and ecosystemic health.

Peters, C. A., et al. (2018). "Pyr-GC/MS analysis of microplastics extracted from the stomach content of benthivore fish from the Texas Gulf Coast." Marine Pollution Bulletin **137**: 91-95.

Fish ingestion of microplastic has been widely documented throughout freshwater, marine, and estuarine species. While numerous studies have quantified and characterized microplastic particles, analytical methods for polymer identification are limited. This study investigated the applicability of pyr-GC/MS for polymer identification of microplastics extracted from the stomach content of marine fish from the Texas Gulf Coast. A total of 43 microplastic particles were analyzed, inclusive of 30 fibers, 3 fragments, and 10 spheres. Polyvinyl chloride (PVC) and polyethylene terephthalate (PET) were the most commonly identified polymers (44.1%), followed by nylon (9.3%), silicone (2.3%), and epoxy resin (2.3%). Approximately 42% of samples could not be classified into a specific polymer class, due to a limited formation of pyrolytic products, low product abundance, or a lack of comparative standards. Diethyl phthalate, a known plasticizer, was found in 16.3% of the total sample, including PVC (14.3%), silicone (14.3%), nylon (14.3%), and sample unknowns (57.2%).

Peters, C. A., et al. (2017). "Foraging preferences influence microplastic ingestion by six marine fish species from the Texas Gulf Coast." Marine Pollution Bulletin **124**(1): 82-88.

This study evaluated the influence of foraging preferences on microplastic ingestion by six marine fish species from the Texas Gulf Coast. A total of 1381 fish were analyzed and 42.4% contained ingested microplastic, inclusive of fiber (86.4%), microbead (12.9%%), and fragment

(<1.0%) forms. Despite a substantial overlap in diet, ordination of ingested prey items clustered samples into distinctive species groupings, reflective of the foraging gradient among species. Orthopristis chrysoptera displayed the lowest overall frequency of microplastic ingestion and the most distinctive ordination grouping, indicating their selective invertebrate foraging preferences. Cluster analysis of O. chrysoptera most closely classified microplastic with the ingestion of benthic invertebrates, whereas the ingestion of microplastic by all other species most closely classified with the ingestion of vegetation and shrimp. O. chrysoptera, as selective invertebrate foragers, are less likely to ingest microplastics than species exhibiting generalist foraging preferences and methods of prey capture.

Peters, J., et al. (2013). "Colour-encoded paramagnetic microbead-based direct inhibition triplex flow cytometric immunoassay for ochratoxin A, fumonisins and zearalenone in cereals and cereal-based feed." Analytical & Bioanalytical Chemistry **405**(24): 7783-7794.

A combined (triplex) immunoassay for the simultaneous detection of three mycotoxins in grains was developed with superparamagnetic colour-encoded microbeads, in combination with two bead-dedicated flow cytometers. Monoclonal antibodies were coupled to the beads, and the amounts of bound mycotoxins were inversely related to the amounts of bound fluorescent labelled mycotoxins (inhibition immunoassay format). The selected monoclonal antibodies were tested for their target mycotoxins and for cross-reactivity with relevant metabolites and masked mycotoxins. In the triplex format, low levels of cross-interactions between the assays occurred at irrelevant high levels only. All three assays were influenced by the sample matrix of cereal extracts to some extent, and matrix-matched calibrations are recommended for quantitative screening purposes. In a preliminary in-house validation, the triplex assay was found to be reproducible, sensitive and sufficiently accurate for the quantitative screening at ML level. The triplex assay was critically compared to liquid chromatography-tandem mass spectrometry using reference materials and fortified blank material.

Peters, J. H., et al. (2008). "Clinical grade Treg: GMP isolation, improvement of purity by CD127^{pos} depletion, Treg expansion, and Treg cryopreservation." PLoS ONE **3 (9) (no pagination)**(e3161).

Background: Treg based immunotherapy is of great interest to facilitate tolerance in autoimmunity and transplantation. For clinical trials, it is essential to have a clinical grade Treg isolation protocol in accordance with Good Manufacturing Practice (GMP) guidelines. To obtain sufficient Treg for immunotherapy, subsequent ex vivo expansion might be needed. Methodology/Principal Findings: Treg were isolated from leukapheresis products by CliniMACS based GMP isolation strategies, using anti-CD25, anti-CD8 and anti-CD19 coated microbeads. CliniMACS isolation procedures led to 40-60% pure CD4^{pos}CD25^{high}FoxP3^{pos} Treg populations that were anergic and had moderate suppressive activity. Such CliniMACS isolated Treg populations could be expanded with maintenance of suppressive function. Alloantigen stimulated expansion caused an enrichment of alloantigen-specific Treg. Depletion of unwanted CD19^{pos} cells during CliniMACS Treg isolation proved necessary to prevent B-cell outgrowth during expansion. CD4^{pos}CD127^{pos} conventional T cells were the major contaminating cell type in CliniMACS isolated Treg populations. Depletion of CD127^{pos} cells improved the purity of CD4^{pos}CD25^{high}FoxP3^{pos} Treg in CliniMACS isolated cell populations to approximately 90%. Expanded CD127^{neg} CliniMACS isolated Treg populations showed very potent suppressive capacity and high FoxP3 expression. Furthermore,

our data show that cryopreservation of CliniMACS isolated Treg is feasible, but that activation after thawing is necessary to restore suppressive potential. Conclusions/Significance: The feasibility of Treg based therapy is widely accepted, provided that tailor-made clinical grade procedures for isolation and ex vivo cell handling are available. We here provide further support for this approach by showing that a high Treg purity can be reached, and that isolated cells can be cryopreserved and expanded successfully. © 2008 Peters et al.

Petousis, I., et al. (2007). "Transient behaviour of magnetic micro-bead chains rotating in a fluid by external fields." Lab on a Chip **7**(12): 1746-1751.

Magnetic micro-beads can facilitate many functions in lab-on-a-chip systems, such as bio-chemical labeling, selective transport, magnetic sensing and mixing. In order to investigate potential applications of magnetic micro-beads for mixing in micro fluidic systems, we developed a pin-jointed mechanism model that allows analysing the behaviour of rotating superparamagnetic bead chains. Our numerical model revealed the response of the chains on a rotating magnetic field over time. We could demonstrate that the governing parameters are the Mason number and number of beads in the chain. The results are in agreement with the simplified analytical model, assuming a straight chain, but also allow prediction of the transient chain shape. The modelled chains develop an anti-symmetric S-shape that is stable, if the Mason number for a given chain length does not surpass a critical value. Above that value, rupture occurs in the vicinity of the chain centre. However, variations in bead susceptibility can shift the location of rupture. Moreover, we performed experiments with superparamagnetic micro-beads in a small fluid volume exposed to a uniform rotating magnetic field. Our simulation could successfully predict the observed transient chain form and the time for chain rupture. The developed model can be used to design optimised bead based mixers in micro fluidic systems.

Petrackova, D., et al. (2013). "Surface hydrophobicity and roughness influences the morphology and biochemistry of streptomycetes during attached growth and differentiation." FEMS Microbiology Letters **342**(2): 147-156.

Streptomycetes, soil-dwelling mycelial bacteria, can colonise surface of organic soil debris and soil particles. We analysed the effects of two different inert surfaces, glass and zirconia/silica, on the growth and antibiotic production in Streptomyces granaticolor. The surfaces used were in the form of microbeads and were surrounded by liquid growth media. Following the production of the antibiotic granaticin, more biomass was formed as well as a greater amount of antibiotic per milligram of protein on the glass beads than on the zirconia/silica beads. Comparison of young mycelium (6 h) proteomes, obtained from the cultures attached to the glass and zirconia/silica beads, revealed three proteins with altered expression levels (dihydrolipoamide dehydrogenase, amidophosphoribosyltransferase and cystathionine beta-synthase) and one unique protein (glyceraldehyde-3-phosphate dehydrogenase) that was present only in cells grown on glass beads. All of the identified proteins function primarily as cytoplasmic enzymes involved in different parts of metabolism; however, in several microorganisms, they are exposed on the cell surface and have been shown to be involved in adhesion or biofilm formation.

Petrich, C. R., et al. (1998). "Encapsulated Cell Bioremediation: Evaluation on the Basis of Particle Tracer Tests." Ground Water **36**(5): 771-778.

Microencapsulation of degradative organisms enhances microorganism survivability (Stormo and Crawford 1994). The use of encapsulated cell microbeads for in situ biodegradation depends not only on microorganism survival but also on microbead transport characteristics. Two forced-gradient, recirculating-loop tracer experiments were conducted to evaluate the feasibility of encapsulated cell transport and bioremediation on the basis of polystyrene microsphere transport results. The tracer tests were conducted in a shallow, confined, unconsolidated, heterogeneous, sedimentary aquifer using bromide ion and 2 mu m, 5 mu m, and 15 mu m microsphere tracers. Significant differences were observed in the transport of bromide solute and polystyrene microspheres. Microspheres reached peak concentrations in monitoring wells before bromide, which was thought to reflect the influence of aquifer heterogeneity. Greater decreases in microsphere C/C sub(0) ratios were observed with distance from the injection wells than in bromide C/C sub(0) ratios, which was attributed to particle filtration and/or settling. Several methods might be considered for introducing encapsulated cell microbeads into a subsurface environment, including direct injection into a contaminated aquifer zone, injection through a recirculating ground water flow system, or emplacement in a subsurface microbial curtain in advance of a plume. However, the in situ use of encapsulated cells in an aquifer is probably limited to aquifers containing sufficiently large pore spaces, allowing passage of at least some encapsulated cells. The use of encapsulated cells may also be limited by differences in solute and microbead transport patterns and flowpath clogging by larger encapsulated cell microbeads.

Petrossian, K., et al. (2007). "Lectin binding and effects in culture on human cancer and non-cancer cell lines: examination of issues of interest in drug design strategies." Acta Histochemica **109**(6): 491-500.

By using a non-cancer and a cancer cell line originally from the same tissue (colon), coupled with testing lectins for cell binding and for their effects on these cell lines in culture, this study describes a simple multi-parameter approach that has revealed some interesting results that could be useful in drug development strategies. Two human cell lines, CCL-220/Colo320DM (human colon cancer cells, tumorigenic in nude mice) and CRL-1459/CCD-18Co (non-malignant human colon cells) were tested for their ability to bind to agarose microbeads derivatized with two lectins, peanut agglutinin (Arachis hypogaea agglutinin, PNA) and Dolichos biflorus agglutinin (DBA), and the effects of these lectins were assessed in culture using the MTT assay. Both cell lines bound to DBA-derivatized microbeads, and binding was inhibited by N-acetyl-D-galactosamine, but not by L-fucose. Neither cell line bound to PNA-derivatized microbeads. Despite the lack of lectin binding using the rapid microbead method, PNA was mitogenic in culture at some time points and its mitogenic effect displayed a reverse-dose response. This was also seen with effects of DBA on cells in culture. While this is a simple study, the results were statistically highly significant and suggest that: (1) agents may not need to bind strongly to cells to exert biological effects, (2) cell line pairs derived from diseased and non-diseased tissue can provide useful comparative data on potential drug effects and (3) very low concentrations of potential drugs might be initially tested experimentally because reverse-dose responses should be considered.

Petry, M. V. and V. R. F. Benemann (2017). "Ingestion of marine debris by the White-chinned petrel (Procellaria aequinoctialis): is it increasing over time off southern Brazil?" Marine Pollution Bulletin **117**(1/2): 131-135.

Seabirds are amongst the most affected organisms by plastic pollution worldwide. Ingestion of marine debris has been reported in at least 122 species, and owing to the increasing global production and persistence of these anthropogenic materials within the marine environment, it is expected to be a growing problem to the marine fauna. Here we report evidence of an increasing frequency in marine debris ingestion and a decrease in the amount of plastic pellets ingested by White-chinned Petrels attending south Brazilian waters during the last three decades. Future studies comprising large temporal scales and large sample sizes are needed to better understand the trends of marine debris ingestion by seabirds. We expect our findings to highlight the need for prevention policies and mitigation measures to reduce the amount of solid litter in the oceans.

Pfitzenmaier, J., et al. (2007). "The detection and isolation of viable prostate-specific antigen positive epithelial cells by enrichment: a comparison to standard prostate-specific antigen reverse transcriptase polymerase chain reaction and its clinical relevance in prostate cancer." Urologic Oncology **25**(3): 214-220.

PURPOSE: To isolate prostate epithelial cells from the peripheral blood and bone marrow, and compare prostate-specific antigen (PSA) reverse transcriptase polymerase chain reaction (RT-PCR) performed on unenriched or epithelial enriched peripheral blood and bone marrow samples.

PATIENTS AND METHODS: Peripheral blood samples from 371 patients with prostate cancer and 141 controls, and bone marrow samples from 292 patients with prostate cancer and 43 controls were obtained. One aliquot was assessed with PSA RT-PCR. Another was enriched for epithelial cells with paramagnetic immune microbeads and assessed for: (1) PSA immunohistochemistry, (2) PSA RT-PCR, and (3) immunofluorescent detection of epithelial cells.

RESULTS: In the bone marrow ($P < 0.01$), but not the peripheral blood ($P = 0.62$), we observed significantly higher detection rates of disseminated PSA expressing epithelial cells after enrichment. The presence of epithelial cells with or without evidence of PSA production was uncommon among controls both in peripheral blood (1% and 0%) and bone marrow (11% and 0%). In patients with active prostate cancer, 46% to 74% had epithelial cells in peripheral blood, and 20% to 64% had PSA expressing epithelial cells. In bone marrow, 55% to 92% had epithelial cells, and 43% to 83% had PSA expressing epithelial cells. Particularly in bone marrow, circulating cells were frequently detected in men without evidence of disease after prostatectomy. With limited follow-up, the detection of epithelial cells or PSA expressing epithelial cells in peripheral blood or bone marrow before radical prostatectomy does not define a population of patients that will have biochemical failure.

CONCLUSIONS: Immunomagnetic enrichment frequently detects epithelial, presumably malignant, cells in the peripheral blood and, especially, the bone marrow of patients with prostate cancer. Viable cells can be acquired for gene expression and phenotyping studies.

Pflieger, M., et al. (2017). "Extraction of Organochlorine Pesticides from Plastic Pellets and Plastic Type Analysis." Journal of Visualized Experiments **125**(07): 01.

Plastic resin pellets, categorized as microplastics (<=5 mm in diameter), are small granules that can be unintentionally released to the environment during manufacturing and transport. Because of their environmental persistence, they are widely distributed in the oceans and on beaches all over the world. They can act as a vector of potentially toxic organic compounds (e.g., polychlorinated biphenyls) and might consequently negatively affect marine organisms. Their possible impacts along the food chain are not yet well understood. In order to assess the hazards associated with the occurrence of plastic pellets in the marine environment, it is necessary to develop methodologies that allow for rapid determination of associated organic contaminant levels. The present protocol describes the different steps required for sampling resin pellets, analyzing adsorbed organochlorine pesticides (OCPs) and identifying the plastic type. The focus is on the extraction of OCPs from plastic pellets by means of a pressurized fluid

extractor (PFE) and on the polymer chemical analysis applying Fourier Transform-InfraRed (FT-IR) spectroscopy. The developed methodology focuses on 11 OCPs and related compounds, including dichlorodiphenyltrichloroethane (DDT) and its two main metabolites, lindane and two production isomers, as well as the two biologically active isomers of technical endosulfan. This protocol constitutes a simple and rapid alternative to existing methodology for evaluating the concentration of organic contaminants adsorbed on plastic pieces.

Pham, C. K., et al. (2017). "Plastic ingestion in oceanic-stage loggerhead sea turtles (Caretta caretta) off the North Atlantic subtropical gyre." Marine Pollution Bulletin **121**(1/2): 222-229.

Juvenile oceanic-stage sea turtles are particularly vulnerable to the increasing quantity of plastic coming into the oceans. In this study, we analysed the gastrointestinal tracts of 24 juvenile oceanic-stage loggerheads (Caretta caretta) collected off the North Atlantic subtropical gyre, in the Azores region, a key feeding ground for juvenile loggerheads. Twenty individuals were found to have ingested marine debris (83%), composed exclusively of plastic items (primarily polyethylene and polypropylene) identified by micro -Fourier Transform Infrared Spectroscopy. Large microplastics (1-5 mm) represented 25% of the total number of debris and were found in 58% of the individuals sampled. Average number of items was 15.83+or-6.09 (+or-SE) per individual, corresponding to a mean dry mass of 1.07+or-0.41 g. The results of this study demonstrate that plastic pollution acts as another stressor for this critical life stage of loggerhead turtles in the North Atlantic.

Pham, N. M., et al. (2018). "A bead-based immunogold-silver staining assay on capillary-driven microfluidics." Biomedical Microdevices **20**(2): 41.

Point-of-care (POC) diagnostics are critically needed for the detection of infectious diseases, particularly in remote settings where accurate and appropriate diagnosis can save lives. However, it is difficult to implement immunoassays, and specifically immunoassays relying on signal amplification using silver staining, into POC diagnostic devices. Effective immobilization of antibodies in such devices is another challenge. Here, we present strategies for immobilizing capture antibodies (cAbs) in capillary-driven microfluidic chips and implementing a gold-catalyzed silver staining reaction. We illustrate these strategies using a species/anti-species immunoassay and the capillary assembly of fluorescent microbeads functionalized with cAbs in "bead lanes", which are engraved in microfluidic chips. The microfluidic chips are fabricated in silicon (Si) and sealed with a dry film resist. Rabbit IgG antibodies in samples are captured on the beads and bound by detection antibodies (dAbs) conjugated to gold nanoparticles. The gold nanoparticles catalyze the formation of a metallic film of silver, which attenuates fluorescence from the beads in an analyte-concentration dependent manner. The performance of these immunoassays was found comparable to that of assays performed in 96 well microtiter plates using "classical" enzyme-linked immunosorbent assay (ELISA). The proof-of-concept method developed here can detect 24.6 ng mL⁻¹ of rabbit IgG antibodies in PBS within 20 min, in comparison to 17.1 ng mL⁻¹ of the same antibodies using a ~140-min-long ELISA protocol. Furthermore, the concept presented here is flexible and necessitate volumes of samples and reagents in the range of just a few microliters.

Philip, M. and F. Al-Azzawi (2018). "Effects of Natural and Artificial Weathering on the Physical Properties of Recycled Poly(ethylene terephthalate)." Journal of Polymers & the Environment **26**(8): 3139-3148.

In accelerated weathering tests, specimens are exposed to higher radiation intensity, temperature and humidity than is likely under natural weathering in order to achieve rapid

degradation of the polymer in a convenient short time. In the current work, a correlation between the two environments is attempted so that a prediction of lifetimes in the natural environment can be achieved. During aging, surface flaws are created due to the chain scission process. This is initiated by the absorption of ultra-violet light and directly affects visual appearance and impact strength. After natural weathering, the material shows only plastic deformation in an impact test. However, after artificial weathering to 5000 h of UV exposure, there is a decrease of 85% in impact strength. Colour change occurs at a high rate in the early stages of UV exposure. Beyond 2000 h of exposure, the colour change approaches a steady state and a correlation between the changes under natural and artificial weathering becomes apparent for a potential prediction of lifetimes. From the analysis including the specular component (SCI), taking surface roughening into account, 1 year under natural weathering was found to be equivalent to 25 days under accelerated weathering. [ABSTRACT FROM AUTHOR]

Philippeos, C., et al. (2010). "Effects of ascitic fluid on alginate-encapsulated human hepatocytes in vitro." Hepatology **1)**: 1106A.
Human hepatocyte transplantation is an attractive option in the management of acute liver failure, however infusion of cells into the liver of a coagulopathic patient and the need for immunosuppression are major limiting factors. Intraperitoneal transplantation of microencapsulated hepatocytes without immunosuppression could address these issues. The aim of this study was to determine the function of microencapsulated human hepatocytes in vitro in the presence of ascitic fluid (AF), to which they would be exposed in the peritoneum. METHOD(S): Encapsulation of human hepatocytes was optimised by varying the alginate percentage, density of cells and the encapsulator frequency, amplitude, voltage and syringe speed settings. The optimum settings resulted in human hepatocyte microbeads (o 400-500Μm) in 1.5% clinical grade sodium alginate at a density of 2.5x106 cells/ml. Microbeads were either maintained in Williams' E medium (WEM) supplemented with insulin, dexamethasone, and antibiotics (humidified incubator; 37degreeC, 5% CO<inf>2</inf>), or AF, obtained from children, post liver transplant with ascites. Hepatocyte overall activity and viability were determined by MTT assay and fluorescein diacetate/ethidium bromide (FDA/EtBr) staining at days 1, 2, 3, and 7 of culture. Urea synthesis was assessed in WEM containing 5mM NH<inf>4</inf>Cl with urea colorimetrically measured in the supernatant. Data is presented as mean+/-SD per 100mg microbeads. RESULT(S): Optimisation experiments resulted in reproducible clinical grade alginate-encapsulated human hepatocytes. On average 2.86+/-0.40 Μg/ml urea and 8.34+/-0.30 ng/ml albumin were produced each day for 72h. Factor VII reached a concentration of 3.33+/-0.88 ng/ml after incubating microbeads for 7 days. Microbeads maintained in AF showed higher viability (FDA/EtBr staining) than those in medium, at all time points. Mitochondrial dehydrogenase activity (MTT assay) of microbeads cultured in AF was significantly greater (p<0.001) than control microbeads (not exposed to AF) cultured in WEM at both 24h (OD<inf>630</inf>= 0.149+/-0.013 vs. 0.086+/-0.008, respectively) and 7 days (OD<inf>630</inf>= 0.067+/-0.006 vs. 0.018+/-0.004) of culture. Urea production after 24h was highest from microbeads incubated in AF, 5.10+/-0.58 Μg/ml, compared to control microbeads producing 3.62+/-0.32 Μg/ml (p=0.018). After 7 days of culture AF and control

microbeads produced 2.53+/-0.06 Μg/ml and 1.42+/-0.14 Μg/ml urea, respectively (p<0.001). CONCLUSION(S): Incubation of alginate-encapsulated human hepatocytes in ascitic fluid did not have detrimental effects on overall cell metabolic activity and urea production.

Philippon, M. J., et al. (2011). "Contributions of the iliofemoral ligaments and the acetabular labrum in hip stability." Arthroscopy - Journal of Arthroscopic and Related Surgery **1)**: e96-e97.

Introduction: A variety of pathologic conditions have been associated with increased hip motion in recent years. Specifically, injuries to the capsular (iliofemoral-IF) ligaments and acetabular labrum have gained interest because they have been reported to serve as primary contributors to joint stability. However, the relative role of each of these structures in maintaining hip stability has not been shown. The purpose of this study was to determine the relative contributions of the acetabular labrum and IF ligaments in maintaining hip stability as measured by external rotation and anterior translation of the femur relative to the center of the acetabulum when performing the log roll test (also known as the dial test). Hypothesis: It was hypothesized that each of these structures are vital for the stability of the hip, with increased stability provided by the IF ligament compared to the labrum. Moreover, we hypothesized that once torn, these structures could be surgically repaired to restore the stability of the hip as measured by the log roll test. Method(s): Fifteen fresh-frozen cadaveric hips with no evidence of prior injury, arthritis, or other abnormalities were used for this study. Each specimen was selectively skeletonized by removing all musculature and soft tissue, leaving only the IF ligament and acetabular labrum intact. Four tantalum microbeads with a diameter of 1.0 mm were embedded into both the femoral head and pelvis of each hip. Each specimen was mounted into a custom built hip jig that positioned the pelvis laterally in the biplane fluoroscopy system. Designed to simulate the log roll test, the femoral shaft was centered and fixed in an apparatus that allowed for 5 N*m external rotation torques to be applied. The hips were tested by sectioning and later repairing the acetabular labrum (LabTorn) and IF ligament (LigTorn) in a randomized order. IF ligament tears were created through the entire medial and lateral arms of the ligament at a level 1 cm distal to the edge of the acetabulum, mimicking the positioning of a capsulotomy performed arthroscopically. Labral tears were created from the 12 o'clock to the 3 o'clock position on right hips and the corresponding anteriore superior location on left hips, which correlated with the most commonly reported labral tear locations. In specimens where the labral tear was created prior to the IF ligament tear, a 5 mm longitudinal incision was made in the anterior capsule and this tissue was reapproximated with a single #0 suture. The labrum was repaired (LabRepaired) using two 2.3 mm suture anchors. IF ligament repairs (LigRepaired) were completed using interrupted #0 sutures with care taken to re-approximate the ligament and not to overconstrain it. At each testing condition the hips were tested in the following positions: 10 deg extension, 0 deg, 10 deg flexion, and 40 deg flexion. In order to test the reliability of the testing apparatus, the BothTorn condition was repeated at each joint angle after a thirty minute time interval and values were compared to the respective conditions. Hip kinematics were determined as described in the literature [1]. Reconstructed from CT scans, the bone contours were detected semi-automatically from the fluoroscopy images using model based RSA (Medis Specials, Leiden, THE NETHERLANDS). The beads were automatically detected in each image and matched to its respective location in each view by finding the intersections of the rays originiating from the focus positions of the x-ray generators and extending to the centers of the detected beads in the imaging planes. A 2-way ANOVA with independent factors of hip position and sectioned condition was used to analyze the degree of external and internal rotations as well as translations. Adjusted Bonferroni/Dunn post hoc analyses were applied where appropriate with significance set at p<0.05. Result(s): Significant main effects were found for both the sectioned condition and hip flexion angle with regards to external rotation, but there was no interaction between the two. Post hoc analysis of the effect of sectioned condition revealed that external rotation significantly increased from the intact condition to the LigTorn condition and both torn condition (Intact: 41.5 = 7.4 deg vs. LigTorn: 54.4 = 6.6; p<0.0001; Both Torn: 61.5 = 5.7; p<0.0001), but there was not a significant increase in external rotation in the labral torn condition. This relationship was mirrored in the repair conditions. No significant reduction in external rotation was observed in the LabRepaired condition compared to the both torn condition, while the LigRepaired condition resulted in an average of 19.0 degrees less external rotation compared to the BothTorn condition (BothTorn: 61.5 deg = 5.7 vs. LigRepaired 42.5 = 6.1; p<0.0001). Additionally, the Intact and BothRepaired conditions did not display any differences in rotation (Intact: 41.5 = 7.4 deg vs Both-Repaired: 40.3 = 6.7 deg). For hip flexion angle, the average external rotation across all cuts significantly decreased by an average of 4.8 deg = 1.5 for each position as hip flexion decreased from 40degree flexion to 10degree extension. The reliability test showed no differences between the repeated BothTear conditions at any of the flexion angles, validating the testing apparatus for repeatability. Anterior/Posterior translations were observed to significantly vary across sectioned conditions but not across flexion angles. LigTorn, BothTorn, and LabRepaired all resulted in significantly greater translations than the Intact condition (LigTorn: 1.4 mm = 0.5; BothTorn: 2.2 mm = 0.2; LabRepaired: 1.1 = 0.2; vs. Intact: =0.4 mm < 0.1; p<0.001). Additionally, greater translations were observed for LigTorn when compared to that of the LabTorn (LigTorn: 1.4 mm = 0.5 vs. LabTorn: =0.5 +/- 0.3; p<0.001). No differences were observed between the Intact and BothRepaired conditions. Discussion(s): The results of this study indicate that the IF ligaments significantly regulated hip joint stability by limiting external rotation and anterior/posterior translation at varying hip angles (10degree extension, 0degree, 10degree flexion, and 40degree flexion.) The acetabular labrum only has a minor role in the stabilization of the hip during the log roll test and was most effective at limiting external rotation and anterior translation when paired with an intact or repaired IF ligament. These findings have significant clinical implications because they demonstrate that once torn, both the acetabular labrum and IF ligaments can be surgically repaired to restore the native stability observed in the hip. In addition, we recommend to repair the arthroscopic capsulotomy incision to avoid increased hip motion.

Philips, L. A., et al. (2017). "Holographic characterization of contaminants in water: Differentiation of suspended particles in heterogeneous dispersions." Water Research **122**: 431-439.

Determining the size distribution and composition of particles suspended in water can be challenging in heterogeneous multicomponent samples. Light scattering techniques can measure the distribution of particle sizes, but provide no basis for distinguishing different types of particles. Direct imaging techniques can categorize particles by shape, but offer few insights into their composition. Holographic characterization meets this need by directly measuring the size, refractive index, and three-dimensional position of individual particles in a suspension. The ability to measure an individual colloidal particle's refractive index is a unique capability of holographic characterization. Holographic characterization is fast enough, moreover, to build up population distribution data in real time, and to track time variations in the concentrations of different dispersed populations of particles. We demonstrate these capabilities using a model system consisting of polystyrene microbeads co-dispersed with bacteria in an oil-in-water emulsion. We also demonstrate how the holographic fingerprint of different contaminants can contribute to identifying their source.

Phillips, C. (2017). "Discerning ocean plastics: Activist, scientific, and artistic practices." Environment &

Planning A **49**(5): 1146-1162.

For almost 50 years scientists have been drawing attention to marine plastics, working to increase what we know about their incidence and impacts. However, how we come to know things is just as important as what we know. How do oceanic plastics become understood and how does this influence what we decide to do about them? Drawing upon discard studies and cultural geographies, this paper details processes of understanding and problematising marine debris by considering the practices of: an activist working with Indigenous communities to track and manage discarded fishing gear, a scientist investigating the influence of plastics in the lives of sea turtles, and Indigenous artists using oceanic debris as their material. Rather than categorising these knowledge as either lay or scientific, creating a sense of opposition, the concept of traces – material, immaterial, methodological – is employed to foreground the contingency and multiplicity involved. In this way, insight is gained about the materials, embodiments, affects and techniques involved in producing knowledge about oceanic plastics, as well as about how responses to this detritus become articulated and shared with wider publics. [ABSTRACT FROM AUTHOR]

Phillips, M. B. and T. H. Bonner (2015). "Occurrence and amount of microplastic ingested by fishes in watersheds of the Gulf of Mexico." Marine Pollution Bulletin **100**(1): 264-269.

Ingestion of microplastics by fishes could be an emerging environmental crisis because of the proliferation of plastic pollution in aquatic environments. Microplastics in marine ecosystems are well documented, however only one study has reported percent occurrence of microplastics in freshwater fishes. The purpose of this study was to quantify the occurrences and types of microplastics ingested by fishes within several freshwater drainages of the Gulf of Mexico and an estuary of the Gulf of Mexico. Among 535 fishes examined in this study, 8% of the freshwater fishes and 10% of the marine fishes had microplastics in their gut tract. Percentage occurrence of microplastics ingested by fishes in non-urbanized streams (5%) was less than that of one of the urbanized streams (Neches River; 29%). Percent occurrence of microplastics by habitat (i.e., benthic, pelagic) and trophic guilds (herbivore/omnivore, invertivore, carnivore) were similar. Low but widespread occurrences among drainages, habitat guilds, and trophic guilds indicate proliferation of plastic pollution within watersheds of the Gulf of Mexico, but consequences to fish health are unknown at this time.

Phillips, R. A. and C. M. Waluda (2020). "Albatrosses and petrels at South Georgia as sentinels of marine debris input from vessels in the southwest Atlantic Ocean." Environment International **136**: 105443.

Increasing amounts of anthropogenic debris enter the ocean because of mismanagement in coastal communities and, despite a global ban on deliberate dumping, also from vessels, endangering wildlife. Assessing marine plastic pollution directly is challenging, and an alternative is to use seabirds as bioindicators. Our analyses of long time-series (26-years) revealed substantial variation in the amount, characteristics and origin of marine debris (mainly macroplastics and mesoplastics, and excluding fishing gear) associated with seabirds at South Georgia, and, for two species, long-term increases in incidence since 1994. Annual debris recovery rates (items per capita) were 14 x higher in wandering albatrosses Diomedea exulans, and 6 x higher in grey-headed albatrosses Thalassarche chrysostoma and giant petrels Macronectes spp., than in black-browed albatrosses T. melanophris, partly related to differences in egestion (regurgitation), which clears items from the proventriculus. Although some debris types were common in all species, wandering albatrosses and giant petrels ingested higher proportions that were food-related or generic wrapping, gloves, clear or mixed colour, and packaged in South America. This was highly likely to originate from vessels, including the large South American fishing fleets with which they overlap. Debris associated with the two smaller albatrosses was more commonly shorter, rigid (miscellaneous plastic and bottle/tube caps), and packaged in East Asia. Grey-headed albatrosses are exposed to large and increasing amounts of user plastics transported from coastal South America in the Subantarctic Current, or discarded from vessels and circulating in the South Atlantic Gyre, whereas the lower debris ingestion by black-browed albatrosses suggests that plastic pollution in Antarctic waters remains relatively low. Current plastic loads in our study species seem unlikely to have an impact at the population level, but the results nevertheless affirm that marine plastics are a major, trans-boundary animal-welfare and environmental issue that needs to be addressed by much-improved waste-management practices and compliance-monitoring both on land and on vessels in the south Atlantic.

Phuong, L. T., et al. (2017). "The effect of textural attributes on the applicability of gel-based microcapsules as micro delivery system for probiotic bacteria." Acta Microbiologica et Immunologica Hungarica **64 (Supplement 1)**: 178.

Probiotic bacteria are common ingredients used in several food products, such as yogurt or other dairy products, due to their health-promoting effects in humans. For this property to be efficacious, sufficiently high number of viable probiotic cells should reach the large intestine. Cell microencapsulation (micro delivery system) provides a chance for probiotics to keep their viability and beneficial effects by being protected against harmful and often lethal external environment. One of the key issues that affects the efficiency of microencapsulation and the viability of cells is the selection of the capsule material. In this study, a probiotic bacterium (Lactobacillus casei 01) was incorporated into Ca-alginate, kappa-carrageenan-locust bean gum and gellan gum-xanthan gum microbeads. Moreover, the Ca-alginate based microgels were modified by combining with a variety of prebiotic components like lactulose, lactosucrose (LS40L and LS55L) and resistant starch, and by coating with polymers like chitosan and DEAE Sephadex A-50. The study focuses on the texture profile of these gel capsules and its relationship with encapsulation efficiency and viability of the bacteria exposed to simulated complex digestive (acidic and bile) conditions. The texture properties of the microgels were quantified by Brookfield LFRA Texture Analyzer. For obtaining springiness and mechanical strength related information both non-destructive and destructive texture measurements were carried out, respectively. Parameters such as hardness, area cycle, fracture force (brittleness) and adhesive force values were observed in both methods. Based on the statistical analysis of all these parameters, it was found that the resistant starch-alginate and the lactosucrose LS55L-alginate beads are the hardest whereas the gellan gum-xanthan gum and the chitosan coated alginate beads have the softest texture in overall. Pearson correlation analysis highlighted that there is no significant linearity between any of the texture related parameters and the encapsulation efficiency. According to the viability study, the hardest beads showed the most effectiveness at protecting L. casei 01 under simulated complex gastrointestinal conditions; however not the softest ones provided the least protection. Therefore, the texture profile of beads did not appear to have an obvious effect on the viability of enclosed probiotic bacteria under simulated complex gastrointestinal conditions.

Phuong, N. N., et al. (2018). "Microplastic abundance and characteristics in French Atlantic coastal sediments using a new extraction method." Environmental Pollution **243**(Pt A): 228-237.

The ubiquitous presence of microplastics (MPs) has been demonstrated in all environmental compartments in the recent years. They are detected in air, freshwater, soil, organisms and particularly in marine ecosystems. Since sediments are known to be the major sink of many organic and inorganic pollutants, the aim of this study was to develop and validate a fast and cheap methodology to assess the MP contamination in intertidal sediments from the Gulf of Biscay (Pays de la Loire region, France). Sediments were sampled at three locations (Pays de la Loire region, France) and during two seasons: October 2015 and March 2016. The analytical protocol involved MP extraction from dried sediments using milliQ water and a centrifugation technique. After a filtration step of supernatants, MPs were detected and directly identified on the membrane filters using muFTIR spectroscopy in reflection mode. For the first time, the number of replicates allowing to obtain a satisfying representativeness of the whole sampled sediment was also evaluated at 10 replicates of 25g each. The average number of MPs in sediments was 67 (+/-76) MPs/kg dw (N=60) with no significant difference between sites and seasons. Ten different compositions of MPs were defined by muFT-IR with a high proportion of polypropylene (PP) and polyethylene (PE), 38 and 24%, respectively. Among MPs, mainly fragments (84%) were observed with main size classes corresponding to [>100mum] and [50-100mum] but no particles>1mm could be found suggesting that mainly small microplastics (<1mm) were subject to vertical transport.

Phuong, N. N., et al. (2016). "Is there any consistency between the microplastics found in the field and those used in laboratory experiments?" Environmental Pollution **211**: 111-123.

The ubiquitous presence and persistency of microplastics (MPs) in aquatic environments are of particular concern since they represent an increasing threat to marine organisms and ecosystems. Great differences of concentrations and/or quantities in field samples have been observed depending on geographical location around the world. The main types reported have been polyethylene, polypropylene, and polystyrene. The presence of MPs in marine wildlife has been shown in many studies focusing on ingestion and accumulation in different tissues, whereas studies of the biological effects of MPs in the field are scarce. If the nature and abundance/concentrations of MPs have not been systematically determined in field samples, this is due to the fact that the identification of MPs from environmental samples requires mastery and execution of several steps and techniques. For this reason and due to differences in sampling techniques and sample preparation, it remains difficult to compare the published studies. Most laboratory experiments have been performed with MP concentrations of a higher order of magnitude than those found in the field. Consequently, the ingestion and associated effects observed in exposed organisms have corresponded to great contaminant stress, which does not mimic the natural environment. Medium contaminations are produced with only one type of polymer of a precise sizes and homogenous shape whereas the MPs present in the field are known to be a mix of many types, sizes and shapes of plastic. Moreover, MPs originating in marine environments can be colonized by organisms and constitute the sorption support for many organic compounds present in environment that are not easily reproducible in laboratory. Determination of the mechanical and chemical effects of MPs on organisms is still a challenging area of research. Among the potential chemical effects it is necessary to differentiate those related to polymer properties from those due to the sorption/desorption of organic compounds.

Piao, m., et al. (2019). "Research on ecotoxicology of microplastics on freshwater aquatic organisms."

Environmental Pollutants & Bioavailability **31**(1).
As a new type of pollutant, microplastics are an emerging scientific and social concern in the environment and are widely distributed in the aquatic environment and organism. Nowadays, researches on microplastic pollution mainly focus on the marine environment. As a bridge for the migration of microplastics from the terrestrial environment to the marine environment, the freshwater environment has been deserved more attention. Published articles on microplastics in freshwater environments were reviewed in this paper, and four typical behaviors of microplastics were summarized: biological ingestion, biological attachment, adsorption of pollutants and release of plasticizers. In addition, the progress in research and results on the ecological toxicity of microplastics to freshwater organisms was also analyzed. Finally, emphasis on future research on the toxicity of microplastics to freshwater aquatics organisms was made throughout this review as a tool in microplastic risk assessment research.

Piarulli, S., et al. (2019). "Microplastic in wild populations of the omnivorous crab Carcinus aestuarii: a review and a regional-scale test of extraction methods, including microfibres." Environmental Pollution **251**: 117-127.
Microplastic (MP) has become ubiquitous in the marine environment. Its threat to marine organisms has been demonstrated under laboratory conditions, yet studies on wild populations still face methodological difficulties. We reviewed the methods used to separate MP from soft animal tissues and highlighted a lack of standardised methodologies, particularly critical for synthetic microfibres. We further compared enzymatic and a potassium hydroxide (KOH)-based alkaline digestion protocols on wild crabs (Carcinus aestuarii) collected from three coastal lagoons in the north Adriatic Sea and on laboratory-prepared synthetic polyester (PES) of different colour and polypropylene (PP). We compared the cost-effectiveness of the two methods, together with the potential for adverse quantitative or qualitative effects on MP that could alter the capability of the polymers to be recognised via microscopic or spectroscopic techniques. Only 5.5% of the 180 examined crabs contained MP in their gastrointestinal tracts, with a notably high quantitative variability between individuals (from 1 to 117 particles per individual). All MP found was exclusively microfibres, mainly PES, with a mean length (+or-SE) of 0.5+or-0.03 mm. The two digestion methods provided comparable estimates on wild crabs and did not cause any visible physical or chemical alterations on laboratory-prepared microfibres treated for up to 4 days. KOH solution was faster and cheaper compared to the enzymatic extraction, involving fewer procedural steps and therefore reducing the risk of airborne contamination. With digestion times longer than 4 days, KOH caused morphological alterations of some of the PES microfibres, which did not occur with the enzymatic digestion. This suggests that KOH is effective for the digestion of small marine invertebrates or biological samples for which shorter digestion time is required, while enzymatic extraction should be considered as alternative for larger organisms or sample sizes requiring longer digestion times.

Piazza, A., et al. (2001). "Impact of donor-specific antibodies on chronic rejection occurrence and graft loss in renal transplantation: Posttransplant analysis using flow cytometric techniques." Transplantation **71**(8): 1106-1112.
Background. Improvements in immunosuppressive therapy have greatly reduced acute rejection (ARj) episodes, ensuring better short-term graft outcome, but have not modified long-term survival in renal transplantation. It is now well accepted that chronic rejection (CRj) can be determined by both immune and/or nonimmune mechanisms. The aim of this study was to evaluate the importance of the posttransplant humoral immune response towards mismatched HLA graft antigens in CRj occurrence and graft outcome. Methods. Serum samples from 120

nonpresensitized renal transplant recipients were prospectively screened for 1 year after surgery by means of flow cytometry cross-match (FCXM) and FlowPRA beads (microbeads coated with purified HLA class I and class II antigens) assays. All transplants were followed-up for 2 years or until graft removal. Results. FCXM monitoring identified donor-specific antibodies (DS-Abs) in 29 (24.2%) of 120 transplanted patients. Correlation with clinical data highlighted a higher incidence of ARj in DS-Abs-positive patients compared to negative patients (62% vs. 13%, P<0.00001). Furthermore, graft failure occurred more frequently among FCXM-positive patients than among negative patients (34% vs. 1%, P<0.00001). The deleterious effect of DS-Abs on graft function was confirmed by serum creatinine levels 2 years after transplantation. These were in fact higher in subjects producing DS-Abs than in subjects with only ARj (mean creatinine: 2.5+/-1.3 mg/dL vs.1.7+/-0.5 mg/dL, P=0.04). Flow-PRA analysis of DS-Ab HLA specificity highlighted the presence of anti-HLA class I antibodies in 85% of FCXM-positive patients, who also presented with a higher incidence of HLA-B mismatches than FCXM-negative patients (1.23+/-0.66 vs. 0.92+/-0.59, P=0.02). Conclusions. Flow cytometric techniques are precious tools for investigating the activation of the humoral response against HLA antigens of the graft in renal transplantation. DS-Abs production has a worse impact on organ function and survival than ARj episodes. These findings represent further proof of the threat posed by DS-Abs on long-term graft function and draw attention to the need for a specific immunosuppressive therapy aimed at counteracting the different kinds of immune activation toward graft.

Piccoli, G. B. and D. Mery (2017). "Sister Earth, Our Common Home: Toward a Sustainable, Planet Friendly Approach to Dialysis, a Paradigm of High Technology Medicine." Journal of Renal Nutrition **27**(6): 478-484.

In our high-technology, highly polluted world, medicine plays an important role balancing saving lives with the expenses of growing amounts of waste products, not only biologically dangerous (the potentially "contaminated" or "hazardous" waste) but also potentially harmful for the planet (nonrecyclable, plastic waste). Dialysis, the prototype of high-technology medicine, is central to these problems, as the present treatment of about 2 million patients produces an enormous quantity of waste (considering hazardous waste only about 2 kg per session, with 160 sessions per year, that is 320 kg per patient, or about 640,000 tons of hazardous waste per year for 2 million patients, roughly corresponding to 6 nuclear aircraft carriers). Furthermore, obsolete dialysis machines, and water treatments are discharged, adding to the "technological waste." Water produced by the reverse osmosis is also discharged; this is the only nonhazardous, nonpolluting waste, but in particular in dry areas, wasting water is a great ecologic concern. The present review is aimed at discussing strategies already in place and to be further implemented for reducing this particular "uremic toxin" for the earth: dialysis waste, including dialysis disposables, water, and dialysis machines.

Pico, Y., et al. (2020). "Pharmaceuticals, pesticides, personal care products and microplastics contamination assessment of Al-Hassa irrigation network (Saudi Arabia) and its shallow lakes." Science of the Total Environment **701**: 135021.

This study assess the presence of pharmaceutical and personal care products (PPCPs) and pesticides in different environmental compartments and microplastics in water of a characteristic lagoon wetland in Saudi Arabia to establish the transport, accumulation and fate of these pollutants in a water-stressed area under high anthropogenic pressure. In water, diazinon (up to 1016ng L⁻¹), caffeine (up to 20,663ng L⁻¹), diclofenac (up to 1390ng L⁻¹) and paracetamol (up to 3069ng L⁻¹) were at the highest concentrations. The substances with the highest frequency of detection were carbendazim, atorvastatin, caffeine, etoricoxib, lorazepam, metformin, ofloxacin, paracetamol, salicylic acid and tramadol. Considerably less pesticides and PPCPs at concentrations ranging from 0.01 to 126ngg⁻¹ dry weight (d.w.) were detected in the other matrices (sediment>>soil>plants). The concentration of microplastics in water ranged from 0.7 to 7.8 items/L in the Al-Asfar lake and from 1.1 to 9.0 items/L in the Al-Hubail lake. Risk assessment [using hazards quotients (HQ)] was used to highlight pesticides and PPCPs of major ecological concern that should be closely monitored to avoid adverse effects.

Picuno, P. and C. Sica (2004). "Mechanical and spectroradiometrical characteristics of agricultural recycled plastic films." Agricultural Engineering International **6**(04).

The increasing use of plastic materials in agriculture, particularly for protected cultivation, creates at the end of their use a large amount of plastic waste that, if not correctly managed, can produce negative effects on the landscape and on the whole ecosystem; mechanical recycling appears on the other hand one of the more suitable processes for a sound disposal of agricultural plastic films. This paper reports first results of a research project that investigates the possibility to mechanically recycle post-consume agricultural plastic films for the production of new regenerated film. Three different recycled films have been produced, characterized by mechanical tests and spectroradiometrical analysis, and compared to virgin LDPE films. The results show that all these recycled films have worse properties than the virgin material, so confirming that, without improvements in the formulation of blends and additives, the recycling of agricultural film into new regenerated film for agricultural application would remain a solution not interesting from a technical and economical point of view.

Picuno, P., et al. (2012). "Experimental tests and technical characteristics of regenerated films from agricultural plastics." Polymer Degradation and Stability **97**(9): 1654-1661.

Current agricultural practices require the use of large quantities of plastics, which contribute to a significant increase of the quantity and quality of agricultural production, but also require high quantities of plastic waste to be disposed in such way that will not have a negative effect on the landscape and the agro-ecosystem. In this paper the results of an experimental investigation of the possibilities of producing new regenerated plastic films through mechanical recycling, from post-consume agricultural plastic films are analysed. Six recycled films, made from agricultural low tunnel and greenhouse covering films as well as from HDPE bags for agrochemical packaging, have been extruded producing films of different thickness. These regenerated films were characterized by means of mechanical and spectrometric tests and SEM+EDS analysis. The obtained results show that without adding any additives into the blends good mechanical and spectral properties can be achieved by mixing the greenhouse and low tunnel recycled plastic film coverings.

Picuno, P., et al. (2010). "Mechanical properties of structural sections for recycling agricultural plastic film." Colture Protette **39**(6).

The use of plastic material in the European agriculture is continuously increasing; as a direct consequence, large amounts of plastic waste are generated, and they should be disposed in a correct way. The material reutilization through its mechanical recycling is an environmentally friendly alternative for the plastic waste disposal. With the aim to evaluate the mechanical characteristics of plastic products obtained by recycling different polymeric mixtures of agricultural plastic film, experimental tests were performed on different blends of heterogeneous material. New bars with prismatic shape from post-consume agricultural plastic film were produced through mechanical recycling, adding in some cases additives in the waste stream. In this paper the results of laboratory tests on some regenerated profiles are reported and discussed.

Piehl, S., et al. (2018). "Identification and quantification of macro- and microplastics on an agricultural farmland." Scientific Reports **8**(1): 17950.

Microplastic contamination of aquatic ecosystems is a high priority research topic, whereas the issue on terrestrial ecosystems has been widely neglected. At the same time, terrestrial ecosystems under human influence, such as agroecosystems, are likely to be contaminated by plastic debris. However, the extent of this contamination has not been determined at present. Via Fourier transform infrared (FTIR) analysis, we quantified for the first time the macro- and microplastic contamination on an agricultural farmland in southeast Germany. We found 206 macroplastic pieces per hectare and 0.34 +/- 0.36 microplastic particles per kilogram dry weight of soil. In general, polyethylene was the most common polymer type, followed by polystyrene and polypropylene. Films and fragments were the dominating categories found for microplastics, whereas predominantly films were found for macroplastics. Since we intentionally chose a study site where microplastic-containing fertilizers and agricultural plastic applications were never used, our findings report on plastic contamination on a site which only receives conventional agricultural treatment. However, the contamination is probably higher in areas where agricultural plastic applications, like greenhouses, mulch, or silage films, or plastic-containing fertilizers (sewage sludge, biowaste composts) are applied. Hence, further research on the extent of this contamination is needed with special regard to different cultivation practices.

Piera-Velazquez, S., et al. (2015). "Paracrine effect of proteins secreted by normal lung microvascular endothelial cells undergoing endothelial mesenchymal transition on the expression of genes associated with tissue fibrosis in normal human lung fibroblasts." Arthritis and Rheumatology. Conference: American College of Rheumatology/Association of Rheumatology Health Professionals Annual Scientific Meeting, ACR/ARHP **67**(SUPPL. 10).

Background/Purpose: Progressive tissue fibrosis and microvascular alterations are the hallmarks of Systemic Sclerosis (SSc). The mechanisms involved in SSc pathogenesis are complex and have not been fully elucidated. One notable feature of SSc is the extension of the pathologic process to normal tissues. The mechanisms involved in this topographic extension have remained elusive. Recent studies suggested that the phenotypic transition of endothelial cells (EC) into mesenchymal cells (endothelial to mesenchymal transition; EndoMT) may be involved in the progressive tissue fibrosis and fibroproliferative vasculopathy in SSc although the mechanisms involved have not been elucidated. We here suggest that one potential mechanism may be that EndoMT activated EC exert paracrine effects on normal/healthy fibroblasts and EC and induce them to express a profibrotic phenotype and transdifferentiate into activated profibrotic cells. The purpose of the study was to evaluate whether secreted molecules released by microvascular lung EC undergoing EndoMT exert paracrine effects on normal human pulmonary fibroblasts inducing them to become profibrotic. Method(s): Normal human lung fibroblasts and microvascular EC were isolated from normal lung tissues by enzymatic digestion with collagenase. The isolated cell suspension was incubated with CD45 microbeads to remove leukocytes. Fibroblasts and EC were isolated employing anti-human CD31 antibody magnetic beads. The CD31- fibroblasts and the CD31+ EC were expanded separately. For EndoMT induction the lung microvascular EC were treated with TGF-beta1 or TGF-beta2 for 48 h. Following a change of media to serum-free media for 24h the supernatants were collected and aliquotes added to triplicate wells of normal human lung fibroblasts. After 24h, culture

supernatants were isolated for Western blot analysis. The cells were lysed and total fibroblast RNA isolated and cDNA generated. Expression of various fibrosis-associated +genes was assessed by quantitative real time PCR. Validation of the gene expression results was performed employing Western blot analysis of secreted and intracellular proteins. Result(s): RTPCR results showed a marked increase in levels of COL1A2, COL3A1, FN1, CTGF and TGFbeta1 mRNA in normal lung fibroblasts treated with supernatants from normal lung microvascular EC pretreated with TGF-beta1 or TGF-beta2 compared to medium from untreated EC. Increased amounts of fibronectin were found in the media of lung fibroblasts treated with supernatants from the lung microvascular EC treated with TGF-beta1 or TGF-beta2. Conclusion(s): Treatment of normal lung fibroblasts with proteins released by cultured human lung microvascular EC induced to undergo EndoMT in vitro resulted in a profound change in the expression of numerous profibrotic genes. The results demonstrated potent paracrine effects of EndoMT-activated lung microvascular EC on normal target lung fibroblasts and suggest a novel mechanism for the progression of SSc-associated pulmonary fibrosis.

Pieszczek, L. and M. Daszykowski (2019). "Improvement of recyclable plastic waste detection - A novel strategy for the construction of rigorous classifiers based on the hyperspectral images." Chemometrics and Intelligent Laboratory Systems **187**: 28-40.

The objective of our study was to evaluate the advantages of the proposed validation framework for a rigorous one-class classifier that operates on the large sets of multivariate pixels that are obtained using the hyperspectral imaging technique that are considered to be individual samples. The performance of the validation strategy was evaluated experimentally using the hyperspectral images of post-consumer waste polymers (high-density polyethylene and polypropylene), which have very similar physico-chemical properties. Rigorous classification models using the partial least squares approach were constructed for the training samples from modeled groups of polymer items. Their aim was to support the process of sorting polymer waste items and to potentially provide a framework to construct an intelligent laboratory system. The results that were obtained in this study provide evidence that the pixel-based approach improves classification in terms of sensitivity and specificity. The models that described high-density polyethylene polymer items and that were built to represent individual pixels were characterized by a sensitivity of more than 98.6% and a specificity of more than 99.5%, whereas the models that were constructed for the polypropylene polymer items had a sensitivity of more than 93.4% and a specificity of more than 99.9%. Copyright © 2019 Elsevier B.V.

Pimenova, M., et al. (2012). "Cytogenetic characteristic of mesenchymal and hematopoetic progenitor cells in myelodysplastic syndromes and acute myeloid leukemias with myelodysplasia-related changes." Blood. Conference: 54th Annual Meeting of the American Society of Hematology, ASH **120**(21).

Background: Abnormal karyotype in bone marrow (BM) cells is detected in 30-70% of patients with myelodysplastic syndromes (MDS) and acute myeloid leukemias with myelodysplasia-related changes (AML). The same cytogenetic abnormalities are found in isolated CD34+ hematopoetic progenitor cells (HPCs) of these patients. According to recent studies cytogenetic abnormalities are described in 10-70% MDS and AML patients in BM derived mesenchymal stromal cells (MSCs) [Flores-Figueroa et al. 2008, Blau et al. 2011]. These abnormalities can be clonal and nonclonal (spontaneous). The goal of the study was to characterize and compare the cytogenetic changes in BM derived MSCs and in CD34+ HPCs isolated from BM and peripheral blood (PB) in MDS and AML patients. Patients and Methods: The data from 35 patients is presented: 6 pts with AML (1 pt with therapy-related AML), 29 pts

with MDS (refractory anemia - 4 pts, refractory cytopenia with multilineage dysplasia - 13 pts, refractory anemia with ringed sideroblasts - 2 pts, refractory anemia with excess blasts - 7 pts, 5q-syndrome - 3 pts). Median age was 60 years (range 19 to 77). Patients' assignment to different groups was made according to the 2008 World Health Organization (WHO) classification. Cytogenetic analysis was performed using G-banding and FISH. MSCs were derived from bone marrow mononuclear cells then plated in 75 cm3flacks and harvested after 2-5 passages. CD34+ HPCs were collected from BM and PB by magnetic separation with anti-CD34 MicroBead Kit human (Miltenyi Biotec). Result(s): BM karyotype was normal in 17 pts, cytogenetic abnormalities were found in 18 pts - 4 AML and 14 MDS: in 9 pts (2 AML/7 MDS) - isolated del(5q), monosomy 7, i(14), inv(3) or trisomy 8; in 8 pts (2 AMl/6 MDS) - two or more abnormalities; and 1 pt displayed only constitutional abnormality (inv(9)(p13q21)). It is worth to note that routine cytogenetic analysis didn't present any mitosis in 3 MDS pts however FISH analysis revealed del(5) and del(7) simultaneously in one of these pts, trisomy 8 in one pt and normal karyotype in another one pt. Cytogenetic analysis of MSCs was carried out in 23 pts - 4 AML and 19 MDS pts. BM karyotype was normal in 10 pts and abnormal in 13 pts. Karyotype in MSCs was normal in all AML pts and in 16 MDS pts. There were cytogenetic changes in 3 MDS pts: in 1 pt - constitutional inversion (inv9(p13q21)), in 1 pt - nonclonal translocation and constitutional inversion (46XY,t(2;22)(p10;q11),inv(9)(p13q21)[1]/46XY,inv(9)(p13q21)[19]) and in 1 pt - clonal abnormalities (46XY,add(2q)[7]/46XY[13]). Patient with clonal cytogenetic abnormalities in MSCs had complex karyotype in BM (45-46XY,-5,-13,der(19),add(q13?or p13?),-20,+marx2,+mar del(13q21)?[15]/45-46XY idem, +dmin[2]/46XY[3]), but these changes were different. Constitutional inversion was confirmed in both cases by cytogenetic analysis in PB lymphocytes. FISH analysis was performed in CD 34+ HPCs magnetically isolated from BM and PB in 24 pts. Fourteen of these pts had normal BM karyotype and we confirmed that using FISH with LSI (5q33-q34), LSI (7q31)/CEP 7, CEP 8 (Vysis). We used the same DNA probes for evaluation of CD34+ HPCs from BM and PB in pts with normal BM karyotype. We used FISH in 10 pts with ascertained cytogenetic abnormalities in BM to confirm these findings with DNA probes LSI (5q33-q34), LSI (7q31)/CEP 7, CEP 8, LSI AML1/ETO, CEP X/CEP Y, LSI (20q12) (Vysis). FISH analysis didn't reveal any aberration in BM and PB CD34+ HPCs in patients with normal BM karyotype. In pts with distinguished abnormalities in BM the same pattern was demonstrated by FISH in CD34+ HPCs. We counted the percent of abnormal nuclei per 200. The means of percentages by FISH of BM, BM CD 34+ HPCs and PB CD34+ HPCs didn't differ and constituted 65.8%, 73.1% and 74.8% respectively. Conclusion(s): Cytogenetic analysis in MSCs revealed aberrations only in MDS patients (3 from 16). No cytogenetic abnormalities in MSCs in AML pts was found. Karyotype in MSCs didn't coincide with BM karyotype in the same patients. Hematopoetic progenitor cells from BM and PB of MDS and AML patients displayed the same cytogenetic abnormalities as the full population of bone marrow cells. The data shows that hematopoetic and mesenchymal precursors in MDS and AML are cytogenetically distinct.

Pinet, O., et al. (2008). "Glass matrices for immobilizing nuclear waste containing molybdenum and phosphorus." Journal of Nuclear Materials **377**(2): 307-312.

Vitrification has been selected in France as the process for immobilizing high-level waste arising from spent fuel reprocessing. Some high-level solutions generated by reprocessing legacy fuel contain high molybdenum concentrations. Molybdenum is known to be sparingly soluble in conventional borosilicate glass, and work is in progress to find suitable glass formulations for such waste. The results of a basic study to identify borosilicate glasses composition zones of potential interest are discussed. A vast composition range was investigated by defining a fine mesh. The limits considered to delimit the range of the study were intentionally extended to identify formulations such as SiO2-B2O3-Al2O3-Na2O-P2O5 that are of interest for vitrifying molybdenum-rich waste. Observation of more than 50 tested mixtures revealed two composition zones of potential interest. One forms a homogeneous glass after melting at 1300 °C and rapid cooling; the other vitreous material comprises unconnected microbeads uniformly dispersed in a borosilicate glass.

Pinheiro, L. M., et al. (2019). "Do beachrocks affect microplastic deposition on the strandline of sandy beaches?" Marine Pollution Bulletin **141**: 569-572.

The strandline is one of the first deposition habitats of microplastics before they are integrated to the beach as a standing stock or finally removed. Beaches, entirely or partially protected by beachrocks, have different sediment dynamics and therefore may present variation in microplastic deposition. The aim of this work was to test if protected and unprotected (i.e., exposed to waves) areas of a sandy beach present different microplastic accumulation on the strandline - a habitat greatly influenced by both water and sediment dynamics. Microplastic (MP) amounts were significantly higher at the protected area (M_{protected}=642.6+/-514.8 MP m⁻², M_{exposed}=130.6+/-126.8 MP m⁻², Mann-Whitney U test, U=14.5, p=0.0009), showing that beachrocks influence microplastic accumulation on the beach face. Therefore, hard structures parallel to the beach may also affect microplastics deposition on beach sediments, being important to consider these structures on microplastic surveys.

Pinho, D., et al. (2017). "In vitro particulate analogue fluids for experimental studies of rheological and hemorheological behavior of glucose-rich RBC suspensions." Biomicrofluidics **11**(5): 054105.

Suspensions of healthy and pathological red blood cells (RBC) flowing in microfluidic devices are frequently used to perform in vitro blood experiments for a better understanding of human microcirculation hemodynamic phenomena. This work reports the development of particulate viscoelastic analogue fluids able to mimic the rheological and hemorheological behavior of pathological RBC suspensions flowing in microfluidic systems. The pathological RBCs were obtained by an incubation of healthy RBCs at a high concentration of glucose, representing the pathological stage of hyperglycaemia in diabetic complications, and analyses of their deformability and aggregation were carried out. Overall, the developed in vitro analogue fluids were composed of a suspension of semi-rigid microbeads in a carrier viscoelastic fluid made of dextran 40 and xanthan gum. All suspensions of healthy and pathological RBCs, as well as their particulate analogue fluids, were extensively characterized in steady shear flow, as well as in small and large amplitude oscillatory shear flow. In addition, the well-known cell-free layer (CFL) phenomenon occurring in microchannels was investigated in detail to provide comparisons between healthy and pathological in vitro RBC suspensions and their corresponding analogue fluids at different volume concentrations (5% and 20%). The experimental results have shown a similar rheological behavior between the samples containing a suspension of pathological RBCs and the proposed analogue fluids. Moreover, this work shows that the particulate in vitro analogue fluids used have the ability to mimic well the CFL phenomenon occurring downstream of a microchannel contraction for pathological RBC suspensions. The proposed particulate fluids provide a more realistic behavior of the flow properties of suspended RBCs when compared with existing non-particulate blood analogues, and consequently, they are advantageous for detailed investigations of microcirculation.

Pinky, R., et al. (2019). "Antimicrobial activity of potato starch-based active biodegradable nanocomposite films." Potato Research **62**(1): 69-83.

Food-borne pathogens such as Escherichia coli (E. coli) and Staphylococcus aureus (S. aureus) create a lot of problems worldwide and are a major concern of food producers and consumers. To protect the food from spoilage due to these bacteria, antimicrobial packaging is one of the most promising active packaging systems. Environmental concerns associated with plastic waste emphasized the development of packaging films from natural polymers such as starch. Therefore, in the present study, potato starch-based biodegradable and antimicrobial nanocomposite films were prepared with constant concentration of zinc oxide nanoparticles using casting method. Films were prepared using three antimicrobial agents, cinnamon oil, clove oil, and potassium sorbate and were tested against four microbes, S. aureus, E. coli, Salmonella typhi (S. typhi), and Campylobacter jejuni (C. jejuni). The films prepared with clove oil were most effective against S. aureus (22-100% inhibition), those prepared with cinnamon oil were effective against C. jejuni (19-22% inhibition) and growth of E. coli was inhibited (33-40% inhibition) to maximum extent by potassium sorbate incorporated films. However, for complete inhibition of C. jejuni and E. coli, higher concentrations of cinnamon oil and potassium sorbate are required. Increasing concentration of antimicrobial agents decreased the tensile strength of the films. Tensile strength decreased up to 13% in cinnamon oil films, 23% in clove oil films and up to 34% in potassium sorbate incorporated films. Based on the results, it can be concluded that cinnamon oil is a better antimicrobial agent due to its least effect on tensile strength and also due to its antibacterial effect against the three bacteria.

Pinochet, J., et al. (2019). "Marine invertebrate larvae love plastics: Habitat selection and settlement on artificial substrates." Environmental Pollution: 113571.

Global urbanization and plastic pollution has increased the availability and variety of substrates for sessile organisms, and are intensively used by invasive species for settlement. Despite extensive literature describing the strong association between artificial structures and invasive species, little effort has been directed towards identifying the larval traits that favor this selection. Larval selection and settlement are crucial as larvae actively search and interpret environmental cues to identify suitable habitats to settle. The aim of this research was to investigate if invertebrate larvae have a preference for a particular anthropogenic substrate, and how pre-settlement behaviors vary when encountering different substrates. We used two invasive bryozoan species, Bugula flabellata and Bugula neritina, which are commonly found in urbanized areas around the world. Energy expenditure during planktonic and benthonic stages, pre-settlement swimming/exploring behaviors, settlement and larval selectivity were quantified under laboratory conditions on different substrates (concrete, wood, polystyrene, polyvinyl chloride, polyethylene terephthalate and polycarbonate). The energy expenditure measured was higher in planktonic larvae than in early settled larvae. Larvae of both species swam less and explored more when exposed to plastic surfaces, suggesting a preference for this substrate and resulting in lower energy expenditures associated with searching for habitat. Larvae actively chose to settle on plastics rather than on wood or concrete substrates. The results suggest that for Bugula larvae, the likelihood of colonizing plastic surfaces is higher than other materials commonly found in urbanized coastal areas. The more quickly they adhere to artificial substrates the lower the energy expenditure, contributing to higher fitness in these individuals. The strong preference of invertebrate larvae for plastics can potentially extend the distribution range of many invasive marine species as they are able to travel long distances attached to floating debris. This phenomenon will likely exacerbate the introduction of exotic species into novel habitats.

Pinto da Costa, J., et al. (2019). "Micro(nano)plastics - Analytical challenges towards risk evaluation."

TrAC - Trends in Analytical Chemistry **111**: 173-184.
The quantification of micro- and nanoplastics in environmental matrices is an analytical challenge and pushes to the use of unrealistic high exposure concentrations in laboratory studies which can lead to manifestations of ecotoxicological effects and risks estimation that are transient under natural conditions. Moreover, in field studies, it is difficult to compare the data obtained due to the lack of sampling protocols, standardized methodologies and techniques for the identification and quantification of micro- and nanoplastics, owing to the inherent physical characteristics of the these materials. Also, the definition of exposure limits is difficult due to the challenge of analytical methodologies. Therefore, this paper aims to characterize the existent analytical challenges in each step from isolation to quantification of nano- and microplastics and their consequences in the estimation of risks. Piotrowski, K., et al. (2011). "Assessment of resolution of molecular mosaic aneuploidy detection in molecular karyotyping technique by BACs-on-BEADSTM system." Chromosome Research **1)**: S221-S222.
Classical methods of prenatal diagnosis in amniocyte cultures have several disadvantages, particularly long time to the final diagnosis. Therefore, new methods of molecular karyotyping from amniocyte DNA without cell cultivation have been introduced. The BACS-on- BEADSTM technique is a relatively new method of molecular karyotyping, performed using multiplex BAC probes localized on microbeads, employing a small amount DNA (~50 ng) and giving a result within 24 h. This method reveals in one run simultaneously all classical aneuploidies and classical microdeletions. For this relatively short time of employment, there are limited data of resolution of this technique for mosaic detection. We performed several analyses of this resolution by producing "artificial" mosaics by admixture of amniocyte DNA with trisomies 13, 18 and 21 confirmed by classical methods with DNA of normal controls with measured proportion of 12.5%, 25%, 30%, 50%and 75% admixture of trisomic DNA to total DNA. DNA from amniotic cells was extracted using QIAamp DNA Blood Mini Kit samples. D concentrations were measured by a spectrophotometer Lambda Bio Plus and in all cases normalized. The level of detection differs between particular trisomies; in trisomy 21, this method regularly detects trisomy whether the concentration of trisomic DNA is 30% (in some but not all cases in 25% and rarely in 12.5%). In trisomies 13 and 18, the borderline of detection is higher and in both stays at the level of 50%.

Piskin, E., et al. (1996). "Protein A carrying monosize PMMA microbeads for the removal of HIgG from human plasma." International Journal of Artificial Organs **19**(5): 311-317.
Protein A-incorporated polymethylmethacrylate (PMMA) microbeads were investigated for specific removal of HIgG from human plasma. The microbeads were prepared by a phase inversion polymerization, and activated by periodate oxidation. Protein A was then incorporated by covalent binding onto these microbeads through hydroxyl groups coming from the stabilizer. The amount of incorporated protein A was controlled by the initial concentrations of protein A in the immobilization medium and pH. The maximum protein A immobilization of 0.615 mg protein A/g PMMA, was observed at a pH of 9.5 corresponding to an initial protein A concentration of 0.1 mg/ml. There was no HIgG adsorption onto the plain PMMA microbeads, while high HIgG adsorptions of up to 32 mg HIgG/g PMMA were achieved with human plasma.

Pita, F. and A. Castilho (2017). "Separation of plastics by froth flotation. The role of size, shape and density of the particles." Waste Management **60**: 91-99.
Over the last few years, new methods for plastic separation in mining have been developed. Froth flotation is one of these techniques, which is based on hydrophobicity differences

between particles. Unlike minerals, most of the plastics are naturally hydrophobic, thus requiring the addition of chemicals that promote the selective wettability of one of its components, for a flotation separation. The floatability of six granulated post-consumer plastic - Polystyrene (PS), Polymethyl methacrylate (PMMA), Polyethylene Terephthalate (PET-S, PET-D) and Polyvinyl Chloride (PVC-M, PVC-D) - in the presence of tannic acid (wetting agent), and the performance of the flotation separation of five bi-component plastic mixtures - PS/PMMA, PS/PET-S, PS/PET-D, PS/PVC-M and PS/PVC-D - were evaluated. Moreover, the effect of the contact angle, density, size and shape of the particles was also analysed.

Pitryuk, A. P., et al. (1974). "Microbial respiration in model porous systems." Pochvovedenie **8**: 131-136.
Glass micro beads (140 mu) placed in liquid nutrient medium stimulated bacterial respiration more than they stimulated yeast and fungal respiration. Larger beads (900 mu) stimulated yeast and fungal respiration more than they stimulated bacterial respiration. Microbial respiration in films of water on micro beads was greater on the small than on the large beads.

Pitt, J. A., et al. (2018). "Uptake, tissue distribution, and toxicity of polystyrene nanoparticles in developing zebrafish (Danio rerio)." Aquatic Toxicology **194**: 185-194.
Plastic pollution is a critical environmental concern and comprises the majority of anthropogenic debris in the ocean, including macro, micro, and likely nanoscale (less than 100 nm in at least one dimension) plastic particles. While the toxicity of macroplastics and microplastics is relatively well studied, the toxicity of nanoplastics is largely uncharacterized. Here, fluorescent polystyrene nanoparticles (PS NPs) were used to investigate the potential toxicity of nanoplastics in developing zebrafish (Danio rerio), as well as to characterize the uptake and distribution of the particles within embryos and larvae. Zebrafish embryos at 6 h post-fertilization (hpf) were exposed to PS NPs (0.1, 1, or 10 ppm) until 120 hpf. Our results demonstrate that PS NPs accumulated in the yolk sac as early as 24 hpf and migrated to the gastrointestinal tract, gallbladder, liver, pancreas, heart, and brain throughout development (48-120 hpf). Accumulation of PS NPs decreased during the depuration phase (120-168 hpf) in all organs, but at a slower rate in the pancreas and gastrointestinal tract. Notably, exposure to PS NPs did not induce significant mortality, deformities, or changes to mitochondrial bioenergetics, but did decrease the heart rate. Lastly, exposure to PS NPs altered larval behavior as evidenced by swimming hypoactivity in exposed larvae. Taken together, these data suggest that at least some nanoplastics can penetrate the chorion of developing zebrafish, accumulate in the tissues, and affect physiology and behavior, potentially affecting organismal fitness in contaminated aquatic ecosystems.

Pitt, J. A., et al. (2018). "Maternal transfer of nanoplastics to offspring in zebrafish (Danio rerio): a case study with nanopolystyrene." Science of the Total Environment **643**: 324-334.
Plastics are ubiquitous anthropogenic contaminants that are a growing concern in aquatic environments. The ecological implications of macroplastics pollution are well documented, but less is known about nanoplastics. The current study investigates the potential adverse effects of nanoplastics, which likely contribute to the ecological burden of plastic pollution. To this end, we examined whether a dietary exposure of adult zebrafish (Danio rerio) to polystyrene nanoparticles (PS NPs) could lead to the transfer of nanoplastics to the offspring, and whether nanoplastics exposure affects zebrafish physiology. Specifically, adult female and male zebrafish (F0 generation) were exposed to PS NPs via diet for one week and bred to produce the F1 generation. Four F1 groups were generated: control (unexposed females and males), maternal (exposed females), paternal (exposed males), and co-parental (exposed males and females).

Co-parental PS NP exposure did not significantly affect reproductive success. Assessment of tissues from F0 fish revealed that exposure to PS NPs significantly reduced glutathione reductase activity in brain, muscle, and testes, but did not affect mitochondrial function parameters in heart or gonads. Assessment of F1 embryos and larvae revealed that PS NPs were present in the yolk sac, gastrointestinal tract, liver, and pancreas of the maternally and co-parentally exposed F1 embryos/larvae. Bradycardia was also observed in embryos from maternal and co-parental exposure groups. In addition, the activity of glutathione reductase and the levels of thiols were reduced in F1 embryos/larvae from maternal and/or co-parental exposure groups. Mitochondrial function and locomotor activity were not affected in F1 larvae. This study demonstrates that (i) PS NPs are transferred from mothers to offspring, and (ii) exposure to PS NPs modifies the antioxidant system in adult tissues and F1 larvae. We conclude that PS NPs could bioaccumulate and be passed on to the offspring, but this does not lead to major physiological disturbances.

Pivnenko, K., et al. (2016). "Recycling of plastic waste: Presence of phthalates in plastics from households and industry." Waste Management **54**: 44-52.

Plastics recycling has the potential to substitute virgin plastics partially as a source of raw materials in plastic product manufacturing. Plastic as a material may contain a variety of chemicals, some potentially hazardous. Phthalates, for instance, are a group of chemicals produced in large volumes and are commonly used as plasticisers in plastics manufacturing. Potential impacts on human health require restricted use in selected applications and a need for the closer monitoring of potential sources of human exposure. Although the presence of phthalates in a variety of plastics has been recognised, the influence of plastic recycling on phthalate content has been hypothesised but not well documented. In the present work we analysed selected phthalates (DMP, DEP, DPP, DiBP, DBP, BBzP, DEHP, DCHP and DnOP) in samples of waste plastics as well as recycled and virgin plastics. DBP, DiBP and DEHP had the highest frequency of detection in the samples analysed, with 360mug/g, 460mug/g and 2700mug/g as the maximum measured concentrations, respectively. Among other, statistical analysis of the analytical results suggested that phthalates were potentially added in the later stages of plastic product manufacturing (labelling, gluing, etc.) and were not removed following recycling of household waste plastics. Furthermore, DEHP was identified as a potential indicator for phthalate contamination of plastics. Close monitoring of plastics intended for phthalates-sensitive applications is recommended if recycled plastics are to be used as raw material in production.

Pivnenko, K., et al. (2017). "Recycling of plastic waste: Screening for brominated flame retardants (BFRs)." Waste Management **69**: 101-109.

Flame retardants are chemicals vital for reducing risks of fire and preventing human casualties and property losses. Due to the abundance, low cost and high performance of bromine, brominated flame retardants (BFRs) have had a significant share of the market for years. Physical stability on the other hand, has resulted in dispersion and accumulation of selected BFRs in the environment and receiving biota. A wide range of plastic products may contain BFRs. This affects the quality of waste plastics as secondary resource: material recycling may potentially reintroduce the BFRs into new plastic product cycles and lead to increased exposure levels, e.g. through use of plastic packaging materials. To provide quantitative and qualitative data on presence of BFRs in plastics, we analysed bromophenols (tetrabromobisphenol A (TBBPA), dibromophenols (2,4- and 2,6-DBP) and 2,4,6-tribromophenol (2,4,6-TBP)), hexabromocyclododecane stereoisomers (alpha-, beta-, and gamma-HBCD), as well as selected

polybrominated diphenyl ethers (PBDEs) in samples of household waste plastics, virgin and recycled plastics. A considerable number of samples contained BFRs, with highest concentrations associated with acrylonitrile butadiene styrene (ABS, up to 26,000,000ngTBBPA/g) and polystyrene (PS, up to 330,000ngHBCD/g). Abundancy in low concentrations of some BFRs in plastic samples suggested either unintended addition in plastic products or degradation of higher molecular weight BFRs. The presence of currently restricted flame retardants (PBDEs and HBCD) identified in the plastic samples illustrates that circular material flows may be contaminated for extended periods. The screening clearly showed a need for improved documentation and monitoring of the presence of BFRs in plastic waste routed to recycling.

Pivokonsky, M., et al. (2018). "Occurrence of microplastics in raw and treated drinking water." Science of the Total Environment **643**: 1644-1651.

The study investigates the content of microplastic particles in freshwater and drinking water. Specifically, three water treatment plants (WTPs) supplied by different kinds of water bodies were selected and their raw and treated water was analysed for microplastics (MPs). Microplastics were found in all water samples and their average abundance ranged from 1473+/-34 to 3605+/-497particlesL⁻¹ in raw water and from 338+/-76 to 628+/-28particlesL⁻¹ in treated water, depending on the WTP. This study is one of very few that determine microplastics down to the size of 1mum, while MPs smaller than 10mum were the most plentiful in both raw and treated water samples, accounting for up to 95%. Further, MPs were divided into three categories according to their shape. Fragments clearly prevailed at two of the WTPs and fibres together with fragments predominated at one case. Despite 12 different materials forming the microplastics being identified, the majority of the MPs (>70%) comprised of PET (polyethylene terephthalate), PP (polypropylene) and PE (polyethylene). This study contributes to fill the knowledge gap in the field of emerging microplastic pollution of drinking water and water sources, which is of concern due to the potential exposure of microplastics to humans.

Piyadeatsoontorn, S., et al. (2019). "Encapsulating Viability of Multi-strain Lactobacilli as Potential Probiotic in Pigs." Probiotics & Antimicrobial Proteins **11**(2): 438-446.

Important aspects of the selection of probiotics to be used for mixing in animal feed include host species specificity and probiotic cell survival during production and storage of their products. The research was to screen and investigate some probiotic properties of lactic acid bacteria (LAB) isolated from pig fecal samples. One hundred and thirty-eight representative LAB isolates, which were isolated from 51 pig fecal samples, were tested for acid and bile tolerance, antimicrobial susceptibility, antibacterial activity, potential adhesion to the cell surface, and survival rates when stored in varied microencapsulation forms: freeze-dried, spray-dried, and micro-beads. The antibacterial activity results of the ten LAB isolates, which were acid- (pH 2, 3 h) and bile- (50% (v/v) fresh pig bile, 8 h) tolerant and suitable for resisting the five antibiotics commonly used for treating pig infections with pathogenic indicator strains, showed that three isolates (L21, L80, L103) had strong inhibition to Escherichia coli, Salmonella group B, and Salmonella group D using co-culturing and agar spot assays. The three isolates had high hydrophobicity (65-73%) and did not show antagonistic growth against each other. All three selected isolates had greater than 80% survival in freeze-dried and micro-bead forms at 25-30 degreeC after 2 days of storage (80.4-86.75%, 7.31-7.89 log CFU/ml). Sequence analysis of the 16S rRNA genes demonstrated that the three isolates belong to Lactobacillus plantarum (strain L21 and strain L80) and L. paraplantarum (strain L103). The single and multiple strains of these

bacteria may have potential use as probiotics in pig diets.

Planus, E., et al. (2005). "Apical rigidity of an epithelial cell monolayer evaluated by magnetic twisting cytometry: ICAM-1 versus integrin linkages to F-actin structure." Clinical Hemorheology & Microcirculation **33**(3): 277-291.

Using Magnetic Twisting Cytometry (MTC) technique, we attempted to characterize in vitro the rigidity of the lining tissue covering the lung alveolar wall from its apical face. We purposely used a cellular model constituted by a monolayer of human alveolar epithelial cell (A549) over which microbeads, fixed to InterCellular Adhesion Molecule (ICAM-1), exert a controlled mechanical stress. ICAM-1 expression was induced by Tumor Necrosis Factor-alpha (TNF-alpha). Rigidity measurements, performed in the course of cytochalasin D depolymerization, reveal the force transmitter role of the transmembrane receptor ICAM-1 and demonstrate that ICAM-1 and F-actin linkages confers mechanical rigidity to the apical face of the epithelial cell monolayer resembling that provided by integrins. These results confirm the ability of MTC in identifying transmembrane mechanoreceptors in relation with F-actin. Molecular linkages between ICAM-1 and F-actin were observed by spatial visualisations of the structure after double staining of F-actin and anti ICAM-1 antibody through confocal microscopy.

Plaseied, A., et al. (2017). "Self-Healing Coatings to Mitigate Post-Impact Corrosion." Corrosion **73**(9): 1091-1097.

Self-healing polymeric coatings have offered tremendous potential for repairing damage and extending the service life and safety of metallic structures. There have been many challenges associated with the catalyst activated version of the self-healing oligomer filled microcapsule coating additives (or microbeads) technology, but a non-catalyst version appears more promising. The objective ofthis study was to identify the effect of self-healing coatings in an epoxy coating system containing the non-catalyst microbeads on post-impact corrosion mitigation of water infrastructure. Experimental results showed that coatings containing microbeads did not fully prevent corrosion of the post-impact exposed metal substrate over the exposure period for this study, especially in salt fog and immersion conditions. However, this coating showed less coating degradation compared to the coating without the presence of microbeads.

Pliszka, S. R., et al. (2017). "Efficacy and Safety of HLD200, Delayed-Release and Extended-Release Methylphenidate, in Children with Attention-Deficit/Hyperactivity Disorder." Journal of Child and Adolescent Psychopharmacology **27**(6): 474-482.

Objective: Evening-dosed HLD200 is a delayed-release and extended-release methylphenidate (DR/ER-MPH) formulation consisting of uniform, dual-layered microbeads with an inner drug-loaded core. DR/ER-MPH is designed to delay the initial release of drug by 8-10 hours, and thereafter, provide a controlled, extended drug release to target onset of effect upon awakening that lasts into the evening. This phase 3 study evaluated the safety and efficacy of DR/ER-MPH on symptoms and temporal at-home functional impairment in children with attention-deficit/hyperactivity disorder (ADHD). Method(s): This 3-week, randomized, double-blind, multicenter, placebo-controlled, parallel-group, forced-dose titration trial evaluated DR/ER-MPH (40-80 mg/day) in children aged 6-12 years with ADHD. Primary efficacy endpoint was the ADHD rating scale-IV (ADHD-RS-IV), and the key secondary endpoints were the Before-School Functioning Questionnaire (BSFQ), and Parent Rating of Evening and Morning Behavior-Revised, morning (PREMB-R AM) and evening (PREMB-R PM). Safety measures included spontaneously reported treatment-emergent adverse events (TEAEs) and two TEAEs of special interest, appetite suppression and insomnia (with direct questioning on sleep disturbance). Result(s): One hundred sixty-one participants were included in the intent-to-treat population (DR/ER-MPH, n = 81; placebo, n = 80). After 3 weeks, DR/ER-MPH achieved significant improvements versus placebo in ADHD symptoms (least-squares [LS] mean ADHD-RS-IV: 24.1 vs. 31.2; p = 0.002), and at-home early morning (LS mean BSFQ: 18.7 vs. 28.4; p < 0.001; LS mean PREMB-R AM: 2.1 vs. 3.6; p < 0.001) and late afternoon/evening (LS mean PREMB-R PM: 9.4 vs. 12.2; p = 0.002) functional impairment. Commonly reported TEAEs (>=10%) were insomnia and decreased appetite. Conclusion(s): DR/ER-MPH was generally well tolerated and demonstrated significant improvements versus placebo in ADHD symptoms and at-home functional impairments in the early morning, late afternoon, and evening in children with ADHD. Pochechueva, T., et al. (2014). "PEGylation of microbead surfaces reduces unspecific antibody binding in glycan-based suspension array." Journal of Immunological Methods **412**: 42-52.

Glycan-based suspension array (SGA) is an "in-house" developed multi-target immunoassay, employing commercially available fluorescent microbeads as a solid support for unique chemically synthesized glycopolymers which capture naturally occurring human anti-glycan antibodies. SGA is a sensitive and reliable tool for the high-throughput screening of anti-glycan antibody alterations characteristic for a vast number of human diseases including cancer. However, unspecific background binding, for instance binding of non-target antibodies, is a common obstacle in such immunoassays. In an attempt to reduce unspecific background binding of serum (or plasma) antibodies, we prepared glycosylated microbeads modified with linear poly(ethylene glycols) (PEGs) of different lengths. We compared several kinds of PEG modifications: (a) partial side-chain substitution of glycopolymers by PEGs of different lengths, (b) end-point addition of biotin-linked PEGs to glycopolymer-coupled beads, and (c) linking of heterobifunctional PEGs to the bead surface prior to glycopolymer immobilization. Among the various modifications investigated, the direct modification of the bead surface with linear heterobifunctional PEGs, consisting of 23- and 60PEG-units significantly reduced the background binding. The end-point addition of biotin-linked PEGs, especially in the case of PEG consisting from 50PEG-units, helped to repel non-target binding caused by endogenous biotin. We observed unspecific binding predominantly for antibodies of IgG but of IgM class. The novel design of fluorescent microbeads allows the detection of human anti-glycan antibodies with increased specificity and opens new horizons for practical application of SGA as a diagnostic tool.

Poerio, T., et al. (2019). "Membrane Processes for Microplastic Removal." Molecules **24**(22): 15.

Plastic pollution of the aquatic environment is a major concern considering the disastrous impact on the environment and on human beings. The significant and continuous increase in the production of plastics causes an enormous amount of plastic waste on the land entering the aquatic environment. Furthermore, wastewater treatment plants (WWTPs) are reported as the main source of microplastic and nanoplastic in the effluents, since they are not properly designed for this purpose. The application of advanced wastewater treatment technologies is mandatory to avoid effluent contamination by plastics. A concrete solution can be represented by membrane technologies as tertiary treatment of effluents in integrated systems for wastewater treatment, in particular, for the plastic particles with a smaller size (< 100 nm). In this review, a survey of the membrane processes applied in the plastic removal is analyzed and critically discussed. From the literature analysis, it was found that the removal of microplastic by membrane technology is still insufficient, and without the use of specially designed approaches,

with the exception of membrane bioreactors (MBRs).

Poertner, L., et al. (2009). "Activation of T- and NK- cells through CD19xCD3 and CD19xCD16A bispecific TandAb antibodies in patients with B-cell non-Hodgkin's lymphoma." Blood. Conference: 51st Annual Meeting of the American Society of Hematology, ASH. New Orleans, LA United States. Conference Publication: **114**(22).

Purpose: Bispecific, tetravalent.antibodies (TandAbs) directed against the B-cell-surface marker CD19 and activating receptors on T or NK cells (CD19xCD3 or CD19xCD16b) have shown promising effects in vitro and in preclinical studies. The present study examines their effects on the cytotoxic responses of viable T and NK cells isolated from patients with B-cell Non Hodgkin Lymphoma (NHL). Method(s): Peripheral Blood MNCs were obtained from 30 patients with B-NHL (High grade=6, low grade=24) after successful prior therapy and from 17 healthy donors (HD) and were enriched for NK cells by immunomagnetic separation with CD56-microbeads, the other one was enriched for T cells. After overnight stimulation (RPMI-1640 with 10% FCS, 1% Pen/Strep and human recombinant IL-2 (Novartis) (NK: 1000U/ml; T: 100U/ml) cells were stained with CD107a, a surface marker indicating cytotoxicity. Cells were exposed to K562 alone, to Raji cells alone and finally to the TandAbs CD19xCD3 (T cells) or CD19xCD16A (NK cells) (conc. 1mug/ml). Using FACS analysis we determined the percent fraction of activated CD3 or CD56 cells being positive for CD107a. Result(s): To look for functional NK cells and T cells of HD and NHL patients first we exposed the cells to the K562 cell line. Both groups, HD and NHL patients expressed CD107a similarly (NK: 27.7+/-12.0% vs. 28.5+/-14.6%; T: 9.75+/-7.1% vs. 8.1+/-5.7%), indicating functional NK and T cells. To observe if NK or T cells would upregulate CD107a expression when exposed to lymphoma cells alone we performed experiments with Raji cells and measured the CD107a response. NK cells of both, patients and HD responded with similar levels of CD107a expression. T-cells of patients showed more cytotoxic activity towards Raji cells than observed in HD (3.1+/-8.4% vs. 0.1+/-0.2%). Next we added the CD19xCD3 or the CD19xCD16 TandAb to T/NK cells in the presence of Raji cells. In the patients' NK-cell-population the fraction of activated cells increased from 10.7% (Raji cells alone) to 30.7+/-19.2% when TandAb was added. The mean reaction in the group of HD was increased from 9.2% up to 27.7%. CD107a expression of T cells from NHL patients increased from 3.1% when exposed to Raji alone up to 21.3+/-14.3% when TandAb was added which was comparable to the results of HD (19.6%+/-11.4%). Conclusion(s): Patients with NHL have functional intact effector cells which show cytotoxic activity in response to TandAbs in presence of lymphoma cells similar to that of HD. These TandAb antibodies are therefore suitable for patients with B-cell NHL as potential maintenance therapy.

Poggi, E., et al. (2013). "Interpreting the results of luminex-single antigen beads assay." Tissue Antigens **81 (5)**: 327.

Anti-human leukocyte antigen (HLA) antibodies are produced by alloimmunization resulting from transfusions, pregnancies or transplants. The recent introduction of the Luminex-single antigen (LSA) beads (a solid phase assay which consists of microbeads coated with recombinant HLA antigens) greatly enhanced antibody characterization of patients on transplant waiting lists. Using this assay, many authors reported the presence of HLA antibodies in patients who have never been alloimmunized. These findings might be due to denatured HLA molecules coated to some beads that could give rise to positive results of unknown clinical significance. Otherwise, the detected HLA antibodies might be produced to cross-reactive epitopes found in microorganisms or ingested proteins. The aim of the study was to characterize the 'kind' of LSA-detected antibodies, using the new iBeads assay (microbeads with a reduced amount of

denatured HLA class I antigens), in serum samples from 30 HLA class I positive patients: 20 patients were non-alloimmunized and the remaining 10 had received sensitizing events that determined production of antibodies with low fluorescence intensity values. Eight of the 20 non-alloimmunized patients showed iBeads negative results, that is to say that these patients had produced antibodies specific for denatured HLA molecules. Twelve non-alloimmunized patients showed iBeads positive results that might be related to an immune response to epitopes shared between HLA and other proteins. Four of the 10 immunized patients showed iBeads negative results and consequently they could not be considered as 'HLA alloimmunized patients', 6 immunized patients had HLA antibodies that reacted positively with iBeads. In conclusion our findings demonstrated that LSA assay was able to detect not only different 'kinds' of HLA reactive antibodies such as alloantibodies, but also antibodies specific for denatured HLA molecules or for cross-reactive epitopes whose clinical relevance has to be investigated. Finally, it is mandatory to discriminate between these different LSA-detected antibodies to define the real immunologic risk of a potential organ transplant.

Poirier, R., et al. (1976). "Comparison between the use of a scintiscanner and angiography in the exploration of pulmonary circulation during primitive bronchial carcinoma. [French]." Revue Francaise des Maladies Respiratoires **4**(12): 963-968.

This study deals with 60 observations of patients with bronchial carcinoma (59 primitive, the majority of which were hilar, localized on the large bronchi; one was secondary). All patients had a double exploration of their pulmonary vascular network: scanning with macro-aggregates labelled with 131 Iodine or with 99 technetium, or with micro-beads of technetium-labelled albumin and angiography by opacification of the blood stream performed on the right side. A comparison of these two investigation techniques was satisfying enough; however, there was some contradiction and the scanning sometimes leads to an overestimation of the reduction in perfusion. Angiography seems more discriminating with respect to the localization of the circulatory cutoff or of blood reflux (complete amputation of a trunk or arterial branch-incomplete stenosis, reduction of capillary bed, etc.). A comparison of the results with the same patients using a scintiscanner and angiography shows the numerous problems involved in pathogenic interpretation of the observed disturbance, which varied according to the lesion in question and the methods used (for instance with scintiscanner, embolus of macro-aggregates or beads, perfusion of these same products; with angiography, injection of an opaque product by massive embolus at the periphery with one or two sites, injection after catheterization of venous sinus or pulmonary artery or one of its branches, etc.). An attempt to quantitatively evaluate the data is presented in reference to these 60 cases. The authors discuss these differences which are mainly due to the principle of the two methods (capillary embolization by bolus of macro-aggregates in the case of scintiscanning: opacification following the bloodstream in the case of angiography). They insist on the subjective nature of this comparison; the quantification of the results if possible only with the scintiscanner.

Poirier, Y., et al. (1995). "Production of polyhydroxyalkanoates, a family of biodegradable plastics and elastomers, in bacteria and plants." Bio/technology (Nature Publishing Company) **13**(2): 142-150.

In response to problems associated with plastic waste and its effect on the environment, there has been considerable interest in the development and production of biodegradable plastics. Polyhydroxyalkanoates (PHAs) are polyesters that accumulate as inclusions in a wide variety of bacteria. These bacterial polymers have properties ranging from stiff and brittle plastics to rubber-like materials. Because of their inherent biodegradability, PHAs are regarded as an attractive source of nonpolluting plastics and elastomers that can be used for specialty and commodity products. The possibility of producing PHAs in large scale and at a cost comparable to synthetic plastics has arisen from the demonstration of PHA accumulation in transgenic Arabidopsis plants expressing the bacterial PHA biosynthetic genes. Synergism between knowledge of the enzymes and genes contributing to PHA synthesis in bacteria and engineering of plant metabolic pathways will be necessary for the development of crop plants that produce biodegradable plastics.

Pok, K. Y., et al. (2012). "Cytokine changes in adult dengue hemorrhagic fever." International Journal of Infectious Diseases **16 (SUPPL.1)**: e93.

Background: Dengue, which is hyperendemic in tropical and subtropical countries, can cause severe plasma leakage, bleeding, and organ impairment. Cytokines associated with disease severity may serve as useful biomarkers for predicting disease outcome. Method(s): From our primarily dengue virus 1-infected adult cohort, we collected blood from 220 polymerase chain reaction (PCR)-positive patients at clinical presentation in 2004-43 with dengue hemorrhagic fever (DHF by World Health Organization 1997 criteria) and 177 with dengue fever (DF). Samples were tested for dengue antibodies IgG/IgM to differentiate between primary and secondary infection. Viral load was approximated using the threshold cycle of dengue real-time PCR, and the multiplex microbead immunoassay was used to quantify 18 different growth factors and cytokines. Result(s): Interferon alpha (IFNalpha) levels were elevated in DHF versus DF patients (22.61 pg/ml vs. 11.32 pg/ml; p = 0.04). Among those who presented during days 1-4 of illness, interleukin 6 (IL6), IL8, IL10, soluble IL2 receptor, and transforming growth factor alpha were significantly higher in DHF versus DF patients. During days 5-7, IFNalpha was significantly higher while IFN gamma (IFNgamma) was lower in DHF versus DF. When comparing secondary to primary infections, IL10 was increased by a factor of 3.07 (p = 0.001), IFNalpha was decreased by 1.54 (p = 0.02), and viral load decreased by 3.21 (p = 0.03). IFNalpha levels were greater in patients with mucosal bleeding versus those without (18.04 pg/ml vs. 11.29 pg/ml; p = 0.04).Among those with hypotension, IL12 p70 was higher than normotensive patients (1.58 pg/ml vs. 0.15 pg/ml; p = 0.03). Conclusion(s): In our adult cohort in Singapore, IFNalpha was expressed prominently in DHF compared to non-DHF patients. Other interleukins and TGFalpha significantly differed between DHF and non-DHF patients in early illness as well.

Poli, C., et al. (2015). "Plastic ingestion by sea turtles in Paraiba State, Northeast Brazil." Iheringia, Serie Zoologia **105**(3): 265-270.

Currently, plastics are recognized as a major pollutant of the marine environment, representing a serious threat to ocean wildlife. Here, we examined the occurrence and effects of plastic ingestion by sea turtles found stranded along the coast of Paraiba State, Brazil from August 2009 to July 2010. Ninety-eight digestive tracts were examined, with plastic found in 20 (20.4%). Sixty five percent (n=13) of turtles with plastic in the digestive tract were green turtles (Chelonia mydas), 25% (n=5) were hawksbills (Eretmochelys imbricata), and 10% (n=2) were olive ridley (Lepidochelys olivacea). More plastic was found in the intestine (85%) than in other parts of the gastrointestinal tract. We observed complete blockage of the gastrointestinal tract due to the presence of plastic in 13 of the 20 turtles that had ingested plastic. No correlation was found between the curved carapace length (CCL) and the number or mass of the plastic ingested items. Significant differences were found between the intake of hard and soft plastic and the ingestion of white/transparent and colored plastic, with soft and white/transparent plastics being more commonly ingested. This study reveals the serious problem of plastic pollution to sea turtles at the area.

Poli, F., et al. (2009). "Clinical relevance of human leukocyte antigen antibodies in kidney transplantation from deceased donors: The North Italy Transplant program approach." Human Immunology **70**(8): 631-635.

At the North Italy Transplant Program (NITp) Reference Center, which is responsible for pre- and posttransplant immunological evaluation and organ allocation, the sera of patients who enter the kidney waiting list are analyzed with complement dependent cytotoxicity (CDC) and a microbead array technique (Luminex). At present, the NITp waiting list includes 2543 patients. The rate of patients with a percentage panel-reactive antibody (PRA) >=30 with CDC is about 8%; among them, 1% exhibits a %PRA >=85. Furthermore, 14% of patients have antibodies detectable only with Luminex. The overall 5-year graft survival in the period 1997-2008 is 85%, whereas that of individuals with a CDC %PRA >=30 is 80.1% (p = 0.0355). A retrospective analysis on the effect of Luminex-detected anti-human leukocyte antigen (HLA) antibodies has suggested that there is a posttransplant immunological response in Luminex-positive patients that can slowly produce kidney damage. Here we present the NITp current policy for the screening and identification of anti-HLA antibodies in relation to kidney allocation algorithm and the authors' view on some aspects of discussion. © 2009 American Society for Histocompatibility and Immunogenetics.

Polonenko, D. R. and G. A. Maclachlan (1984). "Plasma-membrane sheets from pea protoplasts." Journal of Experimental Botany **35**(158): 1342-1349.

Stable protoplasts isolated from apices of 8-day-old etiolated seedlings of pea cv. Alaska were used to prepare sheets of plasma membrane by the following method: positively-charged silica microbeads were bound to the negatively-charged surfaces of intact protoplasts, exposed surfaces of the microbeads were neutralized and the protoplasts were lysed in a hypotonic buffer. Bead-plasma membrane sheets were pelleted by low speed centrifugation and shown by electron microscopy to be free of contamination from intracellular components.

Poma, A., et al. (2019). "In Vitro Genotoxicity of Polystyrene Nanoparticles on the Human Fibroblast Hs27 Cell Line." Nanomaterials **9**(9): 11.

Several studies have provided information on environmental nanoplastic particles/debris, but the in vitro cyto-genotoxicity is still insufficiently characterized. The aim of this study is to analyze the effects of polystyrene nanoparticles (PNPs) in the Hs27 cell line. The viability of Hs27 cells was determined following exposure at different time windows and PNP concentrations. The genotoxic effects of the PNPs were evaluated by the cytokinesis-block micronucleus (CBMN) assay after exposure to PNPs. We performed ROS analysis on HS27 cells to detect reactive oxygen species at different times and treatments in the presence of PNPs alone and PNPs added to the Crocus sativus L. extract. The different parameters of the CBMN test showed DNA damage, resulting in the increased formation of micronuclei and nuclear buds. We noted a greater increase in ROS production in the short treatment times, in contrast, PNPs added to Crocus sativus showed the ability to extract, thus reducing ROS production. Finally, the SEM-EDX analysis showed a three-dimensional structure of the PNPs with an elemental composition given by C and O. This work defines PNP toxicity resulting in DNA damage and underlines the emerging problem of polystyrene nanoparticles, which extends transversely from the environment to humans; further studies are needed to clarify the internalization process.

Pomponi, D., et al. (2012). "Allergen micro-bead array for IgE detection: a feasibility study using allergenic molecules tested on a flexible multiplex flow cytometric immunoassay." PLoS ONE [Electronic Resource] **7**(4): e35697.

BACKGROUND: Allergies represent the most prevalent non infective diseases worldwide. Approaching IgE-mediated sensitizations improved much by adopting allergenic molecules instead of extracts, and by using the micro-technology for multiplex testing.

OBJECTIVE AND METHODS: To provide a proof-of-concept that a flow cytometric bead array is a feasible mean for the detection of specific IgE reactivity to allergenic molecules in a multiplex-like way. A flow cytometry Allergenic Molecule-based micro-bead Array system (ABA) was set by coupling allergenic molecules with commercially available micro-beads. Allergen specific polyclonal and monoclonal antibodies, as well as samples from 167 allergic patients, characterized by means of the ISAC microarray system, were used as means to show the feasibility of the ABA. Three hundred and thirty-six sera were tested for 1 or more of the 16 selected allergens, for a total number of 1,519 tests on each of the two systems.

RESULTS: Successful coupling was initially verified by detecting the binding of rabbit polyclonal IgG, mouse monoclonal, and pooled human IgE toward three allergens, namely nDer s 1, nPen m 1, and nPru p 3. The ABA assay showed to detect IgE to nAct d 1, nAct d 11, rAln g 1, nAmb a 1, nArt v 3, rBet v 1, rCor a 1, nCup a 1, nDer p 1, nDer s 1, rHev b 5, nOle e 1, rPar j 2, nPen m 1, rPhl p 1, and nPru p 3. Results obtained by ABA IgE testing were highly correlated to ISAC testing ($r = 0.87$, $p<0.0001$). No unspecific binding was recorded because of high total IgE values.

CONCLUSION: The ABA assay represents a useful and flexible method for multiplex IgE detection using allergenic molecules. As also shown by our initial experiments with monoclonals and polyclonals, ABA is suitable for detecting other human and non-human immunoglobulins.

Poncelet, D., et al. (1994). "A parallel plate electrostatic droplet generator: Parameters affecting microbead size." Applied Microbiology and Biotechnology **42**(2-3): 251-255.

Polymer microbead production by parallel plate electrostatic extrusion is presented. Factors affecting microbead size such as needle gauge, electrostatic potential, distance between needle and collecting solution, and polymer solution concentration and flow rate were evaluated. Smaller microbeads resulted from reduced needle diameter, reduced needle to collecting solution distance, increased electrostatic potential, and reduced polymer solution concentration and flow rate. In terms of process scale-up, it was shown that a multi-needle (20) device could continuously produce relatively uniform beads via electrostatics. The technology was demonstrated to be feasible for cell encapsulation or immobilization as there was no detectable effect of applied potential on Spodoptera frugiperda viability.

Ponchel, F., et al. (2015). "Naive and memory CD4⁺T-cell DNA methylation profile in RA." Annals of the Rheumatic Diseases **1)**: A9-A10.

Introduction Several abnormal features of T-cell responses are observed in RA. These range from MHC disease association, repertoire distortion, compromised thymic activity, accelerated ageing, abnormal signalling, formation of secondary ectopic lymphoid structure. More recently the RA genetic predisposition has been shown to reside mostly in T-cell related genes. We investigated DNA methylation profiles in naive and memory T-cells isolated from healthy controls and RA patients to identify additional levels of regulation in T-cell functionalities. Methods 6 HC and 10 RA patients (5 ACPA+) were recruited. 30 ml of EDTA blood was collected and naive and memory Tcells purified using cell sorting. DNA was extracted and treated for bi-sulfite conversion. A 450k micro-bead array (Illumina) was used to investigate genome-wide DNA methylation. QA/QC procedure included inspection of beta-value density plots generated using the "minfi" R package. Results 30/32 samples passed QA/QC procedure. Signal from methylated and un-methylated probes was normalised and converted in to M values using the "minfi" package. M values were analysed using t-tests in the "gene filter" R package.

Multidimentional scaling analysis clearly separated naive from memory cells suggesting that the phenotype of the cells (notably between two CD4⁺ subsets) is essential for the detection of disease specific changes. Memory cell analysis revealed 37050 differentially methylated positions between health and RA and 36750 for naive cells (P <= 0.05). We selected the top 1000 most significant differences for both subsets and compared them. Surprisingly only 180 positions were common to the 2 subsets but importantly included 5 positions for the IL-6 gene, 15 for histone deacethylation-4 (HDAC4), 26 in Wnt3/Frizzle8 and homeobox-1 pathway and 43 in various transcription factors (notably FoxP1) all suggestive of a strong disease effect. Memory cells showed additional differential methylation of positions near genes such SMAD 2/7, p21-CIP-1, FGFR-3, HSP70 and TNFR-member-13. Naive cells showed similar differential methylation but for different members of these gene families (TNFR-I, TGFR-3, FGFR-1, HSP40) in addition to other specific genes such as interferon regulator 1, SUMO-1, several PAX transcription factors, P-selectin and importantly the IL-17R. Conclusion These pilot data demonstrate that there are important differences in the methylation of DNA between RA patients and HC that can be identified in relevant pathways provided cells are separated into the same phenotype (naive vs. memory) even if from the same lineage (both CD4⁺T-cells).

Pongstabodee, S., et al. (2008). "Combination of three-stage sink-float method and selective flotation technique for separation of mixed post-consumer plastic waste." Waste Management **28**(3): 475-483.

The aim of this research was to separate the different plastics of a mixed post-consumer plastic waste by the combination of a three-stage sink-float method and selective flotation. By using the three-stage sink-float method, six mixed-plastic wastes, belonging to the 0.3-0.5 cm size class and including high density polyethylene (HDPE), polypropylene (PP), polyvinylchloride (PVC), polystyrene (PS), polyethylene terephthalate (PET) and acrylonitrile-butadiene-styrene copolymers (ABS) were separated into two groups, i.e., a low density plastic group (HDPE and PP) and a high density plastic group (PET, PVC, PS and ABS) by tap water. Plastic whose density is less than that of the medium solution floats to the surface, while the one whose density is greater than that of the medium solution sinks to the bottom. The experimental results elucidated that complete separation of HDPE from PP was achieved by the three-stage sink-float method with 50% v/v ethyl alcohol. To succeed in the separation of a PS/ABS mixture from a PET/PVC mixture by the three-stage sink-float method, a 30% w/v calcium chloride solution was employed. To further separate post-consumer PET/PVC and PS/ABS based on plastic type, selective flotation was carried out. In order to succeed in selective flotation separation, it is necessary to render hydrophilic the surface of one or more species while the others are kept in a hydrophobic state. In flotation studies, the effects of wetting agent, frother, pH of solution and electrolyte on separation were determined. The selective flotation results showed that when using 500 mg l(-1) calcium lignosulfonate, 0.01 ppm MIBC, and 0.1 mg l(-1) CaCl2 at pH 11, PET could be separated from PVC. To separate ABS from PS, 200 mg l(-1) calcium lignosulfonate and 0.1 mg l(-1) CaCl2 at pH 7 were used as a flotation solution. Wettability of plastic increases when adding CaCl2 and corresponds to a decrease in its contact angles and to a reduction in the recovery of plastic in the floated product.

Poonyakan, A., et al. (2018). "Potential Use of Plastic Wastes for Low Thermal Conductivity Concrete." Materials **11**(10): 11.

The use of plastics has increased over the years, thus resulting in a large volume of plastic waste being generated and accumulated in the environment. Due to its non-biodegradability and persistence, recycling processes have become one of the sustainable solutions for preventing

environmental deterioration. Plastic wastes, including high density polyethylene (HDPE), low density polyethylene (LDPE), polypropylene (PP), and polyethylene terephthalate (PET), were collected from industrial sector and used as additional ingredients to improve concrete properties. Prior to concrete processing, an increase in wettability of plastic fibers using nonionic surfactant, Dehydol LS-12, was investigated. At the optimal concentration of 10 times of the critical micelle concentration (CMC), an interfacial tension and a contact angle were reduced to 31-32 mN/m and 65degree-68degree, respectively. Properties of concrete were determined and compared to those of the mortar samples. Porosity was found to increase with higher volume fraction of plastic fibers, whereas decreases in workability, bulk density, thermal conductivity, splitting tensile strength, and compressive strength were encountered. The lowest thermal conductivity was recorded for concrete samples prepared with 30% by volume of LDPE fibers, and the rest in descending order were HDPE, PP, and PET, respectively. Furthermore, the maximal inclusions of plastic fibers were 5% for HDPE and LDPE, 10% for PP, and 50% for PET so as to satisfy the precast concrete wall requirements.

Porter, A., et al. (2019). "The sea urchin Paracentrotus lividus as a bioeroder of plastic." Science of the Total Environment **693**(133621).

It is increasingly recognised that plastic pollution of the marine environment is highly dynamic in nature. Larger plastic items are fragmented or eroded into smaller and smaller pieces as its moves through marine ecosystems and small particles can be fouled or flocculate into larger aggregates. Whilst physical processes play a major part in photo- and oxidative degradation of plastic debris, biological process may also contribute to the breakdown of larger plastic items into smaller particulates, yet this has not been studied well to date. Here, we demonstrate the potential for the sea urchin Paracentrotus lividus to act as bioeroders of macroplastics. We found that urchins readily graze on a plastic surface, with this grazing activity generating microplastics, when held in experimental systems together. On average each urchin produced 91.7 (+or-33.8 pieces) smaller plastic pieces (118-15,797 micro m) from one macroplastic item over a ten day period. This plastic fragmentation by the urchins grazing activity was strongly influenced by the additional availability of natural food and by the presence of fouling of the macroplastic surface. Fragmentation of macroplastic by urchins dropped by 97% when urchins were exposed to virgin plastic in the presence of natural food (kelp). However, when macroplastic was biofouled urchins acted to fragment this plastic irrespective of the presence of additional food. The majority of fragments produced were negatively buoyant due to both the biofouling process and indeed the fouling by faecal matter, sinking to the bottom of the exposure systems. This smaller size range of plastic would then bioavailable to a much wider suite of species than the original macroplastic item; hence this bioerosion process has the potential to contribute to the transfer plastic fragments through benthic food webs.

Porter, B. and C. Wallerstein (2018). "'SAIL AGAINST PLASTIC' EXPEDITION RETURNS FROM ARCTIC." Resurgence & Ecologist(311): 6-6.

The article reports that group of filmmakers, campaigners and scientists have announced findings of expedition to study plastic pollution in island Svalbard and mentions analysis of discovery of microplastic samples in laboratory at University of Exeter.

Pospiskova, K., et al. (2013). "Magnetic particlesabased biosensor for biogenic amines using an optical oxygen sensor as a transducer." Mikrochimica Acta **180**(3): 311-318.

We have developed a fibre optic biosensor with incorporated magnetic microparticles for the determination of biogenic amines. The enzyme diamine oxidase from Pisum sativum was immobilized either on chitosan-coated magnetic microparticles or on commercial microbeads modified with a ferrofluid. Both the immobilized enzyme and the ruthenium complex were incorporated into a UV-cured inorganicaorganic polymer composite and deposited on a lens that was connected, by optical fibres, to an electro-optical detector. The enzyme catalyzes the oxidation of amines under consumption of oxygen. The latter was determined by measuring the quenched fluorescence lifetime of the ruthenium complex. The limits of detection for the biogenic amines putrescine and cadaverine are 25a30 ?mol?L?1, and responses are linear up to a concentration of 1 mmol L?1.

Possatto, F. E., et al. (2011). "Plastic debris ingestion by marine catfish: an unexpected fisheries impact." Marine Pollution Bulletin **62**(5): 1098-1102.

Plastic marine debris is a pervasive type of pollution. River basins and estuaries are a source of plastics pollution for coastal waters and oceans. Estuarine fauna is therefore exposed to chronic plastic pollution. Three important catfish species [Cathorops spixii (N=60), Cathorops agassizii (N=60) and Sciades herzbergii (N=62)] from South Western Atlantic estuaries were investigated in a tropical estuary of the Brazilian Northeast in relation to their accidental ingestion of plastic marine debris. Individuals from all three species had ingested plastics. In C. spixii and C. agassizii, 18% and 33% of individuals had plastic debris in their stomachs, respectively. S. herzbergii showed 18% of individuals were contaminated. All ontogenetic phases (juveniles, sub-adults and adults) were contaminated. Nylon fragments from cables used in fishery activities (subsistence, artisanal and commercial) played a major role in this contamination. These catfish spend their entire life cycles within the estuary and are an important feeding resource for larger, economically important, species. It is not yet possible to quantify the scale and depth of the consequences of this type of pollution. However, plastics are well known threat to living resources in this and other estuaries. Conservation actions will need to from now onto take plastics pollution into consideration.

Potocka, M., et al. (2019). "Plastic pollution affects American lobsters, Homarus americanus." Marine Pollution Bulletin **138**: 545-548.

This paper provides the first record of ingestion of plastic debris by American lobster, Homarus americanus. Plastics particles, identified as rubber pieces, were found in the stomachs of 3 from 17 individuals of lobsters kept in laboratory conditions. Debris had evidence of cuts, what suggest they were actively consumed.

Potreck, J. and P. B. Luppa (2019). "Influence of different bead sizes on the binding affinity of anti-factor VIII and von Willebrand factor as a new diagnostic tool." Journal of Laboratory Medicine **43 (4)**: eA38.

The motto of this year's DGKL conference is the classic modern motto "form follows function". It is not only the abandonment of ornaments in architecture that is described, but rather a description of an approach to perspective from which new materials and technologies have developed in the workshops of Bauhaus. In particular, interdisciplinary work and higher-level thinking can lead to new findings. Transferred to coagulation, this means that many parameters interact with different influencing factors. Only if a trouble-free expiration of all components takes place, the coagulation can run off and the bleeding is stopped. In hemophilia A, the complex coagulation process is disturbed by a lack of factor VIII. Patients with this disease cannot stop bleeding after injury, as well as spontaneous bleeding, especially in large joints. These circumstances affect the daily lives of patients in a massive way. Similar to classic modern, the focus in diagnostics should be placed on the overall picture. Long time the diagnostic considered only on the interaction of FVIII antibodies with FVIII. But the effect of FVIII, von

Willebrand factor (vWF) and anti-FVIII antibodies was neglected. All these parameters are in a direct interaction with each other. For this reason, we develop a special bead-based fluorescence assay to investigate the competition reaction between anti-FVIII antibody and vWF to FVIII as ligand in patient plasma. In order to visualize both parameter, two monoclonal detection antibodies against vWF and anti-FVIII was additionally added. With this structure we could already discover the first surprising findings. By using different bead sizes, we have seen that the VWF preferably binds to 7 mum beads; the vWF preferably binds to 13,5 mum beads. These findings were found both in the control plasma (Bethesda plasma pool) and in patient samples. We cannot yet explain the results to date, but it is thought that the influence of surface curvature, surface functionalization density, and electrostatic interactions play a role. These findings will be examined more closely in the near future. If the binding affinity of the vWF is shown to be influenced by the bead size, then this would be a new approach for the diagnostics of von Willebrand disease (vWD). Instead of using the elaborate multi-parameter analysis, a simpler and faster flow-cytometric method can be established. We take advantage of the property that the big vWF is bound disparately on microbeads of different sizes (from 7 to 20 mu m).

Potts, J. R., et al. (2013). "Circulating granulocyte survival is reduced in inactive alcohol-related cirrhosis." Nuclear Medicine Communications **34 (4)**: 363-364.

Purpose: Although neutrophil dysfunction is associated with chronic liver disease, peripheral blood granulocyte survival half-time (G-t<inf>1/2</inf>) has never been measured in cirrhosis. We aimed to determine G-t<inf>1/2</inf> in cirrhosis. Method(s): Seven subjects with inactive alcohol-related cirrhosis received ¹¹¹In-labelled mixed leucocytes. Blood was sampled over 24 h following administration and granulocytes isolated using a magnetic microbead technique selecting for the granulocyte marker CD15. CD15- associated activity was expressed as percentage of peak activity. G-t<inf>1/2</inf> was estimated from time points up to 10 h and compared with neutrophil half-time (N-t<inf>1/2</inf>) in 7 normal volunteers from a collaborating centre determined in samples up to 12 h using a similar technique that specifically selects neutrophils. Result(s): G-t<inf>1/2</inf> was 2.7+/-0.5 h compared with N-t<inf>1/2</inf> of 5.5+/-3.0 h (P=0.04). CD15-associated activity in 13/14 samples obtained >20 h were above the exponential fit (rate constant 0.23 h-1) to pooled values up to 10 h but the exponential fit to neutrophil-associated activity (0.13 h-1) passed close to late points. Transient rises were seen at 4-6 h in CD15-associated and neutrophil-associated activities in 4 patients and 4 normals, respectively. Conclusion(s): These data suggest neutrophil lifespan is reduced in cirrhosis. ¹¹¹In-labelled eosinophils are not responsible for the transient rise in CD15-associated activity but probably generate the CD15-associated clearance curve 'tail'.

Potts, J. R., et al. (2014). "In vivo circulating granulocyte lifespan is reduced in compensated cirrhosis." Journal of Hepatology **1)**: S73.

Background and Aims: Although granulocyte dysfunction is well described in cirrhosis, the in vivo lifespan of granulocytes in chronic liver disease has not previously been reported. The normal circulating granulocyte survival half-time (G-t<inf>1/2</inf>), determined using indium-111 (111In)-radiolabelled granulocytes, is approximately 7 h. We aimed to measure in vivo G-t<inf>1/2</inf> in inactive alcohol-related cirrhosis (ARC). Method(s): Sequential venous blood samples were obtained from abstinent subjects with ARC over 24h post injection (PI) of minimally manipulated 111In-radiolabelled autologous mixed leucocytes. Purified granulocytes were isolated from each sample using a magnetic microbead-antibody technique positively selecting for the marker CD15. Granulocyte-associated radioactivity was expressed relative to peak activity, plotted over time and G-t<inf>1/2</inf> estimated from data up to 12h PI. This was compared with normal neutrophil half-time (N-t<inf>1/2</inf>), determined using a similar method specifically selecting neutrophils in healthy controls at a collaborating centre. Result(s): Seven patients with ARC (6 male, aged 57.9+/-9.4yrs, all Child-Pugh class A) and seven normal controls (3 male, aged 64.4+/-5.6yrs) were studied. Peripheral blood neutrophil counts were similar in both groups (4.6+/-1.8x10⁹/l vs 4.0+/-1.6x10⁹/l respectively, p = 0.629). G-t<inf>1/2</inf> in ARC was significantly lower than N-t<inf>1/2</inf> in healthy controls (2.7+/-0.5 h vs 4.4+/-1.0 h, p = 0.002). Granulocyte and neutrophil-associated activities transiently rose in 4 patients from each group, typically earlier in ARC (4-6 h PI) than in controls (5-10 h PI), indicating recirculation of radiolabelled cells released from an unidentified focus. Conclusion(s): Reduced in vivo granulocyte lifespan in cirrhosis is a novel finding and potentially another mechanism for immune dysfunction in chronic liver disease. (Figure Presented).

Potts, J. R., et al. (2016). "Circulating granulocyte lifespan in compensated alcohol-related cirrhosis: a pilot study." Physiological Reports **4**(17): 09.

Although granulocyte dysfunction is known to occur in cirrhosis, in vivo studies of granulocyte lifespan have not previously been performed. The normal circulating granulocyte survival half-time (G - t1/2), determined using indium-111 ((111)In)-radiolabeled granulocytes, is ~7 h. In this pilot study, we aimed to measure the in vivo G - t1/2 in compensated alcohol-related cirrhosis. Sequential venous blood samples were obtained in abstinent subjects with alcohol-related cirrhosis over 24 h post injection (PI) of minimally manipulated (111)In-radiolabeled autologous mixed leukocytes. Purified granulocytes were isolated from each sample using a magnetic microbead-antibody technique positively selecting for the marker CD15. Granulocyte-associated radioactivity was expressed relative to peak activity, plotted over time, and G - t1/2 estimated from data up to 12 h PI This was compared with normal neutrophil half-time (N - t1/2), determined using a similar method specifically selecting neutrophils in healthy controls at a collaborating center. Seven patients with cirrhosis (six male, aged 57.8 +/- 9.4 years, all Child-Pugh class A) and seven normal controls (three male, 64.4 +/- 5.6 years) were studied. Peripheral blood neutrophil counts were similar in both groups (4.6 (3.5 - 5.5) x 10(9)/L vs. 2.8 (2.7 - 4.4) x 10(9)/L, respectively, P = 0.277). G - t1/2 in cirrhosis was significantly lower than N - t1/2 in controls (2.7 +/- 0.5 h vs. 4.4 +/- 1.0 h, P = 0.007). Transient rises in granulocyte and neutrophil-associated activities occurred in four patients from each group, typically earlier in cirrhosis (4-6 h PI) than in controls (8-10 h), suggesting recirculation of radiolabeled cells released from an unidentified focus. Reduced in vivo granulocyte survival in compensated alcohol-related cirrhosis is a novel finding and potentially another mechanism for immune dysfunction in chronic liver disease. Larger studies are needed to corroborate these pilot data and assess intravascular neutrophil residency in other disease etiologies.

Poulain, M., et al. (2019). "Small Microplastics As a Main Contributor to Plastic Mass Balance in the North Atlantic Subtropical Gyre." Environmental Science & Technology **53**(3): 1157-1164.

Estimates of cumulative plastic inputs into the oceans are expressed in hundred million tons, whereas the total mass of microplastics afloat at sea is 3 orders of magnitude below this. This large gap is evidence of our ignorance about the fate of plastics, as well as transformations and sinks in the oceans. One of the current challenges consists of identifying and quantifying plastic particles at the microscale, the small microplastics (SMP, 25-1000 mum). The aim of the present study is to investigate SMP concentration in count and in mass at the sea surface in the North Atlantic subtropical gyre during the sea campaign Expedition 7 th Continent. After

isolation, SMP were characterized by micro-Fourier-transform infrared spectroscopy. Microplastic distribution was modeled by a wind-driven vertical mixing correction model taking into account individual particle properties (dimension, shape and density). We demonstrate that SMP buoyancy is significantly decreased compared to the large microplastics (LMP, 1-5 mm) and consequently more susceptible to vertical transport. The uncorrected LMP concentration in count was between 13000 and 174000 pieces km⁻², and was between 5 and 170 times more abundant for SMP. With a wind-driven vertical mixing correction, we estimated that SMP were 300 to 70000 times more abundant than LMP. When discussing this in terms of weight after correction, LMP concentrations were between 50 and 1000 g km⁻², and SMP concentrations were between 5 and 14000 g km⁻².

Powell, M. K., et al. (1998). "Titration of a CD45-FITC conjugate to determine the linearity and dynamic range of fluorescence intensity measurements on lymphocytes." Cytometry **33**(2): 219-224.

To produce biologic calibrators for relative fluorescence intensity (RFI) measurements, we stained leukocytes with serial dilutions of CD45-FITC conjugate and processed them using our regular whole blood lysis procedure. Cells were stained with conjugate concentrations ranging from twice recommended to a million-fold lower. At the highest concentrations of conjugate, the RFI reached a plateau near the top of the third decade, indicating saturation of CD45 binding sites. As the concentration decreased, the RFI declined in a highly linear relationship between the dilution factor and the histogram channel number. For channel numbers corresponding to the lowest percentiles of the RFI distribution, linearity persisted down to the first half decade. The slope of this relationship revealed a true dynamic range of 4.5 decades, which was comparable to the value obtained with microbead standards calibrated in molecules of equivalent soluble fluorochrome (MESF). Our results suggest that the lower limit of linearity for fluorescence intensity from fluorescein isothiocyanate (FITC)-stained lymphocytes is below 500 MESF and that cellular autofluorescence is the major limiting factor in detecting and quantifying FITC-specific staining. This procedure provides an adroit way of characterizing the linearity and dynamic range of measurements for quantitative fluorescence cytometry using exactly the same matrix, stains, and preparation methods as those used for cellular analytes.

Pozo, K., et al. (2019). "Presence and characterization of microplastics in fish of commercial importance from the Biobio region in central Chile." Marine Pollution Bulletin **140**: 315-319.

In this study we have identified and characterized microplastic particles (MPs) found in six fish species of commercial importance in central Chile. The fish species belong to different trophic levels and were obtained from the oceanic and coastal habitats. To analyze MPs, the fish gastrointestinal content was extracted, analyzed and characterized using a microscopy equipped with Fourier-transform infrared spectroscopy (FT-IR). The MPs found in fish samples were mainly constituted by red microfibers (70-100%) with sizes ranging between 176 and 2842 micro m. Polyester, polyethylene (PE) and polyethylene terephthalate (PET) were identified as the prevalent polymers detected. The coastal species showed the presence of microfibers with a higher size and abundance (71%) compared to oceanic species (29%), suggesting there is a greater exposure risk. These findings are consistent with results found in other investigations worldwide. However, further research is still needed to accurately establish the potential exposure risk for the public consuming these fish and the impact of MPs in the Chilean fishery activities.

Pozo, K., et al. (2019). "Presence and characterization of microplastics in fish of commercial importance from the Biobío region in central Chile." Marine Pollution Bulletin **140**: 315.

These findings are consistent with results found in other investigations worldwide. However, further research is still needed to accurately establish the potential exposure risk for the public consuming these fish and the impact of MPs in the Chilean fishery activities.

Pozo, K., et al. (2020). "Persistent organic pollutants sorbed in plastic resin pellet - "Nurdles" from coastal areas of Central Chile." Marine Pollution Bulletin **151 (no pagination)**(110786).

Plastic resin pellets were collected from coastal areas (n = 7) of central Chile. Pellets were analyzed using Fourier-transform infrared spectroscopy for polymer identification and gas chromatography-mass spectrometry for Persistent Organic Pollutants (POPs) determination. Screened compounds were PBDEs (n = 10), PCBs (n = 7), and OCPs (n = 13). Pellets were only found at Lenga Beach (San Vicente Bay), which is likely influenced by the presence of industrial activities in the surrounding coastal area. The diameter of the pellets was 4.0 +/- 0.6 cm (n = 370), the color varied from white (32%) to yellowing (68%), and the most prevalent polymer identified was high-density polyethylene (99%). POPs concentrations (ng/g-pellet) ranged from 10 to 133 for 10PBDEs, from 3 to 60 for 7PCBs and between 0.1 and 7 for DDTs. Levels of POPs are consistent with other investigations around the world and highlight the sorbtion capacity of plastics resin pellets, and consequently transport of POPs into coastal environments. Prata, J. C. (2018). "Airborne microplastics: Consequences to human health?" Environmental Pollution **234**: 115-126.

Microplastics have recently been detected in atmospheric fallout in Greater Paris. Due to their small size, they can be inhaled and may induce lesions in the respiratory system dependent on individual susceptibility and particle properties. Even though airborne microplastics are a new topic, several observational studies have reported the inhalation of plastic fibers and particles, especially in exposed workers, often coursing with dyspnea caused by airway and interstitial inflammatory responses. Even though environmental concentrations are low, susceptible individuals may be at risk of developing similar lesions. To better understand airborne microplastics risk to human health, this work summarizes current knowledge with the intention of developing awareness and future research in this area. [ABSTRACT FROM AUTHOR]

Prata, J. C. (2018). "Microplastics in wastewater: State of the knowledge on sources, fate and solutions."

Marine Pollution Bulletin **129**(1): 262-265.

Microplastics are ubiquitous contaminants that could harm ecosystems. Wastewater contains microplastics and may lead to further contamination of the environment. This focus article presents a summary of current knowledge on microplastics in wastewater and possible solutions, suggesting current research needs.

Prata, J. C., et al. (2020). "An easy method for processing and identification of natural and synthetic microfibers and microplastics in indoor and outdoor air." MethodsX **7**: 1-9.

Microplastics and microfibers can contaminate every matrix, including in the atmosphere, thus leading to incidental inhalation. However, concentrations of airborne synthetic particle in indoor and outdoor environments are not well understood due to the complexities of sampling, sample processing and identification. This work aims at producing a simple protocol to determine the concentrations of airborne microplastics and fibers. This is accomplished by removing organic matter using hydrogen peroxide (H₂O₂), followed by removal of mineral matter by density separation with sodium iodide (NaI). Finally, identification of fibers into synthetic or natural under the stereomicroscope can be achieved following a diagram produced by systematically observing the most common textile fibers. This method produces a recovery rate of 94.4 % for spiked samples and has been proven suitable for environmental samples. *Fibers and microplastics in air are easier to identify after carbonaceous matter removal;*No loss of microfiber is expected from the solutions used;*Recovery rates of spiked samples is 94.4 %.

Prata, J. C., et al. (2019). "Methods for sampling and detection of microplastics in water and sediment: A critical review." TrAC - Trends in Analytical Chemistry **110**: 150-159.

Microplastics are widespread contaminants, virtually present in all environmental compartments. However, knowledge on sources, fate and environmental concentration over time and space still is limited due to the laborious and varied analytical procedures currently used. In this work we critically review the methods currently used for sampling and detection of microplastics, identifying flaws in study design and suggesting promising alternatives. This work provides insights on bulk sample collection, separation, digestion, identification and quantification, and mitigation of cross-contamination. The sampling of microplastics will improve in representativeness and reproducibility through the determination of bulk sample volume, filter's pore size, density separation and digestion solutions, but also through use of novel methods, such as the enhancement of visual identification by staining dyes, and the generalized use of chemical characterization. Prata, J. C., et al. (2019). "Effects of microplastics on microalgae populations: A critical review." Science of the Total Environment **665**: 400-405.

Microplastics are persistent contaminants accumulating in the environment. Aquatic ecosystems have been studied worldwide, revealing ubiquitous contamination with microplastics. Microalgae, one of the most important primary producers in aquatic ecosystems, could suffer from microplastic contamination, leading to larger impacts on aquatic food webs. Nonetheless, little is known about the toxic effects of microplastics on microalgae populations. Thus, the objective of this review was to identify these effects and the impacts of microplastics on microalgae populations based on currently available literature, also identifying knowledge gaps. Even though microplastics seem to have limited effects on parameters such as growth, chlorophyll content, photosynthesis activity and reactive oxygen species (ROS), current environmental concentrations are not expected to induce toxicity. Even so, microplastics could disrupt population regulation mechanisms, by reducing the availability or absorption of nutrients (bottom-up) or reducing the population of predator species (top-down). Microplastics' properties can also influence the effects on microalgae, with smaller sizes and positive surface charges having higher toxicity. Therefore, more research is needed to better understand the effects of microplastics on microalgae, such as adaptation strategies, effects on population dynamics and microplastics properties influencing toxicity.

Prata, J. C., et al. (2020). "Environmental exposure to microplastics: An overview on possible human health effects." Science of the Total Environment **702**: 134455.

Microplastics are ubiquitous environmental contaminants leading to inevitable human exposure. Even so, little is known about the effects of microplastics in human health. Thus, in this work we review the evidence for potential negative effects of microplastics in the human body, focusing on pathways of exposure and toxicity. Exposure may occur by ingestion, inhalation and dermal contact due to the presence of microplastics in products, foodstuff and air. In all biological systems, microplastic exposure may cause particle toxicity, with oxidative stress, inflammatory lesions and increased uptake or translocation. The inability of the immune system to remove synthetic particles may lead to chronic inflammation and increase risk of neoplasia. Furthermore, microplastics may release their constituents, adsorbed contaminants and pathogenic organisms. Nonetheless, knowledge on microplastic toxicity is still limited and largely influenced by exposure concentration, particle properties, adsorbed contaminants, tissues involved and individual susceptibility, requiring further research.

Prata, J. C., et al. (2018). "Influence of microplastics on the toxicity of the pharmaceuticals procainamide and doxycycline on the marine microalgae Tetraselmis chuii." Aquatic Toxicology **197**: 143-152.

Microplastics and pharmaceuticals are considered ubiquitous and emergent pollutants of high concern but the knowledge on their effects on primary producers is still limited, especially those caused by mixtures. Thus, the goal of the present study was to investigate if the presence of microplastics (1-5mum diameter) influences the toxicity of the pharmaceuticals procainamide and doxycycline to the marine microalga Tetraselmis chuii. Bioassays (96h) to investigate the toxicity of those substances individually and in mixtures (i.e. microplastics-procainamide mixtures and microplastics-doxycycline mixtures) were carried out. Effect criteria were the average specific growth rate (growth rate) and chlorophyll a concentration (chlorophyll). EC₁₀, EC₂₀ and EC₅₀ were determined. Microplastics alone had no significant effects on growth rate up to 41.5mg/l, whereas chlorophyll was significantly reduced at 0.9 and 2.1mg/l of microplastics, but not at higher concentrations. The 96h EC₅₀ (growth rate and chlorophyll, respectively) determined for the other bioassays were: 104 and 143mg/l for procainamide alone; 125 and 31mg/l for procainamide in the presence of microplastics; 22 and 14mg/l for doxycycline alone; 11 and 7mg/l for doxycycline in the presence of microplastics. Significant differences (p<0.001) between the toxicity curves of each pharmaceutical alone and in mixture with microplastics were found for procainamide (chlorophyll), and doxycycline (both parameters). Thus, both pharmaceuticals were toxic to T. chuii in the low ppm range, and microplastics-pharmaceutical mixtures were more toxic than the pharmaceuticals alone. Very high decreases of doxycycline concentrations in test media were found, indicating degradation of the antibiotic. Thus, although the biological results are expressed in relation to doxycycline concentration, the effects were likely caused by a mixture of the parental compound and its degradation products. The concentrations of microplastics and pharmaceuticals tested (low ppm range) are higher than those expected to be found in waters of the most part of marine ecosystems (ppt or ppb ranges). However, considering the widespread contamination by microplastics and pharmaceuticals, the concentrations already found in waters, sediments and/or organism of heavily polluted areas, the long-term exposure (over generations) of wild populations to such substances in polluted ecosystems and the possibilities of bioaccumulation and toxicological interactions, these findings are of concern and further research on microplastics-pharmaceuticals toxicological interactions is needed.

Prata, J. C., et al. (2019). "A new approach for routine quantification of microplastics using Nile Red and automated software (MP-VAT)." Science of the Total Environment **690**: 1277-1283.

Microplastics are widespread contaminants in the environment. However, most identification protocols rely on long and subjective visual counting, which could be improved using staining dyes. Thus, the objective of this work is to identify the best staining dye protocol and create an objective and quick automated counting software for microplastics. Tests were conducted to identify the most appropriate of eight staining dye solutions and of six wavelengths for virgin and weathered synthetic polymers, textile fibers, natural organic matter and filters. Nile Red produced the best results (without interfering in infrared spectra) rendering microplastics fluorescent at 254 nm, but with limited number of fluorescent polymers, and at 470 nm (with orange filter), with fluorescence of plastics as well as natural organic matter (requiring a digestion step). Next, a script was developed in ImageJ for the automatic quantification and characterization in shape (fiber, fragment, particle) and size of fluorescent microplastics, the Microplastics Visual Analysis Tool (MP-VAT). MP-VAT was evaluated, producing recovery rates in the range of 89.0-111.1% in spiked filters under 470 nm. Furthermore, this package is accompanied by a script that sets a scale from a known filter diameter, MP-SCALE, and a script that allows user threshold setting, MP-ACT.

Prata, J. C., et al. (2019). "Effects of spatial and seasonal factors on the characteristics and carbonyl index of (micro)plastics in a sandy beach in Aveiro, Portugal." Science of the Total Environment **709**: 135892.

Coastal environments are highly contaminated with plastics of various sizes. In order to understand the distribution and factors influencing (micro)plastics contamination in the environment, sampling of a sandy beach in Costa Nova, Aveiro, Portugal, was conducted by collecting plastic particles and sediments for density separation in transects from the mean low tide line to the dunes, during wet and dry seasons. For surface collection, microplastics comprised 69.4% of plastics, presenting concentrations of 3-6 items m⁻² in the wet season, mostly polyethylene pellets carried ashore by storms, and <1 item m⁻² for dry season, lower due to less backwashing, were found. Collection of infrared spectra of these particles allowed characterization by polymer type and carbonyl index of all particles. Variations in carbonyl index were found to be related to season, site and particle color. Density separated microplastics, mostly fibers, presented 23 times higher concentrations than surface collection (22 microplastics kg⁻¹, 280 microplastics m⁻²), due to the identification of smaller sizes, and with higher concentrations in dry seasons, likely from accumulation in sediment and bathing season. Overall, different sampling methods allowed identification of different particle types and sizes, which may vary according to seasonal and spatial factors.

Prata, J. C., et al. (2019). "Solutions and Integrated Strategies for the Control and Mitigation of Plastic and Microplastic Pollution." International Journal of Environmental Research & Public Health [Electronic Resource] **16**(13): 07.

Plastic pollution is generated by the unsustainable use and disposal of plastic products in modern society, threatening economies, ecosystems, and human health. Current clean-up strategies have attempted to mitigate the negative effects of plastic pollution but are unable to compete with increasing quantities of plastic entering the environment. Thus, reducing inputs of plastic to the environment must be prioritized through a global multidisciplinary approach. Mismanaged waste is a major land-based source of plastic pollution that can be reduced through improvements in the life-cycle of plastics, especially in production, consumption, and disposal, through an Integrated Waste Management System. In this review paper, we discuss current practices to improve life cycle and waste management of plastics that can be implemented to reduce health and environmental impacts of plastics and reduce plastics pollution. Ten recommendations for stakeholders to reduce plastic pollution include (1) regulation of production and consumption; (2) eco-design; (3) increasing the demand for recycled plastics; (4) reducing the use of plastics; (5) use of renewable energy for recycling; (6) extended producer responsibility over waste; (7) improvements in waste collection systems; (8) prioritization of recycling; (9) use of bio-based and biodegradable plastics; and (10) improvement in recyclability of e-waste.

Pravduk, A. I., et al. (2010). "Control rate slow freezing with ice nucleation preserves viability and capacity to multilineage differentiation of mesenchymal stromal cells encapsulated in alginate microbeads." Cryobiology **61 (3)**: 407.

Mesenchymal stromal cells (MSCs) have a unique capacity to multilineage differentiation that makes them attractive for regenerative medicine and tissue engineering. Encapsulation of MSCs in alginate microbeads is a novel approach of tissue engineering. The response of alginate encapsulated cells on cryopreservation factors can be different then in single cell suspension; therefore the influence of cryopreservation on survival and functions of cells encapsulated in alginate microbeads demands of detailed study. The purpose of this study was to investigate the effect of cryopreservation with dimethyl sulfoxide (ME<inf>2</inf>SO) on viability, metabolic activity and capacity to multilineage differentiation of MSCs encapsulated in alginate microbeads. Human adult bone marrow and fetal mesodermal tissues derived MSCs were isolated and expanded in vitro according to Ethical guidelines. Encapsulation was carried out by spraying MSCs suspended in sodium alginate to solution containing calcium ions. Cryopreservation media contain 5% or 10% of ME<inf>2</inf>SO and 10% fetal calf serum. Samples were frozen using three different protocols: conventional two steps slow cooling at 1 degreeC/min to -80 degreeC following immersion to LN2, one step rapid freezing by immediate immersion to LN2, three steps control rate slow cooling at 1 degreeC/min down to -40 degreeC with ice nucleation at -6.3 degreeC and then at 10 degreeC/min from -40 to -80 degreeC with subsequent immersion to LN2. Before thawing samples were stored in LN2 for 1 week. The viability of encapsulated cells was assessed by using confocal laser microscopy after live/dead staining. Metabolic activity of MSCs was assessed by Alamar blue test. Cell differentiation was carried out by culture in mediums containing appropriate supplements. Markers of differentiation were determined by biochemical and histological methods. In experiments with MSCs isolated from human tissues of mesodermal origin was shown that cryopreservation of alginate encapsulated cells included rapid freezing with 10% Me<inf>2</inf>SO resulted in change of alginate hydrogel optical properties and cell death (Viability mean 6 +/- 2%). Cryopreservation with slow two steps freezing allowed to considerably preserve the viability of alginate encapsulated MSCs (viability mean 79 +/- 3%). The response of alginate encapsulated MSCs on cryopreservation procedure during two steps slow freezing in the presence of 10% ME<inf>2</inf>SO did not considerably differ from single cell suspension (viability mean 84 +/-

2%). However, decline Me<inf>2</inf>SO concentration down to 5% resulted in a significant decrease of metabolic activity and viability of cells in microbeads as compared to single cell suspension. Maximal values of viability and metabolic activity of alginate encapsulated MSCs were obtained after cryopreservation in the presence of 10% of Me<inf>2</inf>SO included control rate slow freezing with ice nucleation. This protocol was applied for cryopreservation of alginate encapsulated bone marrow (BM) derived MSCs. After cryopreservation alginate encapsulated BM MSCs demonstrated high viability, metabolic activity and were able to induced differentiation in osteogenic, chondrogenic and adipogenic lineages similar to non-frozen cells in culture.Thus, control rate slow freezing with ice nucleation allows to preserve viability and capacity to multilineage differentiation of MSC encapsulated in alginate microbeads.

Praveen, R., et al. (2017). "Better management of alcohol liver disease using a 'microstructured synbox' system comprising L. plantarum and EGCG." PLoS ONE **12**(1).

Synergistic combination of probiotics with carbohydrate based prebiotics is widely employed for the treatment of various gut related disorders. However, such carbohydrate based prebiotics encourage the growth of pathogens and probiotics, equally. Aim of the study was (i) to explore the possibility of using epigallocatechin gallate (EGCG) a phenolic compound, as a prebiotic for L. plantarum; (ii) to develop and evaluate a microstructured synbox (microencapsulating both probiotic and EGCG together) in rat model of alcohol liver disease (ALD); and, (iii) to confirm whether the combination can address issues of EGCG bioavailability and probiotic survivability in adverse gut conditions. Growth enhancing effect of EGCG on L. plantarum (12.8+or-0.5 log ₁₀ units) was significantly (p<=0.05) better than inulin (11.4+or-0.38 log ₁₀ units), a natural storage carbohydrate. The formulated synbox significantly modulated the levels of alcohol, endotoxin, hepatic enzymes and restored the hepatoarchitecture in comparison to simultaneous administration of free agents. Additionally, using a battery of techniques, levels of various cellular and molecular markers viz. NF-kB/p50, TNF- alpha , IL12/p40, and signalling molecules TLR4, CD14, MD2, MyD88 and COX-2 were observed to be suppressed. Developed microbead synbox, as a single delivery system for both the agents showed synergism and hence, holds promise as a therapeutic option for ALD management.

Praveena, S. M., et al. (2018). "Exploration of microplastics from personal care and cosmetic products and its estimated emissions to marine environment: An evidence from Malaysia." Marine Pollution Bulletin **136**: 135-140.

This study aims understand microplastics from personal care and cosmetic products in Malaysia via quantification and characterization of microplastics together with emission estimation to marine environment. A total of 214 respondents from all over Malaysia were surveyed with identification of top ten personal care and cosmetic products usage. Particles found in facial cleaner/scrub and toothpaste were colored and colorless with majority of granular shapes. Particles in toothpaste were found between 3 and 145mum while particles in facial cleaner/scrub were found to be between 10 and 178mum, stipulating the presence of microplastics. Plastic polymers (LDPE and polypropylene) were found in all facial cleaner/scrub samples while only plastic polymers (LDPE) were present in toothpaste sample G. A total of 0.199 trillion microplastics are expected to be released annually to marine environment in Malaysia. Personal care and cosmetic products are seen as one of the microplastics sources for Malaysia and worldwide.

Pregibon, D. C. (2008). Enabling technologies for multiplexed biomolecule analysis and cell sorting.

The quantification and manipulation of biological entities from a physiological sample is extremely important for a broad range of applications in medical diagnostics, therapeutics, and basic science research. From a diagnostics standpoint, the cells, proteins, and nucleic acids that compose our bodies contain an enormous amount of information that can indicate the presence of, progression of, or even susceptibility to a given disease. However, extracting this information is often quite challenging. New tools are constantly being developed to make diagnostic testing more accurate, less invasive, faster, and less expensive. To this end, this thesis describes that advent of technologies to (1) precisely pattern biologically- and magnetically-active beads in hydrogel substrates for cell sorting and pattering, (2) synthesize morphologically and chemically-complex microparticles in a high-throughput fashion, and (3) perform rapid and accurate multiplexed biomolecule quantification using such particles. Bead-Patterned Hydrogels are a class of materials developed in this thesis that consist of microbeads precisely patterned in poly(ethylene glycol) (PEG) matrices. Using microfluidics and projection lithography on a standard microscope, magnetically-active or protein-decorated beads were patterned in close-packed or disperse-bead patterns on glass substrates with high resolution over large areas. Using slight alterations to the synthesis protocol, bead patterns could be completely encapsulated in a bio-inert PEG matrix, or exposed from the PEG surface. It was shown that bead-patterned hydrogels could be used for the phenotype-specific sorting or patterning of lymphocytes. As was observed in the synthesis of bead-patterned hydrogels, free-radical polymerization is inhibited near microfluidic channel walls due to oxygen diffusion through the porous poly dimethoxysilane (PDMS) elastomer composing devices. By exploiting this phenomenon using projection lithography in an all-PDMS device, Continuous-Flow Lithography was developed. In stark contrast to traditional methods for anisotropie particle synthesis, this one-phase process provides a simple method to synthesize microparticles with complex morphologies and/or multiple adjacent chemistries in a high-throughput fashion. The processes is broadly applicable to any free-radical reacting monomer. For improved resolution and sharpened interfaces between adjacent chemistries, Stop-Flow Lithography was implemented using a valve system to rapidly start and stop flow in a fluidic system. Flow lithography provided unprecedented control over particle shape, composition, and inclusion of multiple functionalities. Utilizing these attributes, Encoded Hydrogel Particles were synthesized bearing multiple functional regions including a graphical barcode and one or more DNA probe-loaded regions. These particles were used for multiplexed detection of deoxyribonucleic acid (DNA) and ribonucleic acids (RNA), affording virtually unlimited multiplexing capabilities, single-color detection, flow-through scanning in a microfluidic device, and low cost. Mathematical models were developed to understand the kinetics of hybridization depending on particle design and assay conditions. Using these models to direct optimization, the method was shown to give attomole-sensitivity, single-nucleotide specificity, and rapid hybridization kinetics. Overall, this thesis demonstrates the combination of hydrogels, lithography, and microfluidics to generate intricate substrates and particles that provide means for high-performance, low-cost bioseparations and molecular screening. (Copies available exclusively from MIT Libraries, Rm. 14-0551, Cambridge, MA 02139-4307. Ph. 617-253-5668; Fax 617-253-1690.)

Pregibon, D. C., et al. (2006). "Magnetically and biologically active bead-patterned hydrogels." Langmuir **22**(11): 5122-5128.

We present a new approach to the direct patterning of biologically and magnetically active microbeads in nonbiofouling polymer scaffolds for use in microfluidic devices. Briefly, the process involves treatment of a glass substrate, conformal contact bonding of a PDMS microchannel on the substrate, filling of the channel with beads and prepolymer solution, and

UV-initiated photopolymerization of a mask-defined pattern using a standard inverted microscope. This versatile and simple method allows for the rapid fabrication of dispersed or packed bead patterns in poly(ethylene glycol) (PEG) hydrogels that are covalently linked to glass surfaces. By exploiting the relative opacity of the microbeads used, we are able to create both partially exposed and fully encapsulated bead patterns. To demonstrate the utility of this new technology, we separated magnetic bead-bound B lymphocytes from T lymphocytes on a PEG-encapsulated magnetic filtration platform and also captured B cells directly on patterned, protein-decorated beads in a flow-through microfluidic device. Beyond cell sorting, the accurate patterning of industrially standardized, chemically diverse microbeads may have significant implications for microchip-based analyte detection.

Prendergast-Miller, M. T., et al. (2019). "Polyester-derived microfibre impacts on the soil-dwelling earthworm Lumbricus terrestris." Environmental Pollution **251**: 453-459.

Microplastic (MP) pollution is everywhere. In terrestrial environments, microfibres (MFs) generated from textile laundering are believed to form a significant component of MPs entering soils, mainly through sewage sludge and compost applications. The aim of this study was to assess the effect of MFs on a keystone soil organism. We exposed the earthworm Lumbricus terrestris to soil with polyester MFs incorporated at rates of 0, 0.1 and 1.0%w/w MF for a period of 35 days (in the dark at 15 degrees C; n=4 for each treatment). Dried plant litter was applied at the soil surface as a food source for the earthworms. We assessed earthworm vitality through mortality, weight change, depurate production and MF avoidance testing. In addition, we measured stress biomarker responses via the expression of metallothionein-2 (mt-2), heat shock protein (hsp70) and superoxide dismutase (sod-1). Our results showed that exposure and ingestion of MFs (as evidenced by subsequent retrieval of MFs within earthworm depurates) were not lethal to earthworms, nor did earthworms actively avoid MFs. However, earthworms in the MF1.0% treatment showed a 1.5-fold lower cast production, a 24.3-fold increase in expression of mt-2 ($p<0.001$) and a 9.9-fold decline in hsp70 expression ($p<0.001$). Further analysis of soil and MF samples indicated that metal content was not a contributor to the biomarker results. Given that burrowing and feeding behaviour, as well as molecular genetic biomarkers, were modulated in earthworms exposed to MFs, our study highlights potential implications for soil ecosystem processes due to MF contamination.

Prenen, H., et al. (2013). "Peripheral blood monocytes as biomarkers for colorectal cancer." Journal of Clinical Oncology. Conference **31**(15 SUPPL. 1).

Background: Peripheral blood monocytes (PBM) represent a reservoir of inflammatory cells that contribute to cancer progression. When recruited into tumors, monocytes give rise to either macrophages or dendritic cells. Tumor-derived soluble factors can influence the differentiation of tumor-associated macrophages (TAMs) and drive their phenotype to either tumoricidal (M1) or pro-tumorigenic macrophages (M2). We hypothesized that PBM might change their phenotype already when in circulation and can be used as potential markers for early diagnosis of colorectal cancer (CRC) and its progression to metastatic disease. Method(s): Monocytes were isolated by using magnetic microbeads conjugated to antibodies against CD14. In a monocentric training set we included 55 (27 non metastatic (NM), 38 metastatic (M)) untreated CRC patients. The third group included age and gender matched healthy volunteers (HV). Following RNA extraction, gene expression profiles of PBM were investigated by high throughput screening using Illumina. Statistical analysis was done on the microarray expression data to delineate a disease specific signature. A cut off was set to select the genes showing a minimum fold change of 1,5. A validation study was performed in three additional major

oncological centers throughout Europe. Result(s): There was a broad overlap in the gene signature of PBM from NM and M patients, indicating that this signature already exists in an early stage. Then we assessed the performance of the gene signature of cancer versus HV as diagnostic tool, in particular the sensitivity and specificity, which were remarkably high in the ROC analysis. Out of 40 differentially expressed genes, 21 genes were confirmed by qRT-PCR analysis on samples processed independently. In the validation study the number of genes was downsized to a 12 gene signature without loss of specificity and sensitivity. Conclusion(s): This first biomarker study of PBM in CRC suggests an 'imprinting' of PBM by the tumor in CRC patients. Since the imprinting profile might also be reversed, the PBM signature might not only be useful in CRC diagnosis, but also for the follow-up of treated CRC patients. Overall, our data offer new opportunities to develop a non-invasive test for CRC detection and monitoring.

Preobrazhensky, S. N. and D. W. Bahler (2009). "Immunomagnetic bead separation of mononuclear cells from contaminating granulocytes in cryopreserved blood samples." Cryobiology **59**(3): 366-368.

Density gradient centrifugation usually allows efficient separation of mononuclear cells from granulocytes using fresh human blood samples. However, we have found that with cryopreserved blood samples, density gradient centrifugation fails to separate granulocytes from mononuclear cells and have explored using immunomagnetic anti-CD15 microbeads as an alternate method to separate these cell populations. Using cryopreserved blood samples from 10 healthy donors we have shown that granulocytes express a significantly higher level of CD15 antigen than monocytes and lymphocytes, which allows for their efficient separation from mononuclear cells using anti-CD15 microbeads. This procedure is critical for purification of individual cell populations from cryopreserved leukocyte samples and could also potentially be applied to avoid granulocyte contamination of mononuclear cells isolated from stored blood and from patients with sepsis or thermal injury.

Prezioso, L., et al. (2013). "Haploidentical stem cell transplantation after negative depletion of T cells expressing the alfa-beta+ chain of the T-cell receptor (TCR) for adults with hematological malignancies." Haematologica **3)**: 165.

Premise. For many years,T cell depletion (TCD) of hematopoietic stem cells (HSCs) has been based on either positive or negative selection of mobilised peripheral blood cells (PBPCs). Selective elimination of + T cells has been recently performed to achieve a 4,5-5 log TCD and to retain in the graft NK, dendritic cells, monocytes and T lymphocytes.A rapid immunological reconstitution and very promising outcome were observed in pediatric patients.With the aims of confirming these results even in adults, we have recently launched this programme and here we report our preliminar clinical data. Methods. Eight patients, median age 40 yrs (range19-65), with AML(n=6), ALL(n=1)or HL(n=1) entered the study.Conditioning consisted of Treosulfan 12gr/sqm x3 days,Fludarabine 30mg/sqm x5 days,Thiotepa 5mg/Kgx2 days and ATG 1,5mg/kg x4 days. G-CSF was used to mobilize PBPCs from one-haplotype mismatched donors (3 mothers,4 brothers,1 cousin). Mobilized mononuclear cells were incubated with a biotinylated anti-TcR antibody and subsequently with an antibiotin antibody conjugated to magnetic microbeads(Miltenyi Biotec,Germany).Under a strong magnetic field,TcR T lymphocytes were retained,whereas all nonmagnetized cells were recovered. Short sirolimus(1mg/day x3 weeks)was used as GVHD prophylaxis in 3 cases whose grafts contained >2x10⁵/kg +Tcells. Results.Grafts contained a median of 14,4x10⁶/kg (range7- 15,7)CD34+ cells, 6,6x10⁶ CD3+Tcells/kg (range 2,14-13) with 19x10⁴/kg (SD 21,24) +T cells and 7,78x10⁶ Tcells/kg (range2,1-12,6), 0,08x10⁶ B cells/kg (range 0,003-0,32) and 24x10⁸ CD56+NKcells/kg (SD 1,04). All but one patient,who required a second graft from the same donor to boost hematopoietic reconstitution,achieved a full donor sustained engraftment. Median time to reach 500 neutrophils and 50,000 platelets was 13 (range 9-18) and 11 days(range 9-13),respectively. Two patients had skin grade I/II aGVHD. No patients has so far developed cGvHD. 100 CD4+cell/mcL were reached in a median of 60 days.Only 1 CMV reactivation occurred. Overall,3 patients have so far died (2 non-hematologic causes and 1 relapse).All were in relapse at transplant. Five survive event-free at a median follow-up of 92 days (range 30-163). Conclusions. The infusion of /CD19-depleted grafts was safe and effective also in adult setting,resulting into rapid donor engraftment and early expansion of donor-derived T lymphocytes,without life-threatening infectious complication.

Prezioso, L., et al. (2013). "Haploidentical stem cell transplantation after negative depletion of T cells expressing the alphabeta chain of the T-cell receptor (TCR) for adults with hematological malignancies." Blood. Conference: 55th Annual Meeting of the American Society of Hematology, ASH **122**(21).

Introduction For many years, T cell depletion (TCD) of hematopoietic stem cells (HSCs) has been based on either positive or negative selection of mobilised peripheral blood cells (PBPCs). After CD34+ cell selection, the T cell repertoire is very narrow since the number of T lymphocytes in the graft has to be particularly low to prevent GvHD and ATG in the conditioning exerts an additional in vivo T cell depletion. Thus the immune recovery is slow and patients tend to remain susceptible to opportunistic infections for several months after HSCT. To hasten and improve post-transplant immune reconstitution broad repertoire various strategies of adoptive donor T cell immunotherapy (e.g. engineering with a suicide gene; depleting alloreactivity by means of photodynamic purging or through the use of freshly purified regulatory T cells) have been investigated over the past years. More recently, selective elimination of alphabeta+ T cells has been performed to achieve a 4,5-5 log TCD and to retain in the graft NK, dendritic cells, monocytes and gammadeltaT lymphocytes. Under this approach, a rapid immunological reconstitution and very promising outcome have been reported in pediatric patients. With the aims of confirming these results even in adults, we have recently launched this programme and here we report our preliminar clinical data. Methods Thirteen patients, median age 40 years (range 19-65), with AML (n=9), ALL (n=2), HL (n=1) or Rhabdomyosarcoma (n=1) entered the study. All but two patients, who were in first remission, were in advanced-stage disease at transplant with five patients in chemoresistant relapse. Conditioning consisted of ATG 1,5 mg/kg from day -13 to day -10, Treosulfan 12gr/sqm from -9 to -7, Fludarabine 30mg/sqm from -6 to -2 and Thiotepa 5mg/Kg on days -5 and -4. Ten mug/kg G-CSF was used to mobilize PBPCs from one-haplotype mismatched donors (4 mothers, 4 brothers, 2 sisters, 1 son, 1 daughter and 1 cousin). Mobilized mononuclear cells were incubated with a biotinylated anti-TcRalphabeta antibody and subsequently with an antibiotin antibody conjugated to magnetic microbeads (Miltenyi Biotec, Germany). Under a strong magnetic field, TcRalphabeta T lymphocytes were retained, whereas all nonmagnetized cells were recovered. Short sirolimus (1mg/day x3 weeks) was used as additional GVHD prophylaxis in 3 cases whose grafts contained more than 2x105/kg alphabeta+Tcells. Results Grafts contained a median of 12,3x106/kg CD34+ cells(range7-19), 6 x106 CD3+Tcells/kg (range 2,3-13)with 10,4x104/kg alphabeta+T cells (range 1,38-62) and 5,8x106 gammadelta+Tcells/kg (range2,1-12,6), 6x104B cells/kg (range 0,2-32) and 34x108 CD56+NKcells/kg (range10-91). All but one patient, who required a second graft from the same donor to boost hematopoietic reconstitution, achieved a full donor sustained engraftment. Median time to reach 500 neutrophils and 50,000 platelets was 13 (range 9-18) and 11 days (range 9-13), respectively. Four patients had skin grade I/II aGVHD. No patients has so far developed chronic GvHD. Median CD4+ cell counts at 30, 60, 90 and 120 days since the

transplant were 33, 122, 190 and 251 n/mL, respectively. CMV reactivation occurred in only 2 cases (in one, CMV serology was unfavourable: CMV-negative donor/CMV-positive recipient). Overall, 3 patients have so far died (2 non-hematologic causes and 1 early relapse). Ten survive disease-free at a median follow-up of 104 days (range 30-178). Conclusions The infusion of alphabeta/CD19-depleted grafts was safe and effective also in adult setting, resulting into rapid donor hematopoietic engraftment and early expansion of donor-derived gammadeltaT lymphocytes, without life-threatening infectious complications.

Priesnitz, W. (2017). "Microfibers - How Your Clothes Could be Polluting the Oceans (and damaging your health)." Natural Life: 28-29.

The article offers information on impact of microfibers of the clothing on polluting the oceans. Topics discussed include microfibers are estimated to be responsible for over eighty percent of shoreline pollution around the world; it has been reported that polar fleece from recycled plastic has been found to release the most fiber; and dangers associated with microbeads in beauty products and property of observing the toxins like pesticides or organic pollutants by the microfibers.

Primiano, F. P., Jr., et al. (1984). "Measurement system for respiratory water vapor and temperature dynamics." Journal of Applied Physiology: Respiratory, Environmental & Exercise Physiology **56**(6): 1679-1685.

An instrumentation system has been developed to simultaneously measure water vapor and temperature at the same point within respiratory airways during breathing. A mass spectrometer was used to analyze gas continuously sampled through a modified inlet catheter. At the tip of the catheter, gas temperature is sensed by a microbead thermistor. Adequate water vapor dynamics is achieved by a two-step procedure. First, the tip of the sampling catheter is constricted to reduce the catheter's internal pressure and thereby prevent condensation and evaporation. Second, the water vapor signal from the mass spectrometer is compensated electronically to improve its transient response. As part of the evaluation of the system, water vapor and gas temperature were measured in the oropharynx of human subjects.

Pringle, J. K., et al. (2008). "Time-lapse geophysical investigations over a simulated urban clandestine grave." Journal of Forensic Sciences **53**(6): 1405-1416.

A simulated clandestine shallow grave was created within a heterogeneous, made-ground, urban environment where a clothed, plastic resin, human skeleton, animal products, and physiological saline were placed in anatomically correct positions and re-covered to ground level. A series of repeat (time-lapse), near-surface geophysical surveys were undertaken: (1) prior to burial (to act as control), (2) 1 month, and (3) 3 months post-burial. A range of different geophysical techniques was employed including: bulk ground resistivity and conductivity, fluxgate gradiometry and high-frequency ground penetrating radar (GPR), soil magnetic susceptibility, electrical resistivity tomography (ERT), and self potential (SP). Bulk ground resistivity and SP proved optimal for initial grave location whilst ERT profiles and GPR horizontal "time-slices" showed the best spatial resolutions. Research suggests that in complex urban made-ground environments, initial resistivity surveys be collected before GPR and ERT follow-up surveys are collected over the identified geophysical anomalies. © 2008 American Academy of Forensic Sciences.

Privalova, A., et al. (2015). "Biodegradable polyester-based microcarriers with modified surface tailored for tissue engineering." Journal of Biomedical Materials Research **103**(3): 939-948.

Microcarriers have been proposed in tissue engineering, namely for bone, cartilage, skin, vascular, and central nervous system. Although polyester-based microcarriers have been already used for this purpose, their surface properties should be improved to provide better cell growth. The goal of this study was to prepare microbeads based on poly(d,l-lactide) acid, poly(l-lactide) acid, and to study cell behavior (adhesion, spreading, growth, and proliferation) in function of microbead topography and surface chemistry. To improve L-929 fibroblasts adhesion, microbead surface has been modified with three polycations: chitosan, poly(2-dimethylamino ethylmethacrylate) (PDMAEMA), or chitosan-g-oligolactide copolymer (chit-g-OLA). Although modification of the microbead surface with chitosan and PDMAEMA was performed through physical adsorption on the previously prepared microbeads, chit-g-OLA copolymer was introduced directly during microbead processing. This simple approach (1) bypass the use of an emulsifier (polyvinyl alcohol, PVA); (2) avoid surface "contamination" with PVA molecules limiting a control of the surface characteristics. In vitro study of the growth of mouse fibroblasts on the microbeads showed that both surface topography and chemistry affected cell attachment, spreading, and proliferation. Cultivation of L-929 fibroblasts for 7 days resulted in the formation of a 3D cell-scaffold network. © 2014 Wiley Periodicals, Inc. J Biomed Mater Res Part A: 103A: 939-948, 2015.

Priyanka, M. and S. Dey (2018). "Ruminal impaction due to plastic materials - An increasing threat to ruminants and its impact on human health in developing countries." Veterinary World **11**(9): 1307-1315.

Ruminal impaction due to plastic materials is a condition, in which indigestible plastic foreign bodies accumulate in the rumen of ruminants leading to ruminal impaction, indigestion, recurrent tympany, and many other adverse health effects. It is caused by the indiscriminate feeding of ruminants on indigestible plastic waste materials. The disease is primarily noticed in stray animals residing in urban areas of developing countries. Ingested plastic materials in the rumen slowly release the chemicals in rumen fluid, which intern enter the food chain through milk and meat products. These chemicals have a detrimental effect on human health. At present, exploratory rumenotomy is the only choice for both diagnosis and treatment of ruminal impaction due to plastic materials in ruminants. Control measures include good animal husbandry practices and proper disposal of plastic waste materials. The present review discusses in depth about the epidemiology, pathophysiology, diagnosis, treatment, prevention, and control of ruminal impaction due to plastic materials in ruminants and also highlights its impact on human health.

Procter, J., et al. (2019). "Smells good enough to eat: dimethyl sulfide (DMS) enhances copepod ingestion of microplastics." Marine Pollution Bulletin **138**: 1-6.

Marine copepods have been shown to readily ingest microplastics - a crucial first step in the transfer of plastics into the marine food chain. Copepods have also been shown to elicit a foraging behavioural response to the presence of olfactory stimuli, such as dimethyl sulfide (DMS) - a volatile compound produced by their algal prey. Here, we show that the temperate Calanoid copepod Calanus helgolandicus displays enhanced grazing rates of between 0.7 and 3-fold (72%-292%) on microplastics that have been infused in a DMS solution, compared to DMS-free controls. Environmental exposure of microplastics may result in the development of an olfactory signature that includes algal-derived compounds such as DMS. Our study provides evidence that copepods, which are known to use chemosensory mechanisms to identify and locate dense sources of palatable prey, may be at an increased risk of plastic ingestion if it mimics the scent of their prey.

Prokopijevic, M., et al. (2017). "Tyramine-modified pectins via periodate oxidation for soybean hull peroxidase induced hydrogel formation and immobilization." Applied Microbiology & Biotechnology **101**(6): 2281-2290.

Pectin was modified by oxidation with sodium periodate at molar ratios of 2.5, 5, 10, 15 and 20 mol% and reductive amination with tyramine and sodium cyanoborohydride afterwards. Concentration of tyramine groups within modified pectin ranged from 54.5 to 538 mumol/g of dry pectin while concentration of ionizable groups ranged from 3.0 to 4.0 mmol/g of dry polymer compared to 1.5 mmol/g before modification due to the introduction of amino group. All tyramine-pectins showed exceptional gelling properties and could form hydrogel both by cross-linking of carboxyl groups with calcium or by cross-linking phenol groups with peroxidase in the presence of hydrogen peroxide. These hydrogels were tested as carriers for soybean hull peroxidase (SHP) immobilization within microbeads formed in an emulsion based enzymatic polymerization reaction. SHP immobilized within tyramine-pectin microbeads had an increased thermal and organic solvent stability compared to the soluble enzyme. Immobilized SHP was more active in acidic pH region and had slightly decreased K _m value of 2.61 mM compared to the soluble enzyme. After 7 cycles of repeated use in batch reactor for pyrogallol oxidation microbeads, immobilized SHP retained half of the initial activity.

Provencher, J. F., et al. (2019). "Assessing plastic debris in aquatic food webs: what we know and don't know about uptake and trophic transfer." Environmental Reviews **27**(3): 304-317.

Plastic pollution is now recognized as a global environmental issue that can affect the health of biota and ecosystems. Now that a growing number of species and taxa are known to ingest a diverse range of sizes and types of plastics and retain the plastics in their guts, there are increasing questions relating to the movement of plastics through food webs, and how biota may directly and indirectly ingest plastics. Here, we synthesize what is known from the published, peer-reviewed literature about plastic ingestion by animals and identify critical gaps in our knowledge. We systematically reviewed and examined the literature for studies that reported ingested plastics in marine and freshwater biota at a global scale. Our objective was to inform discussions and future studies regarding what we know about plastic ingestion and fate in food webs. We assessed what regions, ecosystems, and food webs have been studied to date and whether potential information may already be available to assess if trophic transfer of plastics may be occurring. We found 160 relevant publications through 2016. Most studies were concentrated in specific regions and in specific ecosystem types, with freshwater studies being the most limited. Moreover, most studies examined one species at a time with only a handful of regions with multiple taxa examined across multiple studies. Twenty-one percent of the regions have no published data on plastic ingestion to date. Although some studies have measured ingestion in multiple species across trophic levels, few have tested the hypothesis that plastics are transferred across trophic levels. Moreover, none have addressed questions related to biomagnification. While our review suggests that numerous papers have recorded the ingestion of plastics by biota across many trophic levels, habitats, and geographic regions, many questions regarding how or whether biota retain, bioaccumulate, biomagnify, and trophically transfer plastics still need to be addressed.

Provencher, J. F., et al. (2020). "Are phthalate ester contaminants in northern fulmar preen oil higher in birds that have ingested more plastic?" Marine Pollution Bulletin **150**: 110679.

Understanding the impacts of plastic pollution is a global research priority. Previous research has shown that plasticizers such as phthalate esters detected in seabird tissues can be useful non-lethal biochemical markers of plastic ingestion as compared with more standard necropsy techniques. We examined the concentrations of six phthalate esters in the preen oil of Northern Fulmars (Fulmarus glacialis) in relation to their retained plastics. Contrary to a previous study, we found that the phthalates examined were not analytically detectable in fulmar preen oil. Given that the birds we examined had up to 100 pieces of plastics in their stomachs, and all uropygial glands were completely emptied during the necropsies, it does not appear that measuring phthalates in preen oil of Northern Fulmars is a useful, non-lethal technique to determine if individuals ingest plastics, at least not currently given the available commercial analytical detection limits.

Provencher, J. F., et al. (2018). "Are ingested plastics a vector of PCB contamination in northern fulmars from coastal Newfoundland and Labrador?" Environmental Research **167**: 184-190.

While marine animals are exposed to environmental contaminants via their prey, because plastic pollution in the aquatic environment can concentrate some chemicals, ingested plastics are thought to increase the exposure of biota to contaminants. Currently, in the literature there are contradictory results relating to how higher levels of ingested plastics by birds may lead to higher levels of polychlorinated biphenyl (PCBs). To date none of these have incorporated known Toxic Equivalency Factors (TEFs) for non-ortho and mono-ortho congeners of PCB which is critical to assessing the potential effects from PCBs. We examined northern fulmars (Fulmarus glacialis) from the Labrador Sea region Canada, and the ingested plastics from these same birds for comparative PCB concentrations. We found no significant correlations between the PCB concentrations in the birds and the mass or number of retained ingested plastic pieces in the stomach, this held true when PCBs were considered by a number of different ways, including Sigma ₄PCB, Sigma PCB, lower-chlorinated, high-chlorinated, non-ortho PCB, and mono-ortho congeners. PCB concentrations were lower in plastics as compared with livers. We found significant differences in congener profiles between the ingested plastics and seabird livers suggesting that while plastics do not contribute to the PCB concentrations, there may be some interactions between plastics and the chemicals that the birds are exposed to via ingested plastics.

Provencher, J. F., et al. (2015). "Marine birds and plastic debris in Canada: a national synthesis and a way forward." Environmental Reviews **23**(1): 1-13.

Marine plastic ingestion by seabirds was first documented in the 1960s, but over 50 years later our understanding about the prevalence, intensity, and subsequent effect of plastic pollution in the oceans is still developing. In Canada, systematic assessments using recognized standard protocols began only in the mid-2000s. With marine plastic pollution identified by the United Nations Environmental Program (UNEP) as one of the most critical challenges for the environment, a greater understanding of how plastics affect marine birds in Canada, along with a national strategy, is timely and necessary. To better understand which and how many marine birds are affected by marine debris, we reviewed reports of plastic ingestion and nest incorporation in Canada. Of the 91 marine bird species found in Canadian waters, detailed plastic ingestion data from multiple years and locations are available for only six species. Another 33 species have incidental reports, and we lack any data on dozens more. Future efforts should focus on characterizing the risk of plastic ingestion among understudied species and on continued monitoring of species that are known indicators of plastic pollution internationally and found in multiple regions of Canada to facilitate comparisons at the national and international levels.

Provencher, J. F., et al. (2018). "Garbage in guano? Microplastic debris found in faecal precursors of

seabirds known to ingest plastics." Science of the Total Environment **644**: 1477-1484.

Plastic pollution is global environmental contaminant. Plastic particulates break down into smaller fragments in the environment, and these small pieces are now commonly found to be ingested by animals. To date, most plastic ingestion studies have focused on assessing retained plastics or regurgitated plastics, but it is likely that animals also excrete plastic and other debris items. We examined the terminal portion of the gastrointestinal tract of a seabird known to commonly ingest plastics, the Northern Fulmar (Fulmarus glacialis), to determine if seabirds excrete microplastics and other debris via their guano. We also examine how guano collections may be used as an indicator of retained plastics. The frequency of occurrence of microplastics did not correlate between the gut and faecal precursor samples, but there was a positive relationship between the number of pieces of plastics in the gut and the number of microplastics in the guano. Our findings suggest that seabirds are acting as vectors of microplastics and debris in the marine environment where their guano accumulates around their colonies. This transport of microplastics and debris by colonial seabirds needs to be further examined, and considered when designing environmental monitoring for microplastics in regions where seabird colonies are found.

Prunier, J., et al. (2019). "Trace metals in polyethylene debris from the North Atlantic subtropical gyre." Environmental Pollution **245**: 371-379.

Plastic pollution in the marine environment poses threats to wildlife and habitats through varied mechanisms, among which are the transport and transfer to the food web of hazardous substances. Still, very little is known about the metal content of plastic debris and about sorption/desorption processes, especially with respect to weathering. In this study, plastic debris collected from the North Atlantic subtropical gyre was analyzed for trace metals; as a comparison, new packaging materials were also analyzed. Both the new items and plastic debris showed very scattered concentrations. The new items contained significant amounts of trace metals introduced as additives, but globally, metal concentrations were higher in the plastic debris. The results provide evidence that enhanced metal concentrations increase with the plastic state of oxidation for some elements, such as As, Ti, Ni, and Cd. Transmission electron microscopy showed the presence of mineral particles on the surface of the plastic debris. This work demonstrates that marine plastic debris carries complex mixtures of heavy metals. Such materials not only behave as a source of metals resulting from intrinsic plastic additives but also are able to concentrate metals from ocean water as mineral nanoparticles or adsorbed species. Plastic debris collected from the North Atlantic subtropical gyre was analyzed for trace metals. Marine plastic debris carry complex mixtures of heavy metals but it is evidence that plastic oxidation favors their adsorption. Copyright © 2018 Elsevier Ltd

Pruter, A. T. (1987). "Plastics in the marine environment." Fisheries **12**(1): 16-17.

The major sources of plastics in the marine environment were ship-generated litter, rubbish left on beaches, and solid waste dumped at sea or transported via rivers and municipal drainage systems. This plastic debris included various convenience and packaging items (drinking cups, plastic bags, holders for canned drink packs), fishing tackle (rope, lines, nets), and raw plastics (pellets). Birds, fish, seals, sea turtles and other marine wildlife have ingested plastics, or become entangled, with disastrous consequences. Entanglement in fishing net, uncut strapping bands etc., were responsible for approximately 50,000 deaths a year among northern fur seals in the eastern Bering sea. In the absence of international efforts to control this global problem, some suggestions are presented (eg disposing of rubbish on-shore) for minimizing oceanic plastic pollution.

Ptitsyn, K. G., et al. (2018). "[Use of DNA-aptamers for enrichment of low abundant proteins in cellular extracts for quntitative detection by selected reaction monitoring]." Biomeditsinskaia Khimiia **64**(1): 5-9.

The relationship between the amount of a target protein in a complex biological sample and its amount measured by selected reaction monitoring (SRM) mass spectrometry upon the affinity enrichment of target protein with aptamers immobilized on a solid phase was studied. Human thrombin added in known concentrations to cellular extracts derived from bacterial cells was used as model target protein. It has been demonstrated that the affinity enrichment of thrombin in cellular extracts by means of the thrombin-binding aptamer immobilized on the surface of magnetic microbeads results in an approximately 10-fold increase of the concentration of target protein and a 100-fold decrease of the low limit of a target protein concentration range where its quantitative detection by SRM is possible without an interference from other peptides present in a tryptic digest.

Puertas, S., et al. (2011). "Taking advantage of unspecific interactions to produce highly active magnetic nanoparticle-antibody conjugates." Acs Nano **5**(6): 4521-4528.

Several strategies for linking antibodies (Abs) through their Fc region in an oriented manner have been proposed at the present time. By using these strategies, the Fab region of the Ab is available for antigen molecular recognition, leading to a more efficient interaction. Most of these strategies are complex processes optimized mainly for the functionalization of surfaces or microbeads. These methodologies imply though the Ab modification through several steps of purification or the use of expensive immobilized proteins. Besides, the functionalization of magnetic nanoparticles (MNPs) turned out to be much more complex than expected due to the lack of stability of most MNPs at high ionic strength and non-neutral pH values. Therefore, there is still missing an efficient, easy and universal methodology for the immobilization of nonmodified Abs onto MNPs without involving their Fab regions during the immobilization process. Herein, we propose the functionalization of MNPs via a two-steps strategy that takes advantage of the ionic reversible interactions between the Ab and the MNP. These interactions make possible the orientation of the Ab on the MNP surface before being attached in an irreversible way via covalent bonds. Three Abs (Immunoglobulin G class) with very different isoelectric points (against peroxidase, carcinoembryonic antigen, and human chorionic gonadotropin hormone) were used to prove the general applicability of the strategy here proposed and its utility for the development of more bioactive NPs.

Puglisi, E., et al. (2019). "Selective bacterial colonization processes on polyethylene waste samples in an abandoned landfill site." Scientific Reports **9**(1): 14138.

The microbial colonization of plastic wastes has been extensively studied in marine environments, while studies on aged terrestrial wastes are scarce, and mostly limited to the isolation of plastic-degrading microorganisms. Here we have applied a multidisciplinary approach involving culturomics, next-generation sequencing analyses and fine-scale physico-chemical measurements to characterize plastic wastes retrieved in landfill abandoned for more than 35 years, and to assess the composition of bacterial communities thriving as biofilms on the films' surfaces. All samples were characterized by different colors but were all of polyethylene; IR and DSC analyses identified different level of degradation, while FT-Raman spectroscopy and X-ray fluorescence further assessed the degradation level and the presence of pigments. Each plastic type harbored distinct bacterial communities from the others, in agreement with the differences highlighted by the physico-chemical analyses. Furthermore, the most degraded polyethylene films were found to host a bacterial community more similar to the surrounding soil as revealed by both alpha- and beta-diversity NGS analyses. This work confirms the novel hypothesis that different polyethylene terrestrial waste samples select for different bacterial communities, and that structure of these communities can be correlated with physico-chemical properties of the plastics, including the degradation degree.

Puig-De-Morales, M., et al. (2001). "Measurement of cell microrheology by magnetic twisting cytometry with frequency domain demodulation." Journal of Applied Physiology **91**(3): 1152-1159.

Magnetic twisting cytometry (MTC) (Wang N, Butler JP, and Ingber DE, Science 260: 1124-1127, 1993) is a useful technique for probing cell micromechanics. The technique is based on twisting ligand-coated magnetic microbeads bound to membrane receptors and measuring the resulting bead rotation with a magnetometer. Owing to the low signal-to-noise ratio, however, the magnetic signal must be modulated, which is accomplished by spinning the sample at approximately 10 Hz. Present demodulation approaches limit the MTC range to frequencies <0.5 Hz. We propose a novel demodulation algorithm to expand the frequency range of MTC measurements to higher frequencies. The algorithm is based on coherent demodulation in the frequency domain, and its frequency range is limited only by the dynamic response of the magnetometer. Using the new algorithm, we measured the complex modulus of elasticity (G*) of cultured human bronchial epithelial cells (BEAS-2B) from 0.03 to 16 Hz. Cells were cultured in supplemented RPMI medium, and ferromagnetic beads (approximately 5 microm) coated with an RGD peptide were bound to the cell membrane. Both the storage (G', real part of G*) and loss (G", imaginary part of G*) moduli increased with frequency as omega(alpha) (2 pi x frequency) with alpha approximately equal to 1/4. The ratio G"/G' was approximately 0.5 and varied little with frequency. Thus the cells exhibited a predominantly elastic behavior with a weak power law of frequency and a nearly constant proportion of elastic vs. frictional stresses, implying that the mechanical behavior conformed to the so-called structural damping (or constant-phase) law (Maksym GN, Fabry B, Butler JP, Navajas D, Tschumperlin DJ, LaPorte JD, and Fredberg JJ, J Appl Physiol 89: 1619-1632, 2000). We conclude that frequency domain demodulation dramatically increases the frequency range that can be probed with MTC and reveals that the mechanics of these cells conforms to constant-phase behavior over a range of frequencies approaching three decades.

Puig-de-Morales, M., et al. (2004). "Cytoskeletal mechanics in adherent human airway smooth muscle cells: probe specificity and scaling of protein-protein dynamics." American Journal of Physiology - Cell Physiology **287**(3): C643-654.

We probed elastic and loss moduli in the adherent human airway smooth muscle cell through a variety of receptor systems, each serving as a different molecular window on cytoskeletal dynamics. Coated magnetic microbeads were attached to the cell surface via coating-receptor binding. A panel of bead coatings was investigated: a peptide containing the sequence RGD, vitronectin, urokinase, activating antibody against beta(1)-integrin, nonactivating antibody against beta(1)-integrin, blocking antibody against beta(1)-integrin, antibody against beta(1)-integrin, and acetylated low-density lipoprotein. An oscillatory mechanical torque was applied to the bead, and resulting lateral displacements were measured at baseline, after actin disruption by cytochalasin D, or after contractile activation by histamine. As expected, mechanical moduli depended strongly on bead type and bead coating, differing at the extremes by as much as two orders of magnitude. In every case, however, elastic and loss moduli increased with frequency f as a weak power law, f(x-1). Moreover, with few exceptions, data could be scaled such that elastic and frictional responses depended solely on the power law exponent x. Taken together, these data suggest that power law behavior represents a generic feature of underlying protein-protein dynamics.

Puig-de-Morales-Marinkovic, M., et al. (2007). "Viscoelasticity of the human red blood cell." American Journal of Physiology - Cell Physiology **293**(2): C597-605.

We report here the first measurements of the complex modulus of the isolated red blood cell (RBC). Because the RBC is often larger than capillary diameter, important determinants of microcirculatory function are RBC deformability and its changes with pathologies, such as sickle cell disease and malaria. A functionalized ferrimagnetic microbead was attached to the membrane of healthy RBC and then subjected to an oscillatory magnetic field. The resulting torque caused cell deformation. From the oscillatory forcing and resulting bead motions, which were tracked optically, we computed elastic and frictional moduli, g' and g", respectively, from 0.1 to 100 Hz. The g' was nearly frequency independent and dominated the response at all but the highest frequencies measured. Over three frequency decades, g" increased as a power law with an exponent of 0.64, a result not predicted by any simple model. These data suggest that RBC relaxation times that have been reported previously, and any models that rest upon them, are artifactual; the artifact, we suggest, arises from forcing to an exponential fit data of limited temporal duration. A linear range of response was observed, but, as forcing amplitude increased, nonlinearities became clearly apparent. A finite element model suggests that membrane bending was localized to the vicinity of the bead and dominated membrane shear. While the mechanisms accounting for these RBC dynamics remain unclear, methods described here establish new avenues for the exploration of connections among the mechanical, chemical, and biological characteristics of the RBC in health and disease.

Pul, R., et al. (2012). "Glatiramer acetate increases phagocytic activity of human monocytes in vitro and in multiple sclerosis patients." PLoS ONE [Electronic Resource] **7**(12): e51867.

Beside its effects on T cells, a direct influence on cells of the myelo-monocytic lineage by GA becomes evident. Recently, we demonstrated that GA drives microglia to adopt properties of type II antigen presenting cells (APC) and increases their phagocytic activity. In the present work, we focused on human blood monocytes in order to examine whether GA may increase phagocytic activity in vivo and to evaluate the molecular mechanisms explaining this new discovered mode of action. Peripheral blood mononuclear cells (PBMC) were obtained using a Biocoll-Isopaque gradient and monocytes were subsequently isolated by using CD14 MicroBeads. Phagocytic activity was determined by flow cytometric measurement of the ingestion of fluorescent beads. Flow cytometry was also used to assess monocytic differentiation and expression of phagocytic receptors. Monocytes of GA treated MS patients exhibited a significantly higher phagocytic activity than those of healthy controls or non-treated MS patients. In vitro, a significant phagocytic response was already detectable after 1 h of GA treatment at the concentrations of 62.5 and 125 micro g/ml. A significant increase at all concentrations of GA was observed after 3 h and 24 h, respectively. Only monocytes co-expressing CD16, particularly CD14(++)CD16(+) cells, were observed to phagocytose. Treatment of monocytes with IL-10 and supernatants from GA-treated monocytes did not alter phagocytosis. We observed a decrease in CD11c expression by GA while no changes were found in the expression of CD11b, CD36, CD51/61, CD91, TIM-3, and CD206. In our blocking assays, treatment with anti-CD14, anti-CD16, anti-TIM3, anti-CD210, and particularly anti-CD36 antibodies led to a decrease in phagocytosis. Our results demonstrate a new mechanism of action of GA treatment that augments phagocytic activity of human monocytes in vivo and in vitro. This activity seems to arise from the CD14(++)CD16(+) monocyte subset.

Punin, W., et al. (2014). "The feasibility of converting solid waste into refuse-derived fuel 5 via mechanical biological treatment process." Journal of Material Cycles and Waste Management **16**(4): 753-762.

The aim of our study was to investigate the feasibility of utilizing solid waste after mechanical biological treatment (MBT) processing at a landfill site in Phitsanulok, Thailand, as refuse-derived fuel 5 (RDF-5). The waste composition, and physical and chemical characteristics of each waste fraction were determined to evaluate the suitability of the waste for recycling and reuse as RDF-5. Results showed that after MBT processing, the solid waste >40 mm in size was observed to have 33.8 MJ/kg of calorific value. The average concentrations of heavy metals were also found to be within the acceptable limit for plastic waste combustion, thus proving that MBT-processed solid waste >40 mm in size has high potential for use as RDF-5. The optimal weight ratio of MBT-processed solid waste and crude oil sludge for transformation into RDF-5 was found to be 80:20. With this optimum ratio, the average calorific values of the RDF-5 were determined to be 47 MJ/kg, with sulfur and chlorine contents of 0.16 and 0.74 %, respectively. The characteristics of the produced RDF-5 could meet the specified ASTM standards in terms of calorific value (>15 MJ/kg), and sulfur and chlorine contents. In addition, the compressive strength of the produced RDF-5 was also found to be suitable for compact storage and transportation without any damage. Finally, the energy production cost from this RDF-5 process was estimated as USD $0.05/kWh.

Purdy, T. and E. Tarn (2013). Improving plastic wastes recovery from hospitals through innovative environmental management. Proceedings, Annual Conference - Canadian Society for Civil Engineering.

Plastic wastes pose one of the greatest challenges to modern waste management. While much of the focus for recovering and recycling plastics is on industrial, commercial, and residential waste streams, an often overlooked source of waste plastics originates from the healthcare sector, and especially from hospitals. Hospitals could benefit significantly from improved environmental and waste management system practices and techniques to reduce their contribution of waste plastics to the solid waste stream. However, conventional waste management measures do not necessarily work effectively in hospitals. A number of documented challenges are faced by hospitals, particularly in terms of the amount of plastic wastes produced. Because of the focus on patient care, environmental concerns may only be a secondary objective, and modern budget restrictions can limit alternatives for waste management. More critically, issues such as the cross contamination of biohazardous and nonhazardous wastes, inappropriate labeling, and discrepancies in defining infectious wastes, can result in the unnecessary disposal of plastics wastes which could have been otherwise recovered and recycled. This research examines through a case study in progress how an innovative environmental management system can assist a hospital in identifying key issues in handling its plastics wastes by identifying the obvious and hidden sources of plastics wastes in hospital activities, examining how commonly held beliefs can impact plastics handling by hospital personnel, and assessing how handling practices can benefit or disadvantage improved plastics recovery.

Puskic, P. S., et al. (2019). "Uncovering the sub-lethal impacts of plastic ingestion by shearwaters using fatty acid analysis." Conservation Physiology **7**(1): coz017.

Marine plastic pollution is increasing exponentially, impacting an expanding number of taxa each year across all trophic levels. Of all bird groups, seabirds display the highest plastic ingestion rates and are regarded as sentinels of pollution within their foraging regions. The consumption of plastic contributes to sub-lethal impacts (i.e. morbidity, starvation) in a handful of species. Additional data on these sub-lethal effects are needed urgently to better understand the scope and severity of the plastics issue. Here we explore the application of fatty acid (FA) analysis as a novel tool to investigate sub-lethal impacts of plastic ingestion on seabird body condition and health. Using gas chromatography-mass spectrometry, we identified 37 individual FAs within the adipose, breast muscle and liver of flesh-footed (Ardenna carneipes) and short-tailed (Ardenna tenuirostris) shearwaters. We found high amounts of FA 16:0, 18:0, 20:5n3 (eicosapentaenoic acid), 22:6n3 (docosahexaenoic acid) and 18:1n9 in both species; however, the overall FA composition of the two species differed significantly. In flesh-footed shearwaters, high amounts of saturated and mono-unsaturated FAs (needed for fast and slow release energy, respectively) in the adipose and muscle tissues were related to greater bird body mass. While total FAs were not related to the amount of plastic ingested in either species, these data are a valuable contribution to the limited literature on FAs in seabirds. We encourage studies to explore other analytical tools to detect these sub-lethal impacts of plastic.

Putnam, A. L., et al. (2009). "Expansion of human regulatory T-cells from patients with type 1 diabetes." Diabetes **58**(3): 652-662.

OBJECTIVE: Regulatory T-cells (Tregs) have catalyzed the field of immune regulation. However, translating Treg-based therapies from animal models of autoimmunity to human clinical trials requires robust methods for the isolation and expansion of these cells-a need forming the basis for these studies.

RESEARCH DESIGN AND METHODS: Tregs from recent-onset type 1 diabetic patients and healthy control subjects were isolated by fluorescence-activated cell sorting and compared for their capacity to expand in vitro in response to anti-CD3-anti-CD28-coated microbeads and IL-2. Expanded cells were examined for suppressive function, lineage markers and FOXP3, and cytokine production.

RESULTS: Both CD4+CD127(lo/-) and CD4+CD127(lo/-)CD25+ T-cells could be expanded and used as Tregs. However, expansion of CD4+CD127(lo/-) cells required the addition of rapamycin to maintain lineage purity. In contrast, expansion of CD4+CD127(lo/-)CD25+ T-cells, especially the CD45RA+ subset, resulted in high yield, functional Tregs that maintained higher FOXP3 expression in the absence of rapamycin. Tregs from type 1 diabetic patients and control subjects expanded similarly and were equally capable of suppressing T-cell proliferation. Regulatory cytokines were produced by Tregs after culture; however, a portion of FOXP3+ cells were capable of producing interferon (IFN)-gamma after reactivation. IFN-gamma production was observed from both CD45RO+ and CD45RA+ Treg populations.

CONCLUSIONS: The results support the feasibility of isolating Tregs for in vitro expansion. Based on expansion capacity, FOXP3 stability, and functional properties, the CD4+CD127(lo/-)CD25+ T-cells represent a viable cell population for cellular therapy in this autoimmune disease.

Pye, A. (2017). CLEARING OCEANS OF PLASTICS. Environmental Engineering. London, Professional Engineering Publishing Ltd. **30:** 3.

At the annual CEFIC Chemicals Convention 2017 in Vienna in October the special guests included multi-awards winner young entrepreneur Boyan Slat and Ocean Conservancy VP Emily Woglom, who addressed the best approaches to rid the oceans of plastic and the possible role of industry. Michael Gove announced in July that the UK will, from 2018, ban the production and sale of cosmetics containing microbeads -- the small bits of plastic found in cosmetics that end up in the food chain and poison fish and sea mammals. They will join the select group of countries that have bans: USA, Canada, Ireland, New Zealand, Netherlands. Here, Pye discusses clearing oceans of plastic preventing it from breaking down into microplastics.

Qadir, A. and M. Imam (2006). "UTILISATION OF WASTE PLASTIC BAGS IN BITUMINOUS MIX FOR IMPROVED PERFORMANCE OF ROADS." Journal of Solid Waste Technology & Management **32**(3): 185-195.

The quantity and type of waste being generated is growing at enormous rate. The plastic wastes produced particularly in form of bags being non-degradable and with limited recycling options poses disposal problem. The probable solution as mentioned lies in effective recycling of the waste which in fact is restricted by economic and operational constraints hence demanding a sustainable solution for safe and ultimate disposal of waste plastic bags. An academic research aimed at probable use of waste plastic bags in pavement structure so as to come up with an ultimate safe disposal together with improvement in the performance of pavement through better mix design was undertaken. An aggregate material from waste plastic bags referred to as Recycled Plastic Waste Aggregate (RPWA) is developed which would partially replace the conventional material to improve desired mechanical characteristics for a particular road mix. Preliminary investigations have indicated that use of RPWA (1.2 - 3mm in size) in the surface and base mix design, when utilised up to 2.5% by weight substitution has shown improved stability and flow (Marshall test) having unit weight and bulk specific gravity falling within the acceptable limits for light and heavy traffic loads, It is envisaged that use of RPWA in the conventional asphalt hot mix design is likely to improve the pavement performance with a sustainable solution for the disposal of plastic waste. [ABSTRACT FROM AUTHOR]

Qi, R., et al. (2020). "Behavior of microplastics and plastic film residues in the soil environment: A critical review." Science of the Total Environment **703**: 134722.

It is now widely acknowledged that microplastic pollution represents one of the greatest anthropogenically mediated threats to Earth-system functioning. In freshwater and marine ecosystems the presence of large amounts of microplastic appears almost ubiquitous, with frequent reports of negative impacts on aquatic health. In contrast, however, the impact of plastic in terrestrial environments remains poorly understood. In agroecosystems, microplastics (particles<5mm) can enter the soil environment either directly (e.g. from biosolids application, irrigation water, atmospheric deposition), or indirectly through the in situ degradation of large pieces of plastic (e.g. from plastic mulch films). Although we have encouraged the use of plastics over the last 50years in agriculture to promote greater resource use efficiency and food security, the legacy of this is that many soils are now contaminated with large amounts of plastic residue (ca. 50-250kgha⁻¹). Due to difficulties in separating and quantifying plastic particles from soil, our knowledge of their behavior, fate and potential to transfer to other receptors (e.g. surface and groundwater, air) and enter the human food chain remains poor. This information, however, is critical for evaluating the risk of soil-borne microplastic pollution. In this critical review, we systematically summarize (i) the distribution and migration of microplastics in soils, (ii) highlight the separation, extraction, and identification methods for monitoring microplastics in soils, (iii) discuss the ecological effects and pollution mechanisms of soil microplastics, (iv) propose mitigation strategies to help prevent and reduce microplastic pollution, and (v) identify the most important future challenges in soil microplastics research.

Qi, W., et al. (2019). "Growth and survival of microencapsulated probiotics prepared by emulsion and internal gelation." Journal of Food Science and Technology **56**(3): 1398-1404.

Efficient microencapsulation of probiotics by most existing methods is limited by low throughput. In this work, Saccharomyces boulardii and Enterococcus faecium were microencapsulated by a method based on emulsion and internal gelation. The growth and survival of microencapsulated microbes under different stressors were investigated using free non-encapsulated ones as a control. The results showed that the prepared micro-beads by emulsion and internal gelation exhibited a spherical and smooth shape, with sizes between 300 and 500 micro m. Both S. boulardii and E. faecium grew well and survived better when encapsulated in micro-beads. The survival rates were increased 25% and 40% for microencapsulated S. boulardii and E. faecium respectively when compared with non-encapsulated controls under high temperature and high humidity. The increases of survival rates were 60% for microencapsulated S. boulardii and 25% for E. faecium in simulated gastric juice. And the increases were 15% and 20% respectively when the survival rates of the microencapsulated S. boulardii and E. faecium were determined in simulated intestinal juice. The microencapsulation by emulsion and internal gelation offers an effective way to protect microbes in adverse in vitro and in vivo conditions and is promising for the large-scale production of probiotics microencapsulation.

Qi, Y., et al. (2019). "Effects of plastic mulch film residues on wheat rhizosphere and soil properties." Journal of Hazardous Materials: 121711.

Plastic residues could accumulate in soils as a consequence of using plastic mulching, which results in a serious environmental concern for agroecosystems. As an alternative, biodegradable plastic films stand as promising products to minimize plastic debris accumulation and reduce soil pollution. However, the effects of residues from traditional and biodegradable plastic films on the soil-plant system are not well studied. In this study, we used a controlled pot experiment to investigate the effects of macro- and micro- sized residues of low-density polyethylene and biodegradable plastic mulch films on the rhizosphere bacterial communities, rhizosphere volatile profiles and soil chemical properties. Interestingly, we identified significant effects of biodegradable plastic residues on the rhizosphere bacterial communities and on the blend of volatiles emitted in the rhizosphere. For example, in treatments with biodegradable plastics, bacteria genera like Bacillus and Variovorax were present in higher relative abundances and volatile compounds like dodecanal were exclusively produced in treatment with biodegradable microplastics. Furthermore, significant differences in soil pH, electrical conductivity and C:N ratio were observed across treatments. Our study provides evidence for both biotic and abiotic impacts of plastic residues on the soil-plant system, suggesting the urgent need for more research examining their environmental impacts on agroecosystems.

Qi, Y., et al. (2018). "Macro- and micro- plastics in soil-plant system: effects of plastic mulch film residues on wheat (Triticum aestivum) growth." Science of the Total Environment **645**: 1048-1056.

Plastic residues have become a serious environmental problem in the regions with intensive use of plastic mulching. Even though plastic mulch is widely used, the effects of macro- and micro- plastic residues on the soil-plant system and the agroecosystem are largely unknown. In this study, low density polyethylene and one type of starch-based biodegradable plastic mulch film were selected and used as examples of macro- and micro- sized plastic residues. A pot experiment was performed in a climate chamber to determine what effect mixing 1% concentration of residues of these plastics with sandy soil would have on wheat growth in the presence and absence of earthworms. The results showed that macro- and micro- plastic residues affected both above-ground and below-ground parts of the wheat plant during both vegetative and reproductive growth. The type of plastic mulch films used had a strong effect on wheat growth with the biodegradable plastic mulch showing stronger negative effects as compared to polyethylene. The presence of earthworms had an overall positive effect on the wheat growth and chiefly alleviated the impairments made by plastic residues.

Qian, Q., et al. (2014). "Modulating the release of drugs from alginate matrices with the addition of gelatin microbeads." Journal of Bioactive and Compatible Polymers **29**(3): 193-207.

Injectable drug-loaded matrices and controlled release technology offer numerous advantages over conventional dosages. Cross-linkable alginate hydrogels have been proposed for in vivo injection, but their large initial burst release of encapsulated drugs represents a limitation for the transition to the clinical phase. To reduce this effect, a new drug delivery system was prepared by combining uncross-linked, drug-loaded gelatin microbeads with cross-linkable alginate solution. Gelatin microbeads ranging from 5 to 50 mum were obtained depending on gelatin concentration, stirring rate, and emulsifying time. The release behavior of drugloaded gelatin microbeads encapsulated within cross-linked alginate gel was characterized both at room temperature and 37degreeC and compared with the release from gelatin microbeads and cross-linked alginate gel alone. Gelatin microbeads reduced the initial burst release of fluorescein from cross-linked alginate matrix, with a corresponding decrease in the release efficiency. Burst release in the first 2 h was reduced from 30% to about 5%, while cumulative release at 37degreeC declined from about 95% to 50% after 7 days. This system represents a promising approach for the development of novel and versatile injectable drug delivery systems. © The Author(s) 2014.

Qiang, L. and J. Cheng (2019). "Exposure to microplastics decreases swimming competence in larval zebrafish (Danio rerio)." Ecotoxicology and Environmental Safety **176**: 226-233.

Microplastics have been frequently detected in both marine and freshwater ecosystems. Their impact on aquatic organisms has raised much concern. This study investigated the impact of microplastics on zebrafish embryos and larvae, with a special focus on their swimming competence. The zebrafish embryos were exposed to microplastics starting from 4 h post fertilization. Microplastics first adhered to the embryo chorion, then entered the stomach and intestinal tract of the larvae later. In the free swimming test, exposure to 1000 micro g/L (around 1.91x10⁷ particles/L) of microplastics led to a significant decrease in both swimming distance and speed of zebrafish larvae under the dark condition by 3.2% and 3.5% respectively. In the alternating light-to-dark photoperiod stimulation assay, exposure to 100 and 1000 micro g/L (around 1.91x10⁶ and 1.91x10⁷ particles/L) of microplastics caused a 4.6% and 2.6% decrease in swimming distance, and reduced the active speed by 4.9% and 2.8%, possibly as a result of inhibited dark avoidance in treated zebrafish larvae. At the molecular level, exposure to microplastics induced upregulated expression of inflammation (il1b) and oxidative stress (cat) related genes. This study demonstrates that exposure to microplastics significantly decreases larvae swimming competence, which may have significant impacts on its population fitness in the aquatic environment and further ecological consequences.

Qiao, R., et al. (2019). "Accumulation of different shapes of microplastics initiates intestinal injury and gut microbiota dysbiosis in the gut of zebrafish." Chemosphere **236**(124334).

Different shapes of microplastics are widely detected in the environment and organisms and most of them remain in the gut. However, the influences of shapes on the bioaccumulation and toxicity of microplastics in the gut are largely unknown. Three shapes (bead, fragment, and fiber) of microplastics of comparable size in one dimension were prepared to exposure to zebrafish. The accumulation and toxicities of microplastics in the gut were detected. Shape-dependent accumulation in the gut was observed with the order of fibers (8.0 micro g/mg) > fragments (1.7 micro g/mg) > beads (0.5 micro g/mg). The accumulation of microplastics caused multiple toxic effects in fish intestine, including mucosal damage, and increased permeability, inflammation and metabolism disruption. Based on these toxic effects, microplastic fibers resulted in more severe intestinal toxicity than microplastic fragments and beads did. Furthermore, microplastics also induced gut microbiota dysbiosis and specific bacteria alterations, which will provide novel insights into the potential mechanism of microplastics causing intestinal toxicities in fish. Our results also suggested that shape-depended effects should not be ignored in the health risk assessment of microplastics.

Qiao, R., et al. (2019). "Combined effects of polystyrene microplastics and natural organic matter on the accumulation and toxicity of copper in zebrafish." Science of the Total Environment **682**: 128-137.

As emerging contaminants, microplastics (MPs) are predicted to act as vectors for other contaminants and their combined effects are largely unknown. In this study, the combined effects of MPs and natural organic matter (NOM) on the accumulation and toxicity of copper (Cu) in zebrafish (Danio rerio) were investigated. As a result, small-size MPs could absorb more Cu than large-size MPs. The presence of NOM promoted Cu adsorption on MPs in the pH range of 6-8. Our results demonstrate that the combination of MPs and NOM increased Cu accumulation in the livers and guts in a size-depended manner. Correspondingly, the results of biochemical test showed that MPs and NOM could aggravate Cu-toxicity in the livers and guts, which is manifested in the increased levels of malonaldehyde (MDA) and metallothionein (MT) and decreased levels of superoxide dismutase (SOD). Furthermore, the results of transcriptomic analysis suggested that such aggravation of toxicity was mainly attributed to the inhibition of Cu-ion transport and the enhanced oxidative stress. Since the co-existence of MPs and NOM in the environment is inevitable, their enhancement effects on the bioaccumulation and toxicity of other pollutants such as heavy metals deserve more attention. Copyright © 2019 Elsevier B.V.

Qiao, R., et al. (2019). "Microplastics induce intestinal inflammation, oxidative stress, and disorders of metabolome and microbiome in zebrafish." Science of the Total Environment **662**: 246-253.

Microplastics (MPs) can be ingested by a variety of species and mainly accumulate in the gut. However, the consequences of MPs exposure in the gut are largely unknown. Here we evaluated the impacts of MPs exposure in zebrafish gut. Animals were experimentally exposed to polystyrene MPs (5- micro m beads; 50 micro g/L and 500 micro g/L) for 21 days and monitored for alterations in tissue histology, enzymatic biomarkers, gut microbiome and metabolomic responses. Inflammation and oxidative stress were observed in the zebrafish gut after exposed to MPs. Furthermore, significant alterations in the gut microbiome and tissue metabolic profiles were observed, with most of these were associated with oxidative stress, inflammation and lipid metabolism. This study provides evidence that MPs exposure causes gut damage as well as alterations in gut metabolome and microbiome, yielding novel insights into the consequences of MPs exposure.

Qin, M., et al. (2015). "Functional evaluations of ex vivo induced endothelial progenitors for autologous transplantation in non-human primates." Blood **126 (23)**: 4302.

It is possible to treat ischemia and hemophilia A diseases by producing sufficient functional human endothelial progenitor cells (EPCs)/endothelial cells (ECs) in vitro, for use with cell

therapy in the clinic. We have previously reported the ability to produce FVIII-secreting EPCs/ ECs derived from human cord blood CD34⁺ cells. About 1412+/-102 fold expansion over initial EPCs was achieved after culturing for 21 days. An acute liver sinusoidal endothelial cells (LSEC) injury model in NOD/SCID mice was also developed to verify the functional migrating ability of the generated EPCs/ ECs in vivo. Here, we further applied this culturing technique to expand and subsequently differentiate CD34⁺ cells into the EPCs/ ECs derived from mobilized peripheral bloods of both human and cynomolgus monkeys. In brief, the CD34⁺ cells were isolated from human peripheral bloods or from monkeys (n=10) mobilized with human G-CSF/SCF. In the first 6 days, the isolated CD34⁺ cells were expanded in modified IMDM medium supplemented with human cytokine combinations of SCF, Flt-3L, TPO, IL-3, GM-CSF, and VEGF. From days 7 to 36, the adhering EPCs/ ECs were subsequently differentiated in EBM-2 basal medium with 20% FBS and endothelial growth factors of VEGF, IGF, EGF, FGF, and fibronectin. The purities and phenotypes of the induced EPCs/ECs were assessed in vitro by antibodies against human CD31, vWF, and FVIII for the human or Dil- acetylated- low density lipoprotein (ac-LDL) and FITC-lectin double staining for the monkey cells.In addition, the safety and efficacy of the induced monkey EPCs/ECs was determined in vivo by autologous transplantation in monkey LSEC injury model, which was induced by a toxic agent, monocrotaline (MCT), to disrupt the sinusoidal endothelial barrier and stimulate the incorporation of transplanted cells into liver parenchyma. In the transplantation group (n=7), each monkey was injected with double labeled autologous EPCs/ECs preparations (2x10⁸ cells/500mul in saline), whereas in the control group (n=3) was injected with the same volume saline via hepatic portal vein injections. The cross-sections (20mum in depth) of fixed hepatic tissues were analyzed for grafting and functional migration of transplanted EPCs/ECs. The transplanted cells were identified by lenti-viral gene expressed with green fluorescent protein (red) or direct observation using anti-monkey IgG -microbead- FITC conjugates (green). For in vitro induced EPCs/ECs derived from human peripheral blood cell, the expansion of 834.58+/-119.03 fold was achieved from the CD34⁺/VEGFR2⁺ EPCs on day 21. Total more than 2x 10⁸ FVIII-producing EPCs / ECs were produced from one collection of human peripheral blood (250 mL). On the other hand, the CD34⁺/VEGFR2⁺ EPCs (3.6x10⁴ +/-2.1x10³) from one collection of monkey peripheral blood (20ml) were expanded up to 1274+/-166 fold and 7211+/-372 fold on days 24 and 36, respectively (n=4). The EPCs were reached at a logarithmic growth from days 12 to 45. The induced cells can be frozen and resuscitated during any stage of the culturing process. The formation of EC tubes was observed from day 24. Over 80% of expanded cells were EPC/EC-specific and identified by Dil-ac-LDL and FITC-lectin double staining on day 36. All monkeys recoveredfrom the surgeries of portal vein injection and resumed normal diet and behavior after autologous transplantation with cultured EPCs/ECs. Similarly, the routine blood analysis and liver functional enzymes were at the normal level, and no other apparent side effects were observed. About 3.2+/-1.4% and 2.1+/-1.1% of liver cells were observed as Dil-ac-LDL and FITC-lectin double positive in the liver cryosections (25 sections per monkey) on days 7 and 14, respectively, indicating that autologous transplanted EPCs/ECs were capable of repopulating into functional ECs in vivo. Furthermore, the injected EPCs/ECs were scattered in the intercellular spaces of hepatocytes t the hepatic tissues on day 14, suggesting that the transplanted cells could migrate towards injured LSEC sites and reconstitute structurally the sinusoidal endothelial compartment in monkey livers. In summary, the large-scale EPCs/ECs were produced from CD34⁺ cells of both human and monkey peripheral bloods in vitro. The safety and functions of the EPCs/ECs were confirmed in mice and cynomolgus

monkeys, strongly suggesting the potential application of these FVIII-producing EPCs/ECs to future clinical study.

Qin, Y., et al. (2019). "Microplastics in the sediment of Lake Ulansuhai of Yellow River Basin, China." Water Environment Research **02**: 02.

As an emerging organic pollutant, microplastics in the ocean have been the subject of much study. However, there is a lack of research on freshwater environments, notably in sediment, China. Microplastics contamination in sediment of Lake Ulansuhai has been investigated in the study, and its concentration range was from 24 +/- 7 to 14 +/- 3 n/kg. Further, it exhibited a difference in spatial distribution with high content in the north zone of the lake far from the entrance of the drainage canal and it has a decreasing tendency with the flow from north to south in lake. Colored plastic particles acted as the dominated pollution type, and more than 79.69% of microplastics were smaller than 2 mm in size, existed as the form of fibers. FTIR results mirrored that the main types of microplastics were polyethylene, polyethylene terephthalate, polypropylene, and polyvinyl chloride.

Qiu, J., et al. (2015). "Characterization and isolation of splenic littoral cells, a possible cellular niche for extramedullary hematopoiesis in myelofibrosis." Blood **126 (23)**: 3594.

Splenic littoral cells (LC) line the venous sinusoids of the human spleen and have been thought to act as blood cells filters. Little is known about SLCs beyond their preliminary characterization using immunochemistry and electron microscopy by others. Since SLCs comprise a significant portion of spleen, we hypothesized that SLC might be an important component of the splenic microenvironment that contributes to the development of extramedullary hematopoiesis in myelofibrosis (MF) patients. To further phenotypically characterize viable SLCs, surgically removed fresh spleens were treated with collagenase B and the hematopoietic cells were depleted using anti-CD45 micro-beads. The enriched CD45- cells were then stained and analyzed on a FACS analyzer. The SLCs were i, CD3-, CD45-, CD34-, CD8a+, CD31+ (Figure 1), ii, CD206+, CD21-, CD14-, FHOD1+, SIRP1a+, a phenotype identical to that previously reported based on IHC. SLCs and SECs were then identified by IHC in the red pulp of healthy individuals and MF patients using anti- CD8a and CD34 antibodies. SLCs were much more abundant than ECs in normal spleens. MF SLCs were however, much less condensed due to the expansion of hematopoietic cells than normal SLCs and the sinusoids encircled by SLCs were more elongated and had a more irregular shape as compared to normal spleen (Figure 2). To isolate the viable SLC and EC, fresh or cryopreserved spleen single cell suspensions were prepared as above and were FACS sorted for CD3-, CD45-, CD34-, CD8a+, CD31+ SLCs and CD3-, CD45-, CD34+, CD8a-, CD31+ SECs. The SSC/FSC profiles revealed two cell populations which could be distinguished by size and complexity, SLC being bigger and less uniform in size and shape. The CD31 signal intensity was greater in SEC than in SLC. The gene expression profiles of FACS sorted SLC, SEC and mononuclear cells (MNCs) were analyzed using human genome U133 Plus 2.0 arrays. DAVID Functional Annotation Clustering was applied to identify enriched gene clusters in selected lists. MNCs were significantly different from both SLC and EC, which expressed several clusters of genes involved in cell morphology, adhesion, and blood vessel formation. This indicated that SLCs were not closely related to myeloid cells but share features with SEC. SLC could however be differentiated from SEC by expression of genes involved in chromatin modification and regulation of RAS protein signaling, as well as intravesicle transportation genes, which may be related to their assumed capacity for phagocytosis. In addition SLC expressed many cytokines and adhesion molecules known to support hematopoiesis. Transcripts for various cytokines expressed by SEC and SLC were, however, distinct suggesting that they might serve as niches for

different subpopulations of HSC/HPC. Preliminary microarray analysis of SLCs from an MF patient was also performed. Genes associated with apoptosis, intracellular lumens were upregulated as well as a cluster of genes in the cancer pathway. Cell cycle genes, genes of transcription regulation, and proteolysis were down-regulated in MF SLCs. Sorted SLC were also cultured in EC medium (ECM). The cultured SLCs were able to be repeatedly passaged. These cells were wide and spindle shaped. At a lower density, the cells tended to connect and organize into rings with a hollow space in the middle which resembled a splenic sinusoid. Immunostaining for CD8a and FHOD1 were conducted on these cultured cells, revealing that they continued to express these two markers. Interestingly, the expression of FHOD1, a stress fiber inducing protein was strongly polarized. To determine the relationship between SLC and the MF malignant clone SLCs from MF patients were isolated and assayed for JAK2V617F using allele specific NESTED PCR. Samples from three MF patients, were analyzed and no JAK2V617F was detected. In conclusion, we have isolated, cultured and characterized SLCs from normal and MF spleens for the first time. This will allow for further analysis of their function in normal individuals and individuals with blood disea es. (Figure Presented).

Qiu, Q., et al. (2015). "Occurrence of microplastics in the coastal marine environment: First observation on sediment of China." Marine Pollution Bulletin **98**(1-2): 274-280.

Microplastics in sediments from the Beibu Gulf and the coastline of China Sea were investigated to evaluate the occurrence and abundance of microplastics in China for the first time. Microplastics (<5. mm) were taken from sediments by a flotation method. The number of microplastics was counted by a fluorescence microscope, an instrument that is rarely used in the detection of microplastics in sediments. This instrument led to results that were satisfactory. Compared with other sampled areas, microplastics were found in massive concentrations in China. Four types of microplastics, HDPE, PET, PE and PS, were identified. The results will provide useful background information for further investigations. Copyright © 2015 Elsevier Ltd.

Qiu, Q., et al. (2016). "Extraction, enumeration and identification methods for monitoring microplastics in the environment." Estuarine, Coastal and Shelf Science **176**: 102-109.

There is much research on the occurrence, pollution characteristics and impacts of microplastics in the marine environment but this omits factors which play important roles in the analysis of microplastics. This review summarizes the methods and techniques in the extraction from sediment, seawater and organisms, and assesses their advantages and limitations according to different experimental conditions, such as salt solution and reagents added to remove organic matter. Similarly, this overview includes the enumeration methods of microplastics by many kinds of microscopes (e.g. stereomicroscope, fluorescent microscope, scanning electron microscope). Advantages and challenges of using micro-FTIR, ART-FTIR, FPA-FTIR, Pry-GC/MS, and Raman spectroscopy in the identification methods are also discussed. This review suggests that monitoring microplastics needs standardized protocols for extraction, identification and quantification and that further research on the effects of microplastics to human health is needed.

Qiu, Y., et al. (2019). "Potential toxicity of nanopolystyrene on lifespan and aging process of nematode Caenorhabditis elegans." Science of the Total Environment: 135918.

In the environment, nanoplastic particles, such as nanopolystyrene, potentially cause toxicity on organisms at various aspects. We here employed endpoints of lifespan and aging-related phenotypes to further investigate the possible long-term effects of nanopolystyrene (100 nm) in Caenorhabditis elegans. After exposure from L1-larvae to adult day-3, nanopolystyrene at high concentrations (100 and 1000 mug/L) reduced the lifespan. Although nanopolystyrene (1 or 10 mug/L) did not affect the lifespan, nanopolystyrene (1 or 10 mug/L) could induce the more severe intestinal reactive oxygen species (ROS) production and decrease in locomotion behavior during the aging process compared with control. Moreover, nanopolystyrene exposure could cause the severe decrease in expressions of some immune response genes, hsp-6 gene, and genes encoding manganese-superoxide dismutases (Mn-SODs) during aging process, suggesting the severe suppression in innate immune response, inhibition in antioxidation defense system, and suppression in mitochondrial unfolded protein response (mt UPR) by nanopolystyrene. Our results highlight the potential of long-term nanopolystyrene exposure in reducing longevity and in affecting health state during the aging process in environmental organisms.

Qiu, Y., et al. (2019). "Sorption of polyhalogenated carbazoles (PHCs) to microplastics." Marine Pollution Bulletin **146**: 718-728.

The sorption of 5 Polyhalogenated carbazoles (PHCs) [3,6-dibromocarbazole (3,6-BCZ), 3,6-dichlorocarbazole (3,6-CCZ), 3,6-diiodocarbazole (3,6-ICZ), 2,7-dibromocarbazole (2,7-BCZ) and 3-bromocarbazole (3-BCZ)] on to three microplastics [polyethylene (PE), polypropylene (PP), and polyvinyl chloride (PVC)] in a simulated seawater system are studied. Sorption isotherms demonstrated that PVC had the maximum sorption capacity, which can be attributed to polar-polar interaction. The sorption kinetics model showed that the sorption process was controlled by both intraparticle and film diffusion. The sorption of PHCs to microplastics was significantly influenced by temperature, the sorption capacity first increased gradually and then decreased with the increasing temperature. Increasing the salinity decreased the sorption of PHCs onto PP, PE, PVC microplastics. Our results indicated that all three kinds of microplastics can serve as carriers for PHCs in the aquatic environment, which put marine ecosystems at higher risks. Copyright © 2019 Elsevier Ltd

Qu, H., et al. (2019). "Enantiospecific toxicity, distribution and bioaccumulation of chiral antidepressant venlafaxine and its metabolite in loach (Misgurnus anguillicaudatus) co-exposed to microplastic and the drugs." Journal of Hazardous Materials **370**: 203-211.

In present study, we investigated the enantioselective behaviors of the chiral antidepressant venlafaxine and its metabolite O-desmethylvenlafaxine in loach Misgurnus anguillicaudatus (M. anguillicaudatus), as well as effects of microplastic on toxicity, distribution and metabolism through a 40-day co-exposure. The contents of SOD and MDA in loach liver elevated when the loach was exposed to venlafaxine and O-desmethylvenlafaxine. Moreover, co-exposure with microplastic might lead to more adverse effect against loach. The distribution of venlafaxine and O-desmethylvenlafaxine were both detected in loach tissues and liver subcellular. The concentrations of venlafaxine and O-desmethylvenlafaxine were lower in water in microplastic-present treatment. Whilst, more contaminants were accumulated in liver through the "vehicle" (microplastic). Enantioselective behavior of venlafaxine and O-desmethylvenlafaxine occurred with R-enantiomers being preferentially degraded. With microplastic present, the bioaccumulation factor (BAF) of venlafaxine and O-desmethylvenlafaxine in loach tissue amplified more than 10 times. In liver subcellular structure, microplastic may help to transport more compounds into subtle areas and postpone the contaminants metabolism in organisms. The present study for the first time gained an insight into the potential ecological effects and environmental behaviors of combined pollutions of chiral pharmaceuticals and microplastic, which could supply important information for environment risk assessment of concurrent organic pollutants and microplastic.

Qu, H., et al. (2018). "Effects of microplastics on the uptake, distribution and biotransformation of chiral antidepressant venlafaxine in aquatic ecosystem." Journal of Hazardous Materials **359**: 104-112.

In this study, we investigated the enantioselective environmental behaviors of the chiral antidepressant venlafaxine (VFX) in lab-scale aquatic ecosystems in the presence of microplastics (MPs). To determine the bioaccumulation, distribution, and metabolism as well as the effects of MPs on aquatic ecosystems, water-sediment, water-Lemna.minor (L.minor), water-Misgurnus.anguillicaudatus (M.anguillicaudatus), and water-sediment-L.minor-M.anguillicaudatus ecosystems were set up and exposed to venlafaxine and two levels of microplastics over a 90-day period. The removal efficiencies of VFX ranged from 58 to 96% in different ecosystems, and VFX degraded significantly faster in the complex water-sediment-L.minor-M.anguillicaudatus ecosystem with S-enantiomer preferentially enriched. The main metabolite O-desmethylvenlafaxine (O-DVFX) was also observed in ecosystems, displaying similar enantioselectivity. When exposed to 50 mg L⁻¹ of microplastics, the amount of venlafaxine in sediment and loach (M.anguillicaudatus) were significantly higher than that in the 1 mg L⁻¹ microplastics treatments, and enhanced accumulation of O-DVFX was observed in loach. The present study for the first time assessed the combined effects of venlafaxine and microplastics in simulated aquatic microcosms, which could help gain an insight into the potential ecological impacts of chiral pollutants and microplastic, and evaluate their environment risks more accurately in future. Qu, M., et al. (2019). "Neuronal damage induced by nanopolystyrene particles in nematode <i>Caenorhabditis elegans</i> (Electronic supplementary information (ESI) available. See DOI: 10.1039/c9en00473d)." Environmental Science: Nano **6**(8): 2591-2601.

The potential adverse effects of nanoplastics have gradually gained significant attention. Herein, we employed Caenorhabditis elegans to investigate the possible neurotoxic effects of nanopolystyrene particles on the development and function of D-type GABAergic motor neurons. Nanopolystyrene (1000 μg L−1) induced the neurodegeneration of D-type motor neurons in wild-type nematodes, and nanopolystyrene (≥100 μg L−1) further induced the neurodegeneration phenotype in nematodes with a mutation in sod-3, encoding a Mn-SOD or acs-22, which governs the functional state of the intestinal barrier. Meanwhile, nanopolystyrene (≥10 μg L−1) decreased head thrash and body bend, and nanopolystyrene (≥100 μg L−1) altered forward and backward movements in wild-type nematodes. Moreover, nanopolystyrene (≥1 μg L−1) decreased head thrash and body bend and nanopolystyrene (≥10 μg L−1) affected forward and backward movements in sod-3 or acs-22 mutant nematodes. Along with the neurotoxicity observed in nanopolystyrene-exposed nematodes, nanopolystyrene exposure induced a dynamic autophagy induction. RNAi knockdown of lgg-1 encoding a key regulator of autophagy induced susceptibility to the neurotoxic effects of nanopolystyrene particles on the development and function of D-type motor neurons, implying the association of dynamic autophagy induction with the neurotoxicity induced by nanopolystyrene particles. Our results highlight the potential neurotoxicity of long-term nanoplastic exposure in organisms.

Qu, M., et al. (2019). "Nanopolystyrene-induced microRNAs response in Caenorhabditis elegans after long-term and lose-dose exposure." Science of the Total Environment **697**: N.PAG-N.PAG.

microRNAs (miRNAs) usually act post-transcriptionally to suppress the expression of many targeted genes. However, the response of miRNAs to nanoplastics is still unclear. We here employed Caenorhabditis elegans to investigate the response of miRNAs to 100 nm nanopolystyrene at a predicted environmental concentration (1 μg/L). After exposure from

L1-larvae to adult day-3, we found that 7 miRNAs (4 down-regulated (mir-39 , mir-76 , mir-794 , and mir-1830) and 3 up-regulated (mir-35 , mir-38 , and mir-354)) were dysregulated by nanopolystyrene. Expressions of these 7 miRNAs were dose-dependent in nematodes exposed to 1–100 µg/L nanopolystyrene. Among these 7 miRNAs, we found that only mir-35 , mir-38 , mir-76 , mir-354 , and mir-794 were involved in the regulation of response to nanopolystyrene based on phenotypic analysis of both transgenic strains and mutant nematodes. Overexpression of mir-35 , mir-38 , or mir-354 induced a resistance to nanopolystyrene toxicity, and overexpression of mir-76 or mir-794 induced a susceptibility to nanopolystyrene toxicity, which suggested that these 5 miRNAs mediated a protective response to nanopolystyrene. Gene ontology and KEGG analysis further implied that mir-35 , mir-38 , mir-76 , mir-354 , and mir-794 were associated with various biological processes and signaling pathways. Our results suggest the crucial role of a certain number of miRNAs in response to nanopolystyrene after long-term and low-dose exposure in organisms. In nematodes, long-term and low-dose exposure to nanopolystyrene caused the response of limited number of miRNAs. Unlabelled Image • miRNAs responses to nanopolystyrene were investigated in nematode C. elegans. • We identified only 7 miRNAs in response to nanopolystyrene (1 µg/L). • We confirmed functions of 5 miRNAs in regulating the nanopolystyrene toxicity. Qu, M., et al. (2018). "Using acs-22 mutant Caenorhabditis elegans to detect the toxicity of nanopolystyrene particles." Science of the Total Environment **643**: 119-126.

In this study, we employed Caenorhabditis elegans with acs-22 mutation to examine the in vivo effect of functional deficit in intestinal barrier on toxicity and translocation of nanopolystyrene particles. Mutation of acs-22 leads to deficit in intestinal barrier. After prolonged exposure, nanopolystyrene particles at concentrations >=1? micro g/L could cause toxicity on acs-22 mutant nematodes. acs-22 mutation resulted in translocation of nanopolystyrene particles into targeted organs through intestinal barrier in nanopolystyrene particles (1 micro g/L) exposed nematodes. After prolonged exposure, nanopolystyrene particles (1 micro g/L) dysregulated expressions of some genes required for the control of oxidative stress and activated expression of Nrf signaling pathway. Therefore, under certain pathological conditions, our results suggest the potential toxicity of nanoplastic particles at predicted environmental concentration on organisms after long-term exposure.

Qu, M., et al. (2019). "Identification of long non-coding RNAs in response to nanopolystyrene in Caenorhabditis elegans after long-term and low-dose exposure." Environmental Pollution **255**(Pt 1): 113137.

The potential adverse effects of nanoplastics, such as nanopolystyrene, have received the great attention recently. However, the molecular response of organisms to nanoplastics is still largely unknown. In this study, we employed Caenorhabditis elegans as an animal model to investigate the long non-coding RNAs (lncRNAs) in response to long-term exposure to low-dose nanopolystyrene (100nm). Based on Hiseq 2000 sequencing and qRT-PCR confirmation, we identified 36 lncRNAs (21 down-regulated lncRNAs and 15 up-regulated lncRNAs) in response to nanopolystyrene (1mug/L). Using intestinal reactive oxygen species (ROS) production and locomotion behavior as endpoints, we found that RNAi knockdown of linc-2, linc-9, or linc-61 induced a susceptibility to nanopolystyrene toxicity, and RNAi knockdown of linc-18 or linc-50 induced a resistance to nanopolystyrene toxicity. Meanwhile, nanopolystyrene (1mug/L) increased expressions of linc-2, linc-9, linc-18, and linc-61 and decreased linc-50 expression, suggesting that these 5 lncRNAs mediated two different responses to nanopolystyrene exposure. Bioinformatical analysis implied that these 5 lncRNAs were associated with multiple biological processes and signaling pathways. Our results demonstrated the crucial roles of lncRNAs in response to long-term exposure to low-dose nanopolystyrene in organisms.

Qu, S., et al. (2019). "Implications of China's foreign waste ban on the global circular economy." Resources, Conservation & Recycling **144**: 252-255.

As a main destination for recycling, reuse and disposal of solid waste in the global circular economy, China has recently issued a new regulation on its imports, banning 24 types of solid waste in 4 categories, including waste plastics, unsorted scrap papers, discarded textile materials, and vanadium slags. Bans on additional types of solid waste will take effect soon. Here we discuss the possible profound effects of such policy changes on the global circular economy of solid waste. Recycling industries in developed countries will face challenges in the short run, due to their limited capacity and past reliance on exporting, but also opportunities in the long run. Furthermore, developing countries currently without stringent environmental regulations will likely become the new "pollution haven" of solid waste from developed countries and even emerging economies such as China itself. To truly reap the benefits from China's new policies which are originally designed for environmental sustainability and social justice, the global community needs to develop appropriate policy framework to prevent the unintended consequences. [ABSTRACT FROM AUTHOR]

Qu, S., et al. (2017). "[Isolation of polyethylene microbeads in cosmetics by double-density separation]." Wei Sheng Yen Chiu/Journal of Hygiene Research **46**(6): 986-990.

OBJECTIVE: To develop a stable method for isolation and quantitation of polyethylene microbeads in cosmetics and to observe its morphology and size.

METHODS: Polyethylene microbeads were isolated by using the difference of relative density between polyethylene and two kinds of separation solutions(sodium chloride solution and acetonitrile). The contents of polyethylene microbeads in cosmetics were determined by gravimetric method. The morphology and particle size were observed by microscope.

RESULTS: A stable method was developed by optimizing experimental method. The recoveries were from 93. 2% to 98. 2%, and the relative standard deviations varied in the range from 0. 16% to 2. 81%. Samples labeled containing microbeads could be isolated polyethylene microbeads, and the contents were from 0. 11% to 7. 76%, and size ranged from 100 mum to 200 mum. The morphology of isolated polyethylene microbeads were mostly regular, and color were mainly blue and white.

CONCLUSION: The developed method is simple, repeatable and reliable that can be used for isolation and quantitation of polyethylene microbeads with a density lower than 1 g/cm in cosmetics.

Qu, S.-Y., et al. (2017). "Transcription factor RBP-J-mediated signalling regulates basophil immunoregulatory function in mouse asthma model." Immunology **152**(1): 115-124.

Summary Basophils (BA) play an important role in the promotion of aberrant T helper type 2 (Th2) immune responses in asthma. It is not only the effective cell, but also modulates the initiation of Th2 immune responses. We earlier demonstrated that Notch signalling regulates the biological function of BAin vitro. However, whether this pathway plays the same role in vivo is not clear. The purpose of the present study was to investigate the effect of Notch signalling on BA function in the regulation of allergic airway inflammation in a murine model of asthma. Bone marrow BA were prepared by bone marrow cell culture in the presence of recombinant interleukin-3 (rIL-3; 300 pg/ml) for 7 days, followed by isolation of the CD49b+ microbeads. The recombination signal binding protein J (RBP-J-/-) BA were co-cultured with T cells, and the supernatant and the T-cell subtypes were examined. The results indicated disruption of the capacity of BA for antigen presentation alongside an up-regulation of the immunoregulatory function. This was possibly due to the low expression of OX40L in the RBP-J-/- BA. Basophils were adoptively transferred to ovalbumin-sensitized recipient mice, to establish an asthma model. Lung pathology, cytokine profiles of brobchoalveolar fluid, airway hyperactivity and the absolute number of Th1/Th2 cells in lungs were determined. Overall, our results indicate that the RBP-J-mediated Notch signalling is critical for BA-dependent immunoregulation. Deficiency of RBP-J influences the immunoregulatory functions of BA, which include activation of T cells and their differentiation into T helper cell subtypes. The Notch signalling pathway is a potential therapeutic target for BA-based immunotherapy against asthma.

Qu, X., et al. (2018). "Assessing the relationship between the abundance and properties of microplastics in water and in mussels." Science of the Total Environment **621**: 679-686.

Microplastic pollution is increasingly becoming a great environmental concern worldwide. Microplastics have been found in many marine organisms as a result of increasing plastic pollution within marine environments. However, the relationship between micoplastics in organisms and their living environment is still relatively poorly understood. In the present study, we investigated microplastic pollution in the water and the mussels (Mytilus edulis, Perna viridis) at 25 sites along the coastal waters of China. We also, for the first time, conducted an exposure experiment in parallel on the same site using M. edulis in the laboratory. A strong positive linear relationship was found between microplastic levels in the water and in the mussels. Fibers were the dominant microplastics. The sizes of microplastics in the mussels were smaller than those in the water. During exposure experiments, the abundance of microbeads was significantly higher than that of fibers, even though the nominal abundance of fibers was eight times that of microbeads. In general, our results supported positive and quantitative correlations of microplastics in mussels and in their surrounding waters and that mussels were more likely to ingest smaller microplastics. Laboratory exposure experiment is a good way to understand the relative impacts of microplastics ingested by marine organisms. However, significant differences in the results between exposure experiments and field investigations indicated that further efforts are needed to simulate the diverse environmentally relevant properties of microplastics.

Quan, X., et al. (2018). "Three-dimensional stimulation and imaging-based functional optical microscopy of biological cells." Optics Letters **43**(21): 5447-5450.

A new type of functional optical microscope system called three-dimensional (3D) stimulation and imaging-based functional optical microscopy (SIFOM) is proposed, to the best of our knowledge. SIFOM can precisely stimulate user-defined targeted biological cells and can simultaneously record the volumetric fluorescence distribution in a single acquisition. Precise and simultaneous stimulation of fluorescent-labeled biological cells is achieved by multiple 3D spots generated by digital holograms displayed on a phase-mode spatial light modulator. Single-shot 3D acquisition of the fluorescence distribution is accomplished by common-path off-axis incoherent digital holographic microscopy in which a diffraction grating with a focusing lens is displayed on another phase-mode spatial light modulator. The effectiveness of the proposed functional microscope system was verified in experiments using fluorescent microbeads and human lung cancer cells located at various defocused positions. The system can be used for manipulating the states of cells in optogenetics.

Quang, D. V., et al. (2011). "Preparation of amino functionalized silica micro beads by dry method for supporting silver nanoparticles with antibacterial properties." Colloids and Surfaces A: Physicochemical and Engineering Aspects **389**(1-3): 118-126.

The development of resistance to antibiotics and disinfectants as well as the occurrence of many adverse effects caused by using conventional antibacterial agents like chlorine compounds have prompted scientists to search for new antibacterial agents. Among the many nanomaterials, silver nanoparticles have proven to be a good alternative for its antibacterial properties. In this study, silver nanoparticle-supported silica micro beads (Ag-NPBs) with sizes ranging from 180 to 500 mum have been prepared. Silica gel was synthesized by a sol-gel route and crushed into micro beads, which were modified with 3-aminopropyltriethoxysilane by so-called dry method. Silver nanoparticles were directly created on the surface and in the pores of the modified silica by chemical reduction. The prepared materials were characterized with FT-IR, BET, XRD, FE-SEM, FE-STEM, UV-vis spectrophotometer, and optical microscope. Silver nanoparticles mostly distributed at the outer layer of amino functionalized silica beads. Ag-NPBs samples were examined for their antibacterial properties against Escherichia coli (E. coli) and Bacillus subtilis (B. subtilis). The excellent antibacterial properties of Ag-NPBs were confirmed with zone inhibition and test tube test. Zone inhibitory tests proved that Ag-NPBs were effective against both gram negative and gram positive bacteria while test tube tests indicated that no E. coli was detected after 1. min contact. © 2011 Elsevier B.V.

Quartey, E. T., et al. (2015). "Theoretical Framework for Plastic Waste Management in Ghana through Extended Producer Responsibility: Case of Sachet Water Waste." International Journal of Environmental Research & Public Health [Electronic Resource] **12**(8): 9907-9919.

Currently, use and disposal of plastic by consumers through waste management activities in Ghana not only creates environmental problems, but also reinforces the notion of a wasteful society. The magnitude of this problem has led to increasing pressure from the public for efficient and practical measures to solve the waste problem. This paper analyses the impact of plastic use and disposal in Ghana. It emphasizes the need for commitment to proper management of the impacts of plastic waste and effective environmental management in the country. Sustainable Solid Waste Management (SSWM) is a critical problem for developing countries with regards to climate change and greenhouse gas emission, and also the general wellbeing of the populace. Key themes of this paper are producer responsibility and management of products at end of life. The paper proposes two theatrical recovery models that can be used to address the issue of sachet waste in Ghana.

Que, Z., et al. (2019). "Establishment and characterization of a patient-derived circulating lung tumor cell line in vitro and in vivo." Cancer Cell International **19**: 21.

Background: Circulating tumor cells (CTCs) have been described as a population of cells that may

seed metastasis, which is a reliable target for the prevention of metastases in lung cancer patients at the early stage. The culturing of CTCs in vitro can be used to study the mechanism of lung cancer metastasis and to screen antimetastasis drugs. This study aims to establish CTC cell line in vitro and explore the potential mechanism of its metastasis.

Methods: A mixture of EpCAM- and EGFR-coated immunomagnetic microbeads in microfluidic Herringbone-Chip was used to capture CTCs. The CTCs, 95-D and A549 cells was evaluated by cell proliferation assays, clonal formation assays, migration assays and drug resistance. Flow cytometry and cytokine protein chip were used to detect the difference in phenotype and cytokine secretion between CTCs, 95-D and A549 cells. The NOD/SCID mice were used to study tumorigenicity, lung organ colonization and metastasis of CTCs. The H&E staining, immunohistochemistry and immunofluorescence assay were used to detect the pathological status of CTCs.

Results: The number of EpCAM(+)/EGFR(+)/CK(+)/CD45(-) lung CTCs showed a weak negative correlation with clinical stages in patients with non-small cell lung cancer (NSCLC). In a phase IIa lung cancer patient, we successfully establish a permanent CTC cell line, named CTC-TJH-01. In vitro studies showed the CTC-TJH-01 cells were in the intermediate stage of epithelial to mesenchymal transition (EMT), had stem cell characteristics and were drug resistant. In vivo studies showed that CTC-TJH-01 cells can induce tumorigenesis, lung organ colonization and metastasis after xenografting in immunodeficient mice. In addition, the low expression level of CX3CL1 and high expression level of CXCL5 in the CTC-TJH-01 cells may be an important mechanism for their metastasis.

Conclusions: We successfully established a permanent CTC cell line with metastatic ability, which can be used to screen antimetastatic drugs and study the mechanism of lung cancer metastasis.

Quecholac-Pina, X., et al. (2017). "Biodegradation of compostable and oxodegradable plastic films by backyard composting and bioaugmentation." Environmental Science and Pollution Research **24**(33): 25725-25730.

Plastics are widely used in the production of short-life products, which are discarded producing an accumulation of these materials and problems due to their persistence in the environment and waste management systems. Degradable plastics (compostable, oxodegradable) have been presented as an alternative to decrease the negative effect of plastic waste. In this research, the feasibility of degrading a commercially available compostable film and oxodegradable polyethylene, with and without previous abiotic oxidation, is assessed in a home composting system. Reactors (200 L) were used to degrade the plastic films along with a mixture of organic food waste (50%), mulch (25%), and dry leaves (25%), amended with yeast and a solution of brown sugar to increase the speed of the process. The presence of the plastic film did not affect the composting process, which showed an initial increase in temperature and typical profiles for moisture content, pH, with a final C/N of 17.4. After 57 days, the compostable plastic has decreased its mechanical properties in more than 90%, while the oxodegradable film did not show significant degradation if it was not previously degraded by UV radiation. The use of these plastics should be assessed against the prevailing waste management system in each city or country. In the case of Mexico, which lacks the infrastructure for industrial composting, home composting could be an option to degrade compostable plastics along organic waste. However, more testing is needed in order to set the optimal parameters of the process.

Quillen, K., et al. (2011). "Screening plateletpheresis donors for HLA antibodies on two high-throughput platforms and correlation with recipient outcome." Transfusion **51**(3): 504-510.

BACKGROUND: To determine the prevalence and impact of transfusing plasma containing white blood cell antibodies, we compared two high-throughput HLA antibody screening assays and prospectively examined the medical records of all platelet (PLT) recipients to detect subtle manifestations of transfusion-related acute lung injury and other transfusion reactions.

STUDY DESIGN AND METHODS: Serum samples from 136 plateletpheresis donors were tested for HLA Class I and II antibodies using microbead (LABScreen PRA, One Lambda) and microchip (Dynachip, Invitrogen) assays. Electronic medical records of all recipients were reviewed for vital signs and nursing documentation before and after transfusion.

RESULTS: In the microchip assay with a cutoff value of 0.25, 2.9% of samples were positive for Class I and 8.9% for Class II antibodies; with a cutoff value of 0.1, the results were 14.9 and 21.6%, respectively. In the microbead assay (normalized background ratio, 1.5), 15% were positive for Class I and 21% for Class II antibodies. The prevalence of HLA antibodies was 17% in donors without pregnancy or transfusion history and 47% in donors with such history. The PLTs were transfused in 265 episodes to 67 patients. There were no reported reactions; however, symptoms or vital sign changes were noted in seven transfusion episodes. The incidence of reactions was 2.7% (2/75) for antibody-positive units and 2.6% (5/190) for antibody-negative units.

CONCLUSIONS: Microbead and microchip assays yielded similar results. The prevalence of HLA antibodies was greater in donors with a history of pregnancy or transfusion, but no increase in the incidence of transfusion reactions was noted in recipients of components from donors with HLA antibodies.

Quinn, B., et al. (2017). "Validation of density separation for the rapid recovery of microplastics from sediment. (Special Issue: Microplastics in the environment.)." Analytical Methods **9**(9): 1491-1498.

Several density separation techniques using numerous brine solutions have been developed for the separation of microplastics from sediment. The aim of this study was to validate the use of various brine solutions in a relatively rapid, reproducible, low cost single stage method that can deliver consistently high recoveries for different microplastic polymers <1 mm appropriate for monitoring programmes. The recovery of environmentally relevant microplastics (200-400 micro m and 800-1000 micro m) from post-consumer products was tested against tap water and brine solutions of varying density including sodium chloride (NaCl), sodium bromide (NaBr), sodium iodide (NaI) and zinc bromide (ZnBr₂). As expected a general trend of increasing microplastic recovery with increasing solution density was observed, with NaI and ZnBr₂ having significantly (p<=0.001) higher rates of microplastic recovery. Microplastic size was found to influence recovery rates and needs to be taken into consideration when choosing a brine solution. From this work it is evident that density separation recovery tests are needed to validate the use of brine solutions for microplastic recovery and that ZnBr₂ is a novel and appropriate brine solution for microplastic extraction. This study represents the most in depth validation of brine solutions for the density separation of microplastic from sediments undertaken to date.

Raamanathan, A., et al. (2012). "Integrated microfluidic bead-based immunosensor for multiplexed determinations of ovarian cancer biomarkers at the point-of-care." Cancer Research. Conference: 103rd Annual Meeting of the American Association for Cancer Research, AACR **72**(8 SUPPL. 1).

Early detection of ovarian cancer could significantly impact clinical outcome and hence patient survival. Given the biological heterogeneity of ovarian cancer, multi-marker panels will be required. Validation of such panels must utilize pre-clinical serum samples that are available only in small quantities. Diagnostic platforms that are capable of rapid, precise and multiplexed analysis of biomarkers in small quantities of serum should facilitate validation of optimal biomarker panels. Once validated, these platforms could permit rapid screening with finger-stick quantities of blood at point-of-care. The Programmable Bio-Nano-Chip (p-BNC) microfluidic immunosensor provides such a platform. In the p-BNC, serum biomarkers are sequestered and assessed with a fluorescence-based sandwich immunoassay, completed in nano-nets of sensitized agarose microbeads localized in individually addressable wells, housed in a microfluidic module, capable of integrating multiple sample, reagent and biowaste processing and handling steps. Previously, we adapted the p-BNC for the quantification of the CA125 biomarker with low LODs, high precision and a short analysis time of 43 minutes. Here, we adapt the p-BNC to simultaneously assess CA125 and HE4, a promising biomarker panel implicated in early detection. The HE4 immunoassay was developed to perform optimally with the previously established CA125 assay as the rate determining step. Extensive cross reactivity analysis ruled out non-ideal interactions between HE4 and CA125 reagents at the level of capturing antibody, detecting antibody and individual analytes. Wash times were optimized to maximize p-BNC performance. The dose-response curves obtained for the individual analytes (singleplex) were similar to those obtained with multiplex assays. Identical LOD values were noted for the singleplex and multiplex immunoassays with 1.5-fold decrease in precision for the multiplexed assays, demonstrating negligible loss of analytical performance upon multiplexing. For clinical validation, 8 surgically confirmed advanced stage patient sera and 8 age-matched healthy controls were assessed on the multiplexed p-BNC. ROC curve analysis for the CA125-HE4 biomarker combination, interpreted with a Risk of Ovarian Malignancy Algorithm was able to discriminate diseased samples from healthy controls with an AUC of 1.00. The p-BNC indicates strong promise for robust, multiplexed, quantitative measurements of ovarian cancer biomarkers, with high precision and sensitivity to yield clinically pertinent information under 45 minutes. Incorporation of additional biomarkers is underway to establish and validate an optimal panel for early detection of ovarian cancer.

Raamanathan, A., et al. (2012). "Programmable bio-nano-chip systems for serum CA125 quantification: toward ovarian cancer diagnostics at the point-of-care." Cancer Prevention Research **5**(5): 706-716.

Point-of-care (POC) implementation of early detection and screening methodologies for ovarian cancer may enable improved survival rates through early intervention. Current laboratory-confined immunoanalyzers have long turnaround times and are often incompatible with multiplexing and POC implementation. Rapid, sensitive, and multiplexable POC diagnostic platforms compatible with promising early detection approaches for ovarian cancer are needed. To this end, we report the adaptation of the programmable bio-nano-chip (p-BNC), an integrated, microfluidic, and modular (programmable) platform for CA125 serum quantitation, a biomarker prominently implicated in multimodal and multimarker screening approaches. In the p-BNCs, CA125 from diseased sera (Bio) is sequestered and assessed with a fluorescence-based sandwich immunoassay, completed in the nano-nets (Nano) of sensitized agarose microbeads localized in individually addressable wells (Chip), housed in a microfluidic module, capable of integrating multiple sample, reagent and biowaste processing, and handling steps. Antibody pairs that bind to distinct epitopes on CA125 were screened. To permit efficient biomarker sequestration in a three-dimensional microfluidic environment, the p-BNC operating variables (incubation times, flow rates, and reagent concentrations) were tuned to deliver optimal analytical performance under 45 minutes. With short analysis times, competitive analytical performance (inter- and intra-assay precision of 1.2% and 1.9% and limit of detection of 1.0 U/mL) was achieved on this minisensor ensemble. Furthermore, validation with sera of patients with ovarian cancer (n = 20) showed excellent correlation ($R(2) = 0.97$) with gold-standard ELISA. Building on the integration capabilities of novel microfluidic systems programmed for ovarian

cancer, the rapid, precise, and sensitive miniaturized p-BNC system shows strong promise for ovarian cancer diagnostics.

Rack, R., et al. (2011). "Sustainable supply chains: Lessons learned from a long lasting insecticidal net recycling pilot project in Madagascar." American Journal of Tropical Medicine and Hygiene **1)**: 371.

Distribution, use and timely replacement of long-lasting insecticide treated nets (LLINs) are part of a key malaria prevention strategy in Madagascar, where 5.2 million LNs were distributed from 2005-2007. There is a growing awareness of the potential environmental impact of insecticide-embedded plastic waste from the increased number of LNs, if not disposed of or recycled in an environmentally sound manner. We conducted a pilot project to collect and recycle existing old, expired LNs (oLNs) in conjunction with a mass free LN distribution campaign in November, 2010. Six health districts with an estimated population of 1.6 million were targeted for the pilot where 279,000 bed nets had been distributed in 2007. Health volunteers were trained to educate their communities, using a pre-tested job-aid, to voluntarily bring unwanted oLNs for disposal to the closest campaign community distribution point at the time of collecting their new free LNs. oLNs were collected, transported, sorted, compacted, baled and shipped to a plastics recycling company for processing. Over 22,500 oLNs were collected from 394 out of 489 (81%) community collection points. Of these, 90% were collected post-campaign. Community members were more willing to give up oLNs once the new LNs were installed in homes after the campaign distribution. Families with an insuffcient number of new nets, and those using oLNs for other purposes, were reluctant to give up their oLNs. Sites with the most complex transport logistics were less likely to successfully collect oLNs. Post hoc radio messaging was found to be a useful tool to reinforce messages. The cost was $2.72/oLN collected. Costs could be substantially reduced by combining training with other LN distribution campaign preparation activities. LLINs have been successfully recycled and the material is being analyzed and tested for the most appropriate recycling use. In conclusion, collection and recycling of oLNs was found to be acceptable and feasible. Malaria programs and international donors should further explore and implement cost-effective recycling and re-use options.

Racolta, A., et al. (2016). THE ANALYSIS OF PET BOTTLE REUSE AS A ROOF THERMAL INSULATION COMPONENT. Sofia, Surveying Geology & Mining Ecology Management (SGEM). **2:** 731-738.

The sustainability of the built environment is an intensely debated topic and, nowadays, there is a predilection to focus on innovation through new building materials. The process tends to divert attention from the oportunities offered by existing objects. In this respect, rethinking the concept of sustainability becomes an imperative. The object of analysis in this case is the functional reinterpretation of available products that can be exploited in the field of construction systems. The purpose of this study is to highlight an alternative method - the reuse of PET bottles by avoiding recycling which assumes additional processing expense. Although today there are technologies that, in compliance with environmental standards, are capable of recycle and reprocess plastic waste, we highly believe that the reuse of PET bottles is "greener" than recycling which involves considerable energy consumption. This approach concentrates on the analysis of the feasibility of creating an insulating layer on the roof of single-family houses located in disadvantaged areas in relation to existing insulation materials currently on the market. The research is considering ways of grouping items and anchor means for the case of pitched roofs that characterize most single-family houses located in rural areas or less urbanized ones. Thermal and economical performances are analyzed in comparison with the behavior of materials dedicated to the same functionality of insulating the upper level of the houses. The conclusions consider multi-criterial aspects to reveal the feasibility of the option of introducing residual objects - namely, the waste PET bottles - into insulating systems. Furthermore, the paper tries to anticipate several threats that may occur over time together with the changing perception about the potential of easily accessible objects following the adoption of the possible legal regulations.

Radziwon, P., et al. (2016). "Ozone induces generation of microparticles from erythrocytes, leukocytes, platelets and endothelial cells." Vox Sanguinis **111 (Supplement 1)**: 301-302.

Background: Ozone for therapeutic purposes has been applicated in a number of pathologies, such as vascular diseases, ulcers, and acute and chronic viral diseases. Ozone performance arises from generation of highly reactive oxygen species and subsequent activation of antioxidant enzymes. Despite long experience of ozonized autohaemotherapy the putative molecular mechanisms underlying some reported clinical effects of this gas as well adverse effects included myocardial infarction remain mainly unknown. Aim(s): We studied the effect of blood ozonation on the generation of microparticles derived from blood cells and endothelium which may be responsible for some clinical effects of ozone. Method(s): Sixty ml of venous blood was taken from 20 healthy volunteers and anticoagulated with citrate phosphate dextrose solution (0.12% final concentration). Each sample of blood was divided into 4 equal volumes and transferred to separate containers. The first part was not further processed, the second part was aerated, the third and the fourth parts were subjected to ozone in a dose of 15 mug/ml and 30 mug/ ml respectively. The oxygen-ozone gas mixture was freshly prepared from medicalgrade oxygen using ATO-3 MINI ozone generator (CryoFlex, Poland). Blood samples were taken from the blood bag before and after ozonation/aeration. Microparticles derived from erythrocytes (RMP), leukocytes (LMP), platelets (PMP) and endothelial cells (EMP) were quantitatively measured using flow cytometry (FACSCalibur, Becton Dickinson) and murine monoclonal antibodies: anti-CD235 for RMP, anti-CD42 for PMP, CD45 for LMP, anti-CD105 for EMP. For quantitative measurement of microparticles the flow cytometer was calibrated using microspheres size from 1 lm to 1.5 mum (Microbead NIST Traceable Particle Size Standard, Polysciences) and microbeds (TruCount, Becton Dickinson). Result(s): We observed statistically significant larger amounts of microparticles derived from erythrocytes, leukocytes, platelets as well as endothelial cells generated in either aerated or ozonized blood compare to control (blood untreated with any gas). Moreover in ozonized blood were statistically significant more microparticles generated compare to blood subjected to air. The generation of microparticles induced by ozone was dose dependent. Conclusion(s): Aeration or ozonizing of blood induce generation of microparticles from erythrocytes, leukocytes, platelets and endothelial cells. Microparticles may be involved in mechanism of some adverse effects observed after ozonized autohaemotherapy.

Rafiee, M., et al. (2018). "Neurobehavioral assessment of rats exposed to pristine polystyrene nanoplastics upon oral exposure." Chemosphere **193**: 745-753.

The increasing use of plastics has raised concerns about pollution of freshwater by these polymeric materials. Knowledge about their potential effects on environmental and public health is limited. Recent publications have suggested that the degradation of plastics will result in the release of nano-sized plastic particles to the environment. Therefore, it is of utmost importance to gain knowledge about whether and how nanoplastics affect living organisms. The present study aimed to analyse potential neurobehavioral effects of polystyrene nanoparticles (PS-NPs) after long-term exposure on rat. Potential effects of PS-NPs were investigated using four test dosages (1, 3, 6, and 10 mg PS-NPs/kg of body weight/day) administrated orally with adult Wistar male rats for five weeks. Neurobehavioral tests were chosen to assess a variety of behavioral domains. Particle diameters in test suspensions were determined through dynamic light scattering and showed an average hydrodynamic diameter of approximately 38.92 nm. No statistically significant behavioral effects were observed in all tests performed ($p > 0.05$). In the elevated plus maze, PS-NPs-exposed rats showed greater number of entries into open arms compared to controls. Also, PS-NPs had no significant influence on body weight of animals. Taking into account the subtle and transient nature of neurobehavioral consequences, however, these results underline the possibility of even pristine plastic nanoparticles to induce behavioral alteration in the rest of the food web, including for marine biota and humans. Indeed even though studied neurobehavioral effects in our study was not statistically significant, the observed subtle effects may be clinically considerable.

Ragaert, K., et al. (2017). "Mechanical and chemical recycling of solid plastic waste." Waste Management **69**: 24-58.

This review presents a comprehensive description of the current pathways for recycling of polymers, via both mechanical and chemical recycling. The principles of these recycling pathways are framed against current-day industrial reality, by discussing predominant industrial technologies, design strategies and recycling examples of specific waste streams. Starting with an overview on types of solid plastic waste (SPW) and their origins, the manuscript continues with a discussion on the different valorisation options for SPW. The section on mechanical recycling contains an overview of current sorting technologies, specific challenges for mechanical recycling such as thermo-mechanical or lifetime degradation and the immiscibility of polymer blends. It also includes some industrial examples such as polyethylene terephthalate (PET) recycling, and SPW from post-consumer packaging, end-of-life vehicles or electr(on)ic devices. A separate section is dedicated to the relationship between design and recycling, emphasizing the role of concepts such as Design from Recycling. The section on chemical recycling collects a state-of-the-art on techniques such as chemolysis, pyrolysis, fluid catalytic cracking, hydrogen techniques and gasification. Additionally, this review discusses the main challenges (and some potential remedies) to these recycling strategies and ground them in the relevant polymer science, thus providing an academic angle as well as an applied one.

Ragaert, K., et al. (2020). "Design from recycling: A complex mixed plastic waste case study." Resources, Conservation and Recycling **155 (no pagination)**(104646).

With today's continued drive to increase recycling rates of plastics, the low-hanging fruit of clean mono-streams of plastic waste has long since been picked. If Europe's ambitious recycling targets are to be met, plastics waste streams that have until now been labeled 'problematic' and have consistently been sent to incineration, must be considered as well. One such stream is the sink fraction obtained from float-sink sorting of mixed post-consumer packaging waste. It is a very complex stream in terms of composition. Moreover, it contains a sizeable amount of PVC, which is considered detrimental to further mechanical recycling of any mixed plastic waste. Within the current research, the sink fraction was extensively analyzed for composition and mechanical properties, as well as treated for removal of PVC and non-ferrous metals. Subsequently, the Design from Recycling strategy was applied to successfully develop a new product with this material, called the Greentile. The Greentile was effectively manufactured and found to be a useful construction element for slanted green roofs. Copyright © 2019 Elsevier B.V.

Raghu, P. V., et al. (2014). "Upgradation of geotechnical parameters by waste plastic admixture in soil." Journal of Environmental Research and Development **8**(3): 759-765.

Waste plastics impart huge environmental problems. Apparently they are not serious harmful materials but they require huge amount of space in land fills and also consume high amount of energy for its production. Scavenge plastic also poses clogging of drainage conduits and as such often observed rainwater detention in cities and towns. Ministry of Environment and Forest (MoEF) and Central Pollution Control Board (CPCB) inducted rules for plastic waste management and recommended also possible recycling of waste as far as possible. For a sustainable resource management practice, plastic waste are being recycled in many ways. Plastic waste management institute reported about 55% of waste plastic are effectively being utilized in energy recovery and feed stock recycling. All the plastics are not recyclable. A common problem with recycling plastics is that they are often made up of more than one kind of polymer or some sort of fibers added to the plastics (a composite) to give added strength. The above characteristics are helpful for using the waste materials in poor grade soil to enhance the geotechnical properties of soil. Plastic fibers are similar to the roots of trees and vegetation which provide an excellent ingredient to improve the soils and the stability of natural slopes. One of the main advantages of using plastic fibers is the maintenance of strength isotropy and the absence of potential places of weakness that can develop parallel to oriented reinforcement. Polyethylene Terephthalate (PET) materials are used in bottles, food packaging and carpets. Some investigation showed that the PET fiber reinforcement enhances the peak and ultimate strength of both cemented uncemented soil and does not change the initial stiffness of the soil. PET bottle fibers mixed soil behaves as reinforced soil similar to fiber reinforced soil. The introduction of waste plastic as strips or fibers improve the soil texture and strength in terms of compressibility, energy absorption, shear strength, CBR since their addition also helps favorably. The present paper describes the status on uses of various waste plastic fibers for also for the parameters improvement of soil in terms of its geotechnical parameters.

Raghu, P. V., et al. (2015). "Improvement of shear strength of clayey soil using randomly distributed pet bottle strips." Journal of Environmental Research and Development **10**(1): 65-72.

Waste plastics impart adverse environmental problems like clogging in drainage system and need of large space required for solid waste disposal in the metropolitan and over crowded cities. Recycling of plastic waste from water bottles is becoming one of the challenges worldwide. The bottled water is the fastest growing beverage industry in the world. Plastic bottle recycling has not kept pace with the dramatic increase in sale of virgin resin Poly Ethylene Terephthalate (PET) and the same are to reduce/reuse/recycle that has emerged as one of the important need for sustainable development. The introduction of randomly distributed plastic fibers in reinforcing soil has enabled geotechnical engineers to effectively use unsuitable soils as reliable construction material and foundation medium in a wide range of civil engineering applications for ground improvement, sub bases and sub grade preparation in building and road construction. In order to use waste plastic material as means of waste management an experimental work has been undertaken with one type of locally collected clayey soil and two types of amended soil (clayey soil with 10% sand and 20% sand) reinforced with randomly mixed PET bottle strips of different percentages (varying from 0.5% to 2% by weight) with different values of aspect ratio (length/width) with constant width of 5 mm. The work has been done with the objective of examining the improvement of shear strength parameters of a clayey soil by mixing PET bottle strips. A series of triaxial compression tests were carried out adopting standard procedures on those three types of soil with different percentages of plastic strips with varying aspect ratio as mentioned. It is observed that angle of internal friction (phi) enhances with the elevated percentage of sand up to addition of 1% of plastic strips by weight for values of aspect ratio (length/width) 1, 2 and 3. However beyond this value the angle of internal

friction descends gradually, when other parameters do not vary. The present study provides an approach in improvement of strength of weak soil as well as in recycling plastic waste and also brings out change in shear strength parameters of soil with mixing of PET bottle strips in different proportions for its use in geotechnical engineering.

Rahman, A. T., et al. (2015). "Evaluation of Time-Temperature Integrators (TTIs) with Microorganism-Entrapped Microbeads Produced Using Homogenization and SPG Membrane Emulsification Techniques." Journal of Microbiology & Biotechnology **25**(12): 2058-2071.

A comparative study was conducted to evaluate precision and accuracy in controlling the temperature dependence of encapsulated microbial time-temperature integrators (TTIs) developed using two different emulsification techniques. Weissela cibaria CIFP 009 cells, immobilized within 2% Na-alginate gel microbeads using homogenization (5,000, 7,000, and 10,000 rpm) and Shirasu porous glass (SPG) membrane technologies (10 mum), were applied to microbial TTIs. The prepared micobeads were characterized with respect to their size, size distribution, shape and morphology, entrapment efficiency, and bead production yield. Additionally, fermentation process parameters including growth rate were investigated. The TTI responses (changes in pH and titratable acidity (TA)) were evaluated as a function of temperature (20degreeC, 25degreeC, and 30degreeC). In comparison with conventional methods, SPG membrane technology was able not only to produce highly uniform, small-sized beads with the narrowest size distribution, but also the bead production yield was found to be nearly 3.0 to 4.5 times higher. However, among the TTIs produced using the homogenization technique, poor linearity (R(2)) in terms of TA was observed for the 5,000 and 7,000 rpm treatments. Consequently, microbeads produced by the SPG membrane and by homogenization at 10,000 rpm were selected for adjusting the temperature dependence. The Ea values of TTIs containing 0.5, 1.0, and 1.5 g microbeads, prepared by SPG membrane and conventional methods, were estimated to be 86.0, 83.5, and 76.6 kJ/mol, and 85.5, 73.5, and 62.2 kJ/mol, respectively. Therefore, microbial TTIs developed using SPG membrane technology are much more efficient in controlling temperature dependence.

Rainieri, S. and A. Barranco (2019). "Microplastics, a food safety issue? (Special Issue: Keeping food safety on the agenda for 15 years - the SAFE consortium.)." Trends in Food Science & Technology **84**: 55-57.

The risk posed by microplastics for human and environment, has become a hot topic. The concern is focused not only on the effect of microplastics as such but also on additives and chemical contaminants absorbed by microplastics that may be released and affect negatively animals and environmental health. Despite several works have been written on this topic, a number of knowledge gaps still should be filled to enable a correct risk assessment of this important issue. For example, the relevance of microplastics for food safety has not yet been fully established and scientific results aimed at establishing a possible health risk for contaminants associated with microplastics are rather controversial. The risk assessment of microplastics in foodstuff is still at a very early stage and very few studies on the monitoring of microplastics in foodstuff and their effects on human health are available. Additionally, it is difficult to compare results from different studies as methodologies and study designs are not uniform. For this reason, it is not always possible to reach some definitive conclusion. This work sets out to complement the reviews and statements already existing, by updating the

information and identifying if any of the knowledge gaps have been covered and if further ones have been detected with the final aim of properly assessing and managing this emerging risk.

Rainieri, S., et al. (2018). "Combined effects of microplastics and chemical contaminants on the organ toxicity of zebrafish (Danio rerio)." Environmental Research **162**: 135-143.

Microplastics contamination of the aquatic environment is considered a growing problem. The ingestion of microplastics has been documented for a variety of aquatic animals. Studies have shown the potential of microplastics to affect the bioavailability and uptake route of sorbed co-contaminants of different nature in living organisms. Persistent organic pollutants and metals have been the co-contaminants majorly investigated in this field. The combined effect of microplastics and sorbed co-contaminants in aquatic organisms still needs to be properly understood. To address this, we have subjected zebrafish to four different feeds: A) untreated feed; B) feed supplemented with microplastics (LD-PE 125–250 µm of diameter); C) feed supplemented with 2% microplastics to which a mixture of PCBs, BFRs, PFCs and methylmercury were sorbed; and D) feed supplemented with the mixture of contaminants only. After 3 weeks of exposure fish were dissected and liver, intestine, muscular tissue and brain were extracted. After visual observation, evaluation of differential gene expression of some selected biomarker genes in liver, intestine and brain were carried out. Additionally, quantification of perfluorinated compounds in liver, brain, muscular tissue and intestine of some selected samples were performed. The feed supplemented with microplastics with sorbed contaminants produced the most evident effects especially on the liver. The results indicate that microplastics alone does not produce relevant effects on zebrafish in the experimental conditions tested; on the contrary, the combined effect of microplastics and sorbed contaminants altered significantly their organs homeostasis in a greater manner than the contaminants alone. [ABSTRACT FROM AUTHOR]

Rainieri, S., et al. (2018). "Combined effects of microplastics and chemical contaminants on the organ toxicity of zebrafish (Danio rerio). (Special Section: Environmental contaminants in seafood: new findings & innovation challenges.)." Environmental Research **162**: 135-143.

Microplastics contamination of the aquatic environment is considered a growing problem. The ingestion of microplastics has been documented for a variety of aquatic animals. Studies have shown the potential of microplastics to affect the bioavailability and uptake route of sorbed co-contaminants of different nature in living organisms. Persistent organic pollutants and metals have been the co-contaminants majorly investigated in this field. The combined effect of microplastics and sorbed co-contaminants in aquatic organisms still needs to be properly understood. To address this, we have subjected zebrafish to four different feeds: (A) untreated feed; (B) feed supplemented with microplastics (LD-PE 125-250 micro m of diameter); (C) feed supplemented with 2% microplastics to which a mixture of PCBs, BFRs, PFCs and methylmercury were sorbed; and (D) feed supplemented with the mixture of contaminants only. After 3 weeks of exposure fish were dissected and liver, intestine, muscular tissue and brain were extracted. After visual observation, evaluation of differential gene expression of some selected biomarker genes in liver, intestine and brain were carried out. Additionally, quantification of perfluorinated compounds in liver, brain, muscular tissue and intestine of some selected samples were

performed. The feed supplemented with microplastics with sorbed contaminants produced the most evident effects especially on the liver. The results indicate that microplastics alone does not produce relevant effects on zebrafish in the experimental conditions tested; on the contrary, the combined effect of microplastics and sorbed contaminants altered significantly their organs homeostasis in a greater manner than the contaminants alone.

Raj, G., et al. (2009). "Probing cellulose/polylactic acid interactions in model biocomposite by colloidal force microscopy." Colloids and Surfaces A: Physicochemical and Engineering Aspects **352**(1-3): 47-55.
Over the last few years, intensive research has been devoted to the exploitation of "green products" based on natural resources for both matrices and as reinforcements in composite systems. The mechanical properties of reinforced biocomposites, such as flax/polylactic acid (PLA), are largely governed by interfacial properties between the two constituents apart from their intrinsic properties. Although many papers indirectly demonstrate the importance of optimising the interface between these two polymers, the exact nature of the interaction between the natural fibre and the polymeric matrix has not been clearly investigated on a fundamental level and is presently a major technological limitation of these materials. This work presents the first direct study of adhesion forces, by colloidal force microscopy, between smooth PLA films representing the polymer matrix, and a microbead of cellulose that mimic the cellulose material in flax fibres. Normalised adhesion force measurements have shown the importance of capillary forces when experiments were carried out under ambient conditions. Experiments, conducted under dry air, allowed for the deduction of the contribution of pure van der Waals forces, and our results, through the calculation of the Hamaker constant, show that these forces, for the PLA/cellulose/air system, were lower than those obtained for the cellulose/cellulose/air system and hence underlined the importance of optimising the interface among these materials. This study demonstrates the capacity of AFM to probe direct interactions in complex systems by adjusting the nature of the surface and the probe to mimic the materials in contact. Furthermore, the technique can be operated in a variety of environments, consistent with composite making and provides particular opportunity for testing and improving the properties of these new classes of composite materials. © 2009 Elsevier B.V. Raj, M. M., et al. (2015). "Preparation and characterization of alginate/methyl cellulose microbeads of losartan potassium." International Journal of Pharma and Bio Sciences **6**(4): P1-P11.
Losartan Potassium microbeads were formulated by ionotropic gelation technique using a combination of sodium alginate and methyl cellulose. The influence of different concentrations of polymer was studied. Microbeads were assessed for their physicochemical properties and In-vitro drug release studies. FT-IR study confirmed that there was no drug excipient interaction. The prepared microbeads are within specifications for all the physicochemical properties.SEM shows all the beads are spherical and smooth surface. In-vitro release data shows the individual concentration of sodium alginate sustains the drug release up to 8hrs but combinations with methyl cellulose sustain the drug release more than 12 hrs. Methyl cellulose in higher proportion increased the mean diameter of bead and increased encapsulation efficiency up to 93.94 % and drug release was extended up to 13hrs.

Rajak, A., et al. (2020). "Electrospun nanofiber from various source of expanded polystyrene (EPS) waste and their characterization as potential air filter media." Waste Management **103**: 76-86.
This paper reported on the fabrication of nanofibrous membranes from various sources of expanded polystyrene (EPS) waste using electrospinning technique and their application as air

filter media. The filter membranes were made from four EPS waste sources, i.e. food packaging, EPS craft, instant noodle cup, and electronic packaging. The properties of the membranes fabricated from those sources were compared to obtain the best EPS waste source for air filter application. To make the precursor solutions, those samples were dissolved in d-limonene:DMF with the concentration of 15, 20, and 25 wt%. The solid EPS density, solution viscosity, and surface tension were measured. The fiber diameter and morphology of nanofibers were characterized by scanning electron microscopy (SEM) for each EPS variation. The fabricated membrane properties (crystallinity, wettability, and mechanical strength) and filtration properties (pressure drop, PM<inf>2.5</inf> filtration efficiency, and quality factor) were fully characterized and analyzed. Homogeneous fiber diameter with various morphologies (beaded, wrinkled, and smooth fiber) were obtained from all samples with hydrophobic to super-hydrophobic surface (water contact angle ranging from 106 to 153degree). Also, the EPS solid density affected the solution viscosity with the expression of eta = 0.132 rho^{0.29}, which then affected the fabricated membrane packing density, porosity, and mechanical properties. Overall, the experimental results showed that all EPS nanofiber filters had great potential as an air filter media. The EPS filter made from food packaging waste with the solution concentration of 15 wt% exhibited the highest efficiency and quality factor of 99.99% and 0.15 Pa⁻¹, respectively. Rajathurai, T., et al. (2010). "Periadventitial rapamycin-eluting microbeads promote vein graft disease in long-term pig vein-into-artery interposition grafts." Circulation: Cardiovascular Interventions **3**(2): 157-165.

BACKGROUND: Neointima formation and atherosclerosis compromise long-term graft patency in aortocoronary and peripheral vein bypass grafts. We investigated the short- and long-term effects of periadventitial application of a sustained-release formulation of rapamycin on experimental pig vein grafts with similar dimensions and kinetics to human saphenous vein bypass grafts.

METHODS AND RESULTS: Periadventitial application of rapamycin-eluting polyvinyl alcohol microspheres (60 microg . cm(-2)) to porcine saphenous vein-to-carotid artery interposition grafts inhibited vein graft positive and vascular smooth muscle cell proliferation in 1-week grafts. It also decreased neointima formation and wall thickening in 4-week vein grafts compared with controls. The inhibition of vein graft thickening was not sustained; however, a catch-up phenomenon was observed, and there was no therapeutic benefit evident in 12-week grafts. Increasing the dose of rapamycin to 120 microg . cm(-2) was associated with significant local toxicity manifest by high rates of graft rupture (25%), inhibition of adventitial neoangiogenesis, and a paradoxical acceleration of vein graft disease as evidenced by increased vascular smooth muscle cell proliferation.

CONCLUSIONS: Local toxicity and poor long-term efficacy limits the clinical applicability of locally applied, sustained rapamycin release in vein graft disease.

Rajendran, S., et al. (2013). "Plastics recycling: insights into life cycle impact assessment methods." Plastics, Rubber & Composites: Macromolecular Engineering **42**(1): 1-10.

The increased consumption of plastics in day to day life has a significant impact on the environment. Life cycle assessment (LCA) is widely used to select a sustainable alternative in plastic waste management. The LCA studies on mechanical recycling and energy recovery scenarios showed that recycling resulted in lower emissions and provided benefits to the environment. These results are valid only if the performance of the recycled plastic is equivalent to those of the virgin materials. Many LCA studies have been focused on individual impact

categories rather than aggregated single score. The decision making process becomes complex if individual impact categories are used. This research is focused on the comparison of LCA results between individual and aggregated impacts and integration of performance of recycled plastics in LCA. The results indicated that recycling was the preferred option if it could replace a minimum of 70-80% of virgin plastics.

RajeshKumar, A., et al. (2016). "Recycling and reusing of plastic." International Journal of Pharmacy and Technology **8**(4): 20774-20782.

Plastic of things deals with the ways of improving the reuse of plastic waste which harms the environment in many different ways. Plastic, sure is very useful substance and could me made cheaply but the problem in using it is that it cannot be disintegrated both naturally and artificially so, to overcome the problems through plastic wastes the only way possible is reusing it. Plastic when heated under certain pressures could mould into many useful substances. Some methods of changing plastic would be using a centrifuge and some methods include using only heat. In this paper we briefly discuss about methods of synthesizing plastic about the amount of plastic going waste and methods to reuse it and also we discuss about the reactions plastic undergoes with different types of chemicals. Ram, C. (2015). "Advances in biodegradation and bioremediation of industrial waste." Advances in biodegradation and bioremediation of industrial waste **479**.

Advances in Biodegradation and Bioremediation of Industrial Waste examines and compiles the latest information on the industrial waste biodegradation process and provides a comprehensive review. Dedicated to reducing pollutants generated by agriculturally contaminated soil, and plastic waste from various industries, this text is a book that begs the question: Is a pollution-free environment possible? The book combines with current available data with the expert knowledge of specialists from around the world to evaluate various aspects of environmental microbiology and biotechnology. It emphasizes the role of different bioreactors for the treatment of complex industrial waste and provides specific chapters on bioreactors and membrane process integrated with biodegradation process. It also places special emphasis on phytoremediation and the role of wetland plant rhizosphere bacterial ecology and the bioremediation of complex industrial wastewater. The authors address the microbiological, biochemical, and molecular aspects of biodegradation and bioremediation which cover numerous topics, including microbial genomics and proteomics for the bioremediation of industrial waste.

Ramadan, Q., et al. (2006). "An integrated microfluidic platform for magnetic microbeads separation and confinement." Biosensors & Bioelectronics **21**(9): 1693-1702.

An innovative microfluidic platform for magnetic beads manipulation is introduced, consisting of novel microfabricated 3D magnetic devices positioned in a microfluidic chamber. Each magnetic device comprises of an embedded actuation micro-coil in various design versions, a ferromagnetic pillar, a magnetic backside plate and a sensing micro-coil. The various designs of the micro-coils enable efficient magnetic beads trapping and concentration in different patterns. The finite element analysis (FEA) results show a significant increase of the developed force on suspended magnetic beads when the magnetic pillar and backside plate were integrated into the device structure. These simulation results were confirmed experimentally by measuring the magnetic beads trapping ratios for the different designs and structures of the devices under continuous flow conditions. The trapping ratios and profiles were studied using beads counting, measuring the change of inductance with the sensing micro-coil and by image processing. The devices have efficiently demonstrated a controlled and localized magnetic beads trapping and concentration at small spatial locations for the first time. The new results shown in this study demonstrate the feasibility of efficiently using these original devices as key elements in complex bio-analysis systems.

Raman, B., et al. (2007). "Neuromorphic Processing for Optical Microbead Arrays: Dimensionality Reduction and Contrast Enhancement." IEEE Sensors Journal **7**(4): 506-514.

This paper presents a neuromorphic approach for sensor-based machine olfaction that combines a portable chemical detection system based on microbead array technology with a biologically inspired model of signal processing in the olfactory bulb. The sensor array contains hundreds of microbeads coated with solvatochromic dyes adsorbed in, or covalently attached on, the matrix of various microspheres. When exposed to odors, each bead sensor responds with corresponding intensity changes, spectral shifts, and time-dependent variations associated with the fluorescent sensors. The bead array responses are subsequently processed using a model of olfactory circuits that capture the following two functions: chemotopic convergence of receptor neurons and center on-off surround lateral interactions. The first circuit performs dimensionality reduction, transforming the high-dimensional microbead array response into an organized spatial pattern (i.e., an odor image). The second circuit enhances the contrast of these spatial patterns, improving the separability of odors. The model is validated on an experimental dataset containing the responses of a large array of microbead sensors to five different analytes. Our results indicate that the model is able to significantly improve the separability between odor patterns, compared to that available from the raw sensor response.

Ramana Reddy, K. V. and M. V. Nagabhushanam (2017). "Process and parameters affecting drug release performance of prepared cross-linked alginate hydrogel beads for ezetimibe." International Journal of Pharmacy and Pharmaceutical Sciences **9**(2): 254-262.

Objective: The objective of this study was to formulate an oral sustained release delivery system of ezetimibe mucoadhesive beads by ionic gelation technique based on sodium alginate used as a hydrophilic carrier in combination with carbopol 934P which acts as a rate modifier. Method(s): Microbeads of ezetimibe were prepared using an easy method of ionotropic gelation by little modification while in addition of drug. The prepared beads were characterised for mean particle size, entrapment efficiency, swelling capacity, and in vitro release. They were also subjected to various studies such as Fourier Transform Infrared Spectrophotometer (FTIR) Spectroscopy for drug polymer reaction, Scanning Electron Microscopy for surface morphology, and Differential Scanning Calorimetric Analysis to determine the physical state of the drug in the beads. Result(s): The microspheres of ezetimibe were formulated successfully. The addition of drug concentration gives higher drug loading and higher conc. of Alcl<inf>+3</inf> yields small diameter beads and lower drug entrapment. Analysis of the release profiles showed that the data corresponds to zero order release and the diffusion-controlled mechanism as suggested by Higuchi concept. Conclusion(s): It can be concluded that beads produced by the sequential method had higher drug entrapment. Beads produced by simultaneous yields larger beads in diameter. The concept was cleared that drug release was dependent upon the quantity of polymer and increase in conc. of. aluminium chloride retarded the drug release in the sequential method. Prepared beads enhance the dissolution of ezetimibe and the oral bioavailability and also reduce the fluctuations in the oral bioavailability. Copyright © 2016 The Authors.

Ramasamy, R., et al. (2008). "The immunosuppressive effects of human bone marrow-derived mesenchymal stem cells target T cell proliferation but not its effector function." Cellular Immunology **251**(2): 131-136.

Mesenchymal stem cells (MSC) are non-haematopoietic stem cells that are capable of differentiating into tissues of mesodermal origin. MSC play an important role in supporting the development of fetal and adult haematopoiesis. More recently, MSC have also been found to exhibit inhibitory effect on T cell responses. However, there is little information on the mechanism of this immunosuppression and our study addresses this issue by targeting T cell functions at various level of immune responses. We have generated MSC from human adult bone marrow (BM) and investigated their immunoregulatory function at different phases of T cell responses. MSC showed the ability to inhibit mitogen (CD3/CD28 microbeads)-activated T cell proliferation in a dose-dependent manner. In order to evaluate the specificity of this immunosuppression, the proliferation of CD4(+) and CD8(+) cells were measured. MSC equally inhibit CD4(+) and CD8(+) subpopulations of T cells in response to PHA stimulation. However, the antiproliferative effect of MSC is not due to the inhibition of T cell activation. The expression of early activation markers of T cells, namely CD25 and CD69 were not significantly altered by MSC at 24, 48 and 72h. Furthermore, the immunosuppressive effect of MSC mainly targets T cell proliferation rather than their effector function since cytotoxicity of T cells is not affected. This work demonstrates that the immunosuppressive effect of MSC is exclusively a consequence of an anti-proliferative activity, which targets T cells of different subpopulations. For this reason, they have the potential to be exploited in the control of unwanted immune responses such as graft versus host disease (GVHD) and autoimmunity.

Rambaldi, A., et al. (1998). "Innovative two-step negative selection of granulocyte colony-stimulating factor-mobilized circulating progenitor cells: adequacy for autologous and allogeneic transplantation." Blood **91**(6): 2189-2196.

A major obstacle in purifying either autologous or allogeneic hematopoietic stem cells from granulocyte colony-stimulating factor (G-CSF) mobilized circulating progenitor cells (CPC) is represented by the huge cellularity present in each apheretic product. To obtain a significant debulking of unwanted cells from the leukapheresis, we developed a modified protocol of immune rosetting whereby human ABO-Rh- compatible red blood cells (RBCs) are treated with chromium chloride and then coated with murine monoclonal antibodies (MoAbs) against leukocyte antigens. When experiments were performed with leukaphereses obtained from normal donors or from T-cell acute lymphoblastic leukemia (T-ALL) patients, RBCs were coated with murine MoAbs against human mature myeloid cells (CD11b) and T cells (CD6); whereas, in the case of patients with B-precursor ALL, B-cell non-Hodgkin's lymphoma (B-NHL), or multiple myeloma (MM), RBCs were coated with anti-CD11b only. After incubation with CPC, rosetting cells (myeloid precursor cells, granulocytes, monocytes, and T cells) were removed by Ficoll-Hypaque density gradient centrifugation with a blood cell processor apparatus, COBE (Lakewood, CO) 2991. After this step, a significant reduction of the initial cellularity was consistently obtained (range, 72% to 97%), whereas the median absolute recovery of the CD34+ cells was above 85% (range, 64 to 100), with a 10-fold relative enrichment ranging from 3% to 41%. In a second step, CPC can be further purged of contaminating T or B cells by incubation with lymphoid-specific magnetic microbeads (anti-CD2 and -CD7 to remove T cells; anti-CD19 to remove B cells) and elution through a type-D depletion column (composed of ferromagnetic fiber) inserted within a SuperMACS separator device (Miltenyi Biotech, Bergisch-Gladbach, Germany). By this approach, a highly effective (three to four logs) T-cell depletion was achieved in all experiments performed with normal donors or T-ALL patients (median loss of CD3+ cells: 99.8% [range 99.2 to 100]) and an equally efficient B-cell depletion was obtained from

B-precursor ALL, B-NHL, or MM patients. At the end of the procedure the T- or B-cell depleted fraction retained a high proportion of the initial hematopoietic CD34+ stem cells, with a median recovery above 70% (range 48% to 100%) and an unmodified clonogenic potential. In five patients (two follicular NHL and three ALL) the purified fraction of stem cells was found disease free at the molecular level as assessed by polymerase chain reaction (PCR) analysis of the t(14;18) chromosome translocation or clono-specific DNA sequences of IgH or T-cell receptor gamma and delta chain genes. Purified autologous and allogeneic CPCs were transplanted in three and six patients, respectively, who showed a prompt and sustained hematologic engraftment. In conclusion, this method represents a simple and reproducible two-step procedure to obtain a highly efficient purging of T or B cells from G-CSF expanded and mobilized CPCs. This approach might lead to the eradication of the neoplastic clone in the autologous stem cell inoculum as well as for T-cell depletion during allogeneic transplantation.

Ramesha, V., et al. (2017). "Polycyclic hydrocarbon degradation by bacteria: a review." Trends in Biosciences **10**(14): 2465-2473.

Polycyclic hydrocarbons are compounds containing carbon and hydrogen, these are important pollutants found in air, soil and sediments. Polycyclic hydrocarbons and their derivatives are products of incomplete combustion of organic materials arising, in part, from natural combustion such as forest fires and volcanic eruptions, but for the most part by human activities. In recent decades the major source of PAH (polycyclic aromatic hydrocarbons) pollution is industrial production, transportation, refuse burning, gasification and plastic waste incineration. Hydrocarbons usually degraded by aerobic and anaerobic bacteria, compare to anaerobic bacteria aerobic bacteria shows efficient degradation of hydrocarbons. Hydrocarbons contains two groups of compounds which are aromatic and aliphatic, where aromatic hydrocarbons shows much importance because their utilization in manufacturing of different substances and later accumulation in the environment.

Ramirez, L., et al. (2019). "Behavior of TiO₂ and CeO₂ nanoparticles and polystyrene nanoplastics in bottled mineral, drinking and Lake Geneva waters. Impact of water hardness and natural organic matter on nanoparticle surface properties and aggregation." Water **11**(4).

Intensive use of engineered nanoparticles (NPs) in daily products ineluctably results in their release into aquatic systems and consequently into drinking water resources. Therefore, understanding NPs behavior in various waters from naturel to mineral waters is crucial for risk assessment evaluation and the efficient removal of NPs during the drinking water treatment process. In this study, the impact of relevant physicochemical parameters, such as pH, water hardness, and presence of natural organic matter (NOM) on the surface charge properties and aggregation abilities of both NPs and nanoplastic particles is investigated. TiO₂, CeO₂, and Polystyrene (PS) nanoplastics are selected, owing to their large number applications and contrasting characteristics at environmental pH. Experiments are performed in different water samples, including, ultrapure water, three bottled mineral waters, Lake Geneva, and drinking water produced from Lake Geneva. Our findings demonstrate that both water hardness and negatively charged natural organic matter concentrations, which were measured via dissolved organic carbon determination, are playing important roles. At environmental pH, when negatively charged nanoparticles are considered, specific cation adsorption is promoting aggregation so long as NOM concentration is limited. On the other hand, NOM adsorption is expected to be a key process in NPs destabilization when positively charged PS nanoplastics are considered.

Ramirez-Alvarez, N., et al. (2020). "Microplastics: Sources and distribution in surface waters and sediments of Todos Santos Bay, Mexico." <u>Science of the Total Environment</u> **703 (no pagination)**(134838).

Microplastics (MPs) are ubiquitous and a threat to marine and freshwater environments. Effluent waters from secondary wastewater treatment plants (WWTPs) into Todos Santos Bay (TSB) were investigated as sources of MPs. MPs were detected in all analyzed matrices and presented variable morphologies. MPs from surface water samples (n = 18) varied from 0.01 to 0.70 plastic particles/m³ (pp/m³). Fragments (47 +/- 23%) and fibers (47 +/- 23%) were the most abundant particles found in the surface water samples. In sediment samples (n = 11), MPs varied from 85 to 2494 pp/0.1 m². Sediment samples showed fragments of 70 +/- 19%, fibers 28 +/- 18% in mean. The range of MP values from WWTP effluents (n = 24) was 81 to 1556 pp/m³, and fibers (65 +/- 28%) were the most abundant MP particles. Several synthetic polymers (polypropylene, polyethylene, polyethylene-propylene, polyvinyl chloride, cellophane), and natural fibers (cotton and wood) were identified. The surface currents and the parameters that modulate them, are the main factors that dominate the distribution of MPs in surface waters. While in the sediments the parameters such as bathymetry and grain size distribution have more influence on their distribution in the marine environment, where the effluent waters from WWTPs only contributes MPs to the TSB. Ramos, II, et al. (2019). "Automated lab-on-valve sequential injection ELISA for determination of carbamazepine." <u>Analytica Chimica Acta</u> **1076**: 91-99.

The development of an automated miniaturized analytical system that allows for the rapid monitoring of carbamazepine (CBZ) levels in serum and wastewater is proposed. Molecular recognition of CBZ was achieved through its selective interaction with microbeads carrying anti-CBZ antibodies. The proposed method combines the advantages of the micro-bead injection spectroscopy and of the flow-based platform lab-on-valve for implementation of automatic immunosorbent renewal, rendering a new recognition surface for each sample. The sequential (or simultaneous) perfusion of CBZ and the horseradish peroxidase-labelled CBZ through the microbeads is followed by real-time on-column monitoring of substrate (3,3',5,5'-tetramethylbenzidine) oxidation by colorimetry. The evaluation of the initial oxidation rate and also the absorbance value at a fixed time point provided a linear response versus the logarithm of the CBZ concentration. Under the selected assay conditions, a single analysis was completed after only 11min, with a quantification range between 1.0 and 50mugL⁻¹. Detection of CBZ levels in undiluted wastewater samples was feasible after a simple filtration step while good recoveries were attained for spiked certified human serum, analyzed without sample clean-up.

Ramos, II, et al. (2018). "Micro-bead injection spectroscopy for label-free automated determination of immunoglobulin G in human serum." <u>Analytical & Bioanalytical Chemistry</u> **410**(3): 981-988.

Immunoglobulin G (IgG) represents the major fraction of antibodies in healthy adult human serum, and deviations from physiological levels are a generic marker of disease corresponding to different pathologies. Therefore, screening methods for IgG evaluation are a valuable aid to diagnostics. The present work proposes a rapid, automatic, and miniaturized method based on UV-vis micro-bead injection spectroscopy (mu-BIS) for the real-time determination of human serum IgG with label-free detection. Relying on attachment of IgG in rec-protein G immobilized in Sepharose 4B, a bioaffinity column is automatically assembled, where IgG is selectively retained and determined by on-column optical density measurement. A "dilution-and-shoot"

approach (50 to 200 times) was implemented without further sample treatment because interferences were flushed out of the column upon sample loading, with minimization of carryover and cross-contamination by automatically discarding the sorbent (0.2 mg) after each determination. No interference from human serum albumin at 60 mg mL⁻¹ in undiluted sample was found. The method allowed IgG determination in the range 100-300 mug mL⁻¹ (corresponding to 5.0-60 mg mL⁻¹ in undiluted samples), with a detection limit of 33 mug mL⁻¹ (1.7 mg mL⁻¹ for samples, dilution factor of 50). RSD values were < 9.4 and < 11.7%, for intra and inter-assay precision, respectively, while recovery values for human serum spiked with IgG at high pathological levels were 97.8-101.4%. Comparison to commercial ELISA kit showed no significant difference for tested samples (n = 8). Moreover, time-to-result decreased from several hours to < 5 min and analysis cost decreased 10 times, showing the potential of the proposed approach as a point-of-care method. Graphical abstract Micro-Bead Injection Spectroscopy method for real time, automated and label-free determination of total serum human Immunoglobulin G (IgG). The method was designed for Lab-on-Valve (LOV) platforms using a miniaturised protein G bioaffinity separative approach. IgG are separated from serum matrix components upon quantification with low non-specific binding in less than 5 min.

Ramos, J., et al. (2012). "Quantification and Recommended Management of Man-Made Debris Along the Sea Turtle Nesting Beach at Playa Caletas, Guanacaste, Costa Rica." Marine Turtle Newsletter(134): 12.

The predation of sea turtles and nests by coyotes, skunks, raccoons, and crabs is one of the greatest threats at Playa Caletas in Guanacaste, Costa Rica. Another threat to turtles at Caletas is garbage. From causing entanglement, severe lesions, digestive tract obstruction through ingestion, and interference with nesting and hatchling emergence, marine plastic pollution is causing deleterious effects to populations of endangered sea turtles worldwide. Due to the heightened concern of the effects of man-made marine debris pollution on turtle nesting at Playa Caletas, Ramos et al investigate the characteristics of the garbage in terms of size and type and offer recommendations on how to improve sea turtle habitat.

Randall, I. (2013). "Paying with plastic." Green Futures(90): 9-9.

The article describes the Plastic Bank scheme, which is being pilot-tested in Lima, Peru as of October 2013, that aims to encourage people living in poverty to help tackle the problem of plastic pollution and profit from it by collecting plastic and exchanging it at a Plastic Bank for goods.

Rani, M., et al. (2019). "Miniaturized Near-Infrared (MicroNIR) Spectrometer in Plastic Waste Sorting." Materials **12**(17): 27.

Valorisation of the urban plastic waste in high-quality recyclates is an imperative challenge in the new paradigm of the circular economy. In this scenario, a key role in the improvement of the recycling process is exerted by the optimization of waste sorting. In spite of the enormous developments achieved in the field of automated sorting systems, the quest for the reduction of cross-contamination of incompatible polymers as well as a rapid and punctual sorting of the unmatched polymers has not been sufficiently developed. In this paper, we demonstrate that a miniaturized handheld near-infrared (NIR) spectrometer can be used to successfully fingerprint and classify different plastic polymers. The investigated urban plastic waste comprised polyethylene (PE), polypropylene (PP), poly(vinyl chloride) (PVC), poly(ethylene terephthalate) (PET), and poly(styrene) (PS), collected directly in a recycling plastic waste plant, without any kind of sample washing or treatment. The application of unsupervised and supervised chemometric tools such as principal component analysis (PCA) and partial least squares-discriminant analysis (PLS-DA) on the NIR dataset resulted in a complete classification of the polymer classes. In addition, several kinds of PET (clear, blue, coloured, opaque, and boxes) were correctly classified as PET class, and PE samples with different branching degrees were properly separated.

Rani, M., et al. (2015). "Qualitative Analysis of Additives in Plastic Marine Debris and Its New Products." Archives of Environmental Contamination & Toxicology **69**(3): 352-366.

Due to their formulation and/or processing, plastics contain additives and impurities that may leach out under conditions of use and accumulate in the environment. To evaluate their role as vectors of chemical contaminants in marine environment, plastic debris (n = 19) collected from coastal beaches along with new plastics (n = 25; same or same brand) bought from local markets were screened by gas chromatography-mass spectrometry in full scan mode. Detected peaks were identified using NIST library in different polymers (polypropylene (PP) > polyethylene (PE) > PP + PE > polyethyl terephthalate > poly(acylene:styrene) with different use (food, fishery, and general use). A database on the presence of 231 different chemicals were grouped into hydrocarbons, ultra-violet (UV)-stabilizers, antioxidants, plasticizers, lubricants, intermediates, compounds for dyes and inks, flame retardants, etc. The UV326, UV327, UV328, UV320, UvinualMC80, irganox 1076, DEHP, antioxidant no 33, di- n-octylisophthalate, diisooctyl phthalate, hexanoic acid 2-ethyl-hexadecyl ester, and hydrocarbons were most frequently detected. Finding of toxic phthalates and UV stabilizers in those products having moisture contact (like bottles with short use) raised concern to humans and indicated their irregular use. The comparison between new and debris plastics clearly indicated the leaching and absorption of chemicals and supports our assumption of plastic as media for transferring these additives in marine environment. Rani, M., et al. (2017). "Benzotriazole-type ultraviolet stabilizers and antioxidants in plastic marine debris and their new products." Science of the Total Environment **579**: 745-754.

Ultraviolet stabilizers (UVSs) and antioxidants are the most widely used additives in plastics to enhance the lifetime of polymeric materials. There is growing interest in the roles of plastic marine debris and microplastics as source or vector of toxic substances to marine environment and organisms. However, there is limited information available on plastic associated chemicals, particularly additive chemicals. Therefore, to evaluate their extent of exposure from plastics to the marine environment, we determined UVSs and antioxidants in plastic debris (n=29) collected from beaches along with their corresponding new plastic products in markets (n=27) belonging to food, fisheries, and general use. Antioxidants were present at higher concentrations than UVSs in both plastic debris and new plastics, indicative of their high use over UVSs. Irganox 1076 and Irganox 1010 were more commonly used than other chemicals investigated. The irregular use with high concentration of additive chemicals was observed in short-term use plastic products. Except for Irganox 1076 and UV 326, most antioxidants and UVSs were relatively high in new plastics compared to corresponding plastic marine debris, implying their potential leaching or degradation during use or after disposal. The present study provides quantitative information about additive chemicals contained in plastic marine debris and their new products. These results could be useful for better understanding of environmental exposure to hazardous chemicals through plastic pollution.

Rani, M., et al. (2017). "Releasing of hexabromocyclododecanes from expanded polystyrenes in seawater -field and laboratory experiments." Chemosphere **185**: 798-805.

Expanded polystyrene (EPS) is a major component of marine debris globally. Recently, hazardous hexabromocyclododecanes (HBCDDs) were detected in EPS buoys used for aquaculture farming. Subsequently, enrichment of HBCDDs was found in nearby marine sediments and mussels growing on EPS buoys. It was suspected that EPS buoys and their debris might be sources of HBCDDs. To confirm this, the release of HBCDDs from EPS spherules detached from a buoy to seawater was investigated under field (open sea surface and closed outdoor chambers with sun exposure and in the dark) and laboratory (particle-size) conditions. In all exposure groups, initial rapid leaching of HBCDDs was followed by slow desorption over time. Abundant release of HBCDDs was observed from EPS spherules exposed to the open sea surface (natural) and on exposure to sunlight irradiation or in the dark in controlled saline water. Water leaching and UV-light/temperature along with possibly biodegradation were responsible for about 37% and 12% of HBCDDs flux, respectively. Crumbled EPS particles (<=1 mm) in samples deployed on the sea surface for 6 months showed a high degree of weathering. This implies that surface erosion and further fragmentation of EPS via environmental weathering could enhance the leaching of HBCDDs from the surface of EPS. Overall, in the marine environment, HBCDDs could be released to a great extent from EPS products and their debris due to the cumulative effects of the movement of large volumes of water (dilution), biodegradation, UV-light/temperature, wave action (shaking), salinity and further fragmentation of EPS spherules.

Rao, B. B. (2010). "Larval habitats of Aedes albopictus (Skuse) in rural areas of Calicut, Kerala, India." Journal of Vector Borne Diseases **47**(3): 175-177.

During 2006-09, a descriptive observational study was performed to evaluate major larval habitats of A. albopictus in rural areas around Calicut City, in Kerala State, India. A total of 100 houses was covered during house-to-house larval surveys for potential container breeding sources during June and July. Larvae collected were identified for Aedes and A. albopictus larval indices, i.e., container index, house index and breteau index. Container habitats were enumerated and classified according to type, such as coconut shells, plastic objects, tyres, flower pots and glass waste. Overall, container, house and breteau indices were found to be higher than normally acceptable limits. Major breeding sites for Aedes mosquitoes were coconut shells and plastic materials. Tyres, flower pots, earthenware and glass waste were also detected, though in smaller numbers. A similar trend was observed in cases of containers positive for A. albopictus breeding. These results suggest that source reduction programmes should specifically be directed at proper disposal of these objects with special attention to coconut shells, plastic waste and tyres in order to effectively control A. albopictus.

Rao, B. B. and B. George (2010). "Breeding patterns of Aedes stegomyia albopictus in periurban areas of Calicut, Kerala, India." Southeast Asian Journal of Tropical Medicine & Public Health **41**(3): 536-540.

Aedes albopictus has been shown to be a vector for diseases which have been on the increase, such as dengue fever and chikungunya infection. We conducted a study of 100 homes from 2006-2009 to determine the breeding sites for Ae. albopictus mosquitoes in Calicut, Kerala, India. We found the larvae of Ae. albopictus mosquitoes most often in coconut shells and plastic

waste, followed by tires, flower pots, glass products, egg shells and dumped grinding stones. Ae. albopictus control programs in Calicut, Kerala, India should target these objects as part of a control program.

Rao, B. M. (2019). "Microplastics in the aquatic environment: implications for post-harvest fish quality." Indian Journal of Fisheries **66**(1): 142-152.

Though fish meat is good for health, its consumption is determined by post-harvest quality parameters. The "use and dispose" attitude of the public towards plastics coupled with inadequate waste management has led to extensive accumulation of plastic debris in the aquatic environment. Microplastics (plastic particles of <5 mm in their longest dimension) in the aquatic environment and fish gut is an emerging concern that has been reported from different regions of the world. The degradation of plastic polymers to micro- and even to nano sized particles smaller than 100 nm size is of recent major concern. Micro- and nanoplastics are basically inert but they tend to sorb toxic pollutants and harmful microorganisms. Moreover, chemicals added to plastic to impart functional properties pose threat to human health. Fish, either by passive ingestion or active foraging accumulate microplastics in their guts. However, there is paucity of documented evidence on the adverse effect of microplastics on human health due to consumption of such fish. Protocol for the determination of quantity of microplastics in fish flesh needs to be standardised and quality standard to be fixed for the quantity of microplastics that would be considered as a food hazard. There exists an imminent need to perform risk analysis in order to categorise microplastic as a food hazard in fish meant for human consumption. Until then there is no justification to reduce the consumption of fish and fishery products due to apprehension of presence of microplastics.

Rao, J., et al. (2017). "BH3 mimetic ABT-737 induces apoptosis in CD34⁺ acute myeloid leukemia cells and shows synergistic effect with conventional chemotherapeutic drugs." Asia-Pacific Journal of Clinical Oncology **13**(2): e144-e152.

AIMS: Acute myeloid leukemia (AML) is an immunophenotypically heterogenous malignant disease. The early immature CD34⁺ AML cell subpopulation is frequently impervious to intensive chemotherapy, making them largely responsible for relapse of AML. CD34⁺ AML cells have higher level of Bcl-2 protein expression than the CD34⁻ subpopulation. As such, development of drugs that specifically target the Bcl-2 may have the potential to eliminate immature CD34⁺ AML progenitor cells and provide therapeutic benefit. In this work, we made an attempt to investigate the cytotoxic effect of a novel Bcl-2 family inhibitor, ABT-737, on CD34⁺ AML cell lines (KG1a and Kasumi-1) as well as CD34⁺ primary AML cells.

METHODS: Primary human CD34⁺ cells were isolated from bone marrow mononuclear cells using CD34 MicroBead kit. The growth inhibitory effect was measured by cell counting kit-8. Apoptosis was analyzed by annexin V/PI assays. Protein expression was determined by Western blotting analysis.

RESULTS: Inhibition of Bcl-2 by ABT-737 effectively inhibited growth and induced apoptosis in CD34⁺ AML cell lines and CD34⁺ primary AML cells without affecting CD34⁺ normal hematopoietic cells. Furthermore, Western blot analysis showed that ABT-737 induced apoptosis associated with caspase-3 activation and poly ADP-ribose polymerase (PARP) degradation. Finally, ABT-737 synergistically enhanced the cytotoxic effect of cytarabine and daunorubicin in CD34⁺ AML cells.

CONCLUSION: Taken together, these findings indicate that ABT-737 may offer as a promising molecular targeting agent in CD34⁺ AML.

Rao, J., et al. (2011). "Curcumin reduces expression of Bcl-2, leading to apoptosis in daunorubicin-insensitive CD34+ acute myeloid leukemia cell lines and primary sorted CD34+ acute myeloid leukemia cells." Journal of Translational Medicine **9**: 71.

BACKGROUND: Acute myeloid leukemia (AML) is an immunophenotypically heterogeneous malignant disease, in which CD34 positivity is associated with poor prognosis. CD34+ AML cells are 10-15-fold more resistant to daunorubicin (DNR) than CD34- AML cells. Curcumin is a major component of turmeric that has shown cytotoxic activity in multiple cancers; however, its anti-cancer activity has not been well studied in DNR-insensitive CD34+ AML cells. The aim of this study was to therefore to explore curcumin-induced cytotoxicity in DNR-insensitive CD34+ AML cell lines (KG1a, Kasumi-1), DNR-sensitive U937 AML cells, and primary CD34+ AML bone-marrow-derived cells.

METHODS: Primary human CD34+ cells were isolated from peripheral blood mononuclear cells or bone marrow mononuclear cells using a CD34 MicroBead kit. The growth inhibitory effects of curcumin were evaluated by MTT and colony-formation assays. Cell cycle distribution was examined by propidium iodide (PI) assay. Apoptosis was analyzed by Wright-Giemsa, Hoechst 33342 and Annexin-V/PI staining assays. The change in mitochondrial membrane potential (MMP) was examined by JC-1 staining and flow cytometry. Expression of apoptosis-related proteins was determined by reverse transcription-polymerase chain reaction and Western blotting. Short interfering RNA (siRNA) against Bcl-2 was used in CD34+ KG1a and Kasumi-1 cells incubated with/without DNR.

RESULTS: Curcumin inhibited proliferation and induced apoptosis and G1/S arrest in both DNR-insensitive KG1a, Kasumi-1 and DNR-sensitive U937 cells. Curcumin-induced apoptosis was associated with reduced expression of both Bcl-2 mRNA and protein, subsequent loss of MMP, and activation of caspase-3 followed by PARP degradation. Curcumin synergistically enhanced the cytotoxic effect of DNR in DNR-insensitive KG1a and Kasumi-1 cells, consistent with decreased Bcl-2 expression. Accordingly, siRNA against Bcl-2 increased the susceptibility of KG1a and Kasumi-1 cells to DNR-induced apoptosis. More importantly, curcumin suppressed Bcl-2 expression, selectively inhibited proliferation and synergistically enhanced the cytotoxicity of DNR in primary CD34+ AML cells, while showing limited lethality in normal CD34+ hematopoietic progenitors.

CONCLUSION: Curcumin down-regulates Bcl-2 and induces apoptosis in DNR-insensitive CD34+ AML cell lines and primary CD34+ AML cells.

Rao, J., et al. (2017). "A preliminary study of SP70 as a marker to enrich tumor cells from body fluid samples." Journal of the American Society of Cytopathology **6 (5)**: S83-S84.

Introduction: Cytological diagnosis of body fluid samples plays an important role in managing cancer. However, the sensitivity of detecting malignant cells by cytology is low. SP70 is a newly identified marker for adenocarcinoma of lung, breast and colon. A reagent kit with the antibody against SP70 conjugated to microbeads was developed. The goal of this project was to preliminarily test the efficacy of SP70 as a marker to detect metastatic adenocarcinoma in body fluid samples. Material(s) and Method(s): In this study, remnants of 30 body fluid samples (including 15 pleural fluid samples and 15 ascetic fluid samples) were obtained from cytology laboratory after routine cytological evaluation. For each sample, 50 ml samples were processed by centrifuging at 1500 rpm for 10 minutes. The pellet was re-suspended with 2mL NaCl solution mixed with 10mL working bead solution, inverted 5 times, and incubated for an hour. The mixture was washed multiple times with PBST, fixed with 95% ethanol, smeared on the slide, and then stained with DiffQuick. The slides were reviewed independently without the knowledge of cytological diagnosis. Result(s): Total 30 cases, consisting of 7 males and 23 females with an average age of 70 years old, were analyzed. Among which 18 were positive by SP70 test, and 12 were negative. All 10 cases with positive cytological diagnosis were positive by SP70 test. In 20 cytology negative samples, 8 (Figure Presented) had positive SP70 test. Interestingly, 7 of the 8 samples were from patients with history of cancer, and only 1 of 7 samples had positive SP70 in patients with no cancer history. Figure 1 showed a positive sample with a beads-coated cell. Conclusion(s): SP70-based test is feasible in body fluid samples, and the test may have higher sensitivity for detecting malignant cells. Larger studies are warranted to confirm the findings.

Rao, R. R., et al. (2013). "Winner for outstanding research in the Ph.D. category for the 2013 Society for Biomaterials meeting and exposition, April 10-13, 2013, Boston, Massachusetts: Osteogenic differentiation of adipose-derived and marrow-derived mesenchymal stem cells in modular protein/ceramic microbeads." Journal of Biomedical Materials Research. Part A **101**(6): 1531-1538.

Modular tissue engineering applies biomaterials-based approaches to create discrete cell-seeded microenvironments, which can be further assembled into larger constructs for the repair of injured tissues. In the current study, we embedded human bone marrow-derived mesenchymal stem cells (MSC) and human adipose-derived stem cells (ASC) in collagen/fibrin (COL/FIB) and collagen/fibrin/hydroxyapatite (COL/FIB/HA) microbeads, and evaluated their suitability for bone tissue engineering applications. Microbeads were fabricated using a water-in-oil emulsification process, resulting in an average microbead diameter of approximately 130 +/- 25 mum. Microbeads supported both cell viability and cell spreading of MSC and ASC over 7 days in culture. The embedded cells also began to remodel and compact the microbead matrix as demonstrated by confocal reflectance microscopy imaging. After two weeks of culture in media containing osteogenic supplements, both MSC and ASC deposited calcium mineral in COL/FIB microbeads, but not in COL/FIB/HA microbeads. There were no significant differences between MSC and ASC in any of the assays examined, suggesting that either cell type may be an appropriate cell source for orthopedic applications. This study has implications in the creation of defined microenvironments for bone repair, and in developing a modular approach for delivery of pre-differentiated cells.

Rapoport, A., et al. (2015). "NY-ESO T cells administered post ASCT for MM exhibit extended functionality without exhaustion in a natural pattern of effector and memory programming." Cancer Research. Conference: 106th Annual Meeting of the American Association for Cancer Research, AACR **75**(15 SUPPL. 1).

Adoptive immunotherapy for cancer has been limited by a lack of antigen specificity, low levels of target expression, and failure to break self-tolerance. We hypothesized that infusion of genetically modified tumor-specific T cells following autologous stem cell transplant (ASCT) may overcome these barriers for multiple myeloma (MM). To test this, we conducted a phase I/II clinical trial (NCT01352286) in which T cells engineered with an HLA-A*0201 restricted, affinity-enhanced TCR recognizing NY-ESO-1 / LAGE-1 peptides (NY-ESO^{c259}-T), were infused in the setting of profound lymphodepletion that accompanies high-dose chemotherapy given with ASCT. HLA-A*0201 MM patients eligible for ASCT, with antigen positive tumor were enrolled. NY-ESO^{c259}-T was manufactured in a 10 day process using anti-CD3/CD28 microbeads and lentiviral vector, and was administered two days following ASCT. IMWG criteria were used to assess response at day 100 with the addition of a near complete response category (nCR) due to the common occurrence of oligoclonal banding observed following rapid post-ASCT immune reconstitution. Blood and marrow samples were taken at multiple timepoints for serum cytokine analysis, NY-ESO^{c259}-T persistence and trafficking, multiparameter flow analysis to examine the phenotype and function of NY-ESO^{c259}-T, and tumor biomarker analysis. 25 of 29 enrolled patients were infused. A mean of 2.8 x 10⁹ engineered cells were administered (range 8.3 x 10⁸-4.2 x 10⁹), and the average transduction efficiency was 33% (range 30%-45%). Patients tended to have advanced disease (64% chromosomal abnormalities, and 24% prior ASCT). At 3 months, 67% (16/24) and 58% (14/24) of patients were in VGPR and nCR or better, respectively. Infusions were well-tolerated and no cytokine release syndrome was reported. NY-ESO^{c259}-T persisted at 6 months in all but one patient, and in a subset of patients at 2 years; marrow infiltration was consistently observed from day 7 through day 180. NY-ESO^{c259}-T initially displayed a dominant activated effector phenotype which converted towards a dominant effector memory phenotype by 1 year post infusion, in a pattern that mirrored clinical responses. Persisting cells demonstrated a polyfunctional response (IFN-gamma and TNF-alpha) with a cytotoxic (CD107a and granzyme B) signature without overexpression of exhaustion markers (PD-1, LAG-3, and TIM-3). Tumor biomarker analysis is ongoing. MM relapse occurred in 13/25 patients. This data show that NY-ESO^{c259}-T cells exhibit robust trafficking and expansion, durable persistence without exhaustion, and follow a natural immune expansion and contraction pattern consistent with an antigen-driven mechanism of action. Relapse correlated with a loss of persistence or tumor antigen escape, suggesting that targeting multiple antigens and maintenance infusions may increase durable remissions.

Rapoport, A. P., et al. (2013). "Correlates of clinical response following autologous stem cell transplant and adoptive immunotherapy with engineered T cells expressing an affinity-enhanced T cell receptor in patients with mutliple myeloma." Cancer Research. Conference: 104th Annual Meeting of the American Association for Cancer Research, AACR **73**(8 SUPPL. 1).

Background: Adoptive immunotherapy for cancer has been limited by lack of antigen specificity, low levels of target expression, and failure to break self-tolerance. We are conducting an early phase clinical trial (NCT01352286) attempting to overcome these barriers using T cells engineered with an HLA-A0201 restricted, affinity-enhanced TCR that recognizes an epitope expressed by the NY-ESO-1 and LAGE-1 cancer testis antigens; these cells are infused in the setting of profound lymphodepletion that accompanies high-dose chemotherapy with autologous stem cell transplant (aSCT) for patients with high risk or relapsed multiple myeloma (MM). Method(s): Inclusion criteria include: 1) eligibility for aSCT, 2) PS of 0-2, 3) high risk MM or relapse after prior therapy, 4) HLA-A0201 positive, and 5) NY-ESO-1 and/or LAGE-1 positive tumor by PCR. CD25 depleted T cells are activated and expanded using anti-CD3/28 antibody conjugated microbeads, and genetically modified with a lentiviral vector. T cells are administered four days after high dose melphalan and two days following auto-SCT. Patients are evaluated for MM responses in accordance with the IMWG criteria at 6 weeks, and 3 and 6 months. At 3 months, patients with adequate marrow function start lenalidomide maintenance. Blood and marrow are monitored for persistence of engineered cells by qPCR and by surface expression of the NY-ESO-1 / LAGE-1 TCR using dextramerTM reagents. NY-ESO-1 and LAGE-1 antigen expression in marrow was assessed by qRT-PCR at baseline and post infusion. Result(s): As of November 2012, 21 patients have been enrolled, 15 have been infused; 4 were taken off study prior to infusion due to disease progression. An average of 2.7 x 10⁹engineered T cells were administered per patient (range 8.3 x 10⁸-4.2 x 10⁹), and the average transduction efficiency was 33% (range 30%-45%). More than 50% (8/15) of patients have high risk chromosomal abnormalities, and 3 (20%) have

received prior aSCT. At 3 months post aSCT, 73% of patients were in a very good partial response (VGPR) or better. Gastrointestinal toxicity resulting from autologous GVHD (aGVHD) occurred in a subset of patients at a higher rate than reported following aSCT alone or aSCT and T cell infusion, and was resolved in all cases. Infused T cells typically showed peak expansion in blood at day 14, followed by durable persistence in blood and marrow at 6-12 months in all but one patient. Disease progression is typically accompanied by very low levels or loss of engineered T cell persistence or loss of target antigen on tumor. Conclusion(s): We report for the first time that possible correlates of clinical response in this study include persistence of engineered T cells and loss of antigen, suggesting specific activity of the infused cells. Infusions are well tolerated with a possible risk of manageable aGVHD.

Raposo, M. F. d. J. and R. M. S. C. d. Morais (2011). "Chlorella vulgaris as soil amendment: influence of encapsulation and enrichment with rhizobacteria." International Journal of Agriculture and Biology **13**(5): 719-724.

Several trials with five plant growth-promoting rhizobacteria (PGPR) and the chlorophyte Chlorella vulgaris were carried out in order to look for the consortia that could show the best interactions, giving rise to improved growth of mixed cultures. Pseudomonas putida, Serratia proteomaculans and Stenotrophomonas maltophilia were the chosen bacteria for the consortia with Chlorella, while the proportions of microalgae/bacteria tested were 2:1, 3:1 and 3:1, respectively. Three replicates of 20 treatments were performed and studied, after sowing 20 seeds per replicate, for each of the consortia. Plantlets were left to grow for a two-week period. Maltodextrin (MD) and arabic gum (GA) or gelatine (G) were used as coats for the freeze-dried biomass microbeads. Longest roots were obtained with the consortium Chlorella:Serratia but encapsulates of Chlorella:Stenotrophomonas gave rise to meadow clover plantlets with the highest root and shoot system dried biomass, especially with coating proportions of 1:1 MD:G and MD:GA. Results obtained with this last consortium suggested some interactions with the plant metabolism, as well as some synergistic effects between Chlorella and bacteria.

Rasmussen, L. T. and R. Seljelid (1989). "The modulatory effect of lipoproteins on the release of interleukin 1 by human peritoneal macrophages stimulated with beta-1,3-D-polyglucose derivatives." Scandinavian Journal of Immunology **29**(4): 477-484.

Human peritoneal macrophages were stimulated in vitro with beta-1,3-D-polyglucose-derivatized microbeads (GDM) or soluble aminated beta-1,3-D-polyglucose (AG) in combination with lipoproteins. The release of interleukin 1 (IL-1) was analysed in cell supernatants in a thymocyte proliferation assay. We report that the release of IL-1 is markedly enhanced in macrophages stimulated with polyglucose in either form in combination with native low-density lipoprotein (LDL) or acetyl LDL at a concentration of 100 micrograms/ml. By increasing the amount of lipoproteins up to 10-fold, the IL-1 release decreased sharply. There was only a slight increase in activity when high-density lipoprotein (HDL) or very low-density lipoprotein (VLDL) were added. Other stimulatory agents, such as gamma interferon (IFN-gamma) and lipopolysaccharide (LPS) showed about half the activity of polyglucose. There was no significant difference between native LDL and acetyl LDL in potentiating effect. Our observations also suggest that the potentiating effect of LDL or acetyl LDL is not dependent on binding to their specific receptors. These findings provide a connection between macrophages, lipoproteins, and cytokines with regard to their role in the inflammatory response.

Rassam, S. M., et al. (2013). "T-cell and monocyte profiling shows marked differences in fresh tissue

gene expression between positively selected tumour infiltrating and peripheral blood cells in follicular non-hodgkin's lymphoma (FL): Possible role of heat shock protein 70 (HSP70) and B-cell receptor activating genes in disease progression and transformation." Hematological Oncology **1)**: 149.

Introduction: T-cells and macrophages/monocytes (MM) have an important role in the biology of follicular lymphoma (FL). There is conflicting data on the number role of tumour-infiltrating T-cells (TIL) and MM in predicting outcome. A National Cancer Institute study showed prediction of survival in FL based on the gene expression profiling of TIL. Other studies have shown multiple TIL functional defects. However, these studies used non-trizol frozen material, and the selected cells were stimulated with CD3 and grown in culture that could have changed the signatures. In the National Cancer Institute study, T-cells were negatively selected and mixed with other non-B-cells, and the study did not look at peripheral blood (PB) T-cell or MM profiles. No studies have looked specifically at fresh MM signatures, although there are reports implicating their number in transformation to diffuse large B-cell lymphoma. Aims and Methods: In the first stage reported here, we looked at positively selected TIL and MM gene expression profile signatures in fresh diagnostic samples of histologically confirmed grades 1-3a FL in 14 patients and compared the profiles with similarly selected cells from PB samples taken at the same time. The analysis was controlled with four histologically proven reactive hyperplasia lymph nodes. Tissue samples were digested with a cocktail of enzymes, Ficol separated and then positively selected for CD2, CD14 and CD19 in that order using microbead technology. CD2 selection and no expansion in culture were used to minimize T-cell receptor stimulation and change of expression. Some isolated T-cells were expanded in culture for purity assessment by flow cytometry. T-cells and MM were liquidized in Trizol prior to liquid nitrogen freezing. RNA was extracted at the same time and analysed using affymetrix microarray chips. Statistical analysis used three parameters to define significant change in expression: fold change of >1.5, pvalue of >1x10,³and FDR of <0.05. Samples were analysed as paired and pooled with a fold (over or under expressed) cut off threshold of 10. Results were validated with qPCR for 10 of the most under or overexpressed genes. Result(s): T-cells: paired samples (10) showed 97 over-expressed (41) or underexpressed (56) genes in TIL compared with peripheral blood T-cell, whereas pooled samples (14) showed 778 over-expressed (380) or under-expressed (398) genes. The top over-expressed genes using both methods of analysis are CXCL13, a B-cell chemotactic gene, IGJ, which helps in Ig assembly, CTLA4, a regulatory molecule, and CD200, which delivers an inhibitory signal to macrophages. These define a T-helper phenotype. Several heat shock protein (HSP) genes are over expressed relating to HSP70 pathway. The top underexpressed genes include genes that regulate T-cell adhesion, migration and cytotoxicity such as a number of flow cytometry receptor genes needed for antibody dependant cell cytotoxicity, genes involved in adhesion and migration, and granzyme, granulosin, lysosyme and other genes involved in T-cell cytotoxocity. MMs: Only pooled analysis was performed as the cell numbers were too small to have paired analysis. Many more (3239) genes were overexpressed (1494) or under-expressed (1745) in lymph node compared with PB MM. The top over-expressed genes include genes that stimulate B-cell receptor, growth and transformation such as IGJ, BLNK, PAX5, PTTG1 and C4orf7, CXCL13, signal transduction inhibitors and again HSP70. The top under-expressed genes include those that regulate cell adhesion, proliferation, migration and survival, and flow cytometry receptors, IL-1 and complement genes necessary for cell cytotoxicity. Conclusion(s): We believe this is the first study of this design with novel data suggesting that TIL and tissue MM support B-cell growth and transformation in FL whilst inheriting several defects in direct and indirect cell cytotoxicity. Over-expression of the HSP70 pathway supporting tumour growth and metastasis is a novel finding which could potentially lead to new treatment options. MMs appear to play a role in diffuse large Bcell lymphoma transformation of FL and their regulation may reduce the rate of progression and transformation.

Rassam, S. M. B., et al. (2012). "T-cell profiling shows marked differences in gene expression between tumour infiltrating (TIL) and peripheral blood (PB) antibody-bead selected T-cells from fresh lymph node and PB samples in follicular non-hodgkin's lymphoma (FL): Possible implications for immunomodulatory therapy." Blood. Conference: 54th Annual Meeting of the American Society of Hematology, ASH **120**(21).

Introduction: FL is one of the commonest B-cell lymphomas accounting for 25-30% of all newcases of non-Hodgkin's lymphoma. Median survival ranges from 6-10 years with a constant annual rate of relapse and death. The cellular immune system through T-cells and macrophages/monocytes (MMs) has an important role in the response to therapy and long term remissions. Evidence for this stemmed from increased incidence and the poor response rates and survival in patients with inherited or acquired T-cell defects, and the graft-versus-leukaemia effect of allogeneic stem cell transplants. The number of tumour infiltrating lymphocytes (TILs) and MMs appear to predict clinical response and outcome in FL. A recent National Cancer Institute study looked at the prediction of survival in FL based on the molecular features of TILs with positive findings. However, this study used frozen material which could have changed the signatures, T-cells were not positively selected and would have been mixed with other non B-cells, negatively selected cells were stimulated with CD3 which could have changed the gene expression profile, the study looked only at the predictive value in relation to prognosis and did not look at PB T-cell (PBT)profile. Aims and methods: In the first stage reported here, we looked at positively selected TILs, PBT and MMs gene expression profile signatures in fresh lymph node samples (LNs) of histologically confirmed grades 1-3 FL in 14 patients and compared the profile results with similar cells positively selected from PB samples taken at the same time. The analysis was controlled with 4 histologically proven reactive hyperplasia LNs. Tissue samples were digested with a cocktail of enzymes, ficol separated and then positively selected for CD2, CD19, CD14 in that order using Dynabeads (Dynall) initially then Microbeads (Miltenyl Biotech) subsequently. CD2 was used to avoid T-cell receptor stimulation and change of expression with CD3. Some isolated T-cells were initially expanded in culture for purity assessment only by flow cytometry. T-cells and MMs were liquid nitrogen frozen in trisol whilst B-cells were stored in DMSO. RNA was extracted at the same time and analysed using Affymetrix Microarray Chips. Statistical analysis used 3 parameters to define significant change in expression: fold change of >1.5, p value of > 1x10-3and FDR of >0.5. Samples were analysed as paired and pooled as some cases did not yield adequate paired samples. Result(s): T-cell paired (10) samples showed 97 over (41) or under (56) expressed genes in TILs compared to PBT whilst pooled samples (14) showed 778 over (380) or under (398) expressed genes. The top over expressed genes (10 fold plus) using both methods of analysis were CXCL13 a B-cell chemotactic gene, IGJ which helps in assembling IgG and IgM, CTLA4 a regulatory molecule, CD200 which delivers an inhibitory signal for the macrophage lineage and several heat shock protein (HSP) genes. The top under-expressed genes (10 fold plus) include genes that regulate T-cell adhesion, migration and direct and indirect cytotoxicity such as a number of FC receptor genes needed for antibody dependant cell cytotoxicity, killer cell lectin-like receptor genes, fractalkine genes involved in the adhesion and migration of leukocytes, and granzyme, granulosin, lysosyme and other genes involved in T-cell cytotoxocity. MMs: Only pooled samples were analysed as the extracted cell numbers were too small to have paired analysis. Many more (3239) genes were over (1494) or under (1745) expressed in LN MMs compared to PB MMs. The top over expressed genes include genes that support B cell growth such as IGJ, BLNK and C4orf7, the B cell chemotactic gene CXCL13, signal transduction inhibitors and HSPs. The top underexpressed genes include those that regulate cell adhesion and survival, cell proliferation and migration and extracellular matrix assembly. Others include FC receptor, IL-1 and compliment genes necessary for cell cytotoxicity, and thrombomodulin genes. Conclusion(s): We believe this is novel data suggesting that TILs and tissue MMs appear to support B-cell growth in FL whilst inheriting several defects in direct and indirect cell cytotoxicity. Downregulating the significantly overexpressed and upregulating the under expressed genes through targeted therapy may provide the basis of non-chemotherapy immunomodulatory treatment of B-cell lymphomas.

Rassam, S. M. B., et al. (2015). "Novel findings for the role of microenvironment and Heat Shock Proteins (HSP) in B-Cell Recptor (BCR) activation, disease progression and transformation of follicular non-hodgkin lymphoma (FL): Gene Expression Profiling (GEP) and Immuno-Histochemical (IH) studies reveal new pathways for potential targeted therapies." Blood **126 (23)**: 3897.

Introduction: Tumour infiltrating lymphocytes (TIL), tissue macrophages/monocytes (TMM) and follicular dendritic cells (FDC) have an important role in the biology of FL. Previous GEP studies used stored material, non-trizol freezing, negative T cell selection and CD3 stimulation and culture which could change signatures. None looked at peripheral blood (PB) T-cell (PBT) or MM (PBMM) profiles concurrently or specifically at fresh MM signatures though numbers are implicated in the disease's biology. Aims and methods: In the first stage we looked at positively selected TIL and TMM gene expression profile signatures in fresh diagnostic samples of histologically confirmed grades 1-3a FL in 14 patients and compared the profiles with similarly selected cells from controls and PB samples taken at the same time. We positively selected for CD2, CD14 and CD19 in that order with microbead technology. CD2 selection with no expansion in culture were used to minimise T-cell receptor stimulation. Cells were liquidised in Trizol prior to freezing. RNA was extracted and analysed using Affymetrix Microarray Chips. Statistical analysis used 3 parameters to define significant change in expression: fold change of >1.5, p value of > 1x10⁻³ and FDR of <0.05. Samples were analysed as paired and pooled with a fold (over or under expression) cut off threshold of 10. Results were validated with q-PCR for 10 of the most under or overexpressed genes. In the second stage we performed immunohistochemistry on paraffin embedded tissue from the same sample population looking at expression of HSP70, TLR2 & 4, CD21, CD22, CD200, PAX 5, p-AKT, and NF-kappaB p50 and p65. Co-expression by double staining was tested in 4 samples for CD3/HSP70, CD68/200, CD21/CD200 and CD68/PAX5. Result(s): GEP: T-cells paired samples (10) showed 97 over (41) or under (56) expressed genes in TIL compared to PBT whilst pooled samples (14) showed 778 over (380) or under (398) expressed genes. Several HSP genes are over expressed relating to HSP70 pathway. MM: Only pooled analysis was performed as the cell numbers were small. More (3239) genes were over (1494) or under (1745) expressed in LN compared to PBMM. The top over expressed genes include those that stimulate B cell receptor (BCR) growth and transformation and HSP70. Immunohistochemistry: FL cells lack nuclear HSP70 expression though TIL, TMM and FDC universally express it. Cytoplasmic NF-kappaB p50 and p65 and p-AKT are uniformly expressed in FL whilst TIL and TMM are weak or negative. FL cells strongly express TLR4 and to lesser extent TLR2 and are much weaker in TIL and TMM. CD200 is strongly expressed by FDC which show co-localisation with HSP70 and PAX5 double staining. TMM have granular cytoplasmic CD22 expression. Discussion(s): HSP suppress the apoptotic signalling at the premitochondrial stage through regulation of the pro-survival signalling and can be actively released extracellularly from inflammatory cells through the Golgi complex and passively from necrotic cells. HSP70 as a TLR4 and 2 ligand has a potent cytokine activity rapidly activates the MyD88/IRAK/NF-kappaB and TRIF pathways through MAPK/AP-1 and AKT increasing cell proliferation, adhesion and migration and resistance to apoptosis. Entry of the activated

NF-kappaB into nuclei is the final step of signalling cascades and contributes to enhanced BCL-2 expression in FL. Our immunohistochemical and GEP findings are complimentary and show for the first time that in FL, HSP70 expressed and probably released by TIL and TMM for self-preservation could act as a ligand for TLR2 & 4, activating the NF-kappaB and p-AKT pathways leading to tumour growth and metastasis. We also show novel data that TMM and FDC appear to play a major role in disease proliferation and transformation through expression and secretion of BCR activating ligands. Targeting the HSP70/TLR pathway could induce apoptosis of both FL and TIL cells inhibiting tumour growth and spread whilst targeting HSP70, TMM and FDC could in addition abrogate histological transformation.

Rastogi, N., et al. (1992). "A rapid microbead method for breaking pathogenic mycobacteria: Application in SDS-PAGE and Western blot analysis." Current Microbiology **24**(6): 311-317.

Ravindran, R., et al. (2010). "Validation of multiplex microbead immunoassay for simultaneous serodetection of multiple infectious agents in laboratory mouse." Journal of Immunological Methods **363**(1): 51-59.

Multiplex methodologies enable simultaneous detection of antibodies against several infectious agents allowing sample conservation, cost effectiveness, and amenability to high-throughput/automation. We have previously described a multiplex microbead immunoassay for serodetection of ten, high-priority mouse infectious pathogens. Here, we present a validation of this multiplex diagnostic system using approximately four hundred serum samples from different groups of mice. Computer assisted multivariate analysis of the resulting high volume data (8000 data points) was performed. This computational approach enabled presentation of data in a variety of easily interpretable formats (e.g., correlation tables and heat maps). Importantly, this computer aided approach was instrumental for the evaluation of assay accuracy, sensitivity, specificity, and robustness during the study. Crucial pieces of information were obtained to make timely adjustments for assay refinement. This progressive approach to developing an implementation-ready clinical assay, facilitated by computational analysis, produced a highly efficient, accurate and dependable serodiagnostics system. This system has effectively replaced the current state-of-the-art methodology (ELISA) used in mouse colony health management at the University of California and the Jackson Laboratory. A pathway to develop multiplex serology tests for infectious disease diagnosis described here serves as a model for multiplex immunoassay design, clinical validation, refinement and implementation.

Ravindran, R., et al. (2013). "Exploratory study on plasma immunomodulator and antibody profiles in tuberculosis patients." Clinical & Vaccine Immunology: CVI **20**(8): 1283-1290.

Host immune responses to Mycobacterium tuberculosis are generally able to contain infection and maintain a delicate balance between protection and immunopathology. A shift in this balance appears to underlie active disease observed in about 10% of infected individuals. Effects of local inflammation, combined with anti-M. tuberculosis systemic immune responses, are directly detectable in peripheral circulation, without ex vivo stimulation of blood cells or biopsy of the affected organs. We studied plasma immunomodulator and antibody biomarkers in patients with active pulmonary tuberculosis (TB) by a combination of multiplex microbead immunoassays and computational tools for data analysis. Plasma profiles of 10 immunomodulators and antibodies against eight M. tuberculosis antigens (previously reported by us) were examined in active pulmonary TB patients in a country where TB is endemic, Pakistan. Multiplex analyses were performed on samples from apparently healthy individuals without active TB from the same community as the TB patients to establish the assay baselines

for all analytes. Over 3,000 data points were collected from patients (n = 135) and controls (n = 37). The data were analyzed by multivariate and computer-assisted cluster analyses to reveal patterns of plasma immunomodulators and antibodies. This study shows plasma profiles that in most patients represented either strong antibody or strong immunomodulator biomarkers. Profiling of a combination of both immunomodulators and antibodies described here may be valuable for the analysis of host immune responses in active TB in countries where the disease is endemic.

Ravindranath, M. and P. Terasaki (2013). "A monoclonal antibody which possibly may replace the therapeutic intravenous immunoglobulin." American Journal of Transplantation **5)**: 477.

The value of intravenous immunoglobulin (IVIg) in lowering HLA antibodies (Abs) has recently come into question. High variability in different therapeutic preparations may account for the variable outcomes. We have produced a monoclonal Ab (mAb) which mimic immunoreactivity and immunosuppressive capabilities of IVIg and provide a stable reliable replacement for current IVIg.Four IVIg preparations were tested for their reactivity of HLA class-Ia and Ib alleles, and shown to have high reactivity to HLA class-I alleles (high mean fluorescent intensity and titers up to 1/512, by Luminex microbead testing) and to HLA-E. The numbers of HLA class-Ia allelic reactivities of IVIg preparations are shown in A. Since the blood of healthy individuals was shown to have HLA-Ia IgG Abs, the concentration of IgG from the plasma pooled from of donors accounts for the high levels of anti-HLA-Ia reactivities. Importantly, depleting anti-HLA-E Abs from IVIg totally eliminated the HLA-Ia reactivity of IVIg. We accordingly developed mAbs against recombinant HLA-E, which had reactivity to HLA class-I alleles identical to the different preparations of IVIg (A). Inhibition of the antibody reactivities with synthetic peptides showed that HLA-E shares epitopes with HLA-Ia alleles.The immunosuppressive functions of IVIg were then compared among different preparations by suppression of PHA-activated proliferation of CD4+ T cells with that of the two anti-HLA-E mAbs. Carboxyfluorescein succinimidyl ester (CFSE) staining was used to monitor proliferation of T cells after different treatments. A striking similarity was noted between different preparations of IVIg (Figure B) and the anti HLA E mAbs (Figures C and D) in the dose dependent inhibition of PHA-stimulated blastogenesis of CD4+ T cells.Since CD4+ T cells are involved in donor specific antigen presentation in allograft recipients for production of plasma B cells, inhibition of their proliferation and blastogenesis may account for their ability to reduce antibodies. We conclude that our unique anti-HLA-E mAb have the potential to replace the current IVIg, pooled and purified from the plasma of thousands donors. (Figure Presented).

Ravindranath, M. H., et al. (2010). "Antibodies to HLA-E in nonalloimmunized males: pattern of HLA-Ia reactivity of anti-HLA-E-positive sera." Journal of Immunology **185**(3): 1935-1948.

Natural anti-HLA Abs found in sera of healthy nonalloimmunized males recognize HLA-Ia alleles parallel to those recognized by anti-HLA-E mAbs (MEM-E/02/06/07). Therefore, some of the HLA-Ia Abs seen in healthy males could be due to anti-HLA-E Abs cross-reacting with HLA-Ia. If anti-HLA-E Abs occur in healthy nonalloimmunized males, it can be assessed whether they evoke HLA-Ia reactivity as do mouse HLA-E mAbs. IgG and IgM Abs to HLA-E and HLA-Ia alleles are identified in sera of healthy males using microbeads coated with recombinant denatured HLA-E or a panel of rHLA-Ia alleles. The pattern of allelic recognition is comparable to that of anti-HLA-E mAbs. Sixty-six percent of the sera with HLA-E IgG have a high level of HLA-Ia IgG, whereas 70% of those with no anti-HLA-E Abs have no HLA-Ia Abs. HLA-E IgM/IgG ratios of sera are divided into four groups: IgM(Low)/IgG(Low), IgM(High)/IgG(Low), IgM(High)/IgG(High), and IgM(Low)/IgG(High). These groups correspond to anti-HLA-Ia IgM/IgG ratio groups. When HLA-E

IgM and IgG are absent or present in males, the IgM or IgG of HLA-Ia are similarly absent or present. The mean fluorescent intensity of HLA-Ia Abs correlates with that of anti-HLA-E Abs. Most importantly, HLA-E and HLA-Ia reactivities of the sera are inhibited by the shared, but cryptic, peptide sequences (117)AYDGKDY(123) and (137)DTAAQIS(143). Therefore, Abs to the H chain of HLA-E may be responsible for some of the HLA-Ia allele reactivity of the natural HLA-Ia Ab in human sera. Absence of any anti-HLA-Ia Abs in 112 nonvegans and the presence of the same in vegans suggest that dietary meat proteins might not have induced the natural allo-HLA Abs.

Ravindranath, M. H., et al. (2013). "Therapeutic preparations of IVIg contain naturally occurring anti-HLA-E antibodies that react with HLA-Ia (HLA-A/-B/-Cw) alleles." Blood **121**(11): 2013-2028.

The US Food and Drug Administration approved intravenous immunoglobulin (IVIg), extracted from the plasma of thousands of blood donors, for removing HLA antibodies (Abs) in highly sensitized patients awaiting organ transplants. Since the blood of healthy individuals has HLA Abs, we tested different IVIg preparations for reactivity to HLA single antigen Luminex beads. All preparations showed high levels of HLA-Ia and -Ib reactivity. Since normal nonalloimmunized males have natural antibodies to the heavy chains (HCs) of HLA antigens, the preparations were then tested against iBeads coated only with intact HLA antigens. All IVIg preparations varied in level of antibody reactivity to intact HLA antigens. We raised monoclonal Abs against HLA-E that mimicked IVIg's HLA-Ia and HLA-Ib reactivity but reacted only to HLA-I HCs. Inhibition experiments with synthetic peptides showed that HLA-E shares epitopes with HLA-Ia alleles. Importantly, depleting anti-HLA-E Abs from IVIg totally eliminated the HLA-Ia reactivity of IVIg. Since anti-HLA-E mAbs react with HLA-Ia, they might be useful in suppressing HLA antibody production, similar to the way anti-RhD Abs suppress production. At the same time, anti-HLA-E mAb, which reacts only to HLA-I HCs, is unlikely to produce transfusion-related acute lung injury, in contrast to antibodies reacting to intact-HLA. Rawluk, J., et al. (2013). "Striking, aggressive synchronous non-small cell lung cancer (NSCLC) in a multiple myeloma (MM) patient (PT) and circulating tumor cell (CTC) detection." Onkologie **7)**: 255.

Introduction: Different neoplasms (DN), apart from the MM itself, synchronously detected or after 1.-line- and maintenance-treatment have recently been reported, questioning whether specific risk factors for MM exist. Moreover 2. tumors have gained more attention, since MM pts live longer and randomized data show associations between newer drugs and excess risk of DNs. Large population-based databases offer powerful sample sizes, but bear the limitation of focusing on primary tumors, therefore well-documented registry analyses are of value. Methods & Results: We report on a 62-year old pt, who was diagnosed with (w) IgM lambda (l) MM w diffuse osteolyses in conventional and CT-radiographs. Via histopathology Waldenstrom's macroglobulinaemia was excluded. The hemoglobin at initial diagnosis (ID) was 13 g/dl, l-SFLC 32.5 g/l, BM infiltration 15% w del13q14 and ISS I. Due to symptomatic MM, he was included in the DSMM XII trial which applies 4 cycles of RAD (Knop S, Blood 2009) followed by SCT. Neither the initial conventional lung-x-ray nor bone-CT-scans described thoracic abnormalities. After ASCT, the pt reported about haemoptysis; extensive diagnostics revealed central squamous cell NSCLC. Retrospectively, this NSCLC was already detectable w ID of the MM, suspecting that both neoplasms had occurred simultaneously. He underwent R0-resection, the tumor stage was pT2pN2cM0,L2,G2. Since biopsy of the osteolytic lesions was unfeasible, a bilateral BM-re-evaluation was done, that revealed no epithelial tumor cells. Re-staging diagnostics determined no metastases, albeit CTCs were detected by image cytometry and immunofluorescence. CTCs were enriched using CD326 (EpCAM)-microbeads and magnet-assisted cell sorting: w the former 59 EpCAM+ cells were captured from 1.2e5 cells (0.05%), w the latter 8 EpCAM+/CD45- cells from 800 cells detected in the EpCAM+ fraction (1%). These CTCs were substantially higher than in 5 other NSCLC pts (range 0-4). VGPR of the MM was obtained after the 1. ASCT, but due to the NSCLC, no 2. ASCT or maintenance were performed. Instead, the pt received mediastinal irradiation, but refrained from adjuvant CTx. 6 months after NSCLC-resection, he showed liver metastases. Despite palliative multi-agent CTx, he died of progressing NSCLC 5 months later and 20 months after ID of his NSCLC. Conclusion(s): CTCs in this pt preceded detection of aggressive NSCLC- metastases by conventional imaging and may prompt adjuvant CTx application in the future.

Ray, A., et al. (2018). "Targeting tryptophan catabolic kynurenine pathway enhances anti-tumor immunity and cytotoxicity in multiple myeloma." Blood. Conference: 60th Annual Meeting of the American Society of Hematology, ASH **132**(Suppl. 1).

Introduction. Plasmacytoid dendritic cells (pDCs) play an integral role in MM pathogenesis (Chauhan et al, Cancer Cell 2009, 16:309-323). pDCs interactions with tumor cells and T/NK effector cells in the MM-BM milieu induce immune suppression and MM cell proliferation (Chauhan et al, Cancer Cell 2009, 16:309-323; Ray et al, Leukemia 2015, 29:1441-1444). A direct interruption of pDC-MM and pDC-T cells interactions with novel agents will enhance cytotoxicity and anti-tumor immunity. In this context, our DNA microarray analysis identified upregulation of tryptophan catabolic kynurenine (Kyn) pathway during pDC-MM interactions. To date, the role of Kyn pathway in MM is unclear, but two rate-limiting enzymes of Kyn pathway, kynurenine 3-monooxygenase (KMO) and indoleamine 2,3-dioxygenase 1 (IDO1), have been implicated in various cancers. Overexpression of these enzymes causes hyper-accumulation of terminal metabolites, thereby triggering immune suppression via disruption of bidirectional signaling axes between antigen-presenting cells and T cells. In our study, we found that KMO and IDO1 are increased in both pDCs and MM cells during pDC-MM interactions. To assess the functional significance of these findings, we used our pDC/MM or pDC/T cells co-culture models, and show that targeting Kyn pathway generates MM-specific CTL activity. Moreover, the combination of KMO/IDO1 inhibitors with anti-PD-L1 Ab enhances anti-tumor immunity and cytotoxicity in MM. Methods MicroArray: MM cells were cocultured with pDCs for 72h; separated using CD138 Microbeads; poly RNA was subjected to microarray analysis using HG-U133 plus 2.0 plus Affymetrix chip. Gene expression patterns for MM cells cultured in the presence vs absence of pDCs were compared (>1.5-fold change was considered significant, CI > 95%). pDC-induced overexpression of target proteins: MM cells were cocultured with pDCs for 24h; analyzed by flow to detect KMO/IDO1 expression. CTL or NK activity assays: Minimally cytotoxic concentrations of inhibitors were used to assess immune functions. MM-BM CD8+ T or NK- cells were cultured with autologous pDCs (pDC:T/NK; 1:10 ratio) in the presence or absence of KMO (Ro 61-8048: 100 nM) or IDO1 (INCB 024360: 0.1 muM) inhibitors (Selleck Chemicals) for 5 days; drug washed, prestained MM cells were added for 24-48h (E/T ratio 10:1, T/NK:MM), followed by quantification of viable MM cells by FACS. Degranulation assay was quantified using cell surface CD107a. Osteoclast and osteoblast formations were assessed from TRAP and Alizarin Red staining, respectively. Results. 1) Normalized microarray expression profile showed pDC-induced upregulation of KMO in MM cells (2.153 fold vs MM alone; n=3; CI > 95%). 2) Both pDCs and MM cells expressed KMO and IDO1; pDC-MM coculture further increased KMO expression in MM cells (2-3-fold vs MM; p = 0.006); KMO MM cell populations also increased after coculture (~1.2 fold; p <0.05). Importantly, IDO1 expression in MM cells is also enhanced after co-culture; validating the importance of Kyn pathway in the context of pDC-MM interactions (MFI: 1.5-2 fold; p=0.006); IDO1 MM cell populations increased by ~1.5 fold after coculture (p <0.05). 3) KMOi directly activates pDCs and upregulates functional markers on pDCs (CD80: 1.19 fold; CD83: 1.4 fold; p <0.05). 4) KMOi activates patient BM-CD8 T cells in autologous pDCs/T cell coculture; triggers robust allogeneic and autologous MM-specific CD8 CTL activity (~2.0 fold vs control; p = 0.009). 5) In agreement with above findings, KMOi also increased surface CD107a expression on NK and CD8+T cells (CD56+NK: 1.41 fold; p = 0.004; CD8+T: 1.6 fold; p= 0.001). 6) Importantly, the combination of KMOi or IDO1i and anti-PD-L1 Ab (5 mug/ml) triggers a more robust MM-specific CD8⁺CTL activity than single agent (%MM viability: KMOi: 72%; KMOi + anti-PD-L1 Ab: 57%; IDOi: 82%; IDOi + anti- PD-L1 Ab: 70%; n=7; p = 0.01). Finally, 7) Both KMOi and IDO1i blocked monocyte-derived osteoclast formation, as well as restored MM patient BM-derived osteoblast formation. Conclusio s pDC-MM interactions upregulate immunosuppressive enzymes in Kyn pathway; and importantly, blockade of Kyn pathway enzymes induces MM-specific CD8 CTL activity. Our preclinical data therefore provides provides the basis for novel immune-based therapeutic approaches targeting kynurenine (Kyn) pathway enzymes KMO and IDO1 to enhance MM cytotoxicity and restore anti-MM immunity.

Raz, O., et al. (2018). "Chronic lymphocyte leukemia cells share a unique circular RNA expression pattern." HemaSphere **2 (Supplement 2)**: 114.

Background: MicroRNAs are known to be dysregulated in CLL and have been shown to be involved in the initiation and progression of the disease. The role of other non-coding RNAs in the pathobiology of CLL is less clear. Circular RNAs (circRNAs) are endogenous noncoding RNAs that represent approximately 10% of the human transcriptome. They result from noncanonical alternative splicing which generates a stable circular form through a covalent bond between their 3' and 5' ends. The expression profile of circRNAs has been shown to have a unique pattern in various pathological conditions. Yet, their expression has not been tested in CLL. Although the exact mechanism of action of circRNAs remains to be clarified, one suggested mode of action is regulation of gene expression via an interaction with miRNAs thus functioning as miRNA sponges. Other alternative modes of action include protein binding or regulation of transcription and post-transcriptional modifications. Through these functions, circRNAs may act as tumor suppressors or as oncogenes and contribute to the pathogenesis and/or progression of CLL Aims: To decipher the circRNA expression profile in CLL cells and compare it to that of normal B-lymphocytes and to evaluate the potential impact of the CLL specific circRNA profile on the pathogenesis and/or progression of CLL. Method(s): Lymphocytes from 6 CLL patient and 3 healthy volunteers were separated on a ficoll gradient and B cells were sorted with the aid of magnetic anti-CD19+ microbeads. circRNA expression in CLL lymphocytes was identified and quantified using a microarray based platform, provided by Arraystar Inc. Real-time PCR was used to validate the microarray results. Extensive bioinformatics analysis was performed in order to construct circRNA- miRNA-mRNA-protein networks and to identify pathways that may be influenced by these differently expressed circRNAs. Result(s): Of the 13,438 circRNAs transcripts that are represented in the array, 13,195 (98%) were present in at least 3 of 9 sample tested, indicating that circRNAs are abundant in both normal and neoplastic lymphocytes. Overall, 397 circRNAs were upregulated in CLL cells compared to normal B cells and 688 were downregulated. This downregulation of circRNA expression is 2 folds more than is expected by chance (P<0.01), suggesting a possible global downregulation of cirRNA transcription activity in CLL cells. Next, in an attempt to model a possible sponge effect, we constructed four circRNA-miRNA-mRNA networks. Two networks represent up regulated circRNAs (hsa-circRNA-104424, hsa-circRNA-100251) and two represent downregulated circRNAs

(hsa-circRNA-102680, hsa-circRNA- 001430). Each network consists of one circRNA, five miRNAs and over 1000 target genes. Deregulated expression of all of the circRNAs was verified by real-time PCR. Multiple fundamental biological processes that may be associated with the deregulated circRNAs including; apoptosis, cell cycle regulation, B cell activation and RNA transcription and processing were revealed by the DAVID and WebGestalt database resource and by GO enrichment analysis. Summary and Conclusion(s):Our study demonstrates that the circRNA profiling of CLL cells is significantly different from that of normal B-cells and revealed that the deregulated circRNAs may have profound impact on the pathogenesis of CLL. This is the first study publishing circRNA profiling in CLL thus paving the way towards an understanding of whether a specific expression pattern is associated with prognosis and whether targeting circRNAs may have therapeutic benefit in CLL.

Razanajatovo, R. M., et al. (2018). "Sorption and desorption of selected pharmaceuticals by polyethylene microplastics." Marine Pollution Bulletin **136**: 516-523.

The aim of the present study was to evaluate the sorption and desorption of sulfamethoxazole (SMX), propranolol (PRP) and sertraline (SER) by polyethylene (PE) microplastics in water. After the 96h mixture, the sorption percentages of pharmaceuticals on PE microplastics decreased according to the following order: SER (28.61%)>PRP (21.61%)>SMX (15.31%). The sorption kinetics were fitted well with the pseudo-second-order model. Both linear and Freundlich models were able to describe the sorption isotherm. The results suggest that the sorption process of the pharmaceuticals may be adequately described by their hydrophobicity and electrostatic interactions. The desorption results showed that 8% and 4% of PRP and SER, respectively, were released from the microplastics within 48h, but the sorption of SMX was irreversible. The results indicate the potential risks of PRP and SER for bioaccumulation in aquatic organisms via ingestion of the microplastics in aquatic environments.

Razza, F., et al. (2009). "Compostable cutlery and waste management: An LCA approach." Waste Management **29**(4): 1424-1433.

The use of disposable cutlery in fast food restaurants and canteens in the current management scenario generates mixed heterogeneous waste (containing food waste and non-compostable plastic cutlery). The waste is not recyclable and is disposed of in landfills or incinerated with or without energy recovery. Using biodegradable and compostable (B&C) plastic cutlery, an alternative management scenario is possible. The resulting mixed homogeneous waste (containing food waste and compostable plastic cutlery) can be recycled through organic recovery, i.e., composting. This LCA study, whose functional unit is “serving 1000 meals”, shows that remarkable improvements can be obtained by shifting from the current scenario to the alternative scenario (based on B&C cutlery and final organic recovery of the total waste). The non-renewable energy consumption changes from 1490 to 128MJ (an overall 10-fold energy savings) and the CO2 equivalents emission changes from 64 to 22 CO2 eq. (an overall 3-fold GHG savings). Re, F., et al. (1994). "Inhibition of anchorage-dependent cell spreading triggers apoptosis in cultured

human endothelial cells." Journal of Cell Biology **127**(2): 537-546.
When cultivated on substrates that prevent cell adhesion (the polymer polyhydroxyethylmethacrylate, bovine serum albumin, and Teflon), human endothelial cells (EC) rapidly lost viability with a half-life of approximately 10 h. Dying EC showed the morphological and biochemical characteristics of apoptosis. The apoptotic process of suspended EC was delayed by the protein synthesis inhibitor cycloheximide. To obtain information as to the mechanism involved in the apoptosis of suspended EC, we investigated whether adhesion to matrix proteins or integrin occupancy in EC retaining a round shape may affect EC suicide. EC bound to low coating concentration of either fibronectin or vitronectin, retaining a round shape and failing to organize actin microfilaments, underwent to rapid cell death; by contrast, cells on high substrate concentrations became flattened, showed actin microfilament organization, and retained viability. Addition of saturating amounts of soluble vitronectin to suspended round-shaped EC did not reduce the process of apoptosis. Finally, when suspended EC bound Gly-Arg-Gly-Asp-Ser-coated microbeads (approximately 10 microbeads/cell), yet retaining a round shape, the apoptotic process was not affected. Oncogene-transformed EC in suspension were less susceptible to cell death and apoptosis than normal EC. Overall, these data indicate that cell attachment to matrix or integrin binding per se is not sufficient for maintaining cell viability, and that cells need to undergo some minimal degree of shape change to survive. Modulation of interaction with the extracellular matrix can, therefore, be an important target for the control of angiogenesis.

Re, V. (2019). "Shedding light on the invisible: addressing the potential for groundwater contamination by plastic microfibers." Hydrogeology Journal **27**(7): 2719-2727.
The processes of microplastic fiber pollution in groundwater are unknown. The recent research on this contaminant threat is generally focused on surface waters (mainly oceans and rivers), while aquifer contamination is only marginally mentioned as an issue needing further investigation. Synthetic microfibers can be introduced into soils in different ways (e.g. wastewater treatment plants or greywater discharge, septic tank outflows, direct injection of contaminated water in cases of managed aquifer recharge, losing streams, etc.), and can thus reach aquifer systems due to leaching or infiltration in soil pores. Microfibers can then adsorb persistent bioaccumulative and toxic chemicals, which include persistent organic pollutants and metals, and become a carrier of harmful substances in the aquifer system, hence contributing to the overall contamination in both urban and rural areas. For this reason, it is of paramount importance, not only to assess the occurrence and fate of microplastic fibers in groundwater, but also to study the role of microplastics as carriers of contaminants within the aquifer and to advance standardization and organization of monitoring campaigns. Only by addressing these key challenges can hydrogeologists contribute to the state of the art on microplastic pollution and ensure that groundwater is not neglected in the environmental assessments tackling this contaminant of emerging concern.Alternate abstract:Les processus de pollution par les fibres micro-plastiques dans les eaux souterraines sont inconnus. Les recherches récentes sur cette menace de contaminants sont généralement axées sur les eaux de surface (principalement les océans et les rivières), tandis que la contamination des aquifères n’est que marginalement mentionnée comme une question nécessitant des recherches plus approfondies. Les microfibres synthétiques peuvent être introduites dans les sols de différentes manières (par ex. rejets de stations de traitement d’eaux usées ou rejets d’eaux grises, sorties de fosses septiques, injection directe d’eau contaminée dans les cas de gestion de la recharge d’aquifère, perte de cours d’eau, etc.) et peuvent ainsi atteindre les systèmes aquifères en raison de lessivage ou d’infiltration dans les pores du sol. Les microfibres peuvent ensuite adsorber des produits

chimiques persistants, bio-accumulatifs et toxiques, qui comprennent les polluants organiques persistants et les métaux, et deviennent porteuses de substances nocives dans les systèmes aquifères, contribuant ainsi à la contamination générale aussi bien dans les zones urbaines que dans les zones rurales. Pour cette raison, il est d'une importance primordiale, non seulement d'évaluer l'occurrence et le devenir des fibres micro-plastiques dans les eaux souterraines, mais aussi d'étudier le rôle des micro-plastiques en tant que porteurs de contaminants dans l'aquifère et de faire progresser la normalisation et l'organisation de campagnes de suivi. Ce n'est qu'en abordant ces principaux défis que les hydrogéologues contribuent à l'état de l'art sur la pollution par les micro-plastiques et veillent à ce que les eaux souterraines ne soient pas négligées dans les évaluations environnementales qui s'attaquent à ce contaminant de préoccupation émergente.Alternate abstract:Se desconocen los procesos de contaminación por fibras microplásticas en el agua subterránea. La investigación reciente sobre esta amenaza de contaminantes se centra generalmente en las aguas superficiales (principalmente los océanos y los ríos), mientras que la contaminación de los acuíferos se menciona sólo marginalmente como un tema que requiere mayor investigación. Las microfibras sintéticas pueden introducirse en los suelos de diferentes maneras (por ejemplo, en plantas de tratamiento de aguas residuales o descarga de aguas grises, desagües de fosas sépticas, inyección directa de agua contaminada en casos de recarga de acuíferos gestionados, pérdida de corrientes, etc.) y, por l tanto, pueden llegar a los sistemas acuíferos debido a la lixiviación o infiltración en los poros del suelo. Las microfibras pueden entonces adsorber productos químicos bioacumulativos y tóxicos persistentes, que incluyen contaminantes orgánicos persistentes y metales, y convertirse en portadores de sustancias nocivas en el sistema acuífero, contribuyendo así a la contaminación general tanto en zonas urbanas como rurales. Por esta razón, es de suma importancia, no sólo evaluar la ocurrencia y el destino de las fibras microplásticas en las aguas subterráneas, sino también estudiar el papel de los microplásticos como portadores de contaminantes dentro del acuífero y avanzar en la estandarización y organización de campañas de monitoreo. Sólo abordando estos desafíos clave pueden los hidrogeólogos contribuir al estado del arte de la contaminación microplástica y asegurar que las aguas subterráneas no sean descuidadas en las evaluaciones ambientales que abordan este contaminante de interés emergente.Alternate abstract:摘要地下水中微塑性纤维污染的过程尚不清楚。最近关于该污染物威胁的研究通常集中在地表水(主要是海洋和河流),而含水层污染仅略微被提到是需要进一步调查的问题。合成微纤维可以不同方式进入土壤(例如废水处理厂或灰水排放,化粪池出流,管理的含水层补给或河流补给地下水等情况下直接补给污染水),因此由于土壤孔隙中浸出或**渗透作用**污染水可以进入含水层系统。而且微纤维可以吸附包括持久性有机污染物和金属之类的持久性生物蓄积性和有毒的化学物质,并成为含水层系统中有害物质的载体,从而导致城市和农村地区的整体污染。因此至关重要的是,不仅要评估地下水中微塑料纤维的产生和归趋,还要研究微塑料作为含水层内污染载体的作用,并推进监测项目的标准化和组织。只有解决了这些关键问题,水文地质学家才能对微塑性污染的现有技术做出贡献,并**确保在解决新出**现污染的环境评估中地下水不会被忽视。Alternate abstract:Os processos de poluição de fibra de microplástico em águas subterrâneas são desconhecidos. A pesquisa recente sobre essa ameaça de contaminantes é geralmente focada em águas superficiais (principalmente oceanos e rios), enquanto a contaminação de aquíferos é apenas marginalmente mencionada como uma questão que necessita de investigação adicional. As microfibras sintéticas podem ser introduzidas nos solos de diferentes maneiras (por exemplo, estações de tratamento de águas residuais, vazamentos de tanques sépticos, injeção direta de água contaminada em casos de recarga gerenciada de aquíferos, influência de córregos, etc.) e podem atingir sistemas aquíferos devido à lixiviação ou infiltração nos poros do solo. As microfibras podem, então, adsorver

substâncias químicas bioacumulativas e tóxicas persistentes, que incluem poluentes orgânicos persistentes e metais, e se tornarem portadoras de substâncias nocivas no sistema aquífero, contribuindo assim para a contaminação geral em áreas urbanas e rurais. Por essa razão, é de suma importância não apenas avaliar a ocorrência e o destino das fibras de microplásticos nas águas subterrâneas, mas também estudar o papel dos microplásticos como portadores de contaminantes no aquífero e avançar na padronização e organização das campanhas de monitoramento. Somente abordando esses desafios chave, os hidrogeólogos podem contribuir para o estado da arte sobre a poluição por microplásticos e garantir que as águas subterrâneas não sejam negligenciadas nas avaliações ambientais que tratam desse contaminante de preocupação emergente.

Rebeiz, K. S. and A. P. Craft (1995). "Plastic waste management in construction: Technological and institutional issues." Resources, Conservation and Recycling **15**(3-4): 245-257.

The main objective of a solid waste management system is to effectively safeguard the public health, safety, and welfare. The various options involved in a waste management process are land-filling, incineration, and recycling wastes into useful products. Plastics recycling, in particular, would not be successful unless the proper infrastructure to collect the waste is being set, the technology to economically reprocess the waste into new products is available, and the establishment of markets for the cost-effective use of recycled products are developed. The development of new construction materials using recycled plastics is important to both the construction and the plastics recycling industries. Extensive research investigated the use of resins based on recycled poly(ethylene terephthalate) (PET) plastic waste for the production of a high performance composite material, namely polyester concrete (PC). Resins using recycled PET offer the possibility of a lower source cost of materials for forming good quality PC. PC products also allow the long-term disposal of PET waste, an important advantage in recycling applications.

Rebibou, J. M., et al. (2002). "Flow cytometric evaluation of pregnancy-induced anti-HLA immunization and blood transfusion-induced reactivation." Transplantation **74**(4): 537-540.

Background. Pregnancy-induced alloimmunization (PIA) may decrease to a level that becomes undetectable by complement-dependent cytotoxicity (CDC). Nevertheless, such alloimmunization may provoke acute rejections after kidney transplantation and lead to broad-spectrum immunizations after transfusion. Flow-cytometry (FC) was used to estimate the frequency of low-level PIA and to evaluate its influence on posttransfusion alloimmunization profiles. Methods. To evaluate the frequency of low-level PIA, the sera of 36 women, free of CDC-detectable anti-HLA IgG (CDC-IgG-negative), were cross-matched by FC against their husband's or offspring's lymphocytes and further analyzed with human leukocyte antigen (HLA) Ag-coated microbeads (Flow-PRA One-Lambda, Canoga Park, CA). To evaluate the influence of low-level alloimmunization on posttransfusion appearance of CDC-IgG, pretransfusion sera of a second cohort of 43 women, also CDC-IgG-negative and included in a transfusion protocol, were analyzed by Flow-PRA. Posttransfusion sera were analyzed for the development of cytotoxic IgG. Results. Ten of the first cohort of 36 (27.8%) CDC-IgG-negative women showed a positive FC cross-match against the husband or offspring lymphocytes. Flow-PRA analysis confirmed that 9 of 10 positive cross-matched sera contained anti-HLA IgG. Among the 43 transfused patients, 11 of 16 (68.7%) of the women who were CDC-IgG-positive after blood transfusion showed FC-detectable IgG before transfusion; although 2 of 27 (7.4%) of the patients who remained CDC-IgG-negative after transfusion showed FC-detectable IgG before transfusion ($P<0.001$). Conclusion. Most of the de novo anti-HLA immunizations detected by CDC after transfusion in previously pregnant women can be detected by Flow-PRA before transfusion.

Rech, S., et al. (2015). "Sampling of riverine litter with citizen scientists - findings and recommendations." Environmental Monitoring & Assessment **187**(6): 1-18.
The quantity and composition of litter at riversides and in the surface waters, as well as the occurrence of illegal dumping sites, were studied along four rivers in Chile. Data generated by volunteers were compared to the results from a professional survey, using an identical protocol. Litter was found in considerable quantities at the riversides and in the surface waters at all the sites investigated. A generalized linear mixed model analysis showed that the recorded litter densities did not differ between volunteers and professionals, even after controlling for river, site, or distance between sampling locations, demonstrating that the volunteers successfully applied the sampling protocol. Differences occurred with respect to litter composition, which is most likely due to difficulties in the classification of litter items and particles and to the underestimation of litter present in surface water samples. Even though this study was only conducted at a small number of rivers and sites, a comparatively consistent pattern of direct and intentional litter deposition at riversides was recorded, highlighting that river basins require more protection. The results also show that the citizen science approach can be a suitable means for more extensive litter surveys at riversides and in other natural environments. [ABSTRACT FROM AUTHOR]

Reddy, T. and S. Tammishetti (2002). "Gastric resistant microbeads of metal ion cross-linked carboxymethyl guar gum for oral drug delivery." Journal of Microencapsulation **19**(3): 311-318.
Ionic cross-linking of sodium carboxymethyl guar gum as a mild method for microencapsulation of sensitive drugs, like proteins, is presented. When a solution of sodium salt of carboxymethyl guar gum, containing BSA as a model drug, is added, as droplets, to different multivalent metal ion solutions, they get cross-linked to form insoluble microbeads. The amount of protein retained, morphology of the resulting beads and the subsequent release of the retained protein is simulated intestinal fluids varied with the type of metal ion as well as it's concentration. Trivalent metal ions like Al+++ and Fe+++ were found to be superior to divalent metal ions like Ba+ +, Ca++, Cu++ and Cd++. The optimum concentration around which these ions provide maximum drug retention was found to be much lower for trivalent ions. Beads cross-linked with them released the protein over a longer duration in enzyme free simulated intestinal fluid, than those cross-linked with divalent ions. Mg++, Sr++, Co++ and Zn++ failed to form isolable beads.

Redondo-Hasselerharm, P. E., et al. (2018). "Microplastic Effect Thresholds for Freshwater Benthic Macroinvertebrates." Environmental Science & Technology **52**(4): 2278-2286.
Now that microplastics have been detected in lakes, rivers, and estuaries all over the globe, evaluating their effects on biota has become an urgent research priority. This is the first study that aims at determining the effect thresholds for a battery of six freshwater benthic macroinvertebrates with different species traits, using a wide range of microplastic concentrations. Standardized 28 days single species bioassays were performed under environmentally relevant exposure conditions using polystyrene microplastics (20-500 µm)

mixed with sediment at concentrations ranging from 0 to 40% sediment dry weight (dw). Microplastics caused no effects on the survival of Gammarus pulex, Hyalella azteca, Asellus aquaticus, Sphaerium corneum, and Tubifex spp. and no effects were found on the reproduction of Lumbriculus variegatus. No significant differences in growth were found for H. azteca, A. aquaticus, S. corneum, L. variegatus, and Tubifex spp. However, G. pulex showed a significant reduction in growth (EC10 - 1.07% sediment dw) and microplastic uptake was proportional with microplastic concentrations in sediment. These results indicate that although the risks of environmentally realistic concentrations of microplastics may be low, they still may affect the biodiversity and the functioning of aquatic communities which after all also depend on the sensitive species. [ABSTRACT FROM AUTHOR]

Redondo-Hasselerharm, P. E., et al. (2018). "Ingestion and chronic effects of car tire tread particles on freshwater benthic macroinvertebrates." Environmental Science & Technology **52**(23): 13986-13994.

Micronized particles released from car tires have been found to contribute substantially to microplastic pollution, triggering the need to evaluate their effects on biota. In the present study, four freshwater benthic macroinvertebrates were exposed for 28 days to tread particles (TP; 10-586 micro m) made from used car tires at concentrations of 0, 0.1, 0.3, 1, 3, and 10% sediment dry weight. No adverse effects were found on the survival, growth, and feeding rate of Gammarus pulex and Asellus aquaticus, the survival and growth of Tubifex spp., and the number of worms and growth of Lumbriculus variegatus. A method to quantify TP numbers inside biota was developed and here applied to G. pulex. In bodies and faces of G. pulex exposed to 10% car tire TP, averages of 2.5 and 4 tread particles per organism were found, respectively. Chemical analysis showed that, although car tire TP had a high intrinsic zinc content, only small fractions of the heavy metals present were bioavailable. PAHs in the TP-sediment mixtures also remained below existing toxicity thresholds. This combination of results suggests that real in situ effects of TP and TP-associated contaminants when dispersed in sediments are probably lower than those reported after forced leaching of contaminants from car tire particles.

Reed, C. (2011). "Better drug delivery by design." Machine Design **83**(15): 54-56,58.

Pharmaceutical companies are continually developing new drugs and delivery methods, and liquid-drug formulations are no exception. Packaging for these drugs also continue to be updated and refined, and plastics are at the forefront. The blow-fill-seal (B/F/S) method of packaging liquids in thermoplastics creates aseptic containers that keep contents sterile. B/F/S packaging also replaces glass bottles -- which can break in transit or while drugs are being dispensed and are often shipped in paper and cardboard that can harbor mold and bacteria. Aseptic B/F/S combines blow molding, sterile filling, and hermetic sealing in a continuous, automated operation that takes place in a clean room. The B/F/S process starts with melted granules of thermoplastics like polyethylene and polypropylene. Sterile, HEPA-filtered air blows the melt into a cavity to create a molten parison, an extruded tube of hot plastic resin.

Reed, C. (2018). "The other plastic plague." New Scientist **239**(3186): 37-39.

The article focuses on research examining the role of plastic waste in spreading disease through

the oceans. It states that researcher Joleah Lamb and colleagues detected a connection between the presence of plastic waste and diseased coral, including white syndrome. It mentions concerns that microbe ecosystems living on plastic waste may concentrate pathogens that infect coral after contact. It comments on concerns plastic waste could also encourage diseases including gastroenteritis in humans.

Reed, S., et al. (2018). "Microplastics in marine sediments near Rothera Research Station, Antarctica." Marine Pollution Bulletin **133**: 460-463.

Antarctica and surrounding waters are often considered pristine, but may be subject to local pollution from tourism, fishing and governmental research programme activities. In particular, the quantification of microplastic pollution within the Antarctic Treaty area (south of latitude 60degreeS) has received little attention. We examined microplastic particle concentrations in sediment samples from 20 locations up to 7 km from Rothera Research Station. The highest concentrations of microplastic (<5 particles 10 ml⁻¹) were recorded in sediment collected near the station sewage treatment plant outfall. The concentrations were similar to levels recorded in shallow and deep sea marine sediments outside Antarctica. The detected microplastics had characteristics similar to those commonly produced by clothes washing. We recommend further research on microplastics around Antarctic stations to inform policy discussions and the development of appropriate management responses. Copyright © 2018 Elsevier Ltd

Rees, R. W., et al. (2012). "Ganoderma boninense basidiospores in oil palm plantations: evaluation of their possible role in stem rots of Elaeis guineensis." Plant Pathology **61**(3): 567-578.

Basidiospores are implicated in the distribution and genetic diversity of Ganoderma boninense, cause of basal stem rot (BSR) and upper stem rot (USR) of oil palm (Elaeis guineensis). Measurement of aerial basidiospores within plantations in Sumatra showed continuous and high production over 24 h (range c. 2-11 000 spores m⁻³) with maximum release during early evening. Basidiospores applied to cut surfaces of fronds, peduncles and stems germinated in situ. Equivalent, extensive wounds are created during plantation harvesting and management and represent potential sites for formation of infective heterokaryons following mating of haploid basidiospore germlings. Use of spore-sized micro-beads showed that basidiospores could be pulled up to 10 cm into severed xylem vessels, where they are relatively protected from dehydration, UV irradiation and competing microflora. Diversity of isolates from five locations on two plantations was assessed by RAMS fingerprinting. Isolates from within individual palms with USR were identical and represent single infections, but different USR infections had unique band patterns and revealed separate infections. Some BSR-affected trees contained more than one isolate, and thus had multiple infections. There was one example of adjacent BSR palms with the same isolate, indicating vegetative spread, but there were no identical genets from BSR infections and adjacent fallen palms. Isolate diversity was as great within a plantation as between plantations. It is evident that basidiospores play a major role in spread and genetic variability of G. boninense. Evidence for direct basidiospore infection via cut fronds, indirectly through roots via colonized debris and less frequently, infection by vegetative, clonal spread is considered.

Rego, B. J. (2018). "ASSESSING THE OCCURRENCE OF MICROPLASTIC UPTAKE BY LAKE ERIE PERCH AND WALLEYE AND UNIONID FRESHWATER MUSSELS." The Ohio Journal of Science **118**(1).

Microplastics are defined as plastics under 5 mm in diameter, and can be divided into five groups: fragments, microfibers, beads, foams, and films. Microplastics have been documented

to have harmful effects on aquatic organisms as they can emit toxins and cause blockage in the digestive tracts resulting in irritation and malnutrition. In an ongoing study, 3 different freshwater taxa (Yellow Perch, Perca flavescens, n = 4; Walleye, Sander vitreus, n=4; and Unionid mussels-genus: Anodonta, n = 8) were evaluated to assess the prevalence of microplastics accumulation in digestive tracts or surrounding tissue. Fish were collected from Lake Erie (Fairport Harbor) and mussels were purchased commercially and placed in a mesocosm. The mesocosm consisted of two 25 gallon tanks; one contained microplastics proportional to the composition of microplastics found in the tributaries of the Great Lakes and one did not. The digestive tracts of all species were removed and dissolved using 4N KOH and 30% H2O2. Contents were extracted using a Büchner funnel and dissected for microplastics under a dissection scope. The gill tissue was analyzed separately using the same method for the mussels. 100% of sampled Perch and 50% of Walleye contained microfibers in their digestive tracts. 12% of mussels sampled contained plastic fragments; found in the gill tissue. These data suggest that both fish and mussels are capable of ingesting or accumulating microplastics.

Regtmeier, A., et al. (2012). "Uniform growth of clusters of magnetic nanoparticles in a rotating magnetic field." Journal of Nanoparticle Research **14 (8) (no pagination)**(1061).

It was recently shown that the exposure of magnetic microbeads to a homogeneous magnetic field, which rotates around the axis perpendicular to the field direction, generates highly ordered two-dimensional particle arrays. In this work, the impact of downscaling such systems is analyzed. Dilutions of cobalt nanoparticles with an average diameter of 6 nm were brought into a rotating homogeneous magnetic field. A strong localization of the number of particles within a certain cluster size can be observed if the rotation frequency is adjusted to a specific particle concentration. In particular, we obtain an increase of 85 % of the maximum of the cluster size distribution, when changing the rotation frequency of the magnetic field from 300 to 750 rpm for a cobalt concentration of 35.95 mmol/l. We propose a heuristic model to explain the observed frequency dependence. © 2012 Springer Science+Business Media B.V.

Reguera, P., et al. (2019). "Microplastics in wild mussels (Mytilus spp.) from the north coast of Spain." Scientia Marina **83**(4): 337-347.

Microplastic content (MPs) in mussels (Mytilus spp.) from two areas of the north coast of Spain was measured for the first time. Additionally, a comparison of microplastic levels observed in mussels digested with nitric acid and with potassium hydroxide was carried out. The average microplastic concentration in mussels digested with nitric acid was significantly lower than that observed in mussels digested with potassium hydroxide ($p<0.05$). The average concentration of microplastics in mussels from the Cantabrian Sea (2.55±2.80 MPs g–1 WW) was slightly higher than that in mussels from the Ria of Vigo (1.59±1.28 MPs g–1 WW). Both in the Ria of Vigo and in the Cantabrian Sea the observed pattern of pollution was fitted to the one expected. Consequently, mussels have been confirmed as suitable sentinel organisms for microplastic pollution.

Rehan, M., et al. (2016). "Pyrolytic liquid fuel: a source of renewable electricity generation in Makkah." Energy Sources A: Recovery, Utilization and Environmental Effects **38**(17): 2598-2603.

Millions of Muslims from all over the world visit the Holy Cities of Saudi Arabia: Makkah and Madinah every year to worship in form of Pilgrimage (Hajj) and Umrah. The rapid growth in local population, urbanization, and living standards in Makkah city along with continually increasing number of visitors result in huge municipal solid waste generation every year. Most of this waste is disposed to landfills or dumpsites without material or energy recovery, thus posing

substantial environmental and health risks. The municipal plastic waste is the second largest waste stream (up to 23% of total municipal waste) that is comprised of plastic bottles, water cups, food plates, and shopping bags. The sustainable disposal of plastic waste is challenging task due to its clogging effects, very slow biodegradation rates, and presence of toxic additives and dyes. Pyrolysis is one of the promising waste-to-energy technology for converting municipal plastic waste into energy (liquid fuel) and value-added products like char. The produced liquid fuel has the potential to be used in several energy-related applications such as electricity generation, transportation fuel, and heating purposes. It has been estimated that the plastic waste in Makkah city in 2016 can produce around 87.91 MW of electricity. This is projected to increase up to around 172.80 MW of electricity by 2040. A global warming potential of 199.7 thousand Mt.CO₂ eq. will be achieved with savings of 7.9 thousand tons emission of CH₄, if pyrolysis technology is developed in Makkah city. Furthermore, a total savings of 297.52 million SAR from landfill diversion, electricity generation, and carbon credits would be possible to achieve in 2016 from pyrolysis. These economic benefits will increase every year and will reach up to 584.83 million SAR in 2040.

Rehmert, N., et al. (1992). "A new central supply system as alternative source for bicarbonate dialysate." International Journal of Artificial Organs **15**(6): 339-342.

Bicarbonate dialysis is mandatory for high efficiency treatment. In most cases bicarbonate is delivered either as prepacked powder or as a stable liquid concentrate in 6-10 I plastic containers. With a newly designed central supply system (CSS) using 800 I tanks of custom-made sterile and pyrogen free concentrates, we investigated the risk of bacterial contamination of dialysate in a 30-bed dialysis unit. During three months, samples of reverse osmosis (RO) water, concentrates and dialysate were taken every two weeks. Colony forming units (CFU) were counted after 48 h incubation. Further samples were taken during nine months of continuous use of the CSS without further intermittent disinfection. None of the samples had greater than 10/ml CFU. Pseudomonas, corynebacteria and enterobacter were the predominant species. In summary, this CSS proved reliable in providing bacteriologically safe bicarbonate dialysate as defined by international standards (CFU less than 200/ml). It significantly reduces costs, workload and environmental pollution by plastic waste.

Rehse, S., et al. (2016). "Short-term exposure with high concentrations of pristine microplastic particles leads to immobilisation of Daphnia magna." Chemosphere **153**: 91-99.

Recent studies revealed that freshwaters are not only polluted by chemicals, but also by persistent synthetic material like microplastics (plastic particles <1 mm). Microplastics include a diverse range of characteristics, e.g. polymer type, size or shape, but also their tendency to sorb pollutants or release additives. Although there is rising concern about the pollution of freshwaters by microplastics, knowledge about their potential effects on organisms is limited. For a better understanding of their risks, it is crucial to unravel which characteristics influence their effects on organisms. Analysing effects by the mere particles is the first step before including more complex interactions e.g. with associated chemicals. The aim of this study was to analyse potential physical effects of microplastics on one representative organism for limnic zooplankton (Daphnia magna). We investigated whether microplastics can be ingested and whether their presence causes adverse effects after short-term exposure. Daphnids were exposed for up to 96 h to 1- micro m and 100- micro m polyethylene particles at concentrations between 12.5 and 400 mg L⁻¹. Ingestion of 1- micro m particles led to immobilisation increasing with dose and time with an EC₅₀ of 57.43 mg L⁻¹ after 96 h. 100- micro m particles that could not be ingested by the daphnids

had no observable effects. These results underline that, considering high concentrations, microplastic particles can already induce adverse effects in limnic zooplankton. Although it needs to be clarified if these concentrations can be found in the environment these results are a basis for future impact analysis, especially in combination with associated chemicals.

Rehse, S., et al. (2018). "Microplastics reduce short-term effects of environmental contaminants. Part I: Effects of bisphenol A on freshwater zooplankton are lower in presence of polyamide particles." International Journal of Environmental Research and Public Health **15**(2).

Microplastics can have direct physical effects on organisms in freshwater systems, and are considered as vectors for absorbed environmental pollutants. It is still under discussion if microplastics are relevant pollutant vectors for uptake into aquatic organisms in comparison to further uptake pathways, e.g., via water or sediment particles. We analyzed how the presence of microplastics (polyamide particles, PA) modifies acute effects of the environmental pollutant bisphenol A (BPA) on freshwater zooplankton (Daphnia magna). Daphnids were exposed to PA particles and BPA alone, before combining them in the next step with one concentration of PA and varying concentrations of BPA. The PA particles themselves did not induce negative effects, while the effects of BPA alone followed a typical dose-dependent manner. Sorption of BPA to PA particles prior to exposure led to a reduction of BPA in the aqueous phase. The combination of BPA and PA led to decreased immobilization, although PA particles loaded with BPA were ingested by the daphnids. Calculations based on physiochemistry and equilibrium assumptions indicated lower BPA body burden of daphnids in the presence of PA particles. These results confirm model-based studies, and show that investigated microplastic concentrations are negligible for the overall pollutant uptake of daphnids with water as additional uptake pathway.

Reichert, J., et al. (2019). "Impacts of microplastics on growth and health of hermatypic corals are species-specific." Environmental Pollution **254**(Part B).

Coral reefs are increasingly affected by the consequences of global change such as increasing temperatures or pollution. Lately, microplastics (i.e., fragments <5 mm) have been identified as another potential threat. While previous studies have assessed short-term effects caused by high concentrations of microplastics, nothing is known about the long-term effects of microplastics under realistic concentrations. Therefore, a microcosm study was conducted and corals of the genera Acropora, Pocillopora, Porites, and Heliopora were exposed to microplastics in a concentration of 200 particles L⁻¹, relating to predicted pollution levels. Coral growth and health, as well as symbiont properties were studied over a period of six months. The exposure caused species-specific effects on coral growth and photosynthetic performance. Signs of compromised health were observed for Acropora and Pocillopora, those taxa that frequently interact with the particles. The results indicate elevated energy demands in the affected species, likely due to physical contact of the corals to the microplastics. The study shows that microplastic pollution can have negative impacts on hermatypic corals. These effects might amplify corals' susceptibility to other stressors, further contributing to community shifts in coral reef assemblages.

Reichert, J., et al. (2018). "Responses of reef building corals to microplastic exposure." Environmental Pollution **237**: 955-960.

Pollution of marine environments with microplastic particles (i.e. plastic fragments <5 mm) has increased rapidly during the last decades. As these particles are mainly of terrestrial origin, coastal ecosystems such as coral reefs are particularly threatened. Recent studies revealed that microplastic ingestion can have adverse effects on marine invertebrates. However, little is known about its effects on small-polyp stony corals that are the main framework builders in coral reefs. The goal of this study is to characterise how different coral species (I) respond to microplastic particles and whether the exposure might (II) lead to health effects. Therefore, six small-polyp stony coral species belonging to the genera Acropora, Pocillopora, and Porites were exposed to microplastics (polyethylene, size 37-163 micro m, concentration ca. 4000 particles L⁻¹) over four weeks, and responses and effects on health were documented. The study showed that the corals responded differentially to microplastics. Cleaning mechanisms (direct interaction, mucus production) but also feeding interactions (i.e. interaction with mesenterial filaments, ingestion, and egestion) were observed. Additionally, passive contact through overgrowth was documented. In five of the six studied species, negative effects on health (i.e. bleaching and tissue necrosis) were reported. We here provide preliminary knowledge about coral-microplastic-interactions. The results call for further investigations of the effects of realistic microplastic concentrations on growth, reproduction, and survival of stony corals. This might lead to a better understanding of resilience capacities in coral reef ecosystems.

Reid, A. J., et al. (2019). "Emerging threats and persistent conservation challenges for freshwater biodiversity." Biological Reviews of the Cambridge Philosophical Society **94**(3): 849-873.

In the 12 years since Dudgeon et al. (2006) reviewed major pressures on freshwater ecosystems, the biodiversity crisis in the world's lakes, reservoirs, rivers, streams and wetlands has deepened. While lakes, reservoirs and rivers cover only 2.3% of the Earth's surface, these ecosystems host at least 9.5% of the Earth's described animal species. Furthermore, using the World Wide Fund for Nature's Living Planet Index, freshwater population declines (83% between 1970 and 2014) continue to outpace contemporaneous declines in marine or terrestrial systems. The Anthropocene has brought multiple new and varied threats that disproportionately impact freshwater systems. We document 12 emerging threats to freshwater biodiversity that are either entirely new since 2006 or have since intensified: (i) changing climates; (ii) e-commerce and invasions; (iii) infectious diseases; (iv) harmful algal blooms; (v) expanding hydropower; (vi) emerging contaminants; (vii) engineered nanomaterials; (viii) microplastic pollution; (ix) light and noise; (x) freshwater salinisation; (xi) declining calcium; and (xii) cumulative stressors. Effects are evidenced for amphibians, fishes, invertebrates, microbes, plants, turtles and waterbirds, with potential for ecosystem-level changes through bottom-up and top-down processes. In our highly uncertain future, the net effects of these threats raise serious concerns for freshwater ecosystems. However, we also highlight opportunities for conservation gains as a result of novel management tools (e.g. environmental flows, environmental DNA) and specific conservation-oriented actions (e.g. dam removal, habitat protection policies, managed relocation of species) that have been met with varying levels of success. Moving forward, we advocate hybrid approaches that manage fresh waters as crucial ecosystems for human life support as well as essential hotspots of biodiversity and ecological function. Efforts to reverse global trends in freshwater degradation now depend on bridging an immense gap between the aspirations of conservation biologists and the accelerating rate of species endangerment.

Reihill, J. A., et al. (2016). "Inhibition of Protease-Epithelial Sodium Channel Signaling Improves Mucociliary Function in Cystic Fibrosis Airways." American Journal of Respiratory & Critical Care Medicine **194**(6): 701-710.

RATIONALE: In cystic fibrosis (CF) a reduction in airway surface liquid (ASL) height compromises mucociliary clearance, favoring mucus plugging and chronic bacterial infection. Inhibitors of the epithelial sodium channel (ENaC) have therapeutic potential in CF airways to reduce

hyperstimulated sodium and fluid absorption to levels that can restore airway hydration.

OBJECTIVES: To determine whether a novel compound (QUB-TL1) designed to inhibit protease/ENaC signaling in CF airways restores ASL volume and mucociliary function.

METHODS: Protease activity was measured using fluorogenic activity assays. Differentiated primary airway epithelial cell cultures (F508del homozygotes) were used to determined ENaC activity (Ussing chamber recordings), ASL height (confocal microscopy), and mucociliary function (by tracking the surface flow of apically applied microbeads). Cell toxicity was measured using a lactate dehydrogenase assay.

MEASUREMENTS AND MAIN RESULTS: QUB-TL1 inhibits extracellularly located channel activating proteases (CAPs), including prostasin, matriptase, and furin, the activities of which are observed at excessive levels at the apical surface of CF airway epithelial cells. QUB-TL1-mediated CAP inhibition results in diminished ENaC-mediated Na(+) absorption in CF airway epithelial cells caused by internalization of a prominent pool of cleaved (active) ENaCgamma from the cell surface. Importantly, diminished ENaC activity correlates with improved airway hydration status and mucociliary clearance. We further demonstrate QUB-TL1-mediated furin inhibition, which is in contrast to other serine protease inhibitors (camostat mesylate and aprotinin), affords protection against neutrophil elastase-mediated ENaC activation and Pseudomonas aeruginosa exotoxin A-induced cell death.

CONCLUSIONS: QUB-TL1 corrects aberrant CAP activities, providing a mechanism to delay or prevent the development of CF lung disease in a manner independent of CF transmembrane conductance regulator mutation.

Reimers, D., et al. (2017). "Autoreactive T cell responses in Membranous Nephropathy." European Journal of Immunology **47 (Supplement 2)**: 127.

Membranous Nephropathy (MN) is an immune-mediated glomerular disease. Even with immunosuppressive treatment, MN leads to complete loss of kidney function in about 15 to 20% of patients. MN is caused by binding of autoantibodies against peptide epitopes on glomerular podoctyes. Recently, two podocyte antigens were identified that are recognized by autoantibodies in MN. 70 to 80% of MN patients have antibodies against M-type phospholipase A2 receptor 1 (PLA2R1) and 2 to 3% against the thrombospondin type-1 domain-containing 7A (THSD7A). These autoantibodies are considered central for renal pathology. The detection of anti-PLA2R1 and anti-THSD7A antibodies in serum of patients allows diagnosis for MN. Genome wide association studies demonstrate a correlation of MN with the HLA-DQA1 gene loci, coding for the alpha-chain of HLA-DQ, which implies a role for CD4 T cells in disease development and/or progression. In our current project, we apply a sensitive method for the identification of PLA2R1-specific CD4 T cells to analyze the potential role of autoreactive T cells in patients with MN. Therefore, we isolate Peripheral Blood Mononuclear Cells (PBMCs) from the blood of patients and healthy donors. Isolated cells are stimulated with pools of overlapping peptides covering the sequences of the PLA2R1. Because of the low frequencies of responding cells, CD154+ CD4 T cell are enriched by MACS using biotinylated anti-CD154 mAb and anti-biotin microbeads. The enriched cells are analyzed by multicolor flow cytometry. First results indicate the existence of PLA2R1-reactive CD4 T cells in MN patients. The identified cells produced IFN-gamma, TNF-alpha and IL-17A in an antigen-specific manner. At a lower level, PLA2R1-specific IL-4 and IL-5 producing cells were also detected. The majority of the analyzed CD4 T cells were CD45RA-negative, which implies a memory or effector phenotype of these autoreactive cells. In summary, our results provide the first evidence for a potential role of PLA2R1-specific autoreactive T cells in membranous nephropathy.

Reinholz, J., et al. (2018). "Protein machineries defining pathways of nanocarrier exocytosis and transcytosis." Acta Biomaterialia **71**: 432.

The transport of nanocarriers through barriers like the gut in a living organism involves the transcytosis of these nanocarriers through the cell layer dividing two compartments. Understanding how this process works is not only essential to further developing strategies for a more effective nanocarrier transport system but also for providing fundamental insights into the barrier function as a means of protection against micro- and nanoplastics in the food chain. We therefore set out to investigate the different uptake mechanisms, intracellular trafficking and the routes for exocytosis for small polystyrene nanoparticles (PS-NPs ca. 100 nm) as mimicking nanocarriers in a Caco-2 cell model for gut-blood transition. We used label-free, quantitative mass spectrometry (MS) for determining the proteome that adhered to transversed nanoparticles. From this rich proteomics dataset, as well as previous studies, we generated stable-transfected Caco-2 cell lines carrying the green fluorescent protein (GFP) coupled to proteins of interest for uptake, early, late and exocytotic endosomes. We detected the spatial and temporal overlap of such marked endosomes with the nanocarrier signal in confocal laser scanning and super-resolution microscopy. There was a clear distinction in the time course of nanoparticle trafficking between groups of proteins for endocytosis, intracellular storage and putatively transcytosis and we identified several key transcytotic markers like Rab3 and Copine1. Moreover, we postulate the necessity of a certain protein composition on endosomes for successful transcytosis of nanocarriers. Finally, we define the two-sided impasse of the lysosome as a dead end for nano-plastic and the limit of nanocarriers in the 100 nm range. Statement of Significance Here we focus on mechanisms of transcytosis and how we can follow these with methods not used before. First, we use mass spectrometry of transcytosed nanoparticles to pick proteins of the transcytosis machinery describing key proteins involved. We can detect the complex mixtures of proteins. As this is a dynamic process involving whole families of proteins interacting with each other and as this is an orchestrated process we coined the term protein machineries for this active interplay. By genetically modifying the proteins attaching GFP we are able to follow the transcytosis pathway. We evaluate the process in a quantitative manner over time. This reveals that the most obvious obstacle to transcytosis is a routing of the nanocarriers to the lysosomes.

Reintjes, M. Open-air show 'like the real thing'.

The article discusses the highlights of the biannual Recycling Aktiv open-air show, held at Baden Airpark southwest Germany in September 2013. Figures show the volume of steel scrap, plastics, paper, demolition waste and wood used at the exhibition. Exhibitors like Doppstadt confirmed the improvement in business opportunities by participating in the event. More than 10,000 visitors from various countries attended the open-air show. INSETS: World premiere for Arjes' Tristar;German law 'killing' commercial recyclers;Greemman's versatile cable stripper.

Reintjes, M. (2019). "'No way you can find every lithium battery'." Recycling International: 28-29.

Reis, S. R., et al. (2007). "An in vitro model for dengue virus infection that exhibits human monocyte infection, multiple cytokine production and dexamethasone immunomodulation." Memorias do Instituto Oswaldo Cruz **102**(8): 983-990.

An important cytokine role in dengue fever pathogenesis has been described. These molecules can be associated with haemorrhagic manifestations, coagulation disorders, hypotension and shock, all symptoms implicated in vascular permeability and disease worsening conditions. Several immunological diseases have been treated by cytokine modulation and dexamethasone is utilized clinically to treat pathologies with inflammatory and autoimmune etiologies. We established an in vitro model with human monocytes infected by dengue virus-2 for evaluating immunomodulatory and antiviral activities of potential pharmaceutical products. Flow cytometry analysis demonstrated significant dengue antigen detection in target cells two days after infection. TNF-alpha, IFN-alpha, IL-6 and IL-10 are produced by in vitro infected monocytes and are significantly detected in cell culture supernatants by multiplex microbead immunoassay. Dexamethasone action was tested for the first time for its modulation in dengue infection, presenting optimistic results in both decreasing cell infection rates and inhibiting TNF-alpha, IFN-alpha and IL-10 production. This model is proposed for novel drug trials yet to be applied for dengue fever.

Reisser, J., et al. (2013). "Marine plastic pollution in waters around Australia: characteristics, concentrations, and pathways." PLoS ONE [Electronic Resource] **8**(11): e80466.

Plastics represent the vast majority of human-made debris present in the oceans. However, their characteristics, accumulation zones, and transport pathways remain poorly assessed. We characterised and estimated the concentration of marine plastics in waters around Australia using surface net tows, and inferred their potential pathways using particle-tracking models and real drifter trajectories. The 839 marine plastics recorded were predominantly small fragments ("microplastics", median length = 2.8 mm, mean length = 4.9 mm) resulting from the breakdown of larger objects made of polyethylene and polypropylene (e.g. packaging and fishing items). Mean sea surface plastic concentration was 4256.4 pieces km(-2), and after incorporating the effect of vertical wind mixing, this value increased to 8966.3 pieces km(-2). These plastics appear to be associated with a wide range of ocean currents that connect the sampled sites to their international and domestic sources, including populated areas of Australia's east coast. This study shows that plastic contamination levels in surface waters of Australia are similar to those in the Caribbean Sea and Gulf of Maine, but considerably lower than those found in the subtropical gyres and Mediterranean Sea. Microplastics such as the ones described here have the potential to affect organisms ranging from megafauna to small fish and zooplankton.

Rekha, D., et al. (2014). "Studies on medicinal plants of A.V.V.M. Sri Pushpam College Campus Thanjavur District of Tamil Nadu, Southern India." World Journal of Pharmaceutical Research **3**(5 Suppl): 785-820.

In the present investigation an attempt has been made survey on medicinal plants of Poondi Campus of Thanjavur District of Tamilnadu. The exploration revealed some unknown medical uses of medicinal parts. The scientific name, family, vernacular name (Tamil), parts used, and mode of drug preparation, dosage and duration was also reported and traditional usage of 190 species belonging to 167 genera and 67 Families of angiosperms and gymnosperms were discussed here for the treatment of different ailments viz., snake bite, skin ulcers, urinary bladder, fever, rheumatism, indigestion, cough, cold, acezema, asthma, bone fractures, ear ache, wounds, elephantiasis, vomiting, diarrhoea, hair loss, digestive, stomachic, high blood pressure, diabetes, jaundice, leprosy, toothaches, dysuria, liver, kidney problem and eye infection. The dicotyledons were represented by 177 species of 160 genera and 59 families while monocotyledons were represented by 12 species of 6 genera and 7 Families. Gymnosperms were representing in 1 species of 1 genus 1 families. Poondi campus is in good vegetation status and conservationists should take necessary action to protect this college and plastic pollution. For this, an environmental awareness programmes should be conducted to the local people to safeguard this college from pollution. Conservation and management plan to attain the sustainable biological wealth.

Relja, B., et al. (2014). "Suppressed gene expression of NLRP1 and NLRP3 in monocytes is responsible for their impaired functionality after trauma." Shock **2)**: 28.

Objectives: The IL-1beta-producing activity of monocytes is suppressed after major trauma. The generation of IL-1beta requires its synthesis, the transcription of inflammasome components and their activation. Deregulated NLRP1 and/or NLRP3 inflammasome assembly is associated with several inflammatory diseases, resulting from altered processing of the pro-inflammatory IL-1beta. The present study was designed to determine which NLRP1 and/or NLRP3 inflammasome components are responsible for depressed monocyte function after trauma. Method(s): From ten healthy volunteers and twenty severely injured trauma patients [ISS>= 16] CD14+-monocytes were isolated by microbeads daily up to day 10. Functional analysis of monocytes was performed daily by their ex vivo in vitro LPS-stimulation (10mug/ml, 24h) and subsequent evaluation of the IL-1beta-release by ELISA. Inflammasome activation was verified by protein analysis of cleaved IL-1beta and caspase-1. Gene expression of inflammasome components was analyzed daily before and after LPS-stimulation. Subsequently, isolated monocytes after admission were transfected with expression plasmids encoding for the lacking components identified by gene analyses. Result(s): LPS-induced IL-1beta-release in monocytes from healthy volunteers was significantly suppressed after trauma, with lowest levels at the day of admission (p<0.05). The protein expression of processed IL-1beta and caspase-1 correlated with the IL-1beta-release. IL-1beta, caspase-1 and asc gene expressions were comparable in both, trauma patients and controls after LPS-stimulation during the 10-days course. In contrast, gene expression of nlrp1 and nlrp3 was reduced in trauma patients compared to controls after LPS-stimulation. Transfecting monocytes that were isolated from trauma patients after admission with nlrp1 or nlrp3 recovered the expression of these components as well as the LPS-induced IL-1beta-release to comparable levels of monocytes from healthy volunteers. Conclusion(s): These results indicate that nlrp1 and/or nlrp3 may represent the lacking components in monocytes that are responsible for their suppressed activity after trauma. Regaining all components of NLRP1 and/or NLRP3 inflammasomes in monocytes recovers the monocyte activity after trauma, suggesting new mechanistic targets for balanced immune reaction after trauma.

Relja, B., et al. (2012). "Inflammasome mRNA expression in human monocytes after major trauma." Shock **1)**: 104.

Objectives: Monocytes play a key role in the development of posttraumatic complications due to their central role in the initiation of the inflammatory response by inflammasome activation. Functional capacity of monocytes after trauma is reduced and delayed recovery critically influences the clinical course. We investigated whether the monocytes from patients early after trauma demonstrate alterations in mRNAs for inflammasome compounds in parallel to the reduced monocyte function. Method(s): Severely injured trauma patients [ISSQ16, n=10] and healthy volunteers [n=10] were enrolled. Buffy coats were used for the method verification [n=10]. After isolation of monocytes by CD14+ microbeads, the cells were assayed for ex vivo interleukin-1beta (IL-1beta) production after LPS-stimulation (10 mug/ml, 24 h) by ELISA measurements. Fresh monocyte mRNA was analyzed by qRT-PCR for caspase-1, NALP-1, NALP-3 and IPAF. Result(s): LPS-stimulation increased significantly the IL-1beta release in isolated monocytes from healthy volunteers and buffy coats compared to unstimulated controls (p<0.05). The LPS-response was markedly reduced after trauma compared to healthy volunteers after stimulation. Relative copy numbers for the inflammasome mRNAs for caspase-1 were not markedly enhanced in LPS-stimulated samples. NALP-1 mRNA was significantly enhanced in LPS-stimulated samples from healthy volunteers (p<0.05) and buffy coats (p<0.05), whereas the

NALP-1 mRNA expression remained nearly undetectable in LPS-stimulated monocytes isolated after trauma. NALP-3 and IPAF mRNAs showed no significant changes either after LPS-stimulation or after trauma. Conclusion(s): Monocyte deactivation occurs early after trauma. Reduced monocytic function is paralleled with profound changes in NALP-1 inflammasome mRNA expression, maybe as part of this process.

Rem, P., et al. (2009). "HIGH-PURITY PRODUCTS FROM PLASTIC WASTE: THE W2PLASTICS PROJECT." Environmental Engineering & Management Journal (EEMJ) **8**(4): 963-966.

The European annual consumption of plastic materials has increased from 24.6 Mtons in 1993 to 39.7 M tons in 2003 and it is likely to keep growing. Europe is faced with the challenge of managing millions of tons of waste plastics. At the same time, polymer recyclers and manufacturing industries do not find enough secondary polymers of consistent quality. Plastics production and use has a range of environmental impacts because of the considerable quantity of resources needed as raw materials and process energy. W2Plastics aims to develop a number of novel concepts, in particular Magnetic Density Separation (MDS) and Ultrasound process and quality control, into a new technology to recover high-purity polyolefin's from complex wastes at low cost. The unique promise of this new concept derives from its ability to accurately separate many different materials in a single process step, resulting in an environmentally friendly and cheap process. [ABSTRACT FROM AUTHOR]

Remy, F., et al. (2015). "When Microplastic Is Not Plastic: The Ingestion of Artificial Cellulose Fibers by Macrofauna Living in Seagrass Macrophytodetritus." Environmental Science and Technology **49**(18): 11158-11166.

Dead leaves of the Neptune grass, Posidonia oceanica (L.) Delile, in the Mediterranean coastal zone, are colonized by an abundant detritivorous invertebrate community that is heavily predated by fishes. This community was sampled in August 2011, November 2011, and March 2012 at two different sites in the Calvi Bay (Corsica). Ingested artificial fibers (AFs) of various sizes and colors were found in 27.6% of the digestive tracts of the nine dominant species regardless of their trophic level or taxon. No seasonal, spatial, size, or species-specific significant differences were revealed; suggesting that invertebrates ingest AFs at constant rates. Results showed that, in the gut contents of invertebrates, varying by trophic level, and across trophic levels, the overall ingestion of AFs was low (approximately 1 fiber per organism). Raman spectroscopy revealed that the ingested AFs were composed of viscose, an artificial, cellulose-based polymer. Most of these AFs also appeared to have been colored by industrial dyes. Two dyes were identified: Direct Blue 22 and Direct Red 28. The latter is known for being carcinogenic for vertebrates, potentially causing environmental problems for the P. oceanica litter community. Techniques such as Raman spectroscopy are necessary to investigate the particles composition, instead of relying on fragment size or color to identify the particles ingested by animals. Ren, J., et al. (2019). "Elasticity-Modulated Microbeads for Classification of Floating Normal and Cancer Cells Using Confining Microchannels." ACS Biomaterials Science and Engineering **5**(8): 3889-3898.

Engineered microbeads have a wide range of applications in cancer research including identification, characterization, and sorting of cancer cells. In particular, the microbead-based cancer identification techniques are mainly based on the known genetic or biochemical biomarkers; and detection specificity is yet to be improved. On the other hand, it has been discovered that biomechanical properties of cancer cells such as cell-body elasticity can be considered as cancer biomarkers. Here, we report a straightforward microfluidic classification scheme for floating/dissociated normal and cancer epithelial cells using a confining microchannel device together with calcium-alginate hydrogel microbeads. The hydrogel microbeads are generated based on the microfluidic emulsion process, with characterization on the process parameters (e.g., liquid driving pressure and cross-linking duration) in order to specify the resultant bead diameter and elasticity. These engineered microbeads are first mixed with a cell mixture of dissociated human nasopharyngeal epithelial cells (NP460) and nasopharyngeal carcinoma cells (NPC43). The cell elasticity can then be reflected from the locations of captured cells in the device. Experiments further demonstrate that the cell classification has a success rate of >95%. Furthermore, we performed the microbead-based cell classification on a whole blood sample containing floating human breast epithelial cells (MCF-10A) and breast cancer epithelial cells (MDA-MB-231) with a success rate of >75%, revealing its directly applicability to identification of circulating tumor cells in human blood. Together, this research demonstrates a new application of engineered hydrogel microbeads for classification of cells based on their mechanical properties. © 2019 American Chemical Society.

Ren, L. P., et al. (2012). "Isolation and characteristics of cancer stemness and epithelial-mesenchymal transition of CD133⁺A549 lung cancer cells. [Chinese]." Journal of Shanghai Jiaotong University (Medical Science) **32**(6): 736-740.

Objective: To isolate CD133⁺A549 cells, and investigate the characteristics of cancer stemness and epithelial-mesenchymal transition (EMT). Method(s): A549 cells were isolated by immunomagnetic beads method, and were identified by Real-Time PCR and Western blotting. The expression of cancer stem cell markers (CXCR4, Oct4, CD44, Bmi1 and EpCam) and EMT markers (E-Cadherin and Zeb1) mRNA in CD133⁺A549 cells and CD133⁻A549 cells was detected by Real-Time PC R. The isolated CD133⁺A549 cells and CD133⁻A549 cells were treated with different concentrations (0, 0.25, 0.5 and 1.0 mug/mL) of adriamycin for 72 h, and the relative survival rates of cells were determined by cell viability assay. Result(s): After isolation through CD133 antibody conjugated microbeads, CD133⁺ A549 cells and CD133⁻A549 cells were successfully obtained, and the expression of CD133 in CD133⁺A549 cells was significantly higher than that in CD133⁻A549 cells. Real-Time PCR revealed that the relative expression of Oct 4, CD44, Bmi1 and EpCam mRNA in CD133⁺A549 cells was significantly higher than that in CD133⁻A549 cells [(1+/-0.16) vs(0.66+/-0.12), (1+/-0.07) vs (0.48+/-0.04), (1+/-0.03) vs (0.49+/-0.06), and (1+/-0.14) vs (0.38+/-0.12) ; P<0.05], while there was no significant difference in the relative expression of CXCR4 mRNA between them [(1+/-0.13) vs (0.73+/-0.14), P>0.05]. The relative expression of Zeb1 mRNA in CD133⁺A549 cells was significantly higher than that in CD133⁻A549 cells [(1+/-0.09) vs (0.39+/-0.05), P<0.05], while the relative expression of E-Cadherin mRNA in CD133⁺A549 cells was significantly lower than that in CD133⁻A549 cells [(1+/-0.02) vs (4.98+/-0.04), P<0.05]. Cell viability assay indicated that the relative survival rate of CD133⁺A549 cells was significantly higher than that in CD133⁻A549 cells after treatment with 0.5 and 1.0 mug/mL adriamycin [(85+/-9.4)% vs (67+/-13.1)%, P<0.05; (80+/-14.9)% vs (56+/-6.3)%, P<0.01]. Conclusion(s):

CD133⁺ A549 cells and CD133⁻A549 cells can be successfully isolated by immunomagnetic beads method. There is expression of other cancer stem cell markers in CD133⁺A549 cells, which exhibit characteristics of EMT. CD133 may be a potential biomarker of cancer stemness and EMT in lung cancer.

Ren, S. Y., et al. (2020). "A minimalist approach to quantify emission factor of microplastic by mechanical abrasion." Chemosphere **245 (no pagination)**(125630).

Plastic film has allowed manufacturers to meet varied marketplace demands. Typically, its usage can be divided into two general categories-packaging (food, nonfood and other) and nonpackaging. The microplastics emission resulting from wearing of plastic film is unavoidable in the process of production and use. Currently, no reliable method exists for measure emission factor (EF) of microplastics by mechanical abrasion (MA). In the present study, a simple but effective approach to quantify EF of microplastic by MA was developed. Specifically, the relative light transmittance (RLT) of the plastic film is decreased with increase of MA degree. This quantitative relationship between the two factors can be applied to determine EFs of microplastics induced by MA. The method developed in this study is easy and feasible, but it still has limitations in the standpoint and range, the direction of worthiness of theory. Copyright © 2019 Elsevier Ltd

Ren, W. and W. Zimmermann (2017). "Biocatalysis as a green route for recycling the recalcitrant plastic polyethylene terephthalate." Microbial Biotechnology **10**(6): 1302-1307.

[...]innovative technologies to improve the recycling of plastics and to reduce the consumption of non-renewable fossil feed stocks are required. [...]enzymatic degradation of PET in composite materials such as PET-polyethylene blends, metallized PET-based packaging films or in textiles containing PET could open up further opportunities to recover value from plastic waste using a biocatalytic approach (Gallagher,). [...]PET exhibits a glass transition temperature (Tg) of above 70°C and a melting point (Tm) of over 230°C (Alves et al.,). [...]the microbial biodiversity in environmental samples may allow the identification of further promising polyester hydrolases by metagenomic approaches. [...]protein engineering focusing on key amino acid residues involved in the thermostabilization of polyester hydrolases can be expected to provide further biocatalysts as candidates for industrial PET recycling processes.

Ren, X., et al. (2020). "Effects of microplastics on greenhouse gas emissions and the microbial community in fertilized soil." Environmental Pollution **256**: 113347.

Microplastics (MPs) are characterized by small particle sizes (<5mm) and are widely distributed in the soil environment. To date, little research has been conducted on investigating the effects of MPs on the soil microbial community, which plays a vital role in biogeochemical cycling. In the present study, we investigate the influence of two particle sizes of MPs on dissolved organic carbon (DOC) and its relative functional groups, fluxes of greenhouse gases (GHGs), and the bacterial and fungal communities in fertilized soil. The results showed that a 5% concentration of MPs had no significant effect on soil DOC, whereas the formation of aromatic functional groups was accelerated. In fertilized soil, the existence of MPs decreased the global warming potential (GWP) as a result of a reduction in N₂O emissions during the first three days. A potential mechanism for this reduction in N₂O emissions might be that MPs inhibited the phylum Chloroflexi, Rhodoplanes genera, and increased the abundance of Thermoleophilia on day 3. An increase in N₂O emissions was observed on day 30, mainly due to the acceleration of the NO₃⁻ reduction and a decrease in the abundance of Gemmatimonadacea. The CH₄ uptake was significantly correlated with Hyphomicrobiaceae on day 3 and Rhodomicrobium on day 30. In soil with MPs, Actinobacteria replaced Proteobacteria as the dominant phylum. Larger MPs increased the richness (Chao1) and abundance-based coverage estimators (ACE) and diversity (Shannon) of the bacterial community on day 3, whereas these decreased on day 30. The richness and diversity of the fungal community were also reduced on days 3 and 30. Smaller MPs increased the community richness and diversity of both bacterial and fungal communities in fertilized soil. Our findings suggest that MPs have selective effects on microbes and can potentially have a serious impact on terrestrial biogeochemical cycles.

Ren, X., et al. (2018). "Advances in research on the ecological effects of microplastic pollution on soil ecosystems." Journal of Agro Environment Science **37**(6): 1045-1058.

Microplastics are a new type of environmental pollutants characterized by their small particle size (<5 mm), wide distribution, and resistance to recovery. Owing to their long residue time in soil, microplastics can be accidentally ingested by soil fauna and, thereby, enter the food chain, which can subsequently influence the growth, development, and reproduction of soil fauna by damaging the organisms' organs and DNA. The toxins released during microplastic degradation and the absorption of environmental pollutants by microplastics also threaten soil ecosystems. Primary microplastics are derived from the raw material used for plastic production, whereas secondary microplastics result from the environmental degradation of large plastic products. As microplastics come from many sources, exist in many types, and are found in complex environments, they are difficult to be separated or detected. Recent studies have mainly focused on aquatic ecosystems and have rarely investigated the effects of microplastics on soil ecosystems. However, the plastic materials used in production and manufacturing are abundant, in both quantity and form, and some of these are released into soil systems. This review summarizes the classification, sources, sampling, and detection of microplastics, as well as related environmental problems, such as soil pollution, pollutant absorption, and effects on soil fauna, microbial ecology, and carbon and nitrogen circulation. The discussion of the ecological effects of microplastics could stimulate new ideas for future research.

Renner, G., et al. (2019). "Data preprocessing & evaluation used in the microplastics identification process: A critical review & practical guide." TrAC - Trends in Analytical Chemistry **111**: 229-238.

Characterising microplastics based on spectroscopic measurements is one key step of many studies that analyse the fate of microplastics in the environment. Over the years, many potential sources of error were identified, which can be seen by the implementation of anti-contamination protocols, measuring laboratory blanks or using less aggressive chemicals for sample purification. However, the identification process itself in the meaning of a traceable and transparent documentation is hard to find in many research studies. Unfortunately, this can make it difficult to estimate if the presented results are representative and reproducible, as the evaluation process during microplastics identification depends dramatically on the performed data treatment. To increase the awareness of this often neglected topic, this article reviews suitable data preprocessing and evaluation methods for microplastics identification based on spectroscopic measurements and will recommend a practical workflow or check list that can easily be used for further research studies. Renner, G., et al. (2019). "Robust Automatic Identification of Microplastics in Environmental Samples Using FTIR Microscopy." Analytical Chemistry **91**(15): 9656-9664.

The analysis of microplastics is mainly performed using Fourier transformation infrared spectroscopy/microscopy (FTIR/ muFTIR). However, in contrast to most aspects of the analysis process, for example, sampling, sample preparation, and measurement, there is less known about data evaluation. This particularly critical step becomes more and more important if a large number of samples has to be handled. In this context, it is concerning that the commonly used library searching is not suitable to identify microplastics from real environmental samples automatically. Therefore, many spectra have to be rechecked by the operator manually, which is very time-consuming. In this study, a new fully automated robust microplastics identification method is presented that assigns over 98% of microplastics correctly. The main concept of this new method is to detect and numerically describe the individual vibrational bands within an FTIR absorbance spectrum by curve fitting, which leads to a very compact and highly characteristic peak list. This list allows very accurate and robust library searching. The developed approach is based on the already published microplastics identification algorithm (muIDENT) and extends and improves the field of application to muFTIR data with a special focus on relevant broad, overlapped, or complex vibrational bands.

Renner, G., et al. (2017). "A New Chemometric Approach for Automatic Identification of Microplastics from Environmental Compartments Based on FT-IR Spectroscopy." Analytical Chemistry **89**(22): 12045-12053.

One key step studying interactions of microplastics with our ecological system is to identify plastics within environmental samples. Aging processes and surface contamination especially with biofilms impede this characterization. A complex and time-consuming cleaning procedure is a common solution for this problem. However, it implies an artificial change of sample composition with a risk of losing important information or even damaging microplastic particles. In the present work, we introduce a new chemometric approach to identify heavily weathered and contaminated microplastics without any cleaning. The main idea of this concept is based on an automated curve fitting of most relevant vibrational bands to calculate a highly characteristic fingerprint that contains all vibrational band area ratios. This new data set will be used to estimate the similarity of samples and reference standards for identification. A total of 300 individual naturally weathered plastic particles were measured with Fourier transformation infrared spectroscopy in attenuated total reflection mode (FT-IR ATR) and identified successfully with the new method. To that end, all samples were compared with a selection of common reference plastics and bio polymers. As it turns out, the accuracy of identification rises significantly from 76% by means of conventional library searching algorithms to 96% by identifying microplastics with our new method. Therefore, the new approach can be a useful tool to compare and describe similarities of FT-IR spectra of microplastics, which may improve further research studies on this topic.

Renzi, M. and A. Blaskovic (2018). "Litter & microplastics features in table salts from marine origin: Italian versus Croatian brands." Marine Pollution Bulletin **135**: 62-68.

This study estimates litter content, including microplastics, mesoplastic, and macroplastic in marine table salts coming from Italy and Croatia. Both high (HC) and low (LC) costs commercial brands easily found at the supermarket were analysed. Any macroplastic or mesoplastic were recovered while microplastics and other litter impurities significantly affect table salts of all tested brands. Average microplastic values ranged within 1.57 (HC) - 8.23 (LC) (Italy) and 27.13 (HC) - 31.68 (LC) items/g (Croatia). Microplastics sizes (min-max) ranged within 4-2100mum (Italy) and 15-4628mum (Croatia). In samples from both Nations, a significant general positive correlation between the average number of items/g recorded and the total amount of general impurities was recorded. Concerning microplastic shapes, in Italy, fragments dominated even if fibres, granules, films, and foams are frequently recorded. On the contrary, clear PP fibres dominated in Croatian brands even if also other shape classes were recorded.

Renzi, M., et al. (2018). "Plastic litter transfer from sediments towards marine trophic webs: a case study on holothurians." Marine Pollution Bulletin **135**: 376-385.

This study estimates for the very first time plastic litter levels in sea cucumbers (Echinodermata, Holothuroidea) sampled in situ and their intakes from sediments in three different rocky bottom habitats (slides, cliff, banks) settled in Salina Island (Aeolian Archipelago). Macroplastic were never recorded while meso- and microplastics were identified in all sediment (81-438 items/kg d.w.) and animal samples (1.8-22 items/ind.). Plastic intakes by sea cucumbers resulted frequently associated to the size range included within 100-2000 micro m. Over than 70% of ingested plastic litter is represented by the size fraction >500 micro m. Sediment/animals ratios% are included 2.7+or-2.0% in studied habitats with a selective intake of fragments occurring in slides. Furthermore, results support the occurrence of selective ingestion of plastic litter by holothurians in natural environments underlining the role of these species in microplastic transfer from abiotic towards biotic compartments of the marine trophic web.

Renzi, M., et al. (2019). "Effects of different microplastic types and surfactant-microplastic mixtures under fasting and feeding conditions: a case study on Daphnia magna." Bulletin of environmental contamination and toxicology **103**(3): 367-373.

This study evaluates the mortality and immobilization on Daphnia magna after 24-96 h of exposure to microplastic dispersions (PP, PE, PVC, PVC/PE), and to microplastic + surfactant solutions both under fasting and feeding conditions. The tested microplastics were analysed with micro FT-IR to determine their chemical composition, purity, and dimensions. The results show that: (i) exposure under fasting conditions produces acceptable results on negative controls no later than 24 h; (ii) the dispersion of microplastics forms homo-agglomerates that are able to affect animals' motility and cause mortality and immobilization; (iii) different types of tested microplastic produce different effects on endpoints (the most toxic is PVC+surfactant); (iv) in all cases, the effects were reduced under feeding conditions (i.e. 4 times reduction of PE toxicity); (v) effects of surfactant on observed toxicity are microplastic-type dependent; (vi) the age of the animal affected the mortality and immobilization responses after exposure under both fasting and feeding conditions.

Renzi, M., et al. (2019). "Effects of Different Microplastic Types and Surfactant-Microplastic Mixtures Under Fasting and Feeding Conditions: A Case Study on <i>Daphnia magna</i>." Bulletin of environmental contamination and toxicology **103**(3): 367-373.

This study evaluates the mortality and immobilization on Daphnia magna after 24–96 h of exposure to microplastic dispersions (PP, PE, PVC, PVC/PE), and to microplastic + surfactant solutions both under fasting and feeding conditions. The tested microplastics were analysed with µFT-IR to determine their chemical composition, purity, and dimensions. The results show that: (i) exposure under fasting conditions produces acceptable results on negative controls no later than 24 h; (ii) the dispersion of microplastics forms homo-agglomerates that are able to affect animals’ motility and cause mortality and immobilization; (iii) different types of tested microplastic produce different effects on endpoints (the most toxic is PVC + surfactant); (iv) in all cases, the effects were reduced under feeding conditions (i.e. 4 times reduction of PE toxicity); (v) effects of surfactant on observed toxicity are microplastic-type dependent; (vi) the age of the animal affected the mortality and immobilization responses after exposure under both fasting and feeding conditions.

Renzi, M., et al. (2018). "Microplastic contents from maricultured and natural mussels." Marine Pollution Bulletin **131**(Pt A): 248-251.

Results of this research focuses on microplastic contents (levels, type, size, colour) in maricultured and natural mussels (Mytilus galloprovincialis) from different Italian stocks. No significant differences were found among maricultured and natural stocks. All recovered MPs are filaments ranging within 750-6000mum of maximum length (average values 1150-2290mum). Feeding raw mussel could produce median MP intakes of 6.2-7.2 items/g w.w. Concerning human exposure by diet, both raw and cooked values are important. Some preliminary tests performed in this study evidenced that the cooking process determined lower MPs levels (-14%) in cooked tissues compared to raw ones, MPs were recorded in cooking water and were characterized by a lower size than in raw mussels.

Renzi, M., et al. (2019). "Marine litter in stomach content of small pelagic fishes from the Adriatic Sea: sardines (<i>Sardina pilchardus</i>) and anchovies (<i>Engraulis encrasicolus</i>)." Environmental science and pollution research international **26**(3): 2771-2781.

Marine litter impacts oceans and affects marine organisms, representing a potential threat for natural stocks of pelagic fish species located at the first levels of the marine food webs. In 2013–2014, on a seasonal basis, marine litter and microplastics in stomach contents from Sardinia pilchardus and Engraulis encrasicolus were evaluated. Selected species are plankitivores of great ecological and commercial importance in the Adriatic Sea. Collected data were correlated to possible factors able to affect ingested levels as well as species, season of sampling, biometry and sex of animals. Almost all tested samples (80 organisms for each species) contained marine litter (over 90% of samples from both species) and also microplastics; while any meso- or macroplastics were recorded. On average, recorded items were as follows: 4.63 (S. plichardus) and 1.25 (E. encrasicolus) per individual. Sardines evidenced a higher number of microplastics characterised by a smaller size than those recorded in anchovies. For sardines, sex, Gastro Somatic Index and sampling season showed negligible effects on the number of ingested litter; conversely, anchovies showed differences related with both sex of animals and dominant colour of ingested materials with prevalence for black and blue colours.

Resaz, R., et al. (2015). "A glycogen storage disease type 1a mouse model to study long term liver pathogenesis and cell therapy approaches." Regenerative Medicine **1)**: 208.

Objectives Animal models are powerful tools to study hereditary diseases and guide the development of new therapeutic approaches to correct single gene defects. This is especially valid for genetic syndromes caused by single gene mutations, as is in the case of glycogen storage disease type 1a (GSD-1a), caused by a deficiency in glucose-6-phosphatase (G6Pase, encoded by G6pc) and characterized by impaired glucose homeostasis and long-term complications including hepatic adenomas (that might undergo malignant transformation) and renal disease. A G6pc-null mouse (G6pc-/-) model for GSD-1a has been generated. We have used these mice to analyze the efficacy of cell therapy to treat GSD-1a. We showed that transplantation of normal bone-marrow-derived myelomonocytes (BMMs) into G6pc-/- mice partially reconstitutes the diseased liver and prolongs lifespan. However, the short life span, extreme fragility, and limited number of G6pc- /- offspring represent an obstacle to evaluate long-term effects of BMMs engraftment. To overcome this problem we generated a mouse line (LS-G6pc-/-) carrying liver-specific deletion of G6Pase-alpha as an alternative animal model to study the age-related disease progression and the long-term consequences of BMMs transplant. Material and methods LS-G6pc-/- were generated by crossing mice harboring a conditional null allele for G6pc with transgenic mice expressing Cre under the control of murine albumin enhancer/promoter. Tissue sections were stained with hematoxylin/eosin (H&E), periodic acid-Schiff (PAS), PAS diastase, reticulin stain and Congo red, or treated for G6Pase histochemical assay and Western Blot analysis. Glucose, cholesterol and triglycerides serum levels were measured by commercially available kits. For cell therapy BMMs have been isolated from the femurs of adult C57Bl/6-Tg(ACTB-EGFP)1 Osb/J mice and purified by positive selection on CD11b MicroBeads. Mice have been injected in the temporal vein at two days of age, and then re-injected at thirty days of age directly into the liver, after partial hepatectomy, and in the heart or in the tail vein. Results LS-G6pc-/- mice are viable but exhibit significantly lower blood glucose levels than their control littermates after 6 hours of fasting, hypercholesterolemia and hypertriglyceridemia until they reached the age of 2-4 months. LS-G6pc-/- mice develop hepatomegaly with glycogen accumulation and hepatic steatosis, progressive hepatic degeneration, amyloidosis, multiple hepatocellular adenomas and occasional late development of hepatocellular carcinoma. We are now utilizing this new GSD-1a animal model to evaluate the correction of liver abnormalities by cell therapy and the long-term consequences of BMMs engraftment. Results obtained from this first set of experiments will be presented and discussed. Conclusion LS-G6pc-/- mice manifest hepatic symptoms similar to those of the human GSD-1a and may, therefore, represent a valid model to study long-term liver pathogenesis of GSD-1a and potentially to discover biomarkers and new treatment interventions. In particular, this model might be useful to evaluate the long-term efficacy of cellular therapies in preclinical studies, such as hematopoietic stem cell approaches to regenerate the liver of diseased animals.

Revel, M., et al. (2020). "Realistic environmental exposure to microplastics does not induce biological effects in the Pacific oyster Crassostrea gigas." Marine Pollution Bulletin **150**: 110627.

The aim of the present study was to evaluate the presence and potential toxic effects of plastic fragments (<400mum) of polyethylene and polypropylene on the Pacific oyster Crassostrea gigas. Oysters were exposed to environmentally relevant concentrations (0, 0.008, 10, 100mug of particles/L) during 10 days, followed by a depuration period of 10 days in clean seawater. Effects of microplastics were evaluated on the clearance rate of organisms, tissue alteration, antioxidant defense, immune alteration and DNA damage. Detection and quantification of microplastics in oyster's tissues (digestive gland, gills and other tissues) and biodeposits using infrared microscopy were also conducted. Microplastics were detected in oyster's biodeposits following exposure to all tested concentrations: 0.003, 0.006 and 0.05 particles/mg of biodeposits in oysters exposed to 0.008, 10 and 100mug of particles/L, respectively. No significant modulation of biological markers was measured in organisms exposed to microplastics in environmentally relevant conditions.

Revel, M., et al. (2019). "Tissue-Specific Biomarker Responses in the Blue Mussel Mytilus spp. Exposed to a Mixture of Microplastics at Environmentally Relevant Concentrations." Frontiers in Environmental Science.

The impact of a microplastic (MPs) mixture composed of polyethylene (PE) and polypropylene (PP) plastic particles, prepared from commercially available products, was evaluated in blue mussels Mytilus spp. exposed to three environmentally relevant concentrations: 0.008µg L^{-1} (low), 10 µg L^{-1} (medium) and 100 µg L^{-1} (high). Organisms were exposed for 10 days followed by 10 days of depuration in clean seawater under controlled laboratory conditions. The evaluation of MP effects on mussel clearance rate, tissue structure, antioxidant defences, immune and digestive parameters, and DNA integrity were investigated while the identification of plastic particles in mussel tissues (gills, digestive gland, and remaining tissues), and biodeposits (faeces and pseudofaeces) was performed using infrared microscopy (µFT-IR).

Results showed the presence of MPs only in the digestive gland of mussels exposed to the highest tested concentration of MPs with a mean of 0,75 particle/mussel (after the 10 days of exposure). In biodeposits, PE and PP particles were detected following exposure to all tested concentrations confirming the ingestion of MPs by the organisms. A differential response of antioxidant enzyme activities between digestive gland and gills was observed. Significant increases in superoxide dismutase (SOD) and catalase (CAT) activities were measured in the digestive gland of mussels exposed to the low (0.008µg L^{-1}) and medium (10 µg L^{-1}) concentrations of MPs and in the gills from mussels exposed to the highest concentration (100 µg L^{-1}) of MPs that could be indicative of a change in the redox balance. Moreover, an increase in acid phosphatase activity was measured in hemolymph of mussels exposed to 0.008 and 10 µg L^{-1} concentrations. No significant difference was observed in the clearance rate, and histopathological parameters between control and exposed mussels. This study brings new insights on the potential sublethal impacts of MPs at environmentally relevant concentrations in marine bivalves.

Revel, M., et al. (2018). "Accumulation and immunotoxicity of microplastics in the estuarine worm Hediste diversicolor in environmentally relevant conditions of exposure." Environmental Science & Pollution Research **23**: 23.

The presence of plastic debris < 5 mm called microplastics (MPs) which results mainly from macroplastic's fragmentation has been reported in aquatic ecosystems. Several studies have shown that MPs are persistent and their accumulation was observed in various aquatic species. However, the majority of studies focused on marine species, and much less on continental and estuarine biota. The goal of the present study was to investigate the effects of a mixture of two types of MPs (polyethylene and polypropylene), frequently found in natural environments, towards the ragworm Hediste diversicolor to determine their accumulation in organisms exposed through the water phase or sediment. Two concentrations of exposure were selected for medium and heavily contaminated areas reported for water phase (10 and 100 mug/L) and sediment (10 and 50 mg of MPs/kg). To study the potential toxic effect of MPs, immune parameters were selected since they are involved in many defense mechanisms against xenobiotics or infectious agents. An average number of MP items/worm ranging from 0 to 2.5 and from 1 to 36 were identified in animals exposed to the lowest and the highest concentration of MPs through water exposure. In worms exposed through sediment, less than 1 MP/worm was found and a greater number of particles were identified in depurated sediment. For immunotoxic impact, MP exposure induced a decrease in coelomocytes viability, but no alteration of phagocytosis activity, phenoloxydase, and acid phosphatase was measured. This study brings new results on the potential accumulation and immunotoxicity of MPs for the ragworm H. diversicolor who plays a key role in the structure and functioning of estuarine ecosystem.

Revel, M., et al. (2018). "Accumulation and immunotoxicity of microplastics in the estuarine worm <i>Hediste diversicolor</i> in environmentally relevant conditions of exposure." Environmental science and pollution research international: 1-10.

The presence of plastic debris < 5 mm called microplastics (MPs) which results mainly from macroplastic’s fragmentation has been reported in aquatic ecosystems. Several studies have shown that MPs are persistent and their accumulation was observed in various aquatic species. However, the majority of studies focused on marine species, and much less on continental and estuarine biota. The goal of the present study was to investigate the effects of a mixture of two types of MPs (polyethylene and polypropylene), frequently found in natural environments, towards the ragworm Hediste diversicolor to determine their accumulation in organisms exposed through the water phase or sediment. This study brings new results on the potential accumulation and immunotoxicity of MPs for the ragworm H. diversicolor who plays a key role in the structure and functioning of estuarine ecosystem.

Reynolds, A., et al. (2019). "Evaluation of non-invasive toxicological analysis of nano-polystyrene in relative <i>in vivo</i> conditions to <i>D. magna</i>." Environmental Science: Nano **6**(9): 2832-2849.

Nano-plastic (NP) usage is increasing across many industries; however, the risks posed from waste production or their accidental release into the environment have not been well investigated. Additionally, the resulting effects on the organisms within various environments based on NP exposure have not been thoroughly investigated. To contribute to this information, our current study focused on using an OECD test with additional validation tests to replicate the effects of a specific NP entering the freshwater environment. The current research analysed the potential toxicological, developmental and reproductive effects caused by fluorescent nano-polystyrene spheres (NPS) in juvenile (neonate) freshwater planktonic crustaceans, Daphnia magna. D. magna neonates were exposed for 24 h to a concentration range of 0–100 μg mL−1 of 100 nm diameter NPS as a mortality/immobility (MI) test. MI testing showed that the D. magna exhibited significant NPS consumption at all concentrations; however, adverse effects only occurred after exposure to 30 μg mL−1. The resulting EC50 for the NPS MI testing was 86.3 1 μg mL−1. Florescence imaging showed that the NPS were isolated to the D. magna intestines, even with exposure to a low concentration, producing a distinct emission, with no distinguishable NPS present in the other organs. UV-vis fluorimetry displayed an indirect relation between the initial consumption of NPS and increase in NPS exposure. The fluorimetry results showed an increase in NPS uptake up to 30 μg mL−1, and then a decrease since D. magna slowed consumption, and further increase after 100 μg mL−1. This indicated a change in the ratio of NPS within the intestines of Daphnia, which is independent to the exposure concentration. Raman spectroscopy analysis of the control D. magna produced a consistent emission spectrum, but with large FWHM peaks from its organic structures. The NPS-exposed D. magna clearly produced a clear and sharp peak attributed to a pure polystyrene signal following careful Z-mapping, which was not detected in the control samples. The results clearly present the successful Raman detection of the styrene signal from the NPS-exposed D. magna without significant pre-processing of the neonates.

Reynolds, C. and P. G. Ryan (2018). "Micro-plastic ingestion by waterbirds from contaminated wetlands in South Africa." Marine Pollution Bulletin **126**: 330-333.

Despite a large literature on the impacts of micro-plastic pollution in marine ecosystems, very little research has focused on these pollutants in freshwater ecosystems. Recently, however, a few studies have demonstrated that micro-plastic pollutants are ingested by freshwater taxa,

including birds. To explore this potential environmental threat in African freshwater systems we quantified micro-plastic pollutants in the faeces and feather brushings of seven southern African duck species. We analysed 283 faecal samples and 408 feather brushings, and found that 5% of faecal samples and 10% of feather samples contained micro-plastic fibres. The presence and abundance of micro-fibres differed between sampling sites, with significantly higher amounts recorded for the site that received effluent from a sewage treatment facility. Additionally, micro-fibre presence differed across duck species, indicating that foraging behaviour affects plastic ingestion. Our study confirms that African freshwater ecosystems and the biodiversity they support are under threat from micro-plastic contamination.

Reynolds, M., et al. (2012). "Advanced nitric oxide delivery platforms for therapeutic applications." Nitric Oxide - Biology and Chemistry **1)**: S33.

Nitric oxide (NO) has been identified as a crucial biological signaling molecule in the cardiovascular, nervous, and immune systems. As a result, NO storage and delivery vehicles have been extensively developed to target a range of diseases and to control material-cell interactions. In this presentation, new approaches to store and deliver NO from materials used in therapeutic devices will be discussed. This includes the development of biodegradable and biostable polymers as well as methods to produce NO catalytically from bioavailable sources. The advantages of these systems is that they can tuned to control the NO-loading capacity and then triggered to release NO under various conditions, thereby extending the useful lifetime of currently available NO materials. Further, the delivery platforms have been engineering into a variety of forms including coatings, encapsulated microbeads, and nanofibers. These platforms allow for further tuning of the material properties to maximize control of the bio-interface. Finally, these materials have been extensively characterized for their NO release rates in real-time and under cell culture conditions. These pharmacokinetic profiles have been used to evaluate the physiological effective dosages of NO in cancer, angiogenic, platelet, and infection models.

Rezaei, M., et al. (2019). "Wind erosion as a driver for transport of light density microplastics." Science of the Total Environment **669**: 273-281.

Microplastic pollution in the environment is a growing concern in today's world. Wind-eroded sediment, as an environmental transport pathway of microplastics, can result in environmental and human exposure far beyond its sources. For the first time, this study investigates the presence of microplastics in wind-eroded sediments from different land uses in the Fars Province, Iran. Eleven test plots were selected based on land use and wind erosion risk. On each plot, wind erosion was simulated using a portable wind tunnel and the eroded sediment was collected for further analysis aimed at measuring light density microplastics (LDMP). The LDMPs were extracted in both soil and wind-eroded sediment using a floatation method and then further examined using microscopy. Annual LDMP transport by wind erosion was estimated using wind data from the study areas. LDMPs were detected in six study areas in the Fars Province which are highly prone to wind erosion. Although LDMPs were found mostly in agricultural land, it was also detected in the soils and sediments from two natural areas. The total concentrations of LDMPs in polluted areas were 6.91 and 20.27mgkg⁻¹ of microplastics in soil and wind-eroded sediments, respectively. The enrichment ratio for LDMP ranged from 2.83 to 7.63 in different areas. The erosion rate of LDMP ranged from 0.08 to 1.48mgm⁻²min⁻¹. The results of this study confirmed the key role of wind erosion in the spread of microplastics in terrestrial environments which could form an exposure risk to humans via direct inhalation of the particles transported with the dust.

Rezania, S., et al. (2018). "Microplastics pollution in different aquatic environments and biota: A review of recent studies." Marine Pollution Bulletin **133**: 191-208.

Microplastics (MPs) are generated from plastic and have negative impact to our environment due to high level of fragmentation. They can be originated from various sources in different forms such as fragment, fiber, foam and so on. For detection of MPs, many techniques have been developed with different functions such as microscopic observation, density separation, Raman and FTIR analysis. Besides, due to ingestion of MPs by wide range of marine species, research on the effect of this pollution on biota as well as human is vital. Therefore, we comprehensively reviewed the occurrence and distribution of MPs pollution in both marine and freshwater environments, including rivers, lakes and wastewater treatment plants (WWTPs). For future studies, we propose the development of new techniques for sampling MPs in aquatic environments and biota and recommend more research regarding MPs release by WWTPs. Rhodes, C. J. (2018). "Plastic pollution and potential solutions." Science Progress **101**(3): 207-260.

A review is presented of the manufacture and use of different types of plastic, and the effects of pollution by these materials on animal, human and environmental health, insofar as this is known. Since 2004, the world has made as much plastic as it did in the previous half century, and it has been reckoned that the total mass of virgin plastics ever made amounts to 8.3 billion tonnes, mainly derived from natural gas and crude oil, used as chemical feedstocks and fuel sources. Between 1950 and 2015, a total of 6.3 billion tonnes of primary and secondary (recycled) plastic waste was generated, of which around 9% has been recycled, and 12% incinerated, with the remaining 79% either being stored in landfills or having been released directly into the natural environment. In 2015, 407 million tonnes (Mt) of plastic was produced, of which 164 Mt was consumed by packaging (36% of the total). Although quoted values vary, packaging probably accounts for around one third of all plastics used, of which approximately 40% goes to landfill, while 32% escapes the collection system. It has been deduced that around 9 Mt of plastic entered the oceans in 2010, as a result of mismanaged waste, along with up to 0.5 Mt each of microplastics from washing synthetic textiles, and from the abrasion of tyres on road surfaces. However, the amount of plastics actually measured in the oceans represents less than 1% of the (at least) 150 Mt reckoned to have been released into the oceans over time. Plastic accounts for around 10% by mass of municipal waste, but up to 85% of marine debris items - most of which arrive from land-based sources. Geographically, the five heaviest plastic polluters are P. R. China, Indonesia, Philippines, Vietnam and Sri Lanka, which between them contribute 56% of global plastic waste. Larger, primary plastic items can undergo progressive fragmentation to yield a greater number of increasingly smaller 'secondary' microplastic particles, thus increasing the overall surface area of the plastic material, which enhances its ability to absorb, and concentrate, persistent organic pollutants (POPs) such as dichlorodiphenyltrichloroethane (DDT) and polychlorinated biphenyls (PCBs), with the potential to transfer them to the tissues of animals that ingest the microplastic particles, particularly in marine environments. Although fears that such microparticles and their toxins may be passed via food webs to humans are not as yet substantiated, the direct ingestion of microplastics by humans via drinking water is a distinct possibility - since 92% of samples taken in the USA and 72% in Europe showed their presence - although any consequent health effects are as yet unclear. Foodstuffs may also become contaminated by microplastics from the air, although any consequent health effects are also unknown. In regard to such airborne sources, it is noteworthy that small plastic particles have been found in human lung tissue, which might prove an adverse

health issue under given circumstances. It is also very striking that microplastics have been detected in mountain soils in Switzerland, which are most likely windborne in origin. Arctic ice core samples too have revealed the presence of microplastics, which were most likely carried on ocean currents from the Pacific garbage patch, and from local pollution from shipping and fishing. Thus, sea ice traps large amounts of microplastics and transports them across the Arctic Ocean, but these particles will be released into the global environment when the ice melts, particularly under the influence of a rising mean global temperature. While there is a growing emphasis toward the substitution of petrochemically derived plastics by bioplastics, controversy has arisen in regard to how biodegradable the latter actually are in the open environment, and they presently only account for 0.5% of the total mass of plastics manufactured globally. Since the majority of bioplastics are made from sugar and starch materials, to expand their use significantly raises the prospect of competition between growing cr

Rhodes, C. J. (2019). "Solving the plastic problem: From cradle to grave, to reincarnation." Science Progress **102**(3): 218-248.

Plastic packaging accounts for 36% of all plastics made, but amounts to 47% of all plastic waste; 90% of all plastic items are used once and then discarded, which corresponds to around 50% of the total mass of plastics manufactured. Evidence for the ubiquity of microplastic pollution is accumulating rapidly, and wherever such material is sought, it seems to be found. Thus, microplastics have been identified in Arctic ice, the air, food and drinking water, soils, rivers, aquifers, remote maintain regions, glaciers, the oceans and ocean sediments, including waters and deep sea sediments around Antarctica, and within the deepest marine trenches of the Earth. They have also been detected in the bodies of animals, including humans, and as being passed along the hierarchy of food chains, up to marine top predators. Evidence has also been presented that microplastics are able to cross different life stages of mosquito that use different habitats - larva (feeding) to pupa (non-feeding) to adult terrestrial (flying) - and therefore can be spread from aquatic systems by flying insects. The so-called 'missing plastic problem' appears to be, in part, due to limitations in sampling methods, that is, many of the very small microplastic particles may simply escape capture in the trawl nets that are typically employed to collect them, but have been evidenced in grab-sampling experiments. Moreover, it is simply not possible to measure entirely through the vast, oceanic volumes of the oceans. It can, however, be concluded with some confidence that the majority of the plastic is not located at the sea surface, and indeed, several different sinks have been proposed for microplastics, including the sea floor and sediments, the ocean column itself, ice sheets, glaciers and soils. The treatment of land with sewage sludge is also thought to make a significant contribution of microplastics to soil. A substantial amount of airborne microparticulate pollution is created by the abrasion of tyres on road surfaces (and other 'non-exhaust' sources), meaning that even electric vehicles are not 'clean' in this regard, despite their elimination of tailpipe PM_{2.5} and PM₁₀ emissions. The emergence of nanoplastics in the environment poses a new set of potential threats, although any impacts on human health are not yet known, save, as indicated from model studies. While improved design, manufacture, collection, reuse, repurposing and reprocessing/recycling of plastic items are necessary, overwhelmingly, a curbing in the use of plastic materials in the first place is demanded, particularly from single-use packaging. However, plastic pollution is just one element in the overall matrix of a changing climate ('the world's woes') and must be addressed as part of an integrated consideration of how we use all resources, fossil and otherwise, and the need to change our expectations, goals and lifestyles. In this effort, the role of deglobalisation/relocalisation may prove critical: thus, food and other necessities might be produced more on the local than the global scale, with

smaller inputs of fossil fuels for transportation and other purposes, water and fertilisers, along with a marked reduction in the need for plastic packaging.

Riaz, Q. U. and T. Masud (2013). "Recent trends and applications of encapsulating materials for probiotic stability." Critical Reviews in Food Science & Nutrition **53**(3): 231-244.

The importance of probiotics and their live delivery in the gastrointestinal tract has gained much importance in the recent past. Many reports have indicated that there is poor viability of probiotic bacteria in dairy based products, both fermented and non-fermented, and also in the human gastro-intestinal system is questionable. In this case, microencapsulation is the most significant emerging and efficient technology that is being used for the preservation of probiotics against adverse environmental conditions. Apart from different techniques of microencapsulation, various types of encapsulating materials are also used for the process, namely, alginate, chitosan, carrageenan, gums (locust bean, gellan gum, xanthan gum, etc.), gelatin, whey protein, starch, and compression coating. Each one of the encapsulating materials has its own unique characteristics of capsule formation and provision of shape, appearance, and strength to microbeads. The type of encapsulating material also influences the viability of probiotics during storage, processing, and in the gastrointestinal tract. The effectiveness of any material depends not upon its capsule forming capability, strength, and enhancing viability but also on its cheapness, availability, and biocompatibility. So, added convenience and reduced packaging costs may also be used to offset the cost of encapsulating one or more ingredients. Encapsulated forms of ingredients provide a longer shelf life for the product.

Riaz, T., et al. (2019). "In vitro survival of Bifidobacterium bifidum microencapsulated in zein-coated alginate hydrogel microbeads." Journal of Microencapsulation **36**(2): 192-203.

The Bifidobacterium bifidum susceptibility in gastrointestinal conditions and storage stability limit its use as potential probiotics. The current study was design to encapsulate B. bifidum using sodium alginate (SA, 1.4% w/v) and different concentration of zein as coating material, that is, Z₁ (1% w/v), Z₂ (3% w/v), Z₃ (5% w/v), Z₄ (7% w/v), Z₅ (9% w/v). The resultant microbeads were further investigated for encapsulation efficiency, survival in gastrointestinal conditions, release profile in intestinal fluid, storage stability and morphological characteristics. The highest encapsulation efficiency (94.56%) and viable count (>10⁷ log CFU/g) was observed in Z₄ (7% w/v). Viable cell count of B. bifidum was >10⁶ log CFU/g in all the zein-coated microbeads as compare to free cells (10³ log CFU/g) and SA (10⁵ log CFU/g) at 4 degreeC after 32 days of storage. Therefore, B. bifidum encapsulated in zein-coated alginate microbeads present improved survival during gastric transit and storage.

Ribeiro, F., et al. (2017). "Microplastics effects in Scrobicularia plana." Marine Pollution Bulletin **122**(1/2): 379-391.

One of the most common plastics in the marine environment is polystyrene (PS) that can be broken down to micro sized particles. Marine organisms are vulnerable to the exposure to microplastics. This study assesses the effects of PS microplastics in tissues of the clam Scrobicularia plana. Clams were exposed to 1 mg L⁻¹ (20 micro m) for 14 days, followed by 7 days of depuration. A qualitative analysis by infrared spectroscopy in diffuse reflectance mode period detected the presence of microplastics in clam tissues upon exposure, which were not eliminated after depuration. The effects of microplastics were assessed by a battery of biomarkers and results revealed that microplastics induce effects on antioxidant capacity, DNA damage, neurotoxicity and oxidative damage. S. plana is a significant target to

assess the environmental risk of PS microplastics.

Ribeiro, F., et al. (2019). "Accumulation and fate of nano- and micro-plastics and associated contaminants in organisms." TrAC - Trends in Analytical Chemistry **111**: 139-147.

Following a decade of research on the environmental impacts of microplastics, a knowledge gap remains on the processes by which micro and nanoplastics pass across biological barriers, enter cells and are subject to biological mechanisms. Here we summarize available literature on the accumulation of microplastics and their associated contaminants in a variety of organisms including humans. Most data on the accumulation of microplastics in both field and lab studies are for marine invertebrates. Microplastics accumulation data for insects, birds, marine mammals and sea turtles are scarce due to methodological issues. There is no conclusive evidence for the mode of accumulation of microplastics in either mammals or humans. The mechanism of chemical partitioning, role of contaminants associated with plastics, and mode of action of both nano- and micro-plastics and associated chemicals in a range of organisms and associated compartments/tissues also requires further research. © 2018 Elsevier B.V.

Richard, H., et al. (2019). "Biofilm facilitates metal accumulation onto microplastics in estuarine waters." Science of the Total Environment **683**: 600-608.

In aquatic environments, plastic debris accumulates chemical pollutants from the surrounding water, potentially altering the fate of xenobiotics in these ecosystems. The effects of biofouling on the potential for plastic to sorb environmental pollutants remain poorly understood. In this study, we test the hypothesis that concentrations of metals are directly related to biofilm accumulation on microplastics submerged in natural estuarine waters. Two types of pre-production plastic pellets (polylactic acid (PLA) and low-density polyethylene (LDPE)) and glass pellets, were suspended for up to 28 days in an urbanized estuary (San Francisco Bay, California) to investigate how biofilm affects the accumulation of metals on these materials. During the initial weeks of the experiment, biofilm growth differed between locations, but after 28 days, PLA and LDPE had similar amounts of biofilm at the two field sites. Biofilm was the only significant predictor variable for Ba, Cs, Fe, Ga, Ni and Rb, and simple regressions of these metals after one month of submersion predicted much of the variability in the data (respective adjusted R² values: 0.46, 0.90, 0.86, 0.81, 0.87, 0.90; p < 0.001). For other metals influenced by location or substrate material, multivariate analysis showed that increases in metal concentrations were predicted by increases in biofilm for Cu, Pb, Al, K, U, Co, Mg (p < 0.001) and Mn (p < 0.01). This work highlights the role of biofilm in facilitating metal accumulation on plastic debris and contributes to current understanding of the underlying processes that influence the behavior of microplastics as aquatic contaminants. Richards, G. and I. E. Agranovski (2015). "Air emission from the co-combustion of alternative derived fuels within cement plants: Gaseous pollutants." Journal of the Air & Waste Management Association **65**(2): 186-196.

Cement manufacturing is a resource- and energy-intensive industry, utilizing 9% of global industrial energy use while releasing more than 5% of global carbon dioxide (CO2) emissions. With an increasing demand of production set to double by 2050, so too will be its carbon footprint. However, Australian cement plants have great potential for energy savings and emission reductions through the substitution of combustion fuels with a proportion of alternative derived fuels (ADFs), namely, fuels derived from wastes. This paper presents the environmental emissions monitoring of 10 cement batching plants while under baseline and

ADF operating conditions, and an assessment of parameters influencing combustion. The experiential runs included the varied substitution rates of seven waste streams and the monitoring of seven target pollutants. The co-combustion tests of waste oil, wood chips, wood chips and plastic, waste solvents, and shredded tires were shown to have the minimal influence when compared to baseline runs, or had significantly reduced the unit mass emission factor of pollutants. With an increasing ADF% substitution, monitoring identified there to be no subsequent emission effects and that key process parameters contributing to contaminant suppression include (1) precalciner and kiln fuel firing rate and residence time; (2) preheater and precalciner gas and material temperature; (3) rotary kiln flame temperature; (4) fuel-air ratio and percentage of excess oxygen; and (5) the rate of meal feed and rate of clinker produced.

Rickard, D. L., et al. (2010). "Hydration potential of lysozyme: protein dehydration using a single microparticle technique." Biophysical Journal **98**(6): 1075-1084.

For biological molecules in aqueous solution, the hydration pressure as a function of distance from the molecular surface represents a very short-range repulsive pressure that limits atom-atom contact, opposing the attractive van der Waals pressure. Whereas the separation distance for molecules that easily arrange into ordered arrays (e.g., lipids, DNA, collagen fibers) can be determined from x-ray diffraction, many globular proteins are not as easily structured. Using a new micropipette technique, spherical, glassified protein microbeads can be made that allow determination of protein hydration as a function of the water activity (a(w)) in a surrounding medium (decanol). By adjusting a(w) of the dehydration medium, the final protein concentration of the solid microbead is controlled, and ranges from 700 to 1150 mg/mL. By controlling a(w) (and thus the osmotic pressure) around lysozyme, the repulsive pressure was determined as a function of distance between each globular, ellipsoid protein. For separation distances, d, between 2.5 and 9 A, the repulsive decay length was 1.7 A and the pressure extrapolated to d = 0 was 2.2 x 10(8) N/m(2), indicating that the hydration pressure for lysozyme is similar to other biological interfaces such as phospholipid bilayers.

Rico, F., et al. "Nanomechanics of lung epithelial cells." International Journal of Nanotechnology **2**(1/2): 180-194.

Nanobiotechnology provides powerful tools for manipulating cells with nanometric resolution and with simultaneous measurement of force with pN resolution. We review the application of atomic force microscopy (AFM) and magnetic tweezers for probing cell nanomechanics. AFM measures the mechanical properties of the cell by indenting its surface by means of a flexible cantilever with a sharp tip at its end. Magnetic tweezers probe cell mechanics by twisting or pulling a magnetic microbead bound to the cell surface. The stress-strain relationship allows us to compute the complex shear modulus of the cell. Lung epithelial cells probed with AFM and magnetic tweezers exhibit a power-law dynamics with a weak exponent. This dynamics conforms to the rheology of soft glassy materials, suggesting that cytoskeleton internal disorder and matrix agitation could govern the mechanical behaviour of the cell.

Rider, A., et al. (2013). "Induction of T regulatory cells by streptococcus pneumonia." Immunology **1)**: 151.

Background: Streptococcus pneumonia (pneumococcus) is an important human pathogen that causes a number of serious diseases including pneumonia and septicaemia. According to the World Health Organisation, pneumococcal diseases cause around 1.6 million deaths every year worldwide. Th17 and Treg cells have been suggested to play an important role in modulating pneumococcal clearance and carriage in nasopharynx. Th17 cells may mediate the clearance of pneumococcus by the recruitment of phagocytes and Treg cells may act to inhibit the inflammatory response mediated by other effector cells including Th17 cell response. Studies have shown that Foxp3+ Treg cells present in the nasopharynx may have a potent inhibitory effect on effector CD4+ T cell proliferation and could contribute to the persistence of carriage seen in young children. It has been shown in a murine study that a polysaccharide with pneumolysin induces Treg. Aim(s): To study what pneumococcal component(s) induce Foxp3+ Treg cells in humans. Material(s) and Method(s): Mononuclear cells (MNC) from adenotonsillar tissues and peripheral blood mononuclear cells (PBMC) were isolated from children undergoing adenotonsilectomy. Depletion of memory and effector T cells from MNC was performed using CD45RO and CD25 microbeads and MACS cell sorting. Numbers of Treg and Th17 cells were analysed by intracellular staining of Foxp3 and IL-17 following stimulation by concentrated pneumococcal culture supernatant (CCS) derived from a wild type D39 strain, its isogenic mutant lacking pneumolysin (Ply ^{-/-}) or by type 3 pneumococcal polysaccharide plus a pneumolysin toxoid (W433F). Induction of Treg cells and cytokine responses were measured using flowcytometry analysis and immunoassay. Result(s): Stimulation of memory T cell-depleted adenotonsillar MNC or PBMC with pneumococcal CCS induced an increase in numbers of Foxp3+ Treg compared to unstimulated controls, and Ply ^{-/-} CCS appeared to induce less Treg compared to wild-type CCS. Stimulation with type 3 polysaccharide (T3P) and pneumolysin toxoid (W433F) induced a more marked increase in numbers of Foxp3+ Tregs than the control samples. Discussion(s): Stimulation of adeontonsillar MNC and PBMC by a combination of T3P + W433F induced a significant increase in Foxp3+ Treg cells. Further work is ongoing to study whether different types of polysaccharide in combination with pneumolysin or other proteins could also induce Treg cells.

Rieger, B., et al. (2004). "Diffusion of microspheres in sealed and open microarrays." Microscopy Research and Technique **65**(4-5): 218-225.

In several experiments, we study the diffusion of microspheres with different radii in microarrays filled with a variety of aqueous solutions of ethylene glycol. We study diffusion in open and closed (sealed) microarrays. In sealed nanoliter wells, the tracers show pure diffusion, whereas in open reactors, a radial outward-directed evaporation-induced liquid flow is superimposed onto the diffusion. In general, one of the following quantities can be calculated if the others are known: the temperature, the viscosity of the medium, the radius of the microbeads, or the diffusion constant. The estimated diffusion constants in closed microarrays are in good agreement with theoretical predictions based on the Brownian motion. We monitor the motion of the microbeads under a microscope and extract their paths in time from the digital recordings. Ambiguous paths due to the crossing of two trajectories can be detected. We show that low microsphere concentrations or high viscosities do not hamper a robust estimation of the diffusion parameters. Microsc. Res. Tech. 65:218-225, 2004.

Rigamonti, L., et al. (2014). "Environmental evaluation of plastic waste management scenarios." Resources, Conservation and Recycling **85**: 42-53.

The management of the plastic fraction is one of the most debated issues in the discussion on integrated municipal solid waste systems. Both material and energy recovery can be performed on such a waste stream, and different separate collection schemes can be implemented. The aim of the paper is to contribute to the debate, based on the analysis of different plastic waste recovery routes. Five scenarios were defined and modelled with a life cycle assessment approach using the EASEWASTE model. In the baseline scenario (P0) the plastic is treated as residual waste and routed partly to incineration with energy recovery and partly to mechanical

biological treatment. A range of potential improvements in plastic management is introduced in the other four scenarios (P1-P4). P1 includes a source separation of clean plastic fractions for material recycling, whereas P2 a source separation of mixed plastic fraction for mechanical upgrading and separation into specific polymer types, with the residual plastic fraction being down-cycled and used for "wood items". In P3 a mixed plastic fraction is source separated together with metals in a "dry bin". In P4 plastic is mechanically separated from residual waste prior to incineration. A sensitivity analysis on the marginal energy was carried out. Scenarios were modelled as a first step assuming that marginal electricity and heat were based on coal and on a mix of fuels and then, in the sensitivity analysis, the marginal energy was based on natural gas. The study confirmed the difficulty to clearly identify an optimal strategy for plastic waste management. In fact none of the examined scenarios emerged univocally as the best option for all impact categories. When moving from the P0 treatment strategy to the other scenarios, substantial improvements can be obtained for "Global Warming". For the other impact categories, results are affected by the assumption about the substituted marginal energy. Nevertheless, irrespective of the assumptions on marginal energy, scenario P4, which implies the highest quantities of specific polymer types sent to recycling, resulted the best option in most impact categories. © 2014 Elsevier B.V.

Rillig, M. C. and M. Bonkowski (2018). "Microplastic and soil protists: A call for research." Environmental Pollution **241**: 1128-1131.

Microplastic is an emerging contaminant of concern in soils globally, probably gradually increasing in soil due to slow degradation. Few studies on microplastic effects on soil biota are available, and no study in a microplastic contamination context has specifically addressed soil protists. Soil protists, a phylogenetically and functionally diverse group of eukaryotic, unicellular soil organisms, are major consumers of bacteria in soils and are potentially important vehicles for the delivery of microplastics into the soil food chain. Here we build a case for focusing research on soil protists by drawing on data from previous, older studies of phagocytosis in protist taxa, which have long made use of polystyrene latex beads (microspheres). Various soil-borne taxa, including ciliates, flagellates and amoebae take up microplastic beads in the size range of a few micrometers. This included filter feeders as well as amoebae which engulf their prey. Discrimination in microplastic particle uptake depended on species, physiological state as well as particle size. Based on the results of the studies we review here, there is now a need to study microplastic effects in a pollution ecology context: this means considering a broad range of particle types under realistic conditions in the soil, and exploring longer-term effects on soil protist communities and functions.

Rillig, M. C., et al. (2019). "Evolutionary implications of microplastics for soil biota." Environmental Chemistry **16**(1): 3-7.

Microplastic pollution is increasingly considered to be a factor of global change: in addition to aquatic ecosystems, this persistent contaminant is also found in terrestrial systems and soils. Microplastics have been chiefly examined in soils in terms of the presence and potential effects on soil biota. Given the persistence and widespread distribution of microplastics, it is also important to consider potential evolutionary implications of the presence of microplastics in soil; we offer such a perspective for soil microbiota. We discuss the range of selection pressures likely to act upon soil microbes, highlight approaches for the study of evolutionary responses to microplastics, and present the obstacles to be overcome. Pondering the evolutionary consequences of microplastics in soils can yield new insights into the effects of this group of pollutants, including establishing 'true' baselines in soil ecology, and understanding future responses of soil microbial populations and communities.

Rillig, M. C., et al. (2019). "Microplastic effects on plants." New Phytologist **223**(3): 1066-1070.
Microplastic effects in terrestrial ecosystems have recently moved into focus, after about a decade of research being limited to aquatic systems. While effects on soil physical properties and soil biota are starting to become apparent, there is not much information on the consequences for plant performance. We here propose and discuss mechanistic pathways through which microplastics could impact plant growth, either positively or negatively. These effects will vary as a function of plant species, and plastic type, and thus are likely to translate to changes in plant community composition and perhaps primary production. Our mechanistic framework serves to guide ongoing and future research on this important topic.

Rioja, A., et al. (2014). "Directing vascularization using modular microtissues." Tissue Engineering - Part A **1)**: S69-S70.
Critical limb ischemia (CLI) is the reduction of blood flow to the extremities due to an arterial blockage, and can cause pain, disrupted wound healing, and tissue necrosis. Pre-vascularized tissues capable of inosculating with existing host vasculature upon implantation have shown promise in tissue engineering applications, but this approach requires open surgery and has not been tested in CLI models. We are developing pre-vascularized collagen-fibrin microtissues that can be delivered in a minimally invasive manner and are designed to inosculate with one another and with existing host vasculature upon implantation to quickly restore blood flow to ischemic tissue. Studies of these microtissues containing human umbilical vein endothelial cells and normal human lung fibroblasts suggest that a developmental program resembling vasculogenesis can be recapitulated, with evidence of vessel-like networks formed within the microtissues. An 11.5 fold increase in cell incorporation was achieved by augmenting the initial cell density by a factor of 5 without altering the average microbead size (approx. 200 mum in diameter) or aggregation. After the cell encapsulation process, cell viability was 76%. When microtissues were embedded within fibrin hydrogels (a simple model tissue), sprouts emerged and showed evidence of inosculation with those from adjacent microtissues. Current studies are focused on the identification of culture methods (static vs. dynamic) to augment cell proliferation, increase network formation within the microtissues, and enhance sprout inosculation within model tissue constructs. Overall, this strategy may yield new insights into vasculogenesis and lead to a new revascularization therapy to treat CLI.

Rioja, A. Y., et al. (2017). "Distributed vasculogenesis from modular agarose-hydroxyapatite-fibrinogen microbeads." Acta Biomaterialia **55**: 144-152.
Critical limb ischemia impairs circulation to the extremities, causing pain, disrupted wound healing, and potential tissue necrosis. Therapeutic angiogenesis seeks to repair the damaged microvasculature directly to restore blood flow. In this study, we developed modular,

micro-scale constructs designed to possess robust handling qualities, allow in vitro pre-culture, and promote microvasculature formation. The microbead matrix consisted of an agarose (AG) base to prevent aggregation, combined with cell-adhesive components of fibrinogen (FGN) and/or hydroxyapatite (HA). Microbeads encapsulating a co-culture of human umbilical vein endothelial cells (HUVEC) and fibroblasts were prepared and characterized. Microbeads were generally 80-100micro m in diameter, and the size increased with the addition of FGN and HA. Addition of HA increased the yield of microbeads, as well as the homogeneity of distribution of FGN within the matrix. Cell viability was high in all microbead types. When cell-seeded microbeads were embedded in fibrin hydrogels, HUVEC sprouting and inosculation between neighboring microbeads were observed over seven days. Pre-culture of microbeads for an additional seven days prior to embedding in fibrin resulted in significantly greater HUVEC network length in AG+HA+FGN microbeads, as compared to AG, AG+HA or AG+FGN microbeads. Importantly, composite microbeads resulted in more even and widespread endothelial network formation, relative to control microbeads consisting of pure fibrin. These results demonstrate that AG+HA+FGN microbeads support HUVEC sprouting both within and between adjacent microbeads, and can promote distributed vascularization of an external matrix. Such modular microtissues may have utility in treating ischemic tissue by rapidly re-establishing a microvascular network.

STATEMENT OF SIGNIFICANCE: Critical limb ischemia (CLI) is a chronic disease that can lead to tissue necrosis, amputation, and death. Cell-based therapies are being explored to restore blood flow and prevent the complications of CLI. In this study, we developed small, non-aggregating agarose-hydroxyapatite-fibrinogen microbeads that contained endothelial cells and fibroblasts. Microbeads were easy to handle and culture, and endothelial sprouts formed within and between microbeads. Our data demonstrates that the composition of the microbead matrix altered the degree of endothelial sprouting, and that the addition of hydroxyapatite and fibrinogen resulted in more distributed sprouting compared to pure fibrin microbeads. The microbead format and control of the matrix formulation may therefore be useful in developing revascularization strategies for the treatment of ischemic disease.

Rios, L. M., et al. (2010). "Quantitation of persistent organic pollutants adsorbed on plastic debris from the Northern Pacific Gyre's “eastern garbage patch”." Journal of Environmental Monitoring **12**(12): 2226-2236.

Floating marine plastic debris was found to function as solid-phase extraction media, adsorbing and concentrating pollutants out of the water column. Plastic debris was collected in the North Pacific Gyre, extracted, and analyzed for 36 individual PCB congeners, 17 organochlorine pesticides, and 16 EPA priority PAHs. Over 50% contained PCBs, 40% contained pesticides, and nearly 80% contained PAHs. The PAHs included 2, 3 and 4 ring congeners. The PCBs were primarily CB-11, 28, 44, 52, 66, and 101. The pesticides detected were primarily p,p-DDTs and its metabolite, o,p-DDD, as well as BHC (a,b,g and d). The concentrations of pollutants found ranged from a few ppb to thousands of ppb. The types of PCBs and PAHs found were similar to those found in marine sediments. However, these plastic particles were mostly polyethylene which is resistant to degradation and although functioning similarly to sediments in accumulating pollutants, these had remained on or near the ocean surface. Particles collected included intact plastic items as well as many pieces less than 5 mm in size. [ABSTRACT FROM AUTHOR]

Rios Mendoza, L. M. and M. Balcer (2019). "Microplastics in freshwater environments: A review of quantification assessment." TrAC - Trends in Analytical Chemistry **113**: 402-408.

Microplastic (MP) studies in freshwater environments are gaining attention due to the huge quantities of plastic particles reported from lakes and rivers and the potential for negative impacts in these environments. Different units have been used to report MP densities, which makes it difficult to compare data and can result in reports of extremely high concentrations that do not reflect the original sample size. We recommended that the density of MPs from bulk samples be reported as number L⁻¹, while density from net samples should be reported as number m⁻³. If the density of MPs from net samples is expressed on an areal basis, values should be reported as number/1000 m², and not as number km⁻². Spectroscopy (ATR-muFT-IR and muRAMAN) and Pyrolysis-Gas Chromatography coupled to Mass Spectrometry are techniques that could be used for quantitative identification of the various types of polymers in MP particles. Rios, P., et al. (2003). "Plastics disassembly versus bulk recycling: engineering design for end-of-life electronics resource recovery." Environmental Science & Technology **37**(23): 5463-5470.

Annual plastic flows through the business and consumer electronics manufacturing supply chain include nearly 3 billion lb of high-value engineering plastics derived from petroleum. The recovery of resource value from this stream presents critical challenges in areas of materials identification and recycling process design that demand new green engineering technologies applied together with life cycle assessment and ecological supply chain analysis to create viable plastics-to-plastics supply cycles. The sustainable recovery of potentially high-value engineering plastics streams requires that recyclers either avoid mixing plastic parts or purify later by separating smaller plastic pieces created in volume reduction (shredding) steps. Identification and separation constitute significant barriers in the plastics-to-plastics recycling value proposition. In the present work, we develop a model that accepts randomly arriving electronic products to study scenarios by which a recycler might identify and separate high-value engineering plastics as well as metals. Using discrete eventsimulation,we compare current mixed plastics recovery with spectrochemical plastic resin identification and subsequent sorting. Our results show that limited disassembly with whole-part identification can produce substantial yields in separated streams of recovered engineering thermoplastics. We find that disassembly with identification does not constitute a bottleneck, but rather, with relatively few workers, can be configured to pull the process and thus decrease maximum staging space requirements. Ripley, K. (2018). "The OEWG Prepares the Table for COP-14." Environmental Policy and Law **48**(5): 289-295.

OEWG-11 had before it a draft update of the general technical guidelines, new technical guidelines regarding short-chain chlorinated paraffins (SCCP), plus updates of existing technical guidelines on wastes consisting of, containing or contaminated with hexachlorobutadiene (HCBD); hexabromodiphenyl ether and heptabromodiphenyl ether, and tetrabromodiphenyl ether and pentabromodiphenyl ether, to include decabromodiphenyl ether; unintentionally produced polychlorinated dibenzo-p-dioxins, polychlorinated dibenzofurans, hexachlorobenzene, polychlorinated biphenyls, pentachlorobenzene or polychlorinated naphthalenes, to include HCBD.8 The draft update of the general technical guidelines included proposals for provisional definitions of "low POP content" for all POPs regulated by the Stockholm Convention that would provide guidance for situations in which, under that convention, disposal need not destroy or irreversibly transform the POP content of the waste.9 In general this guidance uses values based on European Union (EU) legislation, since most non-EU nations have not adopted the low-POP-content concept in their waste disposal legislation or regulations. The resulting OEWG recommendation adopted the text suggested by the contact group without amendment.23 It sets out draft elements for a COP-14 decision on marine plastic litter, including, * encouraging governments, industry and consumers to make efforts to prevent and minimise the generation of plastic waste and improve the ESM of plastic waste, in particular in order to prevent plastics from entering the marine environment from land-based sources; * considering whether any additional constituents or characteristics should be added to Annex I or Annex III respectively, through the on-going work by the expert working group on review of annexes; * deciding to update the 2002 technical guidelines; * requesting the Household Waste Partnership to coordinate closely with the new partnership on plastic waste to be established; * considering what data should be gathered, and by whom, related to the generation, disposal of, and transboundary movement of plastic wastes in different waste streams; the environmental, economic and social impact of plastic wastes; and national policies and progress towards the ESM of plastic wastes.24 Proposals to Amend Convention Annexes Regarding Plastic Waste Under a procedure adopted by COP-8, Parties can apply for review or adjustment of the lists contained in Convention Annexes VIII (hazardous waste) and IX (waste not normally considered hazardous) by submitting a special form to the Secretariat at least three months prior to an OEWG meeting, which must review the application before making a recommendation to the COP. [...]OEWG-11 accepted an amended version of this proposal as a guide for further work. [...]OEWG-11 adopted the decision drafted by the EU that requests the Secretariat to finish and circulate its report for comment by 15 November 2018, and to include recommendations on opportunities to further develop partnerships under the Basel Convention, taking into account the experience of relevant UN bodies, such as the Economic and Social Council, UN Environment Programme, and the Food and Agriculture Organization, as well as other MEAs such as the Stockholm and Rotterdam Conventions.

Risner, M. L., et al. (2020). "Elevated ocular pressure reduces voltage-gated sodium channel NaV1.2 protein expression in retinal ganglion cell axons." Experimental Eye Research **190**: 107873.

Glaucoma is an age-related neurodegenerative disease that is commonly associated with sensitivity to intraocular pressure. The disease selectively targets retinal ganglion cells (RGCs) and constituent axons. RGC axons are rich in voltage-gated sodium channels, which are essential for action potential initiation and regeneration. Here, we identified voltage-dependent sodium channel, NaV1.2, in the retina, examined how this channel contributes to RGC light responses, and monitored NaV1.2 mRNA and protein expression in the retina during progression of modeled glaucoma. We found NaV1.2 is predominately localized in ganglion cell intraretinal axons with dispersed expression in the outer and inner plexiform layers. We showed Phrixotoxin-3, a potent NaV1.2 channel blocker, significantly decreased RGC electrical activity in a dose-dependent manner with an I_C50 of 40 nM. Finally, we found four weeks of raised intraocular pressure (30% above baseline) significantly increased NaV1.2 mRNA expression but reduced NaV1.2 protein level in the retina up to 57% ($p < 0.001$). Following prolonged intraocular pressure elevation, NaV1.2 protein expression particularly diminished at distal sections of ganglion cell intraretinal axons ($p <= 0.01$). Our results suggest NaV1.2 might

be a therapeutic target during disease progression to maintain RGC excitability, preserving presynaptic connections through action potential backpropagation.

Rist, S., et al. (2019). "Ingestion and effects of micro- and nanoplastics in blue mussel (Mytilus edulis) larvae." Marine Pollution Bulletin **140**: 423-430.

It is well known that mussels are exposed to microplastics but ingestion and potential effects on mussel larvae are not well understood. We quantified ingestion and egestion of 100 nm and 2 micro m polystyrene beads in blue mussel larvae after 4 h exposure and 16 h depuration using different plastic-to-microalgae ratios. Effects on growth and development of mussel larvae were investigated at 0.42, 28.2 and 282 micro gL⁻¹ within 15 days of exposure. We found that, on a mass basis, larvae ingested a higher amount of 2 micro m than 100 nm beads, while egestion was independent of particle size and the plastics-to-algae ratio. Although particle egestion occurred readily, microplastics remained inside the larvae. Larval growth was not affected but abnormally developed larvae increased after exposure to polystyrene beads. Malformations were more pronounced for 100 nm beads, at higher concentration and after longer exposure time.

Rist, S., et al. (2017). "Ingestion of micro- and nanoplastics in Daphnia magna - quantification of body burdens and assessment of feeding rates and reproduction." Environmental Pollution **228**: 398-407.

Evidence is increasing that micro- and nanoplastic particles can have adverse effects on aquatic organisms. Exposure studies have so far mainly been qualitative since quantitative measurements of particle ingestion are analytically challenging. The aim of this study was therefore to use a quantitative approach for determining ingestion and egestion of micro- and nanoplastics in Daphnia magna and to analyze the influence of particle size, exposure duration and the presence of food. One week old animals were exposed to 2 micro m and 100 nm fluorescent polystyrene beads (1 mg/l) for 24 h, followed by a 24 h egestion period in clean medium. During both phases body burdens of particles were determined by measuring the fluorescence intensity in dissolved tissues. Ingestion and egestion were investigated in the absence and presence of food (6.7.10⁵ cells of Raphidocelis subcapitata per ml). Furthermore, feeding rates of daphnids in response to particle exposure were measured as well as effects on reproduction during a 21 days exposure (at 1 mg/l, 0.5 mg/l and 0.1 mg/l) to investigate potential impairments of physiology. Both particle sizes were readily ingested, but the ingested mass of particles was five times higher for the 2 micro m particles than for the 100 nm particles. Complete egestion did not occur within 24 h but generally higher amounts of the 2 micro m particles were egested. Animal body burdens of particles were strongly reduced in the presence of food. Daphnid feeding rates decreased by 21% in the presence of 100 nm particles, but no effect on reproduction was found despite high body burdens of particles at the end of 21 days exposure. The lower egestion and decreased feeding rates, caused by the 100 nm particles, could indicate that particles in the nanometer size range are potentially more hazardous to D. magna compared to larger particle sizes.

Rist, S., et al. (2018). "A critical perspective on early communications concerning human health aspects of microplastics." Science of the Total Environment **626**: 720-726.

Microplastic research in recent years has shown that small plastic particles are found almost everywhere we look. Besides aquatic and terrestrial environments, this also includes aquatic species intended for human consumption and several studies have reported their prevalence in other food products and beverages. The scientific as well as public debate has therefore increasingly focused on human health implications of microplastic exposure. However, there is a big discrepancy between the magnitude of this debate and actual scientific findings, which have merely shown the presence of microplastics in certain products. While plastics can undoubtedly be hazardous to human health due to toxicity of associated chemicals or as a consequence of particle toxicity, the extent to which microplastics in individual food products and beverages contribute to this is debatable. Considering the enormous use of plastic materials in our everyday lives, microplastics from food products and beverages likely only constitute a minor exposure pathway for plastic particles and associated chemicals to humans. But as this is rarely put into perspective, the recent debate has created a skewed picture of human plastic exposure. We risk pulling the focus away from the root of the problem: the way in which we consume, use and dispose of plastics leading to their widespread presence in our everyday life and in the environment. Therefore we urge for a more careful and balanced discussion which includes these aspects.

Rist, S., et al. (2019). "The fate of microplastics during uptake and depuration phases in a blue mussel exposure system." Environmental Toxicology & Chemistry **38**(1): 99-105.

We present a blue mussel exposure system where the fate of microplastics (polystyrene beads) is tracked during exposure and depuration phases. This enabled the establishment of a complete mass balance. Quantification of beads in mussels was done with a novel enzymatic digestion protocol. We found a similar relative distribution of beads for 2 environmentally realistic concentrations (5 and 100 beads L^{-1}) and no substantial egestion of particles within 2 h of depuration. Environ Toxicol Chem 2019;38:99–105. © 2018 SETAC A complete mass balance of microplastic beads in a blue mussel exposure system was established by quantifying beads in 4 compartments: the exposure water, the mussel after exposure, the depuration water, and the mussel after depuration. MP = microplastic. [ABSTRACT FROM AUTHOR]

Rist, S. E., et al. (2016). "Suspended micro-sized PVC particles impair the performance and decrease survival in the Asian green mussel Perna viridis." Marine Pollution Bulletin **111**(1/2): 213-220.

Marine bivalves are known to ingest microplastics, but information on the consequences for their physiological performance is limited. To investigate a potential exposure pathway that has not yet been addressed, we mimicked the resuspension of microplastics from the sediment in a laboratory exposure experiment. For this, we exposed the Asian green mussel Perna viridis to 4 concentrations (0 mg/l, 21.6 mg/l, 216 mg/l, 2160 mg/l) of suspended polyvinylchloride (PVC) particles (1-50 micro m) for two 2-hour-time-periods per day. After 44 days, mussel filtration and respiration rates as well as byssus production were found to be a negative function of particle concentration. Furthermore, within 91 days of exposure, mussel survival declined with increasing PVC abundance. These negative effects presumably go back to prolonged periods of valve closure as a reaction to particle presence. We suggest that microplastics constitute a new seston component that exerts a stress comparable to natural suspended solids.

Rivera-Hernandez, J. R., et al. (2019). "Biodynamics of mercury in mussel tissues as a function of exposure pathway: natural vs microplastic routes." Science of the Total Environment **674**: 412-423.

In the marine environment, metals can be present dissolved or adsorbed to suspended particles.

In the last decades a new type of particle has been introduced, microplastics (MPs). The exposure route of pollutants influences their accumulation and distribution into tissues. A pulse-chase experiment was conducted in which mussels were exposed to Hg: adsorbed onto MPs and microalgae (MA) and dissolved (WB). Mussels accumulated the same amount of Hg independently of particle, due to the Hg loading in both particles and their acceptability were similar. The highest Hg accumulation occurred in gill when the Hg exposure was through water and in digestive gland when Hg was adsorbed to particles. More than 70% of the Hg uptake through MPs was quickly eliminated due to: (i) part of the cleared MPs might not really be ingested but adhered to body surfaces of mussels, (ii) MPs ingested were eliminated through faeces as they are non-nutritive particles which may be rejected in stomach preventing their entry into digestive gland and (iii) high affinity of Hg on surface of MPs which meant that Hg was mainly eliminated jointly to MPs. The organic nature of MA facilitates the entry of Hg into digestive gland where MA are intracellularly digested releasing the Hg adsorbed onto their surfaces. In this case, Hg may reach deeper levels by translocation of the Hg incorporated into gland towards foot and remaining tissues, a process that might occur through haemolymph. All of the Hg accumulated in WB during the exposure was internally absorbed into tissues, and later translocated from gill to gland. Although Hg elimination rate in MPs mussels was greater than in the other exposure pathways, an important amount of Hg was maintained through the depuration period, thus we cannot and should not neglect the risk of MPs as vectors for mercury.

Rivera-Utrilla, J., et al. (2013). "Pharmaceuticals as emerging contaminants and their removal from water. A review." Chemosphere **93**(7): 1268-1287.

The main objective of this study was to conduct an exhaustive review of the literature on the presence of pharmaceutical-derived compounds in water and on their removal. The most representative pharmaceutical families found in water were described and related water pollution issues were analyzed. The performances of different water treatment systems in the removal of pharmaceuticals were also summarized. The water treatment technologies were those based on conventional systems (chlorine, chlorine dioxide, wastewater treatment plants), adsorption/bioadsorption on activated carbon (from lotus stalks, olive-waste cake, coal, wood, plastic waste, cork powder waste, peach stones, coconut shell, rice husk), and advanced oxidation processes by means of ozonation (O<inf>3</inf>, O<inf>3</inf>/H<inf>2</inf>O<inf>2</inf>, O<inf>3</inf>/activated carbon, O<inf>3</inf>/biological treatment), photooxidation (UV, UV/H<inf>2</inf>O<inf>2</inf>, UV/K<inf>2</inf>S<inf>2</inf>O<inf>8</inf>, UV/TiO<inf>2</inf>, UV/H<inf>2</inf>O<inf>2</inf>/TiO<inf>2</inf>, UV/TiO<inf>2</inf>/activated carbon, photo-Fenton), radiolysis (e-Beam, ⁶⁰Co, ¹³⁷Cs. Additives used: H<inf>2</inf>O<inf>2</inf>, SO32-, HCO3-, CH<inf>3</inf>OH, CO32-, or NO3-), and electrochemical processes (Electrooxidation without and with active chlorine generation). The effect of these treatments on pharmaceutical compounds and the advantages and disadvantages of different methodologies used were described. The most important parameters of the above water treatment systems (experimental conditions, removal yield, pharmaceutical compound mineralization, TOC removal, toxicity evolution) were indicated. The key publications on pharmaceutical removal from water were summarized. © 2013 Elsevier Ltd.

Rivers, M. L., et al. (2019). "Quantification is more than counting: Actions required to accurately quantify and report isolated marine microplastics." Marine Pollution Bulletin **139**: 100-104.

Research on marine microplastics continues to increase in popularity, with a large number of studies being published every year. However, with this plethora of research comes the need for a standardised approach to quantification and analysis procedures in order to produce comparative assessments. Using data collected from neuston nets in 2016, parameters for quantifying microplastics were compared. Surface area was the most accurate parameter to describe plastic size and should be used to describe plastic quantity (per km² or m³), alongside abundance. Of the two most commonly used methods for calculating plastic concentration (flowmeter and ship's log), ship's log provided consistently smaller abundances, with the exception of one sample, calling for a standardisation in the techniques and measurements used to quantify floating microplastics.

Ro, K. S., et al. (2014). "Co-pyrolysis of swine manure with agricultural plastic waste: Laboratory-scale study." Waste Management **34**(8): 1520-1528.

Manure-derived biochar is the solid product resulting from pyrolysis of animal manures. It has considerable potential both to improve soil quality with high levels of nutrients and to reduce contaminants in water and soil. However, the combustible gas produced from manure pyrolysis generally does not provide enough energy to sustain the pyrolysis process. Supplementing this process may be achieved with spent agricultural plastic films; these feedstocks have large amounts of available energy. Plastic films are often used in soil fumigation. They are usually disposed in landfills, which is wasteful, expensive, and environmentally unsustainable. The objective of this work was to investigate both the energetics of co-pyrolyzing swine solids with spent plastic mulch films (SPM) and the characteristics of its gas, liquid, and solid byproducts. The heating value of the product gas from co-pyrolysis was found to be much higher than that of natural gas; furthermore, the gas had no detectable toxic fumigants. Energetically, sustaining pyrolysis of the swine solids through the energy of the product gas could be achieved by co-pyrolyzing dewatered swine solids (25%m/m) with just 10% SPM. If more than 10% SPM is used, the co-pyrolysis would generate surplus energy which could be used for power generation. Biochars produced from co-pyrolyzing SPM and swine solid were similar to swine solid alone based on the surface area and the ¹H NMR spectra. The results of this study demonstrated the potential of using pyrolysis technology to manage two prominent agricultural waste streams (SPM and swine solids) while producing value-added biochar and a power source that could be used for local farm operations. © 2014.

Robards, M. D., et al. (1995). "Increasing Frequency of Plastic Particles Ingested by Seabirds in the Subarctic North Pacific." Marine Pollution Bulletin **30**(2): 151.

Stomach samples of 1799 seabirds comprising 24 species were collected over the period 198890 at seven sites in Alaska ranging from Agattu to Prince William Sound. The plastic particles were counted, weighed, and classified according to color, size, shape, and type. Of the 24 species, 15 were found to contain plastic particles. Compared to similar data compiled in 196977, there was an increase in the number of species from 12 to 15, respectively. The number of plastic particles ingested by seabirds in 198890 varied widely among species and areas. However, the number of particles per bird increased significantly between studies. Of the particles examined in the 198890 study, the majority were of two types- pellets and user plastics-and ranged in size from 0.5 to 28 mm.

Roberto, M., et al. (2013). "Can we predict time to tumor progression in early colorectal cancer patients using ctcs count?" Annals of Oncology **4)**: iv25.

Background: Colorectal cancer is the second most common cause of cancer-related death in Europe. Although significant improvements in the primary surgical and chemotherapeutic treatment, it has been estimated that approximately 30% of colorectal cancer patients develop metastases and die. Haematogenous spreading of tumor cells is a pivotal step in the metastatic process. Circulating tumor cells (CTCs) have potential ability to enter the circulation, invade the target organs and subsequently form metastases. Data suggest that the CTCs count before treatment is an independent predictor of progression free survival (PFS) and overall survival (OS) in patients with metastatic colorectal cancer, meanwhile their prognostic role in patients with early disease is uncertain. Method(s): 76 patients with histological diagnosis of colorectal cancer were included in this study. Disease stage was classified according to modified Astler and Coller as follows: 24/76 (31.6%) stages A + B, 30/76 (39.5%) stage C and 22/76 (28.9%) stage D. 7.5 ml of peripheral blood was collected for CTCs evaluation before the start of treatment or follow up. Mononuclear cells were isolated using Ficoll-Paque density centrifugation. CTCs were isolated from mononuclear cells by immunomagnetic enrichment using anti- CD326/EpCAM microbeads (Miltenyi Biotec) according to the manufacturer's instructions. After, they were labeled for an epithelial marker such as CD326, for a nucleic acid dye such as DAPI, and for the leukocyte cell surface marker CD45 and then identified by immunofluorescence method as CD326 + DAPI + CD45- cells. A cut-off of >= 2 CTCs/7.5ml of blood was chosen for the definition of a positive test. Fisher exact test was used to compare frequency distribution of clinicopathologic findings according to CTCs count. A Kaplan-Meier method was applied for time to progression (TTP) curve. Result(s): Twenty-one out of 76 (38%) patients were CTCs + : 4/24 (16.7%), 6/30 (20%), 11/22 (50%) stage A + B, C and stage D respectively. 16/57 (28%) colon and 5/19 (26.3%) rectal cancers were CTCs+. The CTCs positivity showed a correlation with the disease stage (p = 0.01; Table1). At a median follow up of 46.5 months 31 (41%) patients experienced a tumor progression. 62% of the patients with CTCs+ showed tumor progression compared to 33% of those CTCs - (p = 0.03). Tumor progression was significantly correlated with several clinicopathologic features including CTCs (Table2). Time to progression got worse in CTCs positive patients (Figure1) Conclusion(s): This study confirms previous reports on negative prognostic role of the detection of CTCs in colorectal cancer. This was demonstrated in cases including both early and advanced stages of disease. The analysis of predictive role of CTCs treated patients is underway. (Figure Presented).

Roberts, P. A., et al. (2019). "Mathematical model predicts anti-adhesion-antibiotic-debridement combination therapies can clear an antibiotic resistant infection." PLoS Computational Biology **15 (7) (no pagination)**(e1007211).

As antimicrobial resistance increases, it is crucial to develop new treatment strategies to counter the emerging threat. In this paper, we consider combination therapies involving conventional antibiotics and debridement, coupled with a novel anti-adhesion therapy, and their use in the treatment of antimicrobial resistant burn wound infections. Our models predict that anti-adhesion-antibiotic-debridement combination therapies can eliminate a bacterial infection in cases where each treatment in isolation would fail. Antibiotics are assumed to have a bactericidal mode of action, killing bacteria, while debridement involves physically cleaning a wound (e.g. with a cloth); removing free bacteria. Anti-adhesion therapy can take a number of forms. Here we consider adhesion inhibitors consisting of polystyrene microbeads chemically coupled to a protein known as multivalent adhesion molecule 7, an adhesin which mediates the initial stages of attachment of many bacterial species to host cells. Adhesion inhibitors competitively inhibit bacteria from binding to host cells, thus rendering them susceptible to removal through debridement. An ordinary differential equation model is developed and the antibiotic-related parameters are fitted against new in vitro data gathered for the present study. The model is used to predict treatment outcomes and to suggest optimal treatment strategies.

Our model predicts that anti-adhesion and antibiotic therapies will combine synergistically, producing a combined effect which is often greater than the sum of their individual effects, and that anti-adhesion-antibiotic-debridement combination therapy will be more effective than any of the treatment strategies used in isolation. Further, the use of inhibitors significantly reduces the minimum dose of antibiotics required to eliminate an infection, reducing the chances that bacteria will develop increased resistance. Lastly, we use our model to suggest treatment regimens capable of eliminating bacterial infections within clinically relevant timescales. Copyright © 2019 Roberts et al.

Robertson, C. and M. J. Bissell (2017). "Cell motility in a basement membrane gel concentrates ECM around breast epithelial cells, a feature lost in malignant cells." Cancer Research. Conference: AACR Special Conference: Engineering and Physical Sciences in Oncology. United States **77**(Supplement 2).

Introduction: The basement membrane (BM) underlying epithelial cells plays a key role in regulating cell function and suppressing malignancy; loss of this layer of ECM proteins is a hallmark of invasive cancer. Using 3D extracellular matrix (ECM) gels, we sought to understand how this structure develops by comparing nonmalignant breast epithelial cells (BEC), which develop into polarized, growth arrested structures to malignant breast cancer cells (BCC), which form disorganized masses under the same conditions. These two cell types show different movement patterns in the ECM gels: BEC rotate around their center of mass in a process termed coherent angular motion, whereas BCC migrate randomly, with unknown consequences for assembly of ECM into a basement membrane-like layer. We investigated whether coherent angular motion could concentrate exogenous ECM into a BM like structure, and whether these changes were due to the physical forces applied by the cells on their microenvironment. Method(s): To determine if cells undergoing coherent angular motion were better able to concentrate exogenous ECM at their surface compared to malignant cells, single human BEC and BCC from the HMT3522 breast cancer progression series were cultured in fluorescent laminin rich ECM gels (LrECM; using BD Matrigel), and ECM density at the cell surface was measured during growth with confocal microscopy. To determine how motility translated into forces on the microenvironment, cells were embedded in lrECM labeled with a dilute suspension of fluorescent microbeads. Confocal microscopy was performed over the first several days of culture, and traction force microscopy was used to determine the magnitude and spatial pattern of forces applied by the cells. After 5-6 days of culture, cells stained to determine whether cells had developed into polarized structures. Result(s): Over the first several days of culture, non-malignant BEC rotated as a coherent mass. At 24 hours, labeled ECM proteins were observed to concentrate in a spherical shell on surface of rotating clusters of BEC, whereas malignant, non-rotating cell masses had lower levels of ECM at the surface of the mass and higher levels of ECM proteins between the cells. Traction patterns between rotating and non-rotating cell masses were observed to differ-cells undergoing random motility applied strains to the ECM along the line of invasion, whereas cells undergoing coherent angular motion showed shear strains at the cell surface and even inward tractions. Conclusion(s): Coherent angular motion appears to affect concentration of exogenous ECM by physically pulling ECM proteins into an organized shell at the cell surface as an early aspect of formation of a basement membrane-like ECM structure in mammary epithelial cells in culture whereas this process is defective in malignant cells undergoing random motility. Further investigation will determine whether this process of motility, physically altering ECM density, is seen during normal development.

Robidoux, J., et al. (2018). "Measuring red blood cell deformability using a microfluidic device: Development of an external standard based approach to reduce chip-to-chip variations." Transfusion **58 (Supplement 2)**: 205A.

Background/Case Studies: An impaired deformability of red blood cells (RBC) can be related to diseases or consequent to red cell concentrate (RCC) storage. A polydimethylsiloxane (PDMS) microfluidic device especially designed to reproduce RBC circulation in blood vessels was recently developed to assess RBC deformability. This single-use device is made of two inlets, two arrays of channels and a unique outlet. Flow rate measurements near the channel outlets correlates with RBC rheological properties. The analytical approach uses an external standard to account for chip-to-chip variations. This study aims at validating microbeads as an external standard to monitor RBC deformability during storage. Study Design/Method: A dye-doped carboxyl polystyrene microsphere (d = 1 +/- 0.05) solution was used as external standard in this study. The stock solution (DCCR004, BangLabs) was dispersed 1:20 in filtered phosphate buffered saline (PBS). Glycerol was added at 16% to match the average RBC flow rate previously recorded with the same microfluidic device on fresh RBC. Multiple hardware and software parameters were tested for their respective impacts on the performances of the analytical method (i.e. precision, accuracy), measured as the rate of occurrence of plugging events. To validate the external standard approach, three different external standard solutions were prepared (A, B and C) and tested using nine different chips in an experiment designed to evaluate the reproducibility of output results. The chip's left-hand side inlets were filled with standard A, while right-hand side inlets were filled with either standard A, B or C. The right/left flow rate ratios were used as the analytical output signal. RCC samples of different storage ages were analyzed using the external standard approach and compared with respect to their deformability. Results/Finding: Flow rates recorded for the left and right inlets were compared for each chip. The between-channels coefficient of variation (% C.V.) within the same chip was lower than 2 %, which demonstrates a high homogeneity in the channel mask used to fabricate PDMS chips. To evaluate the chip-to-chip manufacturing reproducibility, left inlets on each chip were filled standard A, and flow rates were compared. The % C.V. was <5 %, and was deemed within the acceptable range. Finally, there were no significant differences in recorded flow rates for standards A, B or C, and the overall flow rate for the external standard solution was determined at 0.270 +/- 0.011 nL/s (% C.V. = 4%), which was similar to flow rates observed for RCC samples in a previous study. Conclusion(s): Microfluidic methods are believed to be suitable for precise and sensitive RBC deformability analysis. The development of an appropriate external standard approach can be used to address chip-to-chip vari-ability, and the use of dye-doped carboxyl polystyrene microspheres has been found to be a reproducible method.

Robin, M., et al. (2019). "MEFV/miR-326 axis involvement in human macrophage polarization." Annals of the Rheumatic Diseases **78 (Supplement 1)**: A30-A31.

Introduction Familial Mediterranean fever (FMF) is an inherited autoinflammatory disease, characterized by acute selfresolving attacks of fever and serositis, which mainly prevails in populations around the Mediterranean sea. It is caused by mutations in the MEFV gene, which encodes the pyrin protein. The alteration of MEFV mRNA expression in monocytes is related to both genotype and phenotype of the disease, suggesting that the pathophysiology of FMF can be regulated on a quantitative defect of MEFV mRNA. Objectives Since microRNAs (miRNAs) are implicated in a number of diseases including FMF, the present study aimed at identifying miRNA regulators of MEFV expression involved in monocyte inflammatory response. Methods MiRWalk2.0 database was used to identify putative miRNA target sequences within the 3'-UTR mRNA of MEFV. Human primary CD14+ monocytes were sorted from peripheral blood of healthy donors using magnetic microbeads and differentiated into M1 or M2 macrophages following IFNgamma/ LPS or IL4/IL13 stimulation, respectively. Using RT-qPCR, M1/M2 polarization was validated by measuring the expression of prototypic M1 and M2 markers: the chemokine CXCL10 and the macrophage mannose receptor 1 (MRC1 also known as CD206), respectively, as well as the MEFV mRNA. We used loss-of-function method to evaluate the effect of candidate miRNA on CD14+ monocytes, i.e. its role on macrophages classical versus alternative polarization. IL-10 expression was quantified using ELISA. Results In silico analyses revealed that miR-326 targets putatively the 3'UTR mRNA of MEFV. miRNAs and mRNAs quantification in polarized macrophages showed that miR-326 is mainly expressed by the M2-type macrophages, and MEFV by the M1-type macrophages. Loss-of-function studies showed that neutralization of miR-326 in M2 macrophages induced the expression of MEFV and CXCL10 while reducing MRC1 expression level. Furthermore, enforced expression of miR-326 in M1 macrophages significantly repressed MEFV expression and induced the production of IL-10. Conclusions A miR-326/MEFV axis seems to be implicated in macrophage polarization and might explain the observed monocyte versatility in FMF.

Robin, R. S., et al. (2020). "Holistic assessment of microplastics in various coastal environmental matrices, southwest coast of India." Science of the Total Environment **703**: 134947.

Plastics in the marine environment are introduced through multiple pathways, and pose serious threats to aquatic biota. Recently microplastic pollution and its possible consequences in India have been recognized by the scientific community, however the extent of the crisis has not yet been quantified. The present study attempted to ascertain the abundance, distribution and characteristics of microplastics in coastal waters (14 locations), beach sediments (22 locations) and marine fishes (11 locations) from the state of Kerala, southwest coast of India. The results showed that the mean microplastic abundance was 1.25+/-0.88 particles/m³ in coastal waters and 40.7+/-33.2 particles/m² in beach sediments with higher concentrations in the southern coast of the state. The abundance of microplastics, mostly contributed by fragments, fibre/line and foam, in both coastal waters and beach sediments, were highly influenced by river runoff and proximity to urban agglomeration. Fourier Transform Infrared Spectroscopy-Attenuated Total Reflection (FTIR-ATR) revealed that polyethylene (PE) and polypropylene (PP) were the dominant polymers in the marine environment. The digestive tracts of 15 out of 70 commercially important fishes studied, contained 22 microplastic particles. Polyethylene (PE; 38.46%) followed by cellulose (CE; 23.08%), rayon (RY; 15.38%), polyester (PL; 15.38%) and polypropylene (PP; 7.69%) were the major contributors in the fish ingested microplastic composition. A broad range of heavy metals, metalloids and other elements that are potentially indicative of hazardous chemicals were present in microplastics collected from the beaches of Kerala. These results enhance our understanding on the sources, transport pathways and the associated environmental risks of microplastics to marine ecosystems.

Roccaro, R. M., et al. (2009). "MicroRNA changes occur in multiple myeloma cells in the context of bone marrow milieu." Blood. Conference: 51st Annual Meeting of the American Society of Hematology, ASH. New Orleans, LA United States. Conference Publication: **114**(22).

Background: We and Others have previously demonstrated that primary multiple myeloma (MM) cells are characterized by a specific microRNA (miRNA) signature compared to the related normal plasmacell counterpart; and that miRNAs play a crucial role in regulating MM pathogenesis. Nevertheless, miRNA changes that occur in MM cells in the context of the bone marrow microenvironment have not been previously examined. Therefore, characterization of miRNA profiling of MM cells in conjunction with bone marrow stromal cells (BMSCs) is important to better understand the underlying molecular changes that lead to initiation and progression of this disease. Method(s): We performed miRNA-expression-profiling of MM cell lines (MM.1S; RPMI8226) that were co-cultured with primary BMSCs obtained from 5 MM patients, using liquid phase Luminex microbead miRNA profiling (Luminex, Austin, TX). The expression patterns of unfiltered data were performed using unsupervised hierarchical clustering of samples, based on centroid linkage and 1-correlation distance metric, using dChip (www.dchip.org). To further define those miRNAs differentially expressed between groups (patients vs normal), the data were filtered on significance of differences using ANOVA test, ($P < 0.05$). Microbead-miRNA profiling data were validated data by stem-loop qRT-PCR. To identify specific predicted miRNA-targeted mRNAs, TargetScan, PicTar, and miRanda algorithms were used. Result(s): miRNA profiling of MM cells cultured with primary BMSCs (MM+BMSC system) differs from MM cells which were not grown in contact with primary BMSCs (MM cells alone). Specifically, we observed increased expression of miRNA-450, -432 -299-5p, -409-3p, -29b, -542-5p, -184, -517 -218, 128b, -142-5p and -211 ($P<0.05$) in MM cells obtained from the MM+BMSC system, compared to MM cells alone. Stem-loop qRT-PCR was performed on matched samples and showed expression patterns similar to those observed in miRNA analysis. Using algorithms commonly used to predict human miRNA gene targets (miRanda; TargetScan; PicTar), predicted targets of the increased miRNAs included negative regulators of NFkB, PI3K/Akt/mTOR, and MAPK/ERK signaling pathways, such as PTEN, KSR2, TWEAK, and DUSP; as well as tumor suppressors (MCC, TSSC1, TUSC1, FBW7, RHOBTB), pro-apoptotic factors and cyclin-dependent kinases inhibitors. These data demonstrate that bone marrow stromal cells exert a modulatory effect on miRNA profiling in MM cells, which results in promoting MM cell growth and reducing MM cell survival.

Roch, A., et al. (2019). "The paramagnetic properties of malaria pigment, hemozoin, yield clues to a low-cost system for its trapping and determination." Talanta **197**: 553-557.

The binding of malaria pigment, hemozoin, by a gradient magnetic field has been investigated in a manual trapping column system. Two types of magnetic filling have been tested to produce field gradients: nickel-plated steel wires, wrapped around a steel core, and superparamagnetic microbeads. The latter system allows an efficient trapping (>80%) of beta -hematin (a synthetic pigment with physical and paramagnetic properties analogous to those of hemozoin). Tests with a Plasmodium falciparum 3D7 culture indicate that hemozoin is similarly trapped. Off-line optical spectroscopy measurements present limited sensitivity as the hemozoin we detected from in vitro cultured parasites would correspond to only a theoretical 0.02% parasitemia (1000 parasites/ micro L). Further work needs to be undertaken to reduce this threshold to a practical detectability level. Based on these data, a magneto-chromatographic on-line system with reduced dead volumes is proposed as a possible low-cost instrument to be tested as a malaria diagnosis system.

Roch, S. and A. Brinker (2017). "Rapid and efficient method for the detection of microplastic in the gastrointestinal tract of fishes." Environmental Science & Technology **51**(8): 4522-4530.

The rising evidence of microplastic pollution impacts on aquatic organisms in both marine and freshwater ecosystems highlights a pressing need for adequate and comparable detection methods. Available tissue digestion protocols are time-consuming (>10 h) and/or require several procedural steps, during which materials can be lost and contaminants introduced. This novel approach comprises an accelerated digestion step using sodium hydroxide and nitric acid in combination to digest all organic material within 1 h plus an additional separation step using sodium iodide which can be used to reduce mineral residues in samples where necessary. This method yielded a microplastic recovery rate of >=95%, and all tested polymer types were recovered with only minor changes in weight, size, and color with the exception of polyamide. The method was also shown to be effective on field samples from two benthic freshwater fish species, revealing a microplastic burden comparable to that indicated in the literature. As a consequence, the present method saves time, minimizes the loss of material and the risk of contamination, and facilitates the identification of plastic particles and fibers, thus providing an efficient method to detect and quantify microplastics in the gastrointestinal tract of fishes.

Roch, S., et al. (2019). "A systematic study of the microplastic burden in freshwater fishes of south-western Germany - Are we searching at the right scale?" Science of the Total Environment **689**: 1001-1011.

In a comprehensive study of microplastic contamination in southern Germany, 1167 individual fish of 22 different species were sampled from 11 rivers and 6 lakes across the state. The microplastic burden of investigated fish was analyzed on the basis of habitat type, location, and a number of abiotic and biotic factors. A particle size distribution analysis of the detected microplastics was carried out. The results showed a relatively low plastic prevalence of 18.8%, with significant differences between rivers (20.6%) and lakes (16.5%). The number of ingested plastic particles ranged between 1 and 4 particles per fish. The majority of abiotic and biotic factors seem to play little or no role in the ingestion of microplastics, suggesting that in most cases uptake is passive or accidental. It is notable that piscivorous fish appeared significantly less burdened, suggesting a low transfer rate and no accumulation in the food web. However, size distribution analysis identified a power law growth fit in particle numbers at the smallest end of the distribution. This carries a worrying implication, that >95% of particles are likely to be smaller than 40 mum and thereby beyond the detection range of this and most other microplastic surveys conducted so far. When the frequency development of small particles is taken into account, the likely microplastic prevalence in the present study increases to 100%, with an average intensity of around 23 predominantly small particles per fish. A striking 70% of those particles would be smaller than 5 mum and therefore eligible for translocation into tissues, with critical implications for fish health and consumer exposure. This raises a question as to whether current estimates of microplastic burden in fishes generally might be overlooking a majority of potential contamination within the critical smaller particle size classes. Rocha, R. J. M., et al. (2020). "Do microplastics affect the zoanthid Zoanthus sociatus?" Science of the Total Environment **713**: 136659.

Microplastics (1 mum-5 mm), a ubiquitous and persistent marine pollutant, pose a severe threat to coral reefs when recently associated with physiological distress and increased diseases on corals. Studies conducted so far have only reported effects on scleractinian species. Knowledge about its effects on other corals (e.g. Order Zoantharia) remains uncovered, and responses at biochemical levels remain poorly documented. This study aimed to assess the potential effects induced by the presence of microplastics (1 and 10 mg L⁻¹ low-density polyethylene, LDPE MP, or polyvinyl chloride, PVC MP) in the tropical and subtropical cosmopolitan species Zoanthus sociatus (order Zoantharia. Anthozoa: Hexacorallia), at organism level (survival and behaviour), endosymbionts (photosynthetic efficiency) and the cellular level (oxidative stress, detoxification capacity and energy metabolism). In a short-term exposure (96 h), this species was more sensitive to PVC MP. The presence of this polymer at a concentration of 10 mg L⁻¹ caused a ten-fold higher adhesion to the coral epidermis, increased

photosynthetic efficiency, lipid peroxidation, and antioxidant defences; without, however, inducing energetic costs. Although the observed physiological and biochemical effects did not compromise Z. sociatus survival in the short term, it does not rule out potential long-term (cumulative) effects that could endanger this and other physiologically similar species that underlie coral reefs.

Rochman, C. M. (2013). "Plastics and Priority Pollutants: A Multiple Stressor in Aquatic Habitats." Environmental Science & Technology **47**(6): 2439-2440.

In this article the author discusses the environmental impact of plastics and priority pollutants on aquatic habitats. Topics include the harmful effects of plastic debris on aquatic organisms, including the physical hazards posed from entanglement, ingestion, and smothering, mechanisms that make small plastic debris hazardous, such as sorption of persistent organic pollutants (POPs), and several hazardous monomers that comprise plastics, such as polyvinyl chloride (PVC).

Rochman, C. M., et al. (2016). "Plastic debris and policy: Using current scientific understanding to invoke positive change." Environmental Toxicology and Chemistry **35**(7): 1617-1626.

Captain Charles Moore introduced the world to the "Great Pacific Garbage Patch" in the mid-1990s, and images of plastic debris in the oceans began to sweep the media. Since then, there has been increasing interest from scientists, the public, and policy makers regarding plastic debris in the environment. Today, there remains no doubt that plastic debris contaminates aquatic (marine and freshwater) habitats and animals globally. The growing scientific evidence demonstrates widespread contamination from plastic debris, and researchers are beginning to understand the sources, fate, and effects of the material. As new scientific understanding breeds new questions, scientists are working to fill data gaps regarding the fate and effects of plastic debris and the mechanisms that drive these processes. In parallel, policy makers are working to mitigate this contamination. The authors focus on what is known about plastic debris that is relevant to policy by reviewing some of the weight of evidence regarding contamination, fate, and effects of the material. Moreover, they highlight some examples of how science has already been used to inform policy change and mitigation and discuss opportunities for future linkages between science and policy to continue the relationship and contribute to effective solutions for plastic debris. Rochman, C. M., et al. (2013). "Long-term field measurement of sorption of organic contaminants to five types of plastic pellets: Implications for plastic marine debris." Environmental Science and Technology

47(3): 1646-1654.

Concerns regarding marine plastic pollution and its affinity for chemical pollutants led us to quantify relationships between different types of mass-produced plastic and organic contaminants in an urban bay. At five locations in San Diego Bay, CA, we measured sorption of polychlorinated biphenyls (PCBs) and polycyclic aromatic hydrocarbons (PAHs) throughout a 12-month period to the five most common types of mass-produced plastic: polyethylene terephthalate (PET), high-density polyethylene (HDPE), polyvinyl chloride (PVC), low-density polyethylene (LDPE), and polypropylene (PP). During this long-term field experiment, sorption rates and concentrations of PCBs and PAHs varied significantly among plastic types and among locations. Our data suggest that for PAHs and PCBs, PET and PVC reach equilibrium in the marine environment much faster than HDPE, LDPE, and PP. Most importantly, concentrations of PAHs and PCBs sorbed to HDPE, LDPE, and PP were consistently much greater than concentrations sorbed to PET and PVC. These data imply that products made from HDPE, LDPE, and PP pose a greater risk than products made from PET and PVC of concentrating these hazardous chemicals onto fragmented plastic debris ingested by marine animals. © 2012 American Chemical Society.

Rochman, C. M., et al. (2014). "Early warning signs of endocrine disruption in adult fish from the ingestion of polyethylene with and without sorbed chemical pollutants from the marine environment." Science of the Total Environment **493**: 656-661.

Plastic debris is associated with several chemical pollutants known to disrupt the functioning of the endocrine system. To determine if the exposure to plastic debris and associated chemicals promotes endocrine-disrupting effects in fish, we conducted a chronic two-month dietary exposure using Japanese medaka (Oryzias latipes) and environmentally relevant concentrations of microplastic (<1 mm) and associated chemicals. We exposed fish to three treatments: a no-plastic (i.e. negative control), virgin-plastic (i.e. virgin polyethylene pre-production pellets) and marine-plastic treatment (i.e. polyethylene pellets deployed in San Diego Bay, CA for 3 months). Altered gene expression was observed in male fish exposed to the marine-plastic treatment, whereas altered gene expression was observed in female fish exposed to both the marine- and virgin-plastic treatment. Significant down-regulation of choriogenin (Chg H) gene expression was observed in males and significant down-regulation of vitellogenin (Vtg I), Chg H and the estrogen receptor (ER alpha) gene expression was observed in females. In addition, histological observation revealed abnormal proliferation of germ cells in one male fish from the marine-plastic treatment. Overall, our study suggests that the ingestion of plastic debris at environmentally relevant concentrations may alter endocrine system function in adult fish and warrants further research.

Rochman, C. M., et al. (2014). "Polybrominated diphenyl ethers (PBDEs) in fish tissue may be an indicator of plastic contamination in marine habitats." Science of the Total Environment **476-477**: 622-633.

Abstract: The accumulation of plastic debris in pelagic habitats of the subtropical gyres is a global phenomenon of growing concern, particularly with regard to wildlife. When animals ingest plastic debris that is associated with chemical contaminants, they are at risk of bioaccumulating hazardous pollutants. We examined the relationship between the bioaccumulation of hazardous chemicals in myctophid fish associated with plastic debris and plastic contamination in remote and previously unmonitored pelagic habitats in the South

Atlantic Ocean. Using a published model, we defined three sampling zones where accumulated densities of plastic debris were predicted to differ. Contrary to model predictions, we found variable levels of plastic debris density across all stations within the sampling zones. Mesopelagic lanternfishes, sampled from each station and analyzed for bisphenol A (BPA), alkylphenols, alkylphenol ethoxylates, polychlorinated biphenyls (PCBs) and polybrominated diphenyl ethers (PBDEs), exhibited variability in contaminant levels, but this variability was not related to plastic debris density for most of the targeted compounds with the exception of PBDEs. We found that myctophid sampled at stations with greater plastic densities did have significantly larger concentrations of BDE#s 183 –209 in their tissues suggesting that higher brominated congeners of PBDEs, added to plastics as flame-retardants, are indicative of plastic contamination in the marine environment. Our results provide data on a previously unsampled pelagic gyre and highlight the challenges associated with characterizing plastic debris accumulation and associated risks to wildlife. Rochman, C. M., et al. (2017). "Direct and indirect effects of different types of microplastics on freshwater prey (Corbicula fluminea) and their predator (Acipenser transmontanus)." PLoS ONE **12**(11).
We examined whether environmentally relevant concentrations of different types of microplastics, with or without PCBs, directly affect freshwater prey and indirectly affect their predators. Asian clams (Corbicula fluminea) were exposed to environmentally relevant concentrations of polyethylene terephthalate (PET), polyethylene, polyvinylchloride (PVC) or polystyrene with and without polychlorinated biphenyls (PCBs) for 28 days. Their predators, white sturgeon (Acipenser transmontanus), were exposed to clams from each treatment for 28 days. In both species, we examined bioaccumulation of PCBs and effects (i.e., immunohistochemistry, histology, behavior, condition, mortality) across several levels of biological organization. PCBs were not detected in prey or predator, and thus differences in bioaccumulation of PCBs among polymers and biomagnification in predators could not be measured. One of the main objectives of this study was to test the hypothesis that bioaccumulation of PCBs would differ among polymer types. Because we could not answer this question experimentally, a bioaccumulation model was run and predicted that concentrations of PCBs in clams exposed to polyethylene and polystyrene would be greater than PET and PVC. Observed effects, although subtle, seemed to be due to microplastics rather than PCBs alone. For example, histopathology showed tubular dilation in clams exposed to microplastics with PCBs, with only mild effects in clams exposed to PCBs alone.

Rodale, R. (1989). "ORGANIC LIVING." Organic Gardening (08973792) **36**(2): 23-24.
Discusses the growth of organic gardening in the United States. Severity of the problem of plastic pollution; Increase in public support for recycling policies and plastic use; Number of states that require degradable plastics; Other laws and regulations that will make space for organic methods.

Rodiger, S., et al. (2011). "Fluorescence dye adsorption assay to quantify carboxyl groups on the surface of poly(methyl methacrylate) microbeads." Analytical Chemistry **83**(9): 3379-3385.

Microbead-based assays have evolved into powerful tools for the multiplex detection of biomolecules. Analytes are captured by DNA or protein capture molecules which are coupled on microbead surfaces. A homogeneous carboxylation of microbeads is essential for the optimal and reproducible coupling of capture molecules and thus a prerequisite for an optimal multiplex microbead-based assay performance. We developed a simple fluorescence dye adsorption assay for the description of microbead carboxylation and for the prediction of coupling successes of capture molecules. Using the fluorescence dye SYTO-62 it is possible to quantify the degree of carboxylation of poly(methyl methacrylate) (PMMA) microbeads within 1 h in a multiplex format by fluorescence microscopy or flow cytometry. Compared to conventional bulk assays which only provide an average degree of carboxylation the main advantage of the SYTO-62 assay is the single microbead analysis and therefore the description of the qualitative distribution of carboxylation in microbead populations. The SYTO-62 assay is sensitive enough to even determine weak carboxylation. Also, the quality of microbeads can be evaluated. To our knowledge this is the first report which applies a reversible noncovalent fluorescent dye adsorption assay to quantify the degree of carboxylation on surfaces.

Rodrigo, J., et al. (1997). "Starch determination in plant tissues using a computerized image analysis system." Physiologia Plantarum **99**(1): 105-110.

An image analysis system attached to a microscope developed to detect quantitative variations in starch in particular tissues or cells is presented. The procedure is based on the measurement of the optical density of black and white images obtained from the microscope. The system was used successfully to study the differences in starch content of sections from pistillar structures in apricots cv. Moniqui. Two staining methods, I₂KI (potassium iodide-iodine) and PAS (periodic acid Schiff's reagent), and two embedding techniques, paraffin and JB4 plastic resin, were compared. The best results were obtained using I₂KI-stained sections of paraffin-embedded material. Since the procedures used are non-destructive for the tissues studied, additional information can be obtained, on the same section, by the subsequent use of additional stains.

Rodrigo, P. J., et al. (2006). "GPC-based optical micromanipulation in 3D real-time using a single spatial light modulator." Optics Express **14**(26): 13107-13112.

Using a novel dual-beam readout with the generalized phase contrast (GPC) method, a multiple-beam 3D real-time micromanipulation system requiring only one spatial light modulator (SLM) has been realized. A theoretical framework for the new GPC scheme with two parallel illumination beams is presented and corroborated with an experimental demonstration. Three-dimensional arrays of polystyrene microbeads were assembled in the newly described system. The use of air immersion objective lenses with GPC-based optical trapping allowed the simultaneous viewing of the assemblies in two orthogonal bright-field imaging perspectives.

Rodrigues, A., et al. (2019). "Colonisation of plastic pellets (nurdles) by E. coli at public bathing beaches." Marine Pollution Bulletin **139**: 376-380.

The hard surface of waterborne plastic provides an ideal environment for the formation of biofilm by opportunistic microbial colonisers, and could facilitate a novel means of dispersal for microorganisms across coastal and marine environments. Biofilms that colonise the so-called 'plastisphere' could also be a reservoir for faecal indicator organisms (FIOs), such as Escherichia coli, or pathogenic bacteria such as species of Vibrio. Therefore, the aim of this study was to map the spatial distribution of beach-cast plastic resin pellets (nurdles) at five public bathing beaches, and quantify their colonisation by E. coli and Vibrio spp. Nurdles were heterogeneously

distributed along the high tide mark at all five beaches, and each beach contained nurdles that were colonised by E. coli and Vibrio spp. Knowledge of E. coli colonisation and persistence on nurdles should now be used to inform coastal managers about the additional risks associated with plastic debris.

Rodrigues, J. P., et al. (2019). "Significance of interactions between microplastics and POPs in the marine environment: A critical overview." TrAC - Trends in Analytical Chemistry **111**: 252-260.

The presence of plastic debris in the ocean is increasing and several effects in the marine environment have been reported. A great number of studies have demonstrated that microplastics (MPs) adsorb organic compounds concentrating them several orders of magnitude than the levels found in their surrounding environment, therefore they could be potential vectors of these contaminants to biota. However, a consensus on MPs as vectors of persistent organic pollutants (POPs) has not been reached since are opposing views among different researchers on this topic. However, all agree that more extensive studies are needed to clarify this relationship. This review reunites information reporting the factors that drive the sorption dynamics between MPs and POPs, which essentially corresponds to polymer properties and surrounding environmental variables. Furthermore, this review highlights several supporting and rebuttal arguments in the direction to clear up the real hazard enforced by the presence of MPs in marine environments. Rodrigues, M. O., et al. (2018). "Spatial and temporal distribution of microplastics in water and sediments of a freshwater system (Antua River, Portugal)." Science of the Total Environment **633**: 1549-1559.

Microplastics (particles with a size<5mm), one of the most emerging aquatic pollutants, are of particular concern since they can reach high densities and interact with biotic and abiotic environment. The occurrence of microplastics in freshwater systems is less understood than in marine environment. Hence, the present study aims to provide new insights into microplastics abundances and distribution in Antua River (Portugal) by applying the isolation method of wet peroxide oxidation with addition of zinc chloride to water and sediment samples collected in March and October 2016, in three sampling sites. The abundance of microplastics in water ranged from 5 to 8.3mgm⁻³ or 58-193itemsm⁻³ in March and from 5.8-51.7mgm⁻³ or 71-1265itemsm⁻³ in October. In sediments, the abundance ranged from 13.5-52.7mgkg⁻¹ or 100-629itemskg⁻¹ in March and from 2.6-71.4mgkg⁻¹ or 18-514itemskg⁻¹ in October. The water and sediment samples with the greatest abundances were from Sao Joao da Madeira and Aguincheira, respectively. Spatio-temporal distribution showed different pattern according to methodological approaches, seasonal and hydrodynamic conditions and the proximity to urban/industry areas. Analysis of plastics by Fourier transform infrared spectroscopy underline polyethylene and polypropylene as the most common polymer types identified in this work. The low medium high oxidation ratio was 56:22:22 (%) in March and 61:31:8 (%) in October. Foams and fibers were the most abundant type in Sao Joao da Madeira, while fibers and fragments were the most abundant in Aguincheira and Estarreja in water and sediment samples, respectively. This study emphasizes the importance of rivers as carriage systems of microplastics. Further studies should be performed to identify point sources in order to mitigate the microplastics contamination in aquatic systems.

Rodrigues, M. O., et al. (2019). "Impacts of plastic products used in daily life on the environment and human health: What is known?" Environmental Toxicology & Pharmacology **72**: 103239.

Plastics are indispensable and persistent materials used in daily life that can be fragmented into micro- or nanoplastics. They are long polymer chains mixed with additives that can be toxic when in contact with distinct species. The toxicity can result from polymer matrix, additives, degradation products and adsorbed contaminants. Notwithstanding, there is still an immense gap of information concerning the individual and mixed impacts of plastics. Hence, in this study, we characterize the most common plastic materials widely used in our daily life by its polymer type and compile the environmental and human health hazards of these polymers including the impacts of monomers, additives, degradation products and adsorbed contaminants based on literature review. In summary, polyvinyl chloride is the most toxic polymer type used daily (monomer and additives); additives are more toxic than monomers to wildlife and humans; and the most toxic additives are benzene, phthalates and lead stabilisers.

Rodrigues, M. O., et al. (2018). "Spatial and temporal distribution of microplastics in water and sediments of a freshwater system (Antuã River, Portugal)." Science of the Total Environment **633**: 1549-1559.

Microplastics (particles with a size < 5 mm), one of the most emerging aquatic pollutants, are of particular concern since they can reach high densities and interact with biotic and abiotic environment. The occurrence of microplastics in freshwater systems is less understood than in marine environment. Hence, the present study aims to provide new insights into microplastics abundances and distribution in Antuã River (Portugal) by applying the isolation method of wet peroxide oxidation with addition of zinc chloride to water and sediment samples collected in March and October 2016, in three sampling sites. The abundance of microplastics in water ranged from 5 to 8.3 mg m^{-3} or 58–193 items m^{-3} in March and from 5.8–51.7 mg m^{-3} or 71–1265 items m^{-3} in October. In sediments, the abundance ranged from 13.5–52.7 mg kg^{-1} or 100–629 items kg^{-1} in March and from 2.6–71.4 mg kg^{-1} or 18–514 items kg^{-1} in October. The water and sediment samples with the greatest abundances were from São João da Madeira and Aguincheira, respectively. Spatio-temporal distribution showed different pattern according to methodological approaches, seasonal and hydrodynamic conditions and the proximity to urban/industry areas. Rodrigues, S. M., et al. (2019). "Microplastic contamination in an urban estuary: abundance and distribution of microplastics and fish larvae in the Douro estuary." Science of the Total Environment **659**: 1071-1081.

Estuaries are productive environments used by many fish as nursery grounds. The initial stages of fishes are highly vulnerable to (a)biotic factors, and anthropogenic pressures, influencing fish

larvae assemblages along the estuary. Microplastics (MPs <5 mm) are particularly dangerous to early life stages of fishes because their ingestion can induce gut blockage, limiting food intake or exposing organisms to contamination due to MPs capacity to absorb pollutants. Present work aimed to investigate the contamination of an urban impacted estuary (Douro estuary, NW Portugal) by MPs, and study the abundance and distribution of MPs and fish larvae in this estuary. Monthly sampling surveys were performed from December 2016 to December 2017, in nine stations along the estuary. Sub-surface planktonic horizontal trawls were performed to collect fish larvae and MPs. Planktonic samples were sorted, and fish larvae identified. MPs density was determined using a protocol optimized in our laboratory. A total of 1498 fish larvae belonging to 32 taxa were collected, with a mean density of 11.66 fish larvae 100 m⁻³. During the spring-summer period, it was observed the typical increase in the density and diversity of the larval assemblage. Diversity was generally low, with the high dominance of very few taxa, namely the common goby, Pomatoschistus microps. Different types of MPs were found, namely fibers, soft/hard plastic, colorful/transparent plastic, in a total of 2152 particles, with a mean density of 17.06 MPs 100 m⁻³. Hard MPs and fibers were the most predominant types, representing 83% of the total MPs collected. In some months the number of MPs surpassed the number of fish larvae, with an average ratio of 1.0 fish larvae:1.5 MPs. Such results are concerning, highlighting that a higher availability of MPs may facilitate their ingestion by fish and therefore increase possible impacts in these communities.

Rodrigues, S. M., et al. (2019). "Adaptation of a laboratory protocol to quantity microplastics contamination in estuarine waters." MethodsX **6**: 740-749.

One of the most used protocols to extract and quantify MPs is NOAA protocol in aquatic environments. However, there is still no standardized method to extract and quantify MPs in estuarine waters. The aim of this work was to adapt the NOAA protocol to quantify microplastics in estuarine water and provide all the details and changes to improve the efficiency of the method. For that, four types of plastic (PE-LD; PET; PA; PE-HD) were used in artificial samples to test all the steps of the protocol. Several criteria were tested, namely: (i) quantities of H₂O₂ used for organic matter degradation; (ii) temperatures of drying samples; and (iii) density separation efficacy. With the proposed modifications, the microplastics extraction were above 90%, regardless the type of plastic, with PE-LD reaching 100% of efficiency. The new adapted protocol that we propose will allow a better efficiency in extraction and quantification of microplastics in samples from estuarine environments. *Four different types of plastic (PE-LD; PET; PA; PE-HD) were used to test the efficiency of the protocol*Details as the ideal quantity of H₂O₂, temperature and exact quantity of NaCl were tested and defined during the experiments*Efficiency of the microplastics extraction were above 90.

Rodríguez, A., et al. (2018). "Seabird plastic ingestion differs among collection methods: Examples from the short-tailed shearwater." Environmental Pollution **243**: 1750-1757.

Despite the increase of literature on seabird plastic ingestion in recent years, few studies have assessed how plastic loads vary according to different sampling methods. Most studies use necropsies of seabirds with a natural cause of death, e.g. beached or predated, to determine plastic loads and monitor marine debris. Sampling naturally dead seabirds may be biased as they have perished because of their intrinsic factors, e.g. poor body condition, high parasite loads, sickness or predation, affecting estimates of plastic loads. However, seabirds killed accidentally may be more representative of the population. Here, we used the short-tailed shearwater Ardenna tenuirostris to test different sampling methods: naturally beached fledglings and accidentally road-killed fledglings after being attracted and grounded by artificial lights. We compared plastic load, body condition, and feeding strategies (through using feathers' δ 13C and δ 15N isotope niche) between beached and road-killed fledglings. Beached birds showed higher plastic loads, poorer body condition and reduced isotopic variability, suggesting that this group is not a representative subsample of the whole cohort of the fledgling population. Our results might have implications for long-term monitoring programs of seabird plastic ingestion. Monitoring plastic debris through beached birds could overestimate plastic ingestion by the entire population. We encourage the establishment of refined monitoring programs using fledglings grounded by light pollution if available. These samples focus on known cohorts from the same population. The fledgling plastic loads are transferred from parents during parental feeding, accumulating during the chick-rearing period. Thus, these fledglings provide a higher and valuable temporal resolution, which is more useful and informative than unknown life history of beached birds. Graphical abstract Image 1 Highlights • Beached short-tailed shearwaters showed poorer condition and lower isotopic variability than road-killed ones. • Beached short-tailed shearwaters showed higher plastic loads than road-killed ones. • Plastic loads of beached fledglings are not representative of the fledgling population. • Light-induced shearwaters can be used as a control for the suitability of stranded birds. • Light-induced mortality provides additional samples for marine debris monitoring. Beached short-tailed shearwaters had higher plastic loads, poorer condition and reduced isotopic variability than road-killed individuals, showing that samples from beached seabirds can overestimate and mislead plastic ingestion monitoring studies. Rodriguez, A., et al. (2012). "High prevalence of parental delivery of plastic debris in Cory's shearwaters (Calonectris diomedea)." Marine Pollution Bulletin **64**(10): 2219-2223.

Plastic ingestion by adult Procellariiformes has been widely recorded, but few studies have evaluated intergenerational transfer. We assessed the prevalence of plastic particles, as well as their basic characteristics, in the gut content of dead Cory's shearwater fledglings stranded by light pollution on Canary Islands. Eighty-three percent of birds were affected, containing on average 8.0 plastic pieces per bird. The average plastic weight per bird was low (2.97+or-3.97 mg) compared with other petrel species. We found no relationships between plastic loads and body condition or body size, but negative effects may be hidden or delayed. We propose to use the fledglings stranded by light pollution to carry out more precise studies to understand the potential hidden costs of plastic ingestion; and to monitor in a long-term the marine debris to develop management actions for the control of pollution at the marine environment.

Rodriguez, A. E., et al. (2012). "Molecular characterization of chronic lymphocytic leukemia patients with a high number of losses in 13q14." Blood. Conference: 54th Annual Meeting of the American Society of Hematology, ASH **120**(21).

Deletion at 13q14 (13q) is the most common genomic aberration in CLL. It is present in more than 50% of cases, and is the sole documented cytogenetic abnormality in 36% of the patients. These latter cases are known to have a more favorable clinical course. However, recent data from our group and others, suggest that patients with CLL and 13q deletion as the only FISH

abnormality could have a different outcome depending on the number of cells displaying this aberration. Thus CLL patients with a high number of 13q cells usually had both shorter overall survival and shorter time to first therapy. However, to the best of our knowledge the molecular characteristics of these patients have not been so far analyzed in detail. A total of 102 samples were selected for the study, 32 of which served as a validation cohort. A complete immunophenotypic analysis by flow cytometry and FISH studies were carried out in all cases. The median age was 68 years (range, 35 to 90 years). For the purpose of the study, only samples with one cytogenetic abnormality were included. For the gene expression profile analysis, according to our previous results, two groups of patients with 13q were compared: those in whom 80% or more of cells showed 13q (13qH) and those in whom fewer than 80% of cells showed 13q losses (13qL). The distribution of cases in the study cohort was: 13qH (n=25; 36%), 13qL (n=27; 39%), normal FISH (nCLL, n=8; 11%) and 17p/11q (n= 10; 14%); and in the validation cohort: 13qH (n=7; 22%), 13qL (n=11; 34%) and nCLL (n=9; 28%). Peripheral blood mononuclear cells (PBMCs) were isolated from fresh peripheral blood samples using Ficoll gradient, snapfrozen and stored at 80degreeC. For the validation cohort, CD19positive B cells were purified by magnetically activated cell sorting (MACS) CD19 MicroBeads resulting in a >98% purity, as analyzed by flow cytometry. CD19positive normal B cells from peripheral blood of five healthy donors served as controls. All samples were hybridized with the Affymetrix Human Exon arrays 1.0 ST. A total of 3 450 genes significantly distinguished 13qH from 13qL patients, defining the 13qH signature. To determine the biological significance of the deregulated genes, a further analysis was carried out, revealing that apoptosis, BCR and NFkB signaling were the most significant affected pathways in 13qH CLL patients. Moreover, 13qH CLL patients were also characterized by a striking overrepresentation of deregulated miRNAs. A total of 15 miRNAs were deregulated in 13qH relative to 13qL patients. HsamiR155 was the most highly upregulated miRNA (Rfold=3.70), while hsamiR223 was the most significantly downregulated (Rfold=0.10). The posttranscriptional regulatory network of miRNA and genes in CLL patients with more than 80% of 13q cells was carried out by analyzing the miRNAmRNA relationships and the pathway analysis demonstrated that B cell receptor signaling, PI3K signaling and NFkB signaling were among the most strongly affected pathways in 13qH patients, highlighting the importance of miRNA regulation in CLL. The influence of other factors with prognostic relevance in CLL, such as IGVH mutational status, was discarded. We also analyzed the gene signature of CLL high risk cytogenetic subgroups in comparison with 13q patients. Surprisingly, our results suggest that some of the biological characteristics of 13qH CLL patients were similar to those of highrisk cytogenetic subgroups, since they share the deregulation of several key signaling pathways. To validate the differences observed between the subgroups of 13q CLL patients and get a visualization of these, we applied the Principal Component Analysis (PCA) in an independent series of patients. The expression pattern of CD19+ cells from CLL patients was notably different from the gene expression profile of CD19+ cells from healthy donors. Thus, CLL patients with a high number of 13q cells can be differentiated based on their expression profile. By contrast, the gene expression of B lymphocytes from 13qL and normal FISH subgroups was similar. Therefore, this s udy provides new evidences regarding the heterogeneity of 13q deletion in CLL patients. Thus an overexpression of BCR and NFKB patways and as well as a deregulation of the balance between the proliferative and apoptotic signals and miRNA expression are involved in cases with higher percentages of 13q- cells.

Rodríguez-Hernández, A. G., et al. (2019). "A novel and simple method for polyethylene terephthalate (PET) nanoparticle production." Environmental Science: Nano **6**(7): 2031-2036.

Common plastics, such as polyethylene terephthalate (PET), as pollutants in aquatic

environments in the form of micro/nanoparticles are of environmental and public health concern. Information on the impact of plastic nanoparticles on the environment and on public health is still scarce, thus an important research effort is needed. The lack of enough amounts of nanoparticles to perform these research studies is limiting the understanding of the effects of nanoplastics on the environment and public health. Here, a simple, fast and efficient method to produce PET nanoparticles to be used as nanoplastic models is described. Fine chips of PET were dissolved in a concentrated trifluoroacetic acid solution and reprecipitated as nanoparticles (50–200 nm) by the addition of aqueous solutions of the same solvent. The importance of this method for the production of PET nanoparticles is highly relevant since it could facilitate the PET nanoparticle availability to perform such imperative toxicological studies. The obtained nanosized particles were characterized and their effective ability for cell internalization in human macrophage cells was evaluated.

Rodriguez-Lozano, A. L., et al. (2015). "Antibodies to histocompatibility antigens in juvenile systemic lupus erythematosus patients." Arthritis and Rheumatology. Conference: American College of Rheumatology/Association of Rheumatology Health Professionals Annual Scientific Meeting, ACR/ARHP **67**(SUPPL. 10).

Background/Purpose: Microchimerism with HLA mismatched maternal cells can be readily demonstrated in normal individuals and is now established as a normal biological phenomenon. Pediatric SLE patients have decreased levels of blood maternal microchimerism, suggesting a loss of T-cell tolerance to maternal antigens. Because maternal MHC molecules are the most likely targets of the T-cell hyperactivity, we reasoned that pediatric lupus patients may also have B cell reactivity to maternal MHC. Method(s): To test for loss of B-cell tolerance to maternal MHC, we measured IgG specific for HLA Class II antigens in plasma samples from children who have never been pregnant: 81 with SLE (49 (60%) with active disease, SLEDAI >4), 20 patients (24%) with nephritis. Control groups consisted of 16 systemic sclerosis (SSc), 20 juvenile idiopathic arthritis (JIA), and 78 healthy children. OneLambda, Inc. LABScreen microbeads coated with purified Class II HLA antigens were used to detect specific IgG. Data acquisition and analysis was performed using LABScanTM Statistical analysis was performed using SPSS version 16.0, Mann Whitney was used to determine median difference between groups, Correlations were tested by Spearman and associations by Likelihood ratios or Fisher Exact Test, ROC curves were constructed to test for the specificity of HLAab for lupus diagnosis and active lupus. Result(s): All Subjects: The median values of 90% of specific HLAab were high in patients with SLE compared to controls. HLAab levels in JIA and SSc were similar to controls. Among the SLE patients, 27 out of 77 HLA antigens were increased in patients with active disease compared to those without active disease. Of these, a significant association was found with disease activity in 15 HLAab (see Table 1). ROC curves demonstrated specificity for active SLE in 4 HLAab, with AUC >.700: DQA1*0301-DQB1*0302 (AUC .758, 95% CI 0.66-.86, p<0.001), DQA1*0301-DQB1*0303, (AUC 0.76, 95% CI 0.66-.87, p<0.001), DQA1*0501-DQB1*0201 (AUC 0.73, 95% CI 0.61-.84, P=0.001, and DPB1*1401=DPA1*0201 (AUC 0.72, 95% CI 0.6-.84], P=0.001. Ten HLAab demonstrated a significant median difference between those with and without nephritis, and seven of those showed significant associations (Table 1). Conclusion(s): Children with SLE have high values and a considerable number of anti-HLA class II autoantibodies which seem to be specific, related with disease activity and to a lesser extent with nephritis. If confirmed, HLAab could represent useful biomarkers for disease activity. (Table Presented).

Rodriguez-Munoz, Y., et al. (2009). "Expression imbalance of Angiopoietin/Tie2 system in monocytes and

monocyte derived cells from chronic hepatitis C patients." Hepatology **4)**: 889A.

INTRODUCTION: Chronic hepatitis C (CHC) is a progressive inflammatory liver disease with an increased risk of cirrhosis and hepatocellular carcinoma (HCC) development. Angiogenesis, or the formation of new blood vessels from pre-existing ones, has been described as a pathological phenomenon associated with HCC and other inflammatory liver diseases. Some evidences exist regarding the central role of the Angiopoietin/Tie2 system in the regulation of both, angiogenesis and inflammation. Moreover, it has been recently established the proangiogenic and proinflammatory ability of Tie-2 expressing monocytes (TEMs). The AIM of this study was to analyze the expression of Angiopoietin/Tie-2 system in monocytes and in monocyte-derived macrophages (MDM) or in monocyte-derived dendritic cells (MD-DCs) from CHC patients. MATERIAL AND METHODS: Peripheral blood mononuclear cells (PBMCs) were purified from 10 CHC patients and 10 healthy donors by Ficoll density centrifugation. Monocytes were isolated from PBMCs by positive selection using CD14 microbeads following manufacturer's instructions. The obtained cells were cultured at 1x106 cell/ml density in RPMI medium supplemented with 10% fetal calf serum and 1% penicillin-streptomicin. The differentiation of monocytes to MDMs or MD-DCs was induced by the culture of CD14+ cells with granulocyte macrophage colony-stimulating factor (GMCS-F) or with GMCS-F and IL-4, respectively. MD-DCs were stimulated with LPS to obtain mature MD-DCs. The Tie-2 expression was measured in monocytes, macrophages and inmature/mature MD-DCs by flow cytometry and their Ang-1 and Ang-2 release was evaluated in the culture supernatants by ELISA. RESULT(S): The expression of Ang-2 was notably higher in monocytes as well as in all cell types derived from the monocytes of CHC patients, which resulted statistically significant in macrophages and in mature MD-DCs. On the contrary, the expression of Ang-1 was reduced in the supernatants of all CHC derived monocytic cells. These phenomena were jointed to a significant decrease of Tie-2 expression in mature MD-DCs from CHC patients. CONCLUSION(S): The observed expression imbalance of Angiopoietin/Tie-2 system in monocytes and monocyte-derived cells from CHC patients could account for the inflammatory and angiogenic disorders related to this chronic liver disease. Learning more about the regulation of Angiopoietin/Tie-2 system could be helpful for the design of new therapeutic strategies.

Rodriguez-Munoz, Y., et al. (2011). "Proinflammatory and proangiogenic monocyte subsets are increased in peripheral blood of patients with chronic hepatitis C." Journal of Hepatology **1)**: S124-S125.

Introduction: Hepatitis C virus infection evolves into chronic progressive liver disease due to ineffective immune response that fails to eradicate the virus. Monocytes constitute a heterogeneous group of myeloid cells that mediates both the innate and adaptive immune response. In addition to the pro-inflammatory properties described for CD16+ monocytes, it has recently been established the robust pro-angiogenic potential of the Tie-2+ subgroup of monocytes (TEMs). Our aim was to analyze these different monocyte subsets, particularly TEMs, in the blood of chronic hepatitis C (CHC) patients to examine their role in the disease progression and in the response to antiviral therapies. Material(s) and Method(s): Peripheral blood mononuclear cells were purified from 21 healthy donors and 39 CHC patients by Ficoll density centrifugation. Patients were divided in 3 groups based on their treatment and response: naive, responders and non-responders. Monocytes, isolated by anti-CD14 coupled magnetic microbeads, were cultured at 1x10⁶ cell/ml in complete RPMI medium during 24 hours. Subsequently, they were both individually and simultaneously characterized by flow cytometry with anti-CD14, anti-CD16 and anti-Tie-2 monoclonal antibodies conjugated to different fluorochromes. Angiopoietin-1 (Ang-1), Angiopoietin-2 (Ang-2) and other proangiogenic factors (Angiogenin, EGF, B-FGF, HB-EGF, HGF, Leptin, PDGF-BB, PlGF and VEGF) expression was evaluated in monocytes supernatants by ELISA and immunofluorescence protein arrays. Result(s): CD16 and Tie-2 expressing monocyte percentages were notably enhanced in the blood of CHC patients ($p < 0.005$ and $p < 0.05$, respectively). Monocytes dual immunostaining showed the same results, independently of the expression levels of the other simultaneously analyzed marker (CD16 or Tie2). Related to treatment, TEMs proportion was significantly higher in naive patients compared to non-responders and in non-responders versus responders ($p < 0.05$, both). Ang-1 expression was lower in supernatants of peripheral monocytes from CHC patients ($p < 0.05$), whereas other pro-angiogenic factors such as Angiogenin, B-FGF, Leptin, PDGF-BB and PIGF, were significantly up-regulated. Conclusion(s): The significant enrichment of pro-inflammatory and pro-angiogenic monocyte subsets in the peripheral blood of CHC patients and the imbalanced release of multiple angiogenic factors by these cells may account for the pathologic phenomena frequently related to chronic HCV infection such as angiogenesis, fibrosis and hepatocarcinoma development.

Rodriguez-Seijo, A., et al. (2018). "Oxidative stress, energy metabolism and molecular responses of earthworms (Eisenia fetida) exposed to low-density polyethylene microplastics." Environmental Science and Pollution Research **25**(33): 33599-33610.

Soils are both a sink and a pathway of plastic wastes, but there is a great lack of knowledge regarding their impacts on soil biota. To tackle the mechanisms of toxicity of these contaminants to soil invertebrates, earthworms (Eisenia fetida Savigny, 1826) were exposed during 28 days to different concentrations of low-density polyethylene microplastics (62, 125, 250, 500 and 1000 mg MPs kg⁻¹ soil_{dw}) with sizes ranging between 250 and 1000 micro m, in an artificial soil. The ecotoxicological responses were evaluated by analysing various oxidative stress biomarkers (catalase, glutathione S-transferase and thiobarbituric acid reactive substances), a biomarker of energy metabolism (lactate dehydrogenase) and overall organism molecular changes by Fourier transform infrared spectrometry (FTIR) and nuclear magnetic resonance (NMR) analyses. Significant effects resulting from an unbalanced oxidative stress system, expressed in terms of thiobarbituric acid reactive substances levels were recorded on earthworms exposed at the three highest concentrations tested. Despite that, no significant changes were recorded on the molecular profiles of earthworms by FTIR-ATR. NMR analysis pointed out for differences from the control, only for earthworms exposed to the lowest concentration of MPs. Considering that stress responses are complex, and involve multiple mechanisms, a cluster analysis taking into account all the parameters assessed, clearly identified two groups of earthworms separated by the concentration of 250 mg MPs kg⁻¹ soil_{dw}, above each meaningful effects were recorded.

Rodríguez-Seijo, A., et al. (2018). "Oxidative stress, energy metabolism and molecular responses of earthworms (<i>Eisenia fetida</i>) exposed to low-density polyethylene microplastics." Environmental science and pollution research international **25**(33): 33599-33610.

Soils are both a sink and a pathway of plastic wastes, but there is a great lack of knowledge regarding their impacts on soil biota. To tackle the mechanisms of toxicity of these contaminants to soil invertebrates, earthworms (Eisenia fetida Savigny, 1826) were exposed during 28 days to different concentrations of low-density polyethylene microplastics (62, 125, 250, 500 and 1000 mg MPs kg^{-1} soildw) with sizes ranging between 250 and 1000 μm, in an artificial soil. The ecotoxicological responses were evaluated by analysing various oxidative stress biomarkers (catalase, glutathione S-transferase and thiobarbituric acid reactive substances), a biomarker of energy metabolism (lactate dehydrogenase) and overall organism molecular changes by Fourier transform infrared spectrometry (FTIR) and nuclear magnetic resonance (NMR) analyses.

Significant effects resulting from an unbalanced oxidative stress system, expressed in terms of thiobarbituric acid reactive substances levels were recorded on earthworms exposed at the three highest concentrations tested. Despite that, no significant changes were recorded on the molecular profiles of earthworms by FTIR-ATR. NMR analysis pointed out for differences from the control, only for earthworms exposed to the lowest concentration of MPs. Considering that stress responses are complex, and involve multiple mechanisms, a cluster analysis taking into account all the parameters assessed, clearly identified two groups of earthworms separated by the concentration of 250 mg MPs kg−1 soildw, above each meaningful effects were recorded.

Rodriguez-Seijo, A., et al. (2017). "Histopathological and molecular effects of microplastics in Eisenia andrei Bouche." Environmental Pollution **220**(Part A): 495-503.

The ocean has been assumed as the main sink of microplastics (MPs), however, soils may also receive MPs from different sources and through different pathways, which may affect the biota and their role in soil functions. To the best of our knowledge, only one study, until now, reported the effects of MPs on the survival and fitness of soil organisms (Lumbricus terrestris). In our study, epigeic earthworms, of the species E. andrei, were exposed to different concentrations of MPs (0, 62.5, 125, 250, 500 and 1000 mg/kg soil_{dw}) in an OECD artificial soil and tested for reproduction, survival and growth of adults, following a standard protocol. The size of the polyethylene MPs to which earthworms were exposed ranged between 250 and 1000 micro m. No significant effects were recorded on survival, number of juveniles and, in the final weight of adult earthworms after 28d of exposure, to the different concentrations of MPs. Nevertheless, FTIR-ATR of earthworms and histopathological analysis of the gut provided evidences of damages and immune system responses to MPs.

Rodríguez-Seijo, A., et al. (2019). "Low-density polyethylene microplastics as a source and carriers of agrochemicals to soil and earthworms." Environmental chemistry (Online) **16**(1): 8-17.

Abstract. Microplastics (MPs) are of environmental concern to marine ecosystems owing to the

evidence of their presence in and adverse effects on organisms, but studies to address this problem on soils and its biota are scarce. Several questions can arise related to this major environmental problem and its impact on terrestrial ecosystems, mainly, whether MPs can transport contaminants (e.g. pesticides) to the soil matrix and if they can be a carrier of pesticides to soil biota. To contribute to the understanding of these issues, earthworms (Eisenia fetida) were exposed for 14 days to soil containing two different sized MPs (5?mm and 0.25 µm-1?mm) that were either previously sprayed or not with chlorpyrifos (CPF). Acetylcholinesterase (AChE) activity and thiobarbituric acid reactive substances (TBARS) were measured to track the exposure of the earthworms to MPs, both non-sprayed and sprayed with CPF. The behaviour of the earthworms in the test containers and the movement of MPs in the soil were assessed. The concentration of CPF in soil at the end of the experiment differed between the treatments with MPs of different sizes (17.9?ng?g?1 and 2442?ng?g?1 for large and small MPs, respectively). Despite the ability of the MPs to release CPF to the soil, the earthworms avoided the contaminated MPs at the highest contaminant level. At a lower concentration of CPF (large MPs), the earthworms avoided the MPs, but the contact time with contaminated soil was higher, as shown by the enhanced level of TBARs and AChE inhibition. However, no evidence of MPs uptake was recorded, thus it was not demonstrated that MPs can be carriers of pesticides to earthworms.

Roellecke, K., et al. (2015). "Establishing modified human CYP4B1 as a novel suicide gene system for adoptive T-Cell therapies." Blood **126 (23)**: 5550.

Retargeting autologous T-cells to recognize tumor-associated antigens by genetic modifications with viral vectors that express either enhanced T-cell receptors (TCRs) or chimeric antigen receptors (CARs) has shown successful activity against B-cells malignancies. Equipping the transduced T-cell with a suicide gene can prevent potential safety problems as on-target off-target toxicity, off-target reactivity and cytokine-release syndrome (Casucci et al., 2015). The concept of a suicide gene has already been utilized to prevent a Graft-versus-host-disease (GvHD) following donor lymphocyte infusion (DLI). The first suicide gene system used in clinical phase I/II studies was the human Herpes simplex virus type 1 thymidine kinase with its prodrug ganciclovir that was used to control Graft-versus-host-disease following donor lymphocyte infusion (DLI) for leukemia relapse after allogeneic stem cell transplantation. More recent examples for suicide gene systems are icasp9, an inducible apoptosis switch with a synthetic dimerizer protein as prodrug, and CD20 with rituximab as a prodrug. We recently published a novel potential human suicide gene system by rendering the inactive P450 cytochrome CYP4B1 with 13 amino acid changes into the highly active CYP4B1P+12 in combination with 4-ipomeanol (4-IPO) (Wiek et al., 2015). 4-IPO is furan produced by sweet potatoes infected with the common mold Fusarium javanicum and has been identified as the major lung toxin causing lung edema in livestock (Wilson et al., 1970). A second natural occurring substance causing lung edema in horses is the major component of the Perilla frutenscens fruit oil called perilla ketone (PK) (Wilson et al., 1977). Importantly, the only difference between PK and 4-IPO is a methyl group at C5 in PK, where 4-IPO has a hydroxyl group. Therefore in this work, we tested the hypothesis whether PK could function as a potential new prodrug for the CYP4B1P+12 suicide gene. Initially we compared the cytotoxicity caused by PK and 4-IPO in CYP4B1P+12 transduced primary human T-cells from healthy donors. For these experiments, we used third generation lentiviral vectors with T2A sites to express the suicide gene in combination with a truncated version of the low affinity nerve growth factor receptor (DNGFR) as a selection marker for Miltenyi MACS microbeads. Through the selection process, we were able to enrich the suicide gene expressing T-cell population from 61+/-6.0% to >=95+/-1.8%. After selection, we

challenged the CYP4B1P+12 expressing T-cells with increasing concentrations (2.9-90 muM) of both substrates and analyzed the survival of the cells. After 24h, 65.8+/-5.26% of CYP4B1P+12 positive T-cells incubated with 2.9 muM 4-IPO were still alive, while incubation with 90 muM lead to only 17.5+/-1.45% living T-cells. In contrast, incubation with 2.9 muM PK resulted in only 16.02+/-1.08% living cells, while 90 muM PK induced cell death in 94.2+/-0.79% of cells. Next, we demonstrated that a lower concentration, 0.9 muM, already led to only 13.2+/-0.46% alive cells after 24h. Monitoring apoptosis in the transduced T-cells by flow cytometry demonstrated that incubation with 90 muM 4-IPO for 4h decreased the rate of transduced T-cells to only 87.4+/-2.89%, while 10h and 24h incubation resulted in 20.4+/-4.9% and 5.8+/-0.93% living annexinV-negative cells. In contrast, 2h incubation with only 9 muM PK led to 88.7+/-2.07%, 4h to 60.2+/-5.47% and 10h to only 5.5+/-1.85% living annexinV-negative T-cells. Incubation of the T-cells with 90 muM did not change these numbers. Hence, we were able show that PK is not only more potent as 4-IPO, it also proves to have a faster kinetic in inducing apoptosis. After these promising in vitro results of using PK as a novel more potent prodrug for the CYP4B1P+12 human suicide gene, we performed dose escalation studies of PK in mice with targeted disruption of the Cyp4b1 gene. Using up to 25 mg PK/kg mouse daily up for 3d did not induce any clinical symptoms in the Cyp4b1-/- animals, while Cyp4b1+/+ animals needed to be sacrificed 4h and 7h fter a single i.p. injection of 10 mg/kg or 5 mg/kg PK, respectively, due to severe respiratory distress. Results of in vivo studies analyzing the elimination of CYP4B1P+12 positive syngenic T-cells in Cyp4b1-/- mice after injection with either 4-IPO or PK will be finalized and presented at the meeting.

Rogers, K. R., et al. (1999). "Organophosphorus hydrolase-based assay for organophosphate pesticides." Biotechnology Progress **15**(3): 517-521.

We report a rapid and versatile organophosphorus hydrolase (OPH)-based method for measurement of organophosphates. This assay is based on a substrate-dependent change in pH at the local vicinity of the enzyme. The pH change is monitored using fluorescein isothiocyanate (FITC), which is covalently immobilized to the enzyme. This method employs the use of poly(methyl methacrylate) beads to which the FITC-labeled enzyme is adsorbed. Analytes were then measured using a microbead fluorescence analyzer. The dynamic concentration range for the assay extends from 25 to 400 &mgr;M for paraoxon with a detection limit of 8 &mgr;M. Organophosphorus insecticides measured using this technique included ethylparathion, methylparathion, dursban, fensulfothion, crotoxyphos, diazinon, mevinphos, dichlorvos, and coumaphos. This technique was used to measure coumaphos in biodegradation samples of cattle dip wastes and showed a high correlation (r2 = 0.998) to an HPLC method.

Roggenbuck, D. (2014). "Simultaneous screening and confirmation of autoantibodies associated with autoimmune vasculitis." Clinical Chemistry and Laboratory Medicine **52 (11)**: eA122.

The novel CytoBead technology combines autoantibody analysis by cell-based screening with the confirmation of corresponding autoantigen reactivities by microbead multiplexing using immunofluorescence technique (IFT) in one reaction environment. CytoBead ANCA allows the simultaneous detection of anti-neutrophil cytoplasmic antibodies (ANCA) on ethanol-fixed neutrophils for screening and confirmation thereof using proteinase 3 (PR3) and myeloperoxidase (MPO) coated microbeads. Furthermore, the detection of Goodpasture antibodies is integrated by adding glomerular basement membrane (GBM) coated microbeads. Anti-GBM autoantibodies occur in 10% of rapid progressive glomerulonephritis patients together with ANCA and are required for the differential serological diagnosis in routine diagnostics. This assay format can be interpreted with a standard fluorescence microscope

(having a FITC channel) for semi-quantitative analysis and with the automated interpretation system Aklides for quantitative testing. The performance of the CytoBead ANCA assay was investigated using sera of 666 individuals including 118 patients with ANCA-associated vasculitis, 162 healthy controls, 352 disease controls and 34 anti-GBM positive sera. Receiver operating characteristics and inter-rater agreements (kappa) were used to compare the results of novel CytoBead ANCA assay with routine autoantibody investigation. The comparison of classical ANCA screening with ANCA screening by the novel CytoBead ANCA assay showed good agreement (kappa = 0.73-0.83). The results of anti-PR3, anti-MPO, and anti-GBM detection by this novel method compared to anti-PR3-, anti-MPO as well as anti-GBM by ELISA revealed good to very good agreement (0.72,0.78,0.87; respectively). Consequently, CytoBead ANCA assay is an attractive alternative to classical time-consuming single parameter ANCA and anti-GBM antibody detection and is applicable for high throughput routine diagnostics.

Roh, S., et al. (2017). "3D Printing by Multiphase Silicone/Water Capillary Inks." Advanced Materials **29**(30).

3D printing of polymers is accomplished easily with thermoplastics as the extruded hot melt solidifies rapidly during the printing process. Printing with liquid polymer precursors is more challenging due to their longer curing times. One curable liquid polymer of specific interest is polydimethylsiloxane (PDMS). This study demonstrates a new efficient technique for 3D printing with PDMS by using a capillary suspension ink containing PDMS in the form of both precured microbeads and uncured liquid precursor, dispersed in water as continuous medium. The PDMS microbeads are held together in thixotropic granular paste by capillary attraction induced by the liquid precursor. These capillary suspensions possess high storage moduli and yield stresses that are needed for direct ink writing. They could be 3D printed and cured both in air and under water. The resulting PDMS structures are remarkably elastic, flexible, and extensible. As the ink is made of porous, biocompatible silicone that can be printed directly inside aqueous medium, it can be used in 3D printed biomedical products, or in applications such as direct printing of bioscaffolds on live tissue. This study demonstrates a number of examples using the high softness, elasticity, and resilience of these 3D printed structures.

Roitsch, S., et al. (2018). "Detection by flow cytometry of anti-neutrophil cytoplasmic antibodies in a novel approach based on neutrophil extracellular traps." Autoimmunity **51**(6): 288-296.

BACKGROUND: Anti-neutrophil-cytoplasmic antibodies (ANCA) are auto-antibodies directed against components of neutrophil granulocytes and may be found in various inflammatory conditions, like small-vessel vasculitis or ulcerative colitis (UC). Routine ANCA screening is performed on ethanol-fixed neutrophils using indirect immunofluorescence technique. Yet, how neutrophil granule proteins become available to immunologic presentation is a matter of debate. In recent years, various studies have shown that neutrophils are able to extrude their chromatin decorated with granular proteins as neutrophil extracelullar traps (NETs).

AIM: We hypothesized that (I) ANCA immunoreactivity may be found on NETs and (II) NETs may serve as a useful tool in a novel approach for ANCA detection.

METHODS: Sera from patients suffering from either ANCA-associated vasculitis (n = 10), UC (n = 30) or sera from patients without diagnosed ANCA-associated diseases (n = 20), respectively, were subjected to indirect immunofluorescence and a newly developed method to detect ANCA by flow cytometry employing microbead technology.

RESULTS: ANCA-related immunofluorescence was readily detectable on ethanol-fixed NETs, establishing NETs as a structure carrying ANCA target antigens. Moreover, we observed that neutrophils form NETs in response to microbeads and stick to the surface of these beads. Using these

NET-coated microbeads in flow cytometry, we were capable of reliably detecting p-ANCA, c-ANCA, and a-ANCA in tested patient sera. UC-related complex DNase-1-sensitive ANCA (NET-ANCA) antigens were also detected on NET-coated microbeads.
CONCLUSION: NET-coated microbeads may be commercially developed as a novel tool for automated ANCA screening assays using flow cytometry.

Roje, Ž., et al. (2019). "Synergistic effects of parabens and plastic nanoparticles on proliferation of human breast cancer cells." Archives of Industrial Hygiene & Toxicology / Arhiv za Higijenu Rada I Toksikologiju **70**(4): 310-314.

Many personal care products on the market contain endocrine disrupting chemicals, including parabens. Parabens are well known chemical additives used as preservatives. They have been found in mammary glands and breast cancer tissues. At the same time, the general public is increasingly exposed to plastic micro- and nanoparticles generated during plastic production and waste disposal. Exposure to chemical cocktails is a realistic scenario of high public health interest, in which many types of compounds such as these two may exhibit synergistic or additive adverse effects. This study evaluated the effects of plastic nanoparticles, parabens, and their mixture on the viability and proliferation of two human breast cancer cell lines: MDA-MB 231, which lacks oestrogen receptors, and MCF-7, which expresses these receptors. Parabens increased proliferation of oestrogen-sensitive breast cancer cells, and this effect became synergistic in the presence of plastic nanoparticles. The mechanism behind synergy may be related to the translocation and adsorption properties of nanoplastics, which served as a Trojan horse to expose cells to parabens more efficiently. These preliminary findings support growing evidence warning about the urgent problem of human exposure to combinations of plastic waste and contingent chemicals. [ABSTRACT FROM AUTHOR]

Rokstad, A. M., et al. (2014). "Advances in biocompatibility and physico-chemical characterization of microspheres for cell encapsulation." Advanced Drug Delivery Reviews **67-68**: 111-130.

Cell encapsulation has already shown its high potential and holds the promise for future cell therapies to enter the clinics as a large scale treatment option for various types of diseases. The advancement in cell biology towards this goal has to be complemented with functional biomaterials suitable for cell encapsulation. This cannot be achieved without understanding the close correlation between cell performance and properties of microspheres. The ongoing challenges in the field of cell encapsulation require a critical view on techniques and approaches currently utilized to characterize microspheres. This review deals with both principal subjects of microspheres characterization in the cell encapsulation field: physico-chemical characterization and biocompatibility. The up-to-day knowledge is summarized and discussed with the focus to identify missing knowledge and uncertainties, and to propose the mandatory next steps in characterization of microspheres for cell encapsulation. The primary conclusion of this review is that further success in development of microspheres for cell therapies cannot be accomplished without careful selection of characterization techniques, which are employed in conjunction with biological tests.

Roldan-Alzate, A., et al. (2014). "Non-invasive assessment of cardiac function and pulmonary vascular resistance in an canine model of acute thromboembolic pulmonary hypertension using 4D flow cardiovascular magnetic resonance." <u>Journal of Cardiovascular Magnetic Resonance</u> **16 (1) (no pagination)**(23).

Background: The purpose of this study was to quantify right (RV) and left (LV) ventricular function, pulmonary artery flow (Q<inf>P</inf>), tricuspid valve regurgitation velocity (TRV), and aorta flow (Q<inf>S</inf>) from a single 4D flow cardiovascular magnetic resonance (CMR) (time-resolved three-directionally motion encoded CMR) sequence in a canine model of acute thromboembolic pulmonary hypertension (PH). Methods. Acute PH was induced in six female beagles by microbead injection into the right atrium. Pulmonary arterial (PAP) and pulmonary capillary wedge (PCWP) pressures and cardiac output (CO) were measured by right heart catheterization (RHC) at baseline and following induction of acute PH. Pulmonary vascular resistance (PVR<inf>RHC</inf>) was calculated from RHC values of PAP, PCWP and CO (PVR<inf>RHC</inf> = (PAP-PCWP)/CO). Cardiac magnetic resonance (CMR) was performed on a 3 T scanner at baseline and following induction of acute PH. RV and LV end-diastolic (EDV) and end-systolic (ESV) volumes were determined from both CINE balanced steady-state free precession (bSSFP) and 4D flow CMR magnitude images. Q <inf>P</inf>, TRV, and Q<inf>S</inf> were determined from manually placed cutplanes in the 4D flow CMR flow-sensitive images in the main (MPA), right (RPA), and left (LPA) pulmonary arteries, the tricuspid valve (TRV), and aorta respectively. MPA, RPA, and LPA flow was also measured using two-dimensional flow-sensitive (2D flow) CMR. Result(s): Biases between 4D flow CMR and bSSFP were 0.8 mL and 1.6 mL for RV EDV and RV ESV, respectively, and 0.8 mL and 4 mL for LV EDV and LV ESV, respectively. Flow in the MPA, RPA, and LPA did not change after induction of acute PAH (p = 0.42-0.81). MPA, RPA, and LPA flow determined with 4D flow CMR was significantly lower than with 2D flow (p < 0.05). The correlation between Q<inf>P</inf>/TRV and PVR<inf>RHC</inf> was 0.95. The average Q<inf>P</inf>/Q<inf>S</inf> was 0.96 +/- 0.11. Conclusion(s): Using both magnitude and flow-sensitive data from a single 4D flow CMR acquisition permits simultaneous quantification of cardiac function and cardiopulmonary hemodynamic parameters important in the assessment of PH. © 2014 Roldan-Alzate et al.; licensee BioMed Central Ltd.

Roldan-Alzate, A., et al. (2015). "Non-invasive right ventricular efficiency using 4D flow MRI." <u>Journal of Cardiovascular Magnetic Resonance. Conference: 18th Annual SCMR Scientific Sessions. Nice France. Conference Publication:</u> **17**(SUPPL. 1).

Background: Pulmonary arterial hypertension (PH) is a progressive disease of increased resistance to flow through the lungs, leading to right ventricular (RV) failure [1]. MRI is increasingly used to assess right ventricular (RV) function in PH. RV stroke work (SW) based on invasive pressure and volume measurements, is used to assess ventricular work. Determining RV work from MRI could enable a more complete characterization of RV and PA interactions in PH. The purpose of this study was to non-invasively estimate RV work from simultaneously acquired RV volume (V<inf>RV</inf>) and pulmonary artery flow (Q<inf>PA</inf>) using a 4D flow-sensitive MRI sequence in a canine model. Method(s): After IACUC approval, hemodynamic measurements were performed prior to and following induction of acute PH by injection of embolizing micro-beads; details are available elsewhere [2]. Pre- and postembolization right heart catheterization (RHC) was performed to measure hemodynamic changes in the RV and PA. 4D flow MRI (Phase Contrast with Vastly undersampled Isotropic Projection Reconstruction - PCVIPR) was performed on 3T clinical scanners (MR750, GE Healthcare, Waukesha, WI) after the intravenous administration of gadolinium-based contrast agents. PCVIPR parameters: FOV=32x32x22cm, isotropic 1.3mm spatial resolution, TR/TE=6.3/2.1ms, Venc=150cm/s, scan time: ~10min using adaptive respiratory gating of bellows and retrospective ECG gating [3]. Postprocessing was done using Mimics (Materialise, Ann Arbor, MI) for the segmentation of the V<inf>RV</inf> from dynamic magnitude images and Ensight (CEI, Apex, NC) for quantification of Q<inf>PA</inf>. RV pressure - V<inf>RV</inf> loops were generated to assess SW by calculating the area inside the loop. Q<inf>PA</inf> - V<inf>RV</inf> loops were generated and their area calculated for comparison to the SW calculations (Fig 1). Direct comparison was used for the analysis of the results and a student ttest was used to compare the two methods. Result(s): In all cases embolization induced an increase in SW (180 +/- 140 vs 374 +/- 210mmHg*cm³). Similarly the calculated area of the Q<inf>PA</inf> - V<inf>RV</inf> loops increased for all the cases (369 +/- 210 vs 785 +/- 486 s-1) (Fig 2). No significant difference was found between the percent increase of SW and the Q<inf>PA</inf> - V<inf>RV</inf> loops area (53 +/- 15 vs 52 +/- 12%, p = 0.95). Conclusion(s): QMPA - V<inf>RV</inf> loop area estimated noninvasively using 4D flow MRI can be used to evaluate right ventricular stroke work. The results from this study indicate that 4D flow-sensitive MRI with PC VIPR can also be used to estimate right ventricular work, complementing the analysis of alterations in flow patterns in the heart and pulmonary arteries in patients with cardiopulmonary disease, however more studies need to be done for validation of the model. (Figure Presented).

Roldan-Alzate, A., et al. (2012). "Pulmonary arterial distensibility - 2D phase contrast vs 2D bSSFP." Journal of Cardiovascular Magnetic Resonance. Conference: 15th Annual SCMR Scientific Sessions **14**(SUPPL. 1).

Summary: Main pulmonary artery distensibility is a strong predictor of mortality in patients with pulmonary arterial hypertension. This study shows that either 2D PC or 2D bSSFP can be used to reliably noninvasively assess it by measuring MPA relative area change. Background(s): The pulmonary circulation is a highly compliant system that generates little resistance to blood flow. However, in the presence of pulmonary arterial hypertension (PAH), blood pressure and vascular resistance in the pulmonary circulation are elevated. This leads to distension and stiffening of the main pulmonary artery (MPA) and vessel wall remodeling, which in itself may influence stiffness [1]. Proximal arterial distensibility is a parameter that depends mainly on the anatomy (geometry) of the vessel and can be estimated noninvasively with cross-sectional imaging techniques. In particular, the relative area change (RAC) of the MPA, which is inversely proportional to arterial stiffness, is a strong predictor of mortality in patients with PAH [2]. The purpose of this study was to compare two non-invasive magnetic resonance imaging (MRI) methods for quantification of MPA distensibility using an acute PAH dog model. (Figure presented) Methods: Six adult female beagles were anesthetized with isoflurane. MRI was performed prior to and following injection of micro-beads into the right atrium and ventricle to induce PAH, resulting 12 comparison studies. The presence of PAH was confirmed by right heart catheterization (RHC). All MR images were acquired on a 3T scanner (MR750, GE Healthcare, Waukesha, WI). Double-oblique images perpendicular to the direction of the flow in the MPA were obtained using ECG-triggered 2D CINE balanced steady-state free precession (bSSFP) and through-plane velocityencoded 2D phase contrast (PC) at the same level [3]. PC and bSSFP images were segmented using dedicated cardiovascular analysis software (CV-Flow and and MASS-Analysis, respectively, Medis, Leiden, NL). Maximum and minimum MPA areas (A<inf>max</inf> and A<inf>min</inf>, respectively) were used to calculate RAC = (A<inf>max</inf>-A<inf>min</inf>)/A<inf>max</inf>. Bland-Altman analysis was used to study the differences between PC and bSSFP to calculate A<inf>max</inf>, A<inf>min</inf>, and RAC. Student t-test was used to evaluate statistical significance of the differences between techniques in all three paramenters. Result(s): The mean values for RAC, A<inf>max</inf> and A<inf>min</inf> were 36.38+/-7.86%, 241.98+/-71.62cm2, and 157.06+/-58.51cm2 for PC, respectively and 31.14 +/-6.95%, 220.88+/-62.76cm2, and 155.34+/-58.38cm2 for bSSFP, respectively (p=0.10, 0.45, and 0.94, respectively). The mean differences for RAC, A<inf>max</inf> and A<inf>min</inf> were -5.23+/-8.44%, -21.10+/-40.67cm2, -1.72+/-40.89cm2, respectively. Conclusion(s): No statistically significant difference is present between PC and bSSFP for measuring RAC, A<inf>max</inf> or A<inf>min</inf>. The differences between the two methods for measuring these parameters are small suggesting that either technique (PC or bSSFP) can be used to reliably non-invasively measure MPA distensibility. A benefit of using PC for measuring RAC is that it can also be used to quantify blood flow.

Roloff, A., et al. (2019). "Quantification of Aldehydes on Polymeric Microbead Surfaces via Catch and Release of Reporter Chromophores." Analytical Chemistry **91**(14): 8827-8834.

Aldehyde moieties on 2D-supports or micro- and nanoparticles can function as anchor groups for the attachment of biomolecules or as reversible binding sites for proteins on cell surfaces. The use of aldehyde-based materials in bioanalytical and medical settings calls for reliable methods to detect and quantify this functionality. We report here on a versatile concept to quantify the accessible aldehyde moieties on particle surfaces through the specific binding and subsequent release of small reporter molecules such as fluorescent dyes and nonfluorescent chromophores utilizing acylhydrazone formation as a reversible covalent labeling strategy. This is representatively demonstrated for a set of polymer microparticles with different aldehyde labeling densities. Excess reporter molecules can be easily removed by washing, eliminating inaccuracies caused by unspecific adsorption to hydrophobic surfaces. Cleavage of hydrazones at acidic pH assisted by a carbonyl trap releases the fluorescent reporters rapidly and quasi-quantitatively and allows for their fluorometric detection at low concentration. Importantly, this strategy separates the signal-generating molecules from the bead surface. This circumvents common issues associated with light scattering and signal distortions that are caused by binding-induced changes in reporter fluorescence as well as quenching dye-dye interactions on crowded particle surfaces. In addition, we demonstrate that the release of a nonfluorescent chromophore via disulfide cleavage and subsequent quantification by absorption spectroscopy gives comparable results, verifying that both assays are capable of rapid and sensitive quantification of aldehydes on microbead surfaces. These strategies enable a quantitative comparison of bead batches with different functionalization densities, and a qualitative prediction of their coupling efficiencies in bioconjugations, as demonstrated in reductive amination reactions with Streptavidin.

Roloff, F., et al. (2013). "Schwann cell-free adult canine olfactory ensheathing cell preparations from olfactory bulb and mucosa display differential migratory and neurite growth-promoting properties in vitro." BMC Neuroscience **14**: 141.

BACKGROUND: Transplantation of olfactory ensheathing cells (OEC) and Schwann cells (SC) is a promising therapeutic strategy to promote axonal growth and remyelination after spinal cord injury. Previous studies mainly focused on the rat model though results from primate and porcine models differed from those in the rat model. Interestingly, canine OECs show primate-like in vitro characteristics, such as absence of early senescence and abundance of stable p75NTR expression indicating that this species represents a valuable translational species for further studies. So far, few investigations have tested different glial cell types within the same study under identical conditions. This makes it very difficult to evaluate contradictory or confirmatory findings reported in various studies. Moreover, potential contamination of OEC preparations with Schwann cells was difficult to exclude. Thus, it remains rather controversial whether the different glial types display distinct cellular properties.

RESULTS: Here, we established cultures of Schwann cell-free OECs from olfactory bulb (OB-OECs) and mucosa (OM-OECs) and compared them in assays to Schwann cells. These glial cultures were obtained from a canine large animal model and used for monitoring migration, phagocytosis and the effects on in vitro neurite growth. OB-OECs and Schwann cells migrated faster than OM-OECs in a scratch wound assay. Glial cell migration was not modulated by cGMP and cAMP signaling, but activating protein kinase C enhanced motility. All three glial cell types displayed phagocytic activity in a microbead assay. In co-cultures with of human model (NT2) neurons neurite growth was maximal on OB-OECs.

CONCLUSIONS: These data provide evidence that OB- and OM-OECs display distinct migratory behavior and interaction with neurites. OB-OECs migrate faster and enhance neurite growth of human model neurons better than Schwann cells, suggesting distinct and inherent properties of these closely-related cell types. Future studies will have to address whether, and how, these cellular properties correlate with the in vivo behavior after transplantation.

Roman, L., et al. (2019). "Is plastic ingestion in birds as toxic as we think? Insights from a plastic feeding experiment." Science of the Total Environment **665**: 660-667.

Plastic pollution is a modern tragedy of the commons, with hundreds of species affected by society's waste. Birds in particular mistake plastic for prey, and millions of wild birds carry small plastic loads in their stomach and are exposed to potential toxicological effects. It is currently unknown how severely the toxicological and endocrine disrupting chemicals in plastic affect avian development, reproduction and endocrine function. To address this question, we conducted multi-generational plastic feeding experiments to test the toxicological consequences of plastic ingestion at environmentally relevant loads in Japanese quail, Coturnix japonica, investigating parental and two filial generations. Contrary to expectations, we found no evidence of lasting toxicological effects on mortality, adult body weight, organ histology, hormone levels, fertility, hatch rates and eggshell strength in birds experimentally fed plastic. However, we found plastic ingestion causes higher frequencies of male reproductive cysts and minor delays in chick growth and sexual maturity, though without affecting ultimate survival or reproductive output. We report that although plastic ingestion causes detectable endocrine effects in our model species, our lack of finding mortality, morbidity and adverse reproductive outcomes may challenge the common hypothesis of severe toxicological harm and population-level effects when environmentally relevant loads of plastic are ingested.

Romeo, T., et al. (2016). "First record of plastic debris in the stomach of Mediterranean lanternfishes." Acta Adriatica **57**(1): 115-122.

This study highlights for the first time the presence of plastic debris in the stomachs of Mediterranean lanternfishes (Myctophidae): Electrona risso, Diaphus metopoclampus, Hygophum benoiti and Myctophum punctatum. Samples were collected in the central Mediterranean Sea between 2010 and 2014. Plastics ingested belonged to small microplastics (0.2 - 2 mm), large microplastics (2 - 5 mm) and mesoplastics (5 - 25 mm), having mainly clear colors. Their frequency of occurrence in stomachs was equal to 2.7%, but it increases to 5.8% if only migratory species are considered. The higher number of plastics was found in E. risso and H. benoiti (5 in both species). The plastic ingestion may represent a risk for vertical migrant lanternfishes due to the increase in buoyancy. Ecotoxicological aspects linked to the potential effects of contaminants on lanternfish biology and to the transfer of pollutants throughout the marine trophic web up to top predators should be deepened.Original Abstract: Ova studija istice

po prvi put prisutnost plasticnih otpadaka u zelucima mediteranskih zaboglavki. (Myctophidae): Electrona risso, Diaphus metopoclampus, Hygophum benoiti i Myctophum punctatum. Uzorci su prikupljeni u sredisnjem Mediteranu u periodu izmedu 2010. i 2014. godine. Progu tane cestice plastike pripadaju maloj mikroplastici (0,2-2 mm), velikoj mikroplastici (2-5 mm) i mezoplastici (5-25 mm), te su uglavnom jasnih boja. Njihova ucestalost pojavljivanja u probavilima iznosila je 2.7%, dok je kod migratornih vrsta iznosila 5.8%. Veci broj cestica plastike pronaden je kod vrsta E. risso i H. benoiti (5 po vrsti). Gutanje plastike moze predstavljati rizik za vertikalne migratore iz porodice zaboglavki zbog povecanja uzgona. Potrebno je produbiti istrazivanja ekotoksikoloskih aspekata povezanih s mogucim ucincima zagadivala na biologiju zaboglavki, kao i onih povezanih s prijenosom zagadivala kroz troficku mrezu u moru sve do glavnih grabezljivaca.

Romeo, T., et al. (2015). "First evidence of presence of plastic debris in stomach of large pelagic fish in the Mediterranean Sea." Marine Pollution Bulletin **95**(1): 358-361.

This study focuses, for the first time, on the presence of plastic debris in the stomach contents of large pelagic fish (Xiphias gladius, Thunnus thynnus and Thunnus alalunga) caught in the Mediterranean Sea between 2012 and 2013. Results highlighted the ingestion of plastics in the 18.2% of samples. The plastics ingested were microplastics (<5. mm), mesoplastics (5-25. mm) and macroplastics (>25. mm).These preliminary results represent an important initial phase in exploring two main ecotoxicological aspects: (a) the assessment of the presence and impact of plastic debris on these large pelagic fish, and (b) the potential effects related to the transfer of contaminants on human health. Copyright © 2015 Elsevier Ltd.

Romera-Castillo, C., et al. (2018). "Dissolved organic carbon leaching from plastics stimulates microbial activity in the ocean." Nature communications **9**(1): 1430.

Approximately 5.25 trillion plastic pieces are floating at the sea surface. The impact of plastic pollution on the lowest trophic levels of the food web, however, remains unknown. Here we show that plastics release dissolved organic carbon (DOC) into the ambient seawater stimulating the activity of heterotrophic microbes. Our estimates indicate that globally up to 23,600 metric tons of DOC are leaching from marine plastics annually. About 60% of it is available to microbial utilization in less than 5 days. If exposed to solar radiation, however, this DOC becomes less labile. Thus, plastic pollution of marine surface waters likely alters the composition and activity of the base of the marine food webs. It is predicted that plastic waste entering the ocean will increase by a factor of ten within the next decade, resulting in an increase in plastic-derived DOC that might have unaccounted consequences for marine microbes and for the ocean system.

Romero-Martinez, L., et al. (2017). "Assessment of imaging-in-flow system (FlowCAM) for systematic ballast water management." Science of the Total Environment **603-604**: 550-561.

Assessing the disinfection of ballast water and its compliance with international standards requires determining the size, viability, and concentration of planktonic organisms. The FlowCAM (Flow Cytometer and Microscope) is an Imaging Flow Cytometry designed to obtain the particle concentration, images, and quantitative morphologic information. The objective in this paper is to establish the basis for transforming the FlowCAM from being a laboratory analyzer into a tool for systematic monitoring of ballast water. The capacity of the FlowCAM was evaluated by analyzing artificial microbeads, phytoplankton monocultures, and real seawater samples. Microbead analyses reported high accuracy and precision in size and concentration measurements. Monoculture analyses showed the effect of disinfection treatments in cell appearance and growth. Low concentration and heterogeneity of particles in real seawater

analyses require the comprehensive observation of images by experts. Additionally, some physical characteristics of the device must be improved. The optimization of device configuration enables the quick transferring of files and information between parties involved in ballast water management. FlowCAM may become a feasible technology for this after the device and protocols are adapted.

Ronda, A. C., et al. (2019). "Synthetic microfibers in marine sediments and surface seawater from the Argentinean continental shelf and a Marine Protected Area." Marine Pollution Bulletin **149 (no pagination)**(110618).

In this work, samples were collected from the Argentinean continental shelf -including a Marine Protected Area (MPA) - to assess the occurrence and distribution of synthetic microfibers (MFs), a widespread type of microplastic. MFs were present at 100% of the samples showing an average concentration of 182.85 +/- 115.14 particles per Kg of dry sediment and 0.14 +/- 0.08 items per m³ of marine water. MFs less than 1 mm were the most abundant (56.4% and 63%, for sediment and surface seawater respectively), followed by 1-2 mm and then 2-3 mm. In regards to the colour, both sediments and water had the major percentage of black MFs (25.6% and 28%, respectively) and the lowest one of green MFs (2.5% and 3%, respectively). Finally, MFs content in sediments was inversely correlated with depth (r = -0.93, p < 0.05). These findings provide the first evidence of microplastic contamination at the Argentinean continental shelf. Copyright © 2019

Roppel, R. M. and E. W. Retzlaff (1975). "A technique for evaluating blood perfusion rate in muscle and visceral organs." Biophysical Journal **15**(2 II): 246A.

In efforts to develop a means for evaluating relative rates of blood perfusion through solid tissues, microbead thermistors of special construction were implanted via small hypodermic needles in muscle and visceral organs of hamsters. Both normal animals and a strain bearing hereditary muscular dystrophy were used, the general purpose being to test the hypothesis that the muscle disease is causally related to a defect in vascular control mechanisms. The thermistors were powered by a constant current source to operate in the self heating mode, the voltage drop across the thermistor being taken as a measure of blood perfusion rate in the vicinity of the bead. This potential was recorded as a function of time, while the instrumented hamsters were administered a variety of naturally occurring and synthetic vasoactive substances. Results of these studies are described and the potential of this kind of probe as a diagnostic tool is discussed.

Rosa, D. S., et al. (2009). "Role of polyethylene-graft-glycidyl methacrylate compatibilizer on the biodegradation of poly(Delta *e-caprolactone)/cellulose acetate blends." Polymers for Advanced Technologies **20**(12): 863-870.

Biodegradable polymers provide an attractive solution to reduce environmental pollution caused by the accumulation of plastic waste in landfills. In this study, the effect of polyethylene-graft-glycidyl methacrylate (PE-g-GMA) on the biodegradation of blends of poly(Delta *e-caprolactone) (PCL) and cellulose acetate (CA) (80/20, 60/40, 40/60, and 20/80 PCL/CA, w/w) was assessed by mass retention, tensile strength, and morphological properties. The principal fungal strains present in the soil after biodegradation were also identified. PCL and the blends containing 60% and 80% PCL showed greater mass loss and superficial change in simulated soil. PE-g-GMA increased the tensile strength retention during 3 months of aging in simulated soil. Scanning electron microscopy (SEM) indicated that pure PCL was more porous, which enhanced the hydrolysis and biodegradation of PCL. PE-g-GMA decreased the mass loss of the polymers, possibly by enhancing the interaction between PCL and CA, with the formation of hydrogen bonds between the carbonyl groups of PCL and the hydroxyl groups of CA. This effect was marked in blends with >40% PCL. Microbiological analysis revealed the presence of several species of fungi in the soil.

Rosas, M. A. C. (2018). "FACTORES AMBIENTALES DETERMINANTES DE SALUD EN LOS HABITANTES DE LA COLONIA AMERICAS III, CHETUMAL." Revista Internacional de Contaminacion Ambiental = International Journal of Environmental Pollution **34**: 472.

En la ciudad de Chetumal, Quintana Roo, la colonia Las Américas III es una de las más cercanas al sitio de disposición final de los residuos sólidos de la ciudad. Ubicada apenas a los reglamentarios 500 metros de distancia, inicia la colonia cuyas vías cargadas de residuos, cuentan la evidencia del paso continuo de los camiones recolectores por la colonia para llegar a su destino final. A simple vista se puede apreciar basura, perros y gatos en la calle, una gran cantidad de polvo, pero no se tienen datos precisos sobre las cantidades, ni de fauna o polvo, con la que los habitantes de esta colonia tienen que vivir y convivir en su día a día. Justificación Considerando las condiciones ambientales evidentes a simple vista en la colonia, esta investigación es una primera aproximación hacia el conocimiento de la cantidad de perros en situación de calle, heces fecales en la vía pública, así como caracterización y estimación de la cantidad de polvo a la que está expuesta la población de la colonia. Estos datos serán contrastados con datos perceptuales de la misma población sobre su estado de salud y estadísticos del sector salud. El tener conocimiento de las condiciones ambientales permitirá más adelante el diseño de estrategias que contribuyan a mejorar y mantener la salud de la población. Objetivo: Identificar y cuantificar diversos factores ambientales que potencialmente inciden en la salud de la población de la colonia Américas III, en la ciudad de Chetumal, Quintana Roo. Objetivos específicos: Estimar la población canina en situación de calle por unidad de área en la colonia Las Américas III. Estimar la cantidad y características de excretas en la vía pública por unidad de área en la colonia Las Américas III. Cuantificar y caracterizar el cantidad de polvo por unidad de área, acumulable en una semana, en la colonia Las Américas III. Determinar mediante encuestas, la percepción de salud e incidencia de enfermedades de los habitantes de la colonia Las Américas III. Metodología: La investigación se desarrolló en tres etapas: la primera consistente en la elaboración de los instrumentos para colecta de datos de campo, consistentes en una cédula para el censo de población canina, una cédula para cuantificación e identificación de características de excretas en vía pública, el diseño de los cuadrantes para caracterización de polvo, así como el diseño del cuestionario dirigido a la población y métodos de muestreo. La segunda etapa consistió en el trabajo de campo, realizado en un periodo de cuatro semanas, entre los meses de marzo y abril, en los que se realizaron cuatro visitas (una por semana) para el conteo de excretas y perros, así como la aplicación de las encuestas, colocación y posterior recoja de las trampas de polvo. La tercera etapa consistió en el vaciado, análisis de información y elaboración del reporte final. Resultados. Lo resultados preliminares nos indican que hay diferentes densidades de perros por calle, teniendo el mayor número en la zona norte de la colonia, la más cercana al sitio de disposición final de residuos y los menores en la porción sureste de la colonia, es decir el área más alejada. En cuanto a composición del polvo encontrado se pudo observar presencia de ácaros, pelo de animales y de humanos, arenas, parásitos (lombrices), mosquitos, mosquitas, microfibras, microplásticos, fragmentos de hueso, carbón e incluso fue posible determinar la presencia de bacterias por medio de tinción. En lo que se refiere a las encuestas, en principio los habitantes comentan estar saludables, sin embargo reportan afecciones frecuentes de alergias, infecciones respiratorias, intestinales y se quejan de los frecuentes problemas por malos olores, moscas, humos (cuando el basurero se incendia), e incluso ya han identificado las “temporadas” de los mismos. Conclusiones: La presencia de animales en situación de calle, fecalismo animal al aire libre y la cercanía al sitio de disposición final de residuos de la ciudad, constituyen fact res ambientales determinantes en el deterioro de la salud de los habitantes de la Colonia. La presencia de patógenos, alérgenos y micro-plásticos, así como bacterias en el polvo ambiental, definitivamente se puede asociar a los padecimientos referidos por la población, sin embargo, es necesario realizar otro tipo de análisis (bacteriológico) y llevar un control en mayores escalas de tiempo, por ejemplo en las diferentes estaciones del año, para poder determinar relaciones de estacionalidad y definir los patrones que refieren los habitantes sobre las diferentes “temporadas” de los factores ambientales.

Rose, D. and M. Webber (2019). "Characterization of microplastics in the surface waters of Kingston Harbour." Science of the Total Environment **664**: 753-760.

Microplastic contamination of the marine environment has garnered global attention in recent years, and its distribution and effects in many small island developing states (SIDS) are still undetermined. As such, this study serves to detail an investigation of the abundance, spatial distribution and characteristics of surface water microplastics in the Kingston Harbour, a heavily polluted embayment in Jamaica. Fortnightly sampling with a manta trawl (335mum mesh) revealed non-variable concentrations of 0-5.73 particles/m³ (0-2,697,674.13 particles/km²) across stations adjacent to mangrove forests, key nursery grounds for many commercially important finfish and shellfish. Microplastics found in samples were predominantly fragments and were between 1mm and 2.5mm. Fourier Transform Infrared (FT-IR) spectroscopy identified polyethylene and polypropylene in fragments selected for analysis. These data serve to establish a crucial baseline of the status of microplastic pollution in Kingston Harbour.

Rosenbaum, J., et al. (2012). "Cardiac cirrhosis and hepatocellular carcinoma in a 13-year-old treated with doxorubicin microbead transarterial chemoembolization." Journal of Paediatrics & Child Health **48**(3): E140-143.

Increasing numbers of children are surviving into adulthood following surgery to correct or palliate congenital heart disease. This surgery can occasionally result in long-standing elevated right heart pressures and chronic hepatic venous congestion leading to cardiac cirrhosis. We report the first paediatric case of hepatocellular carcinoma in the setting of cardiac cirrhosis. A 13-year-old girl developed inoperable hepatocellular carcinoma and was treated with transarterial embolization with lipiodol and doxorubicin eluting microbeads. Promoting awareness of this association, even in younger patients, will hopefully result in better surveillance and screening of hepatic complications in survivors of complex cardiac surgery.

Rosenberger, S., et al. (2011). "Principles of an enhanced MBR-process with mechanical cleaning." Water Science & Technology **64**(10): 1951-1958.

Up to date, different physical and chemical cleaning protocols are necessary to limit membrane fouling in membrane bioreactors. This paper deals with a mechanical cleaning process, which aims at the avoidance of hypochlorite and other critical chemicals in MBR with submerged flat sheet modules. The process basically consists of the addition of plastic particles into the loop circulation within submerged membrane modules. Investigations of two pilot plants are presented: Pilot plant 1 is equipped with a 10 m(2) membrane module and operated with a translucent model suspension; pilot plant 2 is equipped with four 50 m(2) membrane modules and operated with pretreated sewage.

Ross, P. S. and C. Morales-Caselles (2015). Out of sight, but no longer out of mind: Microplastics as a global pollutant. **11:** 721-722.

The article reports on the growing problem of global microplastic contamination. Topics discussed include the impact of microplastic debris on marine ecology, the types of microplastics and the sources of microplastics to aquatic environments. Also discussed are the international agreements established to control microplastic pollution and the three levels of actions that the global community should take to combat microplastic contamination.

Rossi, J., et al. (2017). "Polyfunctional anti-CD19 CAR T cells determined by single-cell multiplex proteomics associated with clinical activity in patients with advanced non-Hodgkin's lymphoma." Cancer Research. Conference: American Association for Cancer Research Annual Meeting **77**(13 Supplement 1).

Introduction: Autologous anti-CD19 CAR T cells have shown promising clinical efficacy in B cell malignancies, with T cell expansion and blood levels for IL-15, IL-10 and Granzyme B as correlates of objective response and toxicity (Kochenderfer et al. J Clin Oncol 2016; 34:LBA3010). It is unclear, however, which key immune programs in CAR T cells impact their in vivo expansion and clinical outcome. We evaluated in detail the functionality of anti-CD19 CAR T cells by using single-cell proteomics analysis (Lu et al. PNAS 2015;113:607-615). We explored how the polyfunctionality of pre-infusion CAR T cell products, post-stimulation with the CD19 antigen in vitro, associated with CAR T cell expansion in vivo and objective response. Method(s): Product T cells were separated into CD4+ or CD8+ T cell subsets using microbeads. CD4+ or CD8+ fractions were then co-cultured with CD19-K562 targets or NGFR-K562 control cells, at a 1:2 ratio for 20 hrs. Single cells were then analyzed using a 32-plex panel of secreted cytokines, chemokines, and cytotoxic molecules. Specifically, T cells were loaded onto a single-cell barcode chip capable of assaying 32 secreted proteins/cell. The polyfunctional profile and strength (pSI) of each sample was determined (Ma et al. Cancer Discov 2013;3:418-429) and analyzed relative to in vivo expansion of the CAR T cells and patient response to the CAR T cell therapy. CAR T cell expansion in blood was measured by quantitative PCR. Result(s): Single-cell pSI of patient CAR T cells showed a statistically significant association ($p = 0.011$) with objective response (complete or partial response) to the therapy. While product pSI showed variability across patients, the median pSI was 2+ times higher for responders versus non-responders. The polyfunctional profiles for both CD4+ and CD8+ cells were dominated by effector molecules, stimulatory cytokines and chemokines. Polyfunctional CD4+ and CD8+ subsets with IFN-gamma, IL-8 and/or MIP-1alpha correlated best with patient outcome, with CD8+ T cells showing co-expression of Granzyme B, and CD4+ T cells also comprising IL-17A+IL8+ and IL5+IL8+ subsets. While CAR expansion in vivo also correlated with objective response ($p = 0.032$), the association between product pSI and CAR cell expansion in vivo did not reach statistical significance ($p = 0.079$), suggesting that they bring independent contributions to predicting objective response. In support of that, a composite index integrating pSI and CAR T cell expansion in vivo associated best with clinical response ($p = 0.005$). Conclusion(s): Polyfunctionality of CAR T cells, in conjunction with their expansion in vivo, correlates with clinical outcome in an anti-CD19 CAR T cell clinical trial. Single-cell multiplexed proteomics measurements may provide powerful insight into the clinical performance of CAR T cell products.

Rossol, M. and D. Hinkamp (2001). "Hazards in the theater." Occupational Medicine **16**(4): 595-608, iv.

The authors offer a survey of the myriad and unique safety and health hazards faced past and present by performers and theatrical workers, from preproduction work, through the show, and during the strike (dismantling). Special emphasis is given to health hazards posed by the many new plastic resin systems and adhesives used in set, prop, and costume construction; the hazards of special-effect fogs, smokes, haze, dusts, and pyrotechnic emissions; and theatrical makeup. [References: 72]

Rotjan, R. D., et al. (2019). "Patterns, dynamics and consequences of microplastic ingestion by the temperate coral, Astrangia poculata." Proceedings of the Royal Society of London - Series B: Biological Sciences **286**(1905): 20190726.

Microplastics (less than 5 mm) are a recognized threat to aquatic food webs because they are ingested at multiple trophic levels and may bioaccumulate. In urban coastal environments, high densities of microplastics may disrupt nutritional intake. However, behavioural dynamics and consequences of microparticle ingestion are still poorly understood. As filter or suspension feeders, benthic marine invertebrates are vulnerable to microplastic ingestion. We explored microplastic ingestion by the temperate coral Astrangia poculata. We detected an average of over 100 microplastic particles per polyp in wild-captured colonies from Rhode Island. In the laboratory, corals were fed microbeads to characterize ingestion preference and retention of microplastics and consequences on feeding behaviour. Corals were fed biofilmed microplastics to test whether plastics serve as vectors for microbes. Ingested microplastics were apparent within the mesenterial tissues of the gastrovascular cavity. Corals preferred microplastic beads and declined subsequent offerings of brine shrimp eggs of the same diameter, suggesting that microplastic ingestion can inhibit food intake. The corals co-ingested Escherichia coli cells with microbeads. These findings detail specific mechanisms by which microplastics threaten corals, but also hint that the coral A. poculata, which has a large coastal range, may serve as a useful bioindicator and monitoring tool for microplastic pollution.

Rowdhwal, S. S. S. and J. Chen (2018). "Toxic Effects of Di-2-ethylhexyl Phthalate: An Overview." BioMed Research International **2018**: 1750368.

Di-2-ethylhexyl phthalate (DEHP) is extensively used as a plasticizer in many products, especially medical devices, furniture materials, cosmetics, and personal care products. DEHP is noncovalently bound to plastics, and therefore, it will leach out of these products after repeated use, heating, and/or cleaning of the products. Due to the overuse of DEHP in many products, it enters and pollutes the environment through release from industrial settings and plastic waste disposal sites. DEHP can enter the body through inhalation, ingestion, and dermal contact on a daily basis, which has raised some concerns about its safety and its potential effects on human health. The main aim of this review is to give an overview of the endocrine, testicular, ovarian, neural, hepatotoxic, and cardiotoxic effects of DEHP on animal models and humans in vitro and in vivo.

Roy, E., et al. (2014). "From cellular lysis to microarray detection, an integrated thermoplastic elastomer (TPE) point of care Lab on a Disc." Lab on a Chip **15**(2): 406-416.

We present an all-thermoplastic integrated sample-to-answer centrifugal microfluidic Lab-on-Disc system (LoD) for nucleic acid analysis. The proposed CD system and engineered platform were employed for analysis of Bacillus atrophaeussubsp. globigiispores. The complete assay comprised cellular lysis, polymerase chain reaction (PCR) amplification, amplicon digestion, and microarray hybridization on a plastic support. The fluidic robustness and operating efficiency of the assay were ensured through analytical optimization of microfluidic tools enabling beneficial implementation of capillary valves and accurate control of all flow timing procedures. The assay reliability was further improved through the development of two novel microfluidic strategies for reagents mixing and flow delay on the CD platform. In order to bridge the gap between the proof-of-concept LoD and production prototype demonstration, low-cost thermoplastic elastomer (TPE) was selected as the material for CD fabrication and assembly, allowing the use of both, high quality hot-embossing and injection molding processes. Additionally, the low-temperature and pressure-free assembly and bonding properties of TPE material offer a pertinent solution for simple and efficient loading and storage of reagents and other on-board components. This feature was demonstrated through integration and conditioning of microbeads, magnetic discs, dried DNA buffer reagents and spotted DNA array inserts. Furthermore, all microfluidic functions and plastic parts were designed according to the current injection mold-making knowledge for industrialization purposes. Therefore, the current work highlights a seamless strategy that promotes a feasible path for the transfer from prototype toward realistic industrialization. This work aims to establish the full potential for TPE-based centrifugal system as a mainstream microfluidic diagnostic platform for clinical diagnosis, water and food safety, and other molecular diagnostic applications.

Roy, P. K., et al. (2011). "Degradable polyethylene: fantasy or reality." Environmental Science & Technology **45**(10): 4217-4227.

Plastic waste disposal is one of the serious environmental issues being tackled by our society today. Polyethylene, particularly in packaging films, has received criticism as it tends to accumulate over a period of time, leaving behind an undesirable visual footprint. Degradable polyethylene, which would enter the eco-cycle harmlessly through biodegradation would be a desirable solution to this problem. However, the "degradable polyethylene" which is presently being promoted as an environmentally friendly alternative to the nondegradable counterpart, does not seem to meet this criterion. This article reviews the state of the art on the aspect of degradability of polyethylene containing pro-oxidants, and more importantly the effect these polymers could have on the environment in the long run. On exposure to heat, light, and oxygen, these polymers disintegrate into small fragments, thereby reducing or increasing the visual presence. However, these fragments can remain in the environment for prolonged time periods. This article also outlines important questions, particularly in terms of time scale of complete degradation, environmental fate of the polymer residues, and possible accumulation of toxins, the answers to which need to be established prior to accepting these polymers as environmentally benign alternatives to their nondegradable equivalents. It appears from the existing literature that our search for biodegradable polyethylene has not yet been realized.

Roy, S. and K. M. Manjanna (2012). "Formulation and evaluation of guar gum glipizide microspheres for oral controlled release drug delivery." International Journal of Pharmaceutical Research **4**(4): 85-91.

The successful optimization and development of drug entity, design of dosage form then plays important role. In the present research work, guar gum microspheres containing glipizide were prepared by emulsification cross-linking method using polyvinyl alcohol coating polymer and glutaraldehyde as a cross-linking agent. No significant drug-polymer interactions and physical state of the drug in the formulation were observed by Fourier infrared spectroscopy and differential scanning calorimetry. The shape and surface characteristics were determined by scanning electron microscopy. Particle size distribution was determined by standard sieve analysis. Particle size, shape and surface morphology, swelling ratio, drug entrapment efficiency and in-vitro release were significantly affected by concentration of guar gum and glutaraldehyde. The drug entrapment efficiency was obtained in the range of 81.30-94.24 %w/v. In-vitro drug release profile glipizide from microbeads was examined in simulated intestinal pH 7.4 at end of 12h. The mechanism of drug release from guar gum and polyvinyl alcohol microspheres was diffusion controlled followed by First order kinetics and whereas coated microspheres approaching to near Zero- order kinetics.

Rozenstein, O., et al. (2017). "Development of a new approach based on midwave infrared spectroscopy for post-consumer black plastic waste sorting in the recycling industry." Waste Management **68**: 38-44.

Waste sorting is key to the process of waste recycling. Exact identification of plastic resin and wood products using Near Infrared (NIR, 1-1.7micro m) sensing is currently in use. Yet, dark targets characterized by low reflectance, such as black plastics, are hard to identify by this method. Following the recent success of Midwave Infrared (MWIR, 3-12micro m) measurements to identify coloured plastic polymers, the aim of this study was to assess whether this technique is applicable to sorting black plastic polymers and wood products. We performed infrared reflectance contact measurements of 234 plastic samples and 29 samples of wood and paper products. Plastic samples included black, coloured and transparent Polyethylene Terephthalate (PET), Polyethylene (PE), Polyvinyl Chloride (PVC), Polypropylene (PP), Polylactic acid (PLA) and Polystyrene (PS). The spectral signatures of the black and coloured plastic samples were compared with clear plastic samples and signatures documented in the literature to identify the polymer spectral features in the presence of coloured material. This information was used to determine the spectral bands that best suit the sorting of black plastic polymers. The main NIR-MWIR absorption features of wood, cardboard and paper were identified as well according to the spectral measurements. Good agreement was found between our measurements and the absorption features documented in the literature. The new approach using MWIR spectral features appears to be useful for black plastics as it overcomes some of the limitations in the NIR region to identify them. The main limitation of this technique for industrial applications is the trade-off between the signal-to-noise ratio of the sensor operating in standoff mode and the speed at which waste is moved under the sensor. This limitation can be resolved by reducing the system's spectral resolution to 16cm⁻¹, which allows for faster spectra acquisition while maintaining a reasonable signal-to-noise ratio.

Ruan, J., et al. (2018). "Controlling measures of micro-plastic and nano pollutants: A short review of disposing waste toners." Environment International **118**: 92-96.

Micro-plastic and nano-particle have been the focal pollutants in environmental science. The printer toner is omitted micro-plastic and nano pollutant. It is comprised of micro polyacrylate styrene and nano-Fe<inf>3</inf>O<inf>4</inf> particles. Polyacrylate styrene and nano-metal were proved to be irreversibly toxic to biological cells. Therefore, toners have the potential environmental risk and healthy harm due to include micro plastics and nano-metal. To our knowledge, few studies provided the specific collection and treatment of micro-plastic pollutant. This paper has chosen a kind of micro-plastic and nano pollutant toxic toner and provided technical guidance and inspiration for controlling the micro-plastic and nano pollutants. The method of vacuum-gasification-condensation was adopted for controlling the micro-plastic and nano pollutant toner. We believe this review will open up a potential avenue for controlling micro-plastic and nano pollutants for environmental protection. Copyright © 2018 Elsevier Ltd

Ruan, W., et al. (2007). "Nanobarcode gene expression monitoring system for potential miniaturized space applications." Advances in Space Research **40**(4): 513-522.

Manned mission to space has been threatened by various cosmos risks including radiation, mirogravity, vacuum, confinement, etc., which may cause genetic variations of astronauts and eventually lead to damages of their health. Thus, the development of small biomedical devices, which can monitor astronaut gene expression changes, is useful for future long-term space missions. Using magnetic microbeads packed with nanocrystal quantum dots at controlled

ratios, we were able to generate highly multiplexed nanobarcodes, which can encode a flexible panel of genes. Also, by using a reporter quantum dot, this nanobarcode platform can monitor and quantify gene expression level with improved speed and sensitivity. As a comparison, we studied TGF-β1 induced transcription changes in human bone marrow mesenchymal stem cells with both the nanobarcode microbead system and the Affymetrix GeneChip ® HTA system, which is currently considered as the industrial standard. Though using only 1/20 of the sample RNA, the nanobarcode system showed sensitivity equivalent to Affymetrix GeneChip ® system. The coefficient of variation, dynamic range, and accuracy of the nanobarcodes measurement is equivalent to that of the GeneChip ® HTA system. Therefore, this newly invented nanobarcode microbead platform is thought to be sensitive, flexible, cost-effective and accurate in a level equivalent to the conventional methods. As an extension of the use of this new platform, spacecrafts may carry this miniaturized system as a diagnostic tool for the astronauts. © 2007.

Ruan, Y., et al. (2019). "A preliminary screening of HBCD enantiomers transported by microplastics in wastewater treatment plants." Science of the Total Environment **674**: 171-178.

Hexabromocyclododecane (HBCD), a commonly used flame retardant, causes public concern due to its potential negative effects on organisms. Microplastics are suspected to contain certain amounts of HBCD. Wastewater treatment plants (WWTPs) are believed to be one of the largest sources of microplastics and a sink for micropollutants, providing opportunities for interactions between them, especially for hydrophobic micropollutants such as HBCD. There is a lack of studies focusing on the prevalence of microplastics and HBCD they carry. The present study investigated two typical WWTPs in Hong Kong, Stonecutters Island WWTP (SCI) and Shek Wu Hui WWTP (SWH), which employ different treatment technologies. The abundance of microplastics decreased with the treatment flow, and the microplastic concentrations in effluent were at intermediate levels (0.40 and 0.27particles/L) compared with the levels reported in previous studies. The concentrations of HBCD transported by microplastics reached 4184.4 ng/g in the effluent, whereas that in sewage water (dissolved phase) was 0.8 pg/L. For microplastics, 7.32 x 10⁷ and 2.24 x 10⁷ particles per day were estimated to be released from SCI and SWH, respectively into the environment; the release of HBCD carried by microplastics potentially reached 15.5 g per day, whereas the dissolved HBCD in the effluent may reach 0.067 g per day. A preliminary risk assessment of HBCD transported by microplastics showed that HBCD posed negligible risk; nevertheless, attention should be paid to the continual discharge of microplastics from WWTPs. Rubin, J. P., et al. (2007). "Collagenous microbeads as a scaffold for tissue engineering with adipose-derived stem cells." Plastic & Reconstructive Surgery **120**(2): 414-424.

BACKGROUND: Standard approaches to soft-tissue reconstruction include autologous tissue flaps and alloplastic implants. Both of these approaches have disadvantages, including donor-site morbidity, implant migration, and foreign body reaction. Autologous fat transplantation, with a minimally invasive cannula harvest, has lower donor-site morbidity than tissue flaps do, but there is an unpredictable degree of resorption of the transplanted fat over time. Adipose-derived stem cells isolated from harvested fat are better able to withstand the mechanical trauma from the suction cannula and may allow for improved cell survival and generation of new fat tissue after transfer to another anatomic site. The authors hypothesized that porous collagenous microbeads (CultiSphers; Sigma, St. Louis, Mo.) could be useful as injectable cell delivery vehicles for adipose-derived stem cells. This strategy would allow induction of differentiation ex vivo and precise placement of cells and scaffold in a tissue bed. The objective of this study was to assess the ability of the stem cells to proliferate and differentiate on these microbeads.

METHODS: Adipose-derived stem cells were isolated from discarded human adipose tissue and cultured on porous collagenous microbeads in a stirred bioreactor (spinner flask). The cells attached and proliferated on the microbeads and maintained high viability over several weeks of culture.

RESULTS: When exposed to adipogenic or osteogenic medium, the cells differentiated into adipocytes and osteoblasts, respectively, while attached to the microbeads.

CONCLUSION: Collagenous microbeads are a favorable scaffold for adipose-derived stem cells, allowing ex vivo proliferation and differentiation on particles that are small enough to be injected.

Rubio, L., et al. (2019). "Potential adverse health effects of ingested micro- and nanoplastics on humans. Lessons learned from in vivo and in vitro mammalian models." Journal of Toxicology & Environmental Health Part B: Critical Reviews: 1-18.

In recent years, increasing global attention has focused on "microplastics" (MPs) and "nanoplastics" (NPs) resulting in many studies on the effects of these compounds on ecological and environmental aspects. These tiny particles (<5000 micro m), predominantly derived from the degradation of plastics, pollute the marine and terrestrial ecosystems with the ability to enter into the food chain. In this manner, human consumption of food contaminated with MPs or NPs is unavoidable, but the related consequences remain to be determined. The aim of this review is to complement previous reviews on this topic by providing new studies related to exposure, absorption, and toxicity in mammalian in vivo and in vitro systems. With respect to novel information, gaps and limitations hindering attainment of firm conclusions as well as preparation of a reliable risk assessment are identified. Subsequently, recommendations for in vivo and in vitro testing methods are presented in order to perform further relevant and targeted research studies.

Rubio-Palis, Y., et al. (2017). "Population fluctuations of Aedes aegypti (Diptera: Culicidae) and dengue cases in 6 municipalities of Aragua state, Venezuela." Boletin de Malariologia y Salud Ambiental **57**(1): 1-16.

Aragua State, located in north-central Venezuela, is considered hyperendemic for dengue virus transmission, with circulation of Chikungunya and Zika viruses since 2014. In order to investigate the impact of water supply and climate variability on inmature Aedes aegypti populations and dengue cases, a longitudinal study was conducted in 6 localities situated in 6 different municipalities during 13 months. During the study, 2,296 houses were visited and 9,358 containers were examined for larvae and pupae. The Aedes house index was not homogeneous spatially or temporarily with significant differences among locations (P<0.0001). The 200 L drums were the most frequent type of containers found (82.3%), followed by tanks of 1,000 L or more (9.05%), 12 L containers (4.98%), various types (2.13%) (tires, cans, small plastic waste containers, plant pots, etc.), and 100 L containers (1.58%). During the study 69,765 larvae and 6,896 pupae were collected. The overall container index was 18.63%; tanks of >=1000 L had the highest larvae index per positive container (63.84) while containers of various types had the highest pupae index per positive container (8.03%). Cryptic larval habitats were not observed. Deficiencies in piped water supply was closely related to high Aedes indices. There was significant correlation between monthly total dengue cases and rainfall with lags of one, two and three months in each municipality. The correlations between monthly Ae. aegypti abundance (larvae and pupae, container ratios, container index), climate parameters (monthly rainfall, mean monthly temperature, mean minimum monthly temperature and maximum temperature) and dengue incidence were not significant (P>0.05). Although the container, house and Breteau indices can be used to evaluate the elimination of containers, they are not relevant for the prediction of dengue outbreaks.

Ruddock, J. (2008). "Pub talk gives a measure of progress on plastics." Materials Recycling Week **191**(26): 3-3.

The article comments on developments in plastic recycling in Great Britain. Better designed packaging has made a major contribution to avoiding plastic waste through light-weighting and re-use of materials. Consumers and businesses have an option of using improved technology and developing new facilities towards plastic recycling. Progress in recycling is evident in the increasing number of recycled plastic bottles with more than 90 percent of the region's local authorities offering some kind of plastics recycling service.

Ruiz-Compean, P., et al. (2017). "Baseline evaluation of sediment contamination in the shallow coastal areas of Saudi Arabian Red Sea." Marine Pollution Bulletin **123**(1-2): 205-218.

Despite the growing recognition of the importance of water and sediment quality there is still limited information on contamination levels in many regions globally including the Red Sea. This study provides a comprehensive assessment of three classes of contaminants (Polycyclic Aromatic Hydrocarbons - PAH; metals; plastics) in coastal sediments along the Saudi Arabian Red Sea mainly collected using grabs. Background concentrations are provided for metals in the region. Concentrations of metals and PAH were generally low in comparison to international guidelines. A clear relationship between the concentration of metals and anthropogenic sources was not always apparent and dust and vegetation may be relevant players in the region. Microplastic items (mainly polyethylene) were abundant (reaching up to 1gm⁻² and 160piecesm⁻²) and in general associated with areas of high human activity. This study provides critical information for future monitoring and the development of national policies within the Red Sea region.

Ruiz-Medina, A. and E. J. Llorent-Martinez (2012). Flow optosensing applied to the analysis of trace elements, Nova Science Publishers, Inc.**:** 31-54.

The determination of trace amounts of inorganic ions is of growing interest in several fields including environmental analysis, process control, biology, medicine, etc., and there is now a particular need for simple and fast field analytical tests. In contrast to well-established laboratory methods, such as atomic absorption or emission spectrometry, mass spectrometry or voltammetry, chemical sensors have attracted a great deal of interest in the last decade because of their great potential for in the field, in situ, continuous and remote, if required, applications. Flow-through optosensing emerged from the combination of Solid-Phase Spectroscopy (SPS) and Flow Injection Analysis (FIA). In SPS, an active solid support is used to pre-concentrate the target analyte and its spectroscopic detection is performed on the same solid support microbeads. The most remarkable features of SPS are its high sensitivity (it can be easily increased one hundred-fold due to the concentration of the target analyte on the solid beads) and selectivity (the interaction between the target chemical species and the solid phase beads is usually different from that one of co-existing species). In addition, the implementation of SPS in flow methods of analysis adds the inherent advantages of flow analysis, improving the analytical methods in terms of rapidity, commodity, automation, less consumption of reagents, etc. In these flow optosensors, the (micro) zone of the solid phase, where the signal is continuously monitored, is surrounded by a continuous stream flowing through it. The separation and retention of the species of interest on the solid phase takes place in the detection area itself and the spectroscopic determination is simultaneously performed. In this chapter, we will first describe the fundamentals of SPS from its origin, including some relevant examples. After that, we will focus on the versatility and potential of flow-through optosensing for the analysis of trace elements in a wide variety of samples related to human health, such as clinical samples (drugs, urine, and serum), food or environmental waters, emphasizing the most recent advances and future trends in this field. 2012 Nova Science Publishers, Inc. Ruiz-Orejon, L. F., et al. (2016). "Floating plastic debris in the Central and Western Mediterranean Sea." Marine Environmental Research **120**: 136-144.

In two sea voyages throughout the Mediterranean (2011 and 2013) that repeated the historical travels of Archduke Ludwig Salvator of Austria (1847-1915), 71 samples of floating plastic debris were obtained with a Manta trawl. Floating plastic was observed in all the sampled sites, with an average weight concentration of 579.3 g dw km(-2) (maximum value of 9298.2 g dw km(-2)) and an average particle concentration of 147,500 items km(-2) (the maximum concentration was 1,164,403 items km(-2)). The plastic size distribution showed microplastics (<5 mm) in all the samples. The most abundant particles had a surface area of approximately 1 mm(2) (the mesh size was 333 mum). The general estimate obtained was a total value of 1455 tons dw of floating plastic in the entire Mediterranean region, with various potential spatial accumulation areas.

Ruiz-Orejon, L. F., et al. (2018). "Now, you see me: High concentrations of floating plastic debris in the coastal waters of the Balearic Islands (Spain)." Marine Pollution Bulletin **133**: 636-646.

Coastal ecosystems are under significant human pressure, partly due to the proximity of pollution sources. In this study, a total of 20 samples were taken in summer around the coastal waters of the Balearic Islands (Spain) using a manta trawl net to examine the concentrations of floating plastic debris through the NIXE III project campaign. Although plastic concentrations showed high variability along the coast, the higher particle concentration (max: 4,576,115 items km⁻²) and weight (max: 8,102.94 g(DW) km⁻²) values were located at the north of the Balearic Promontory. The particle size analysis showed the high prevalence of microplastics (< 5mm) in these waters, where particles of approximately 0.7mm and 1mm² were the most frequent in the range analyzed. The high plastic concentration values in the N-NW coast of Ibiza and Mallorca in sparsely populated locations suggest that the plastic particle distribution was mostly conditioned by the hydrodynamic surface conditions.

Ruiz-Palacios, M., et al. (2020). "Establishment of a brain cell line (FuB-1) from mummichog (Fundulus heteroclitus) and its application to fish virology, immunity and nanoplastics toxicology." Science of the Total Environment **708**: 134821.

The marine fish mummichog (Fundulus heteroclitus), extensively used as research model, including in ecotoxicology, for over a century has been surpassed by other fish species. This fact may be associated with the lack of cell lines from this species, excellent models for the comprehension of fish physiology, immunology, toxicology and virology, that contribute to the reduction in the number of animals used in research. We have generated, for the first time, a brain-derived cell line from mummichog, FuB-1, and evaluated its application to the fields of fish virology, immunity and toxicology. First, FuB-1 cells show epithelial morphology and neural stem/astroglial origin. Secondly, FuB-1 cells effectively supports the replication of both spring viremia carp (SVCV) and infectious pancreatic necrosis (IPNV) viruses, but not nodavirus (NNV), indicating its potential use for fish virology. Related to this, FuB-1 cells infected with NNV up-regulate the transcription of genes related to the antiviral immune response, leading to cell resistance; while they are unaltered when infected with IPNV and SVCV, facilitating viral replication. Finally, FuB-1 cells were used for toxicological purposes and we demonstrated that

exposure to either polystyrene nanoplastics (PS-100) or several human-usage pharmaceuticals are cytotoxic. Additionally, PS-100 particles increase the antioxidant catalase and glutathione S-transferase activities and decrease the total non-protein thiols in FuB-1 cells. However, PS-100 particles are able to reduce the cytotoxic effects induced by the pharmaceuticals. In conclusion, we have generated a cell line from mummichog, which might represent a valuable model for fish studies in the fields of virology, immunology and toxicology.

Ruiz-Ruiz, J. C., et al. (2016). "Diospyros cuneata inhibition of Fusarium oxysporum: aqueous extract and its encapsulation by ionic gelation." Journal of Plant Pathology and Microbiology **7**(2).

The application of plant extracts to control fungal crop pathogens is an ecological strategy that could potentially be useful in agriculture. Aqueous extracts of some species of the genus Diospyros spp have been tested against fungal pathogens of crops. Nevertheless, there is no information about the inhibitory effect of aqueous extracts of Diospyros cuneata on the micelial growth of Fusarium oxysporum, a pathogen responsible for "Panama disease" and "vanilla stem rot disease". Therefore, the antifungal activity of aqueous extracts of Diospyros cuneata leaves collected during the dry and rainy seasons was tested in-vitro against spores of Fusarium oxysporum. Only the aqueous extract from leaves collected during the dry season had an inhibitory effect on the micelial growth of asexual spores (2.5% minimum inhibitory concentration). Phytochemical analysis showed that both aqueous extracts contained mainly flavonoids and tannins; the chromatographic profile showed a larger abundance of polar compounds in the dry season extract. Furthermore, the antifungal activity observed is probably correlated with the abundance of some secondary metabolites produced by water stress and dry season conditions. The bioactivity of aqueous extracts of Diospyros cuneata leaves could be stored and released through encapsulation; an effective example of this was tested using alginate-inulin to prepare microbeads by ionic gelation.

Ruj, B. and J. S. Chang (2012). "Combustible gases from thermal plasma treatment of plastic waste with special reference to mobile phone waste." International Journal of Plastics Technology **16**(2): 182-193.

Recently disposal and recycle of mobile phone becomes a significant problem throughout the world. Primordial recycling or disposal of mobile phone waste to landfills and incinerators causes irreversible environmental damage by polluting water and soil, and contaminating air. The disposal of mobile phones thus requires to be considered in an effective, economical and environmental friendly way. The present work describes the treatment of mobile phone waste by thermal plasma under reducing condition. Combustible reformed gas (CO, H sub(2) and hydrocarbons) having high calorific value was recovered. Generation of hydrogen gas and hydrocarbons are from the plastic part (whose major elements are carbon and hydrogen with some trace elements like oxygen and nitrogen) of the mobile phone waste. CO sub(2) generation is almost below the detection limit. No significant other toxic gases such as NO sub(x) and H sub(2)S were observed. For better understanding of treatment under reduced condition, experiments have also been done under argon-air gas mixture condition without mobile phone waste. The present investigation provides an option for energy recovery with volume reduction, reduction of toxic gases and potential recovery of precious metals present in the mobile phone waste.

Rummel, C. D., et al. (2019). "Effects of Leachates from UV-Weathered Microplastic in Cell-Based Bioassays." Environmental Science & Technology **53**(15): 9214-9223.

Standard ecotoxicological testing of microplastic does not provide insight into the influence that environmental weathering by, e.g., UV light has on related effects. In this study, we leached chemicals from plastic into artificial seawater during simulated UV-induced weathering. We tested largely additive-free preproduction polyethylene, polyethylene terephthalate, polypropylene, and polystyrene and two types of plastic obtained from electronic equipment as positive controls. Leachates were concentrated by solid-phase extraction and dosed into cell-based bioassays that cover (i) cytotoxicity; (ii) activation of metabolic enzymes via binding to the arylhydrocarbon receptor (AhR) and the peroxisome proliferator-activated receptor (PPARgamma); (iii) specific, receptor-mediated effects (estrogenicity, ERalpha); and (iv) adaptive response to oxidative stress (AREc32). LC-HRMS analysis was used to identify possible chain-scission products of polymer degradation, which were then tested in AREc32 and PPARgamma. Explicit activation of all assays by the positive controls provided proof-of-concept of the experimental setup to demonstrate effects of chemicals liberated during weathering. All plastic leachates activated the oxidative stress response, in most cases with increased induction by UV-treated samples compared to dark controls. For PPARgamma, polyethylene-specific effects were partially explained by the detected dicarboxylic acids. Since the preproduction plastic showed low effects often in the range of the blanks future studies should investigate implications of weathering on end consumer products containing additives.

Rummel, C. D., et al. (2016). "Plastic ingestion by pelagic and demersal fish from the North Sea and Baltic Sea." Marine Pollution Bulletin **102**(1): 134-141.

Plastic ingestion by marine biota has been reported for a variety of different taxa. In this study, we investigated 290 gastrointestinal tracts of demersal (cod, dab and flounder) and pelagic fish species (herring and mackerel) from the North and Baltic Sea for the occurrence of plastic ingestion. In 5.5% of all investigated fishes, plastic particles were detected, with 74% of all particles being in the microplastic (<5mm) size range. The polymer types of all found particles were analysed by means of Fourier transform infrared (FT-IR) spectroscopy. Almost 40% of the particles consisted of polyethylene (PE). In 3.4% of the demersal and 10.7% of the pelagic individuals, plastic ingestion was recorded, showing a significantly higher ingestion frequency in the pelagic feeders. The condition factor K was calculated to test differences in the fitness status between individuals with and without ingested plastic, but no direct effect was detected.

Rummler, S., et al. (2012). "Extracorporeal treatment of antibody mediated heart or lung transplant rejection." Journal of Heart and Lung Transplantation **1)**: S179.

Purpose: The immunological risk of acute rejection episodes increases particularly with retransplantations and with evidence of human leukocyte antigen antibodies (HLA-ab). Elevated panel reactive antibodies (PRA) prior to transplantation are the only factor with a significant impact on patient survival. Antibody mediated rejection (AMR) remains an unsolved problem and typically does not respond to conventional therapies. An essential pillar of antihumoral therapy are the extracorporeal procedures like plasma exchange (PE), and immunoadsorption (IA) because only they have the ability to quickly and effectively remove preformed or de novo tested antibodies. Methods and Materials: A total of 28 patients (3 patients prior to heart transplantation (HTX), 9 patients after HTX, 3 patients after combined heart and lung transplantation, 2 patients prior to lung transplantation (LuTX) and 11 after LuTX) were treated for prevention or in case of rejection with PE and/or IA. All patients were tested positive for HLAantibodies (HLA-ab) either donor specific or de novo HLA-ab. 6 patients were also tested positive for non HLA-ab, like PF4 antibodies. HLA-ab were detected using immunological tests like complement-dependent cytotoxicity assay (CDC), Enzyme-linked Immunosorbent Assay (ELISA) and microbead array assay (Luminex). Result(s): All heart transplant recipients treated with PE or IA prior to TX have a functioning graft. 6/8 HTX patients with AMR survived with stable graft function. 3 patients with combined H/LuTX developed hyperacute rejection. We used PE and IA to eliminate their non and/or HLA-ab completely. Those patients also survived with stable transplant function. 11/13 LuTX patients we treated have a functioning graft after successful reduction of non- and HLA-ab. One patient with HLA-ab (PRA 73%) suffered from primary graft dysfunction and the other patient suffered from severe sepsis. Both patients deceased. Conclusion(s): The extracorporeal procedures we performed are qualified for rescue therapy of hyperacute and acute rejection episodes.

Rummler, S., et al. (2010). "Desensitization is an efficient rescue therapy for rejection in immunized heart and lung transplant recipients." Tissue Antigens **75 (5)**: 585.

Peritransplant desensitization can be a useful treatment strategy for solid organ graft rejection in immunized patients. In this study, we report on 15 patients who were treated by therapeutic plasma exchange, immunoadsorption or immunofiltration with or without administration of intravenous immunoglobulin. 6 of the patients had received heart transplantation (HTX), 5 lung transplantation (LuTX), 2 combined H/LuTX, and 2 were sensitized patients on the waiting list. All patients had either preformed donorspecific or third party HLA-antibodies (HLA-ab), or de novo production of HLA-ab or non HLA-ab. HLA-ab were detected by immunological assays including the complement-dependent cytotoxicity assay (CDC), the Enzyme-linked Immunosorbent Assay (ELISA) and the microbead array assay (Luminex). Despite negative donor CDC cross matches, the 6 HTX patients developed rejection episodes. 3 of these patients had de novo production of HLA-ab, 1 had primary HLA-ab, 1 had third party HLA-ab and 1 had non HLA-ab. The latter two patients experienced hyperacute rejection episodes. In all 6 cases, we performed daily plasma exchange using SD-plasma with a single plasma volume at least 3 times. Acute rejection episodes > 21 days post-transplant were additionally treated by protein A immunoadsorption. Using these procedures, we were able to rescue the graft in 4 of the 6 patients. Of the 5 LuTX patients, 4 have a functioning graft after successful reduction of non HLA-ab (1 case), third party HLA-ab (1 case), preformed donor specific HLA-ab (1 case) and de novo HLA-ab (1 case). One patient with detection of non HLA-ab (anti-Cardiolipin) suffered from primary graft dysfunction and died. The 2 patients with combined H/LuTX developed hyperacute rejection because of preformed non HLA-ab. We eliminated the antibodies completely and both patients survived with stable transplant function. For the 2 patients on the waiting list, preformed HLA- and non HLA-ab were eliminated by our desensitization procedure, however one of the patients died without receiving a transplant. In conclusion, our protocols of desensitization by extracorporeal procedures are qualified for rescue therapy of hyperacute and acute rejections. Especially non HLA-ab may represent a group of alloantibodies that is often underestimated.

Rustagi, N., et al. (2011). "Public health impact of plastics: An overview." The Indian Journal of Occupational & Environmental Medicine **15**(3): 100-103.

Plastic, one of the most preferred materials in today's industrial world is posing serious threat to environment and consumer's health in many direct and indirect ways. Exposure to harmful chemicals during manufacturing, leaching in the stored food items while using plastic packages or chewing of plastic teethers and toys by children are linked with severe adverse health outcomes such as cancers, birth defects, impaired immunity, endocrine disruption, developmental and reproductive effects etc. Promotion of plastics substitutes and safe disposal of plastic waste requires urgent and definitive action to take care of this potential health hazard in future.

Rusu, M., et al. (2003). "POWDER COATINGS-BASED ORGANIC FILMS." Environmental Engineering & Management Journal (EEMJ) **2**(3): 217-234.

Powder coatings are finely grounded plastic particles consisting of resin, cross-linking agents (not used in thermoplastic powders), pigments, extenders and specific additives. When baked at a sufficiently high temperature, powder coatings melt out to form a continuous film. For thermosetting powders, a chemical reaction, either condensation or addition, also takes place. This fused film has the uniformity, color, toughness, and other properties generally associated with protective and decorative coatings, and presents superior properties, such as adhesion, corrosion and chemical resistance. Powder coatings applied as a dry material contain very little, if any, volatile organic compounds (VOCs). As no solvent is involved in the production and application of powder coatings, there is a reduction in fire risk, there are no costly wastes of organic solvents, and the health hazard to operators is reduced, too. [ABSTRACT FROM AUTHOR]

Ruth, L. H., et al. (2012). "SNPS analysis in pro-inflammatory and anti-inflammatory cytokine polymorphisms: TNF-alpha, TGF-beta, IFN-gamma, IL-6, IL-12P40, IL-10, IL-1-alpha, IL-1-beta, IL-1R and IL-1RA in inflammatory bowel disease (IBD)." Tissue Antigens **79 (6)**: 575.

Pro- and anti-inflammatory cytokines have an important role in inflammatory response. Cytokine/Cytokine receptor interactions not only play a pivotal role in the pathogenesis of inflammatory response, but also cause apoptosis, cell proliferation and differentiation. In this sense, alterations in the regulation of cytokines have been implicated in a variety of autoimmune disorders, including IBD [Crohn's disease (CD) and ulcerative colitis (UC)]. In this sense, IL-1 signalling via IL-1RI is also an important pathway in inflammatory process. These physiological effects are mediated by the activation of JNK and p38 MAP kinases, and up-regulation of genes via NF-kB, AP-1 and C/EBPb. On the other hand, IL-12p40, a subunit of IL-12p70 and IL-23, has previously been shown to inhibit IL-12p70 and IFN-gamma production and plays a key role in promoting Th1 responses. Thus, the aim of this study was to determine the relationship between pro- and anti-inflammatory cytokine polymorphisms and the differential IBD pathologies in a Spanish population. This was performed using PCR-SSOP for the SNPs of cytokines by using a microbeads Luminex assay. The following polymorphisms were determined: TNF-alpha [-238G/A and -308G/A], IFN-gamma [+874A/T], TGF-beta [+869C/T and +915G/C], IL- 10 [-1082A/A, -592A/C, -819C/T], IL-6 [-174C/G], IL-12p40 [3' UTR -1188 A/C (rs3212227)], IL-1-alpha [-889C/T], IL-1- beta [-511C/T and +3962C/T], IL-1R [Pst-1 1970C/T] and IL- 1Ra [Mspa-1 11100C/T]. When investigating each polymorphism separately and in conjunction, no statistical differences in the TNF-alpha, IFN-gamma, TGF-beta, IL-10, IL-6, IL-1 gene cluster genotypes and allele distributions between the IBD groups and controls were found. However, we observed significant differences in the 3' UTR -1188 A/C polymorphism of IL-12 p40. Thus, -1188A allele was increased in UC patients and the -1188C allele (high IL-12p40 production) was increased in CD patients. These data are in concordance with the fact of that CD has been shown to be associated with a Th1 T-cell mediated inflammation and high IL-12/IFN-gamma production at histologically affected sites. These data suggest that the IL-12p40 3' UTR -1188 A/C polymorphism seems to be associated with a differential IBD

development.

Rutkowska, M., et al. (2018). "Birds' feathers - Suitable samples for determination of environmental pollutants." TrAC - Trends in Analytical Chemistry **109**: 97-115.

The intensive development of industry and human population results in large amounts of different xenobiotic emitted into individual ecosystem components. As a consequence, monitoring of the level of pollution of particular elements of the environment by exotoxins has become a common interest. The determination of environmental changes by different types of biological indicators is called bioindication, which is used as one of the basic methods in the monitoring of environmental pollution. The following review paper contains comprehensive information about the use of bird feathers to assess the environmental contamination level. Types of contaminants (trace metals, microplastics, persistent organic pollutants) and analytical methods used for their determination are described in detail. In addition, the types of feathers used and the techniques for preparing them as samples for analysis are summarized. Copyright © 2018 Elsevier B.V.

Rutkowska, M., et al. (2018). "Birds' feathers – Suitable samples for determination of environmental pollutants." TrAC - Trends in Analytical Chemistry **109**: 97-115.

The intensive development of industry and human population results in large amounts of different xenobiotic emitted into individual ecosystem components. As a consequence, monitoring of the level of pollution of particular elements of the environment by exotoxins has become a common interest. The determination of environmental changes by different types of biological indicators is called bioindication, which is used as one of the basic methods in the monitoring of environmental pollution. The following review paper contains comprehensive information about the use of bird feathers to assess the environmental contamination level. Types of contaminants (trace metals, microplastics, persistent organic pollutants) and analytical methods used for their determination are described in detail. In addition, the types of feathers used and the techniques for preparing them as samples for analysis are summarized. © 2018 Elsevier B.V.

Ryan, M. G., et al. (2019). "Hudson River juvenile Blueback herring avoid ingesting microplastics." Marine Pollution Bulletin **146**: 935-939.

Microplastics in aquatic environments, and specifically their effects on the health of organisms, are of growing concern worldwide. Of particular concern are microplastics in a similar size range to zooplankton, as they have been found in the digestive tracks of organisms, such as fish, who typically seek zooplankton as a food source. It is unclear, however, to what degree, if any, fish select for or against microplastic particles when feeding. It is also unclear whether ingestion of microplastics affects fish condition. To answer these questions, the estimated physical condition and degree of selective feeding on microplastics were determined for juvenile fish collected from the Hudson River. Considering only particles 0.335-5.0 mm, microplastics made up 12% of fish diets but 21% of particles found in the surrounding water column. Relying on Jacob's Modified Electivity (JME) to quantify selectivity in feeding, our results reveal selective feeding on zooplankton and avoidance of microplastics. There was no correlation between condition and degree of selectivity toward any particular food types, including microplastics. Future work needs to consider fish with different feeding strategies and potential bioaccumulation of microplastics in the food web. Fish selectivity of ingestion in regards to microplastics should additionally be tested on wider spatial and temporal scales.

Ryan, P. G. (1987). "The incidence and characteristics of plastic particles ingested by seabirds." Marine Environmental Research **23**(3): 175-206.

The ingestion of plastic was recorded for 36 of 60 seabird species sampled in the southern hemisphere (mostly off southern Africa). Biases of different sampling techniques were considered. Plastic was most frequent in procellariiforms, notably Blue Petrels, Great Shearwaters, White-faced Storm-petrels and Pintado Petrels. Particles were compared with those found at sea. The size of ingested particles was related to body size and this affected the proportions of plastic types ingested. Pale particles were underrepresented, suggesting selection for darker-coloured particles. Small species were less colour-selective and exhibited a higher incidence of plastic ingestion than did large species. The incidence of ingested plastic was directly related to foraging technique and inversely related to the frequency of egestion of indigestible stomach contents. Secondary ingestion of plastic through contaminated prey was important in only one species sampled.

Ryan, P. G. (1988). "Concern about plastic pollution in Southern Ocean seabirds." CORMORANT. **16**(1): 1-2.

During the last few years there has been growing concern worldwide about marine plastic pollution. The Southern Ocean has not escaped this problem. Plastic now frequently is encountered at sea in the Southern Ocean and washed up on remote Antarctic and sub-Antarctic beaches. But does plastic pollution have environmental impacts other than reducing the aesthetic appeal of the far south? Seabirds and seals occasionally are entangled in plastic debris, causing debilitating wounds or death. A potentially much more serious problem is that of plastic ingestion by seabirds in the Southern Ocean.

Ryan, P. G. (1988). "Intraspecific variation in plastic ingestion by seabirds and the flux of plastic through seabird populations." Condor **90**(2): 446-452.

Patterns of intraspecific variability of ingested plastic loads in seabirds were examined for species collected off southern Africa. Sampling took place at sea off the southwestern cape, South AFrica, and at Inaccessible Island (37 degree 50'S, 12 degree 30'W), Gough Island (40 degree 21'S, 9 degree 53'W), and the Prince Edward Islands (46 degree 45'S, 37 degree 50'E). The incidence of plastic pollution was shown to be increasing during the 1980s. Both large- and small-scale geographic variation in plastic loads occurred as a function of variable plastic density in the environment. Intergenerational transfer of plastic particles was identified as an important pathway for plastic flow in those species that accumulate plastic particles and feed their chicks by regurgitation.

Ryan, P. G. (2008). "Seabirds indicate changes in the composition of plastic litter in the Atlantic and south-western Indian Oceans." Marine Pollution Bulletin **56**(8): 1406-1409.

I compare plastic ingested by five species of seabirds sampled in the 1980s and again in 1999-2006. The numbers of ingested plastic particles have not changed significantly, but the proportion of virgin pellets has decreased 44-79% in all five species: great shearwater Puffinus gravis, white-chinned petrel Procellaria aequinoctialis, broad-billed prion Pachyptila vittata, white-faced storm petrel Pelagodroma marina and white-bellied storm petrel Fregetta grallaria. The populations sampled range widely in the South Atlantic and western Indian Oceans. The most marked reduction occurred in great shearwaters, where the average number of pellets per bird decreased from 10.5 to 1.6. This species migrates between the South and North Atlantic each year. Similar decreases in virgin pellets have been recorded in short-tailed shearwaters Puffinus tenuirostris in the Pacific Ocean and northern fulmars Fulmarus glacialis in the North

Sea. More data are needed on the relationship between plastic loads in seabirds and the density of plastic at sea in their foraging areas, but the consistent decrease in pellets in birds suggests there has been a global change in the composition of small plastic debris at sea over the last two decades.

Ryan, P. G. (2015). "How quickly do albatrosses and petrels digest plastic particles?" Environmental Pollution **207**: 438-440.
Understanding how rapidly seabirds excrete or regurgitate ingested plastic items is important for their use as monitors of marine debris. van Franeker and Law (2015) inferred that fulmarine petrels excrete ~75% of plastic particles within a month of ingestion based on decreases in the amounts of plastic in the stomachs of adult petrels moving to relatively clean environments to breed. However, similar decreases occur among resident species due to adults passing plastic loads to their chicks. The few direct measures of wear rates and retention times of persistent stomach contents suggest longer plastic residence times in most albatrosses and petrels. Residence time presumably varies with item size, type of plastic, the amount and composition of other persistent stomach contents, and the size at which items are excreted, which may vary among taxa. Accurate measures of ingested plastic retention times are needed to better understand temporal and spatial patterns in ingested plastic loads within marine organisms, especially if they are to be used as indicators of plastic pollution trends.

Ryan, P. G., et al. (2012). "Long-term decreases in persistent organic pollutants in South African coastal waters detected from beached polyethylene pellets." Marine Pollution Bulletin **64**(12): 2756-2760.
Polyethylene pellets provide a convenient means to monitor Persistent Organic Pollutants (POPs) in marine systems. Pellets collected between 1984 and 2008 at three South African beaches were analysed for PCB, HCH and DDT. Concentrations of all three POPs decreased over the last two decades, although this signal was less clear for PCBs, and further monitoring is needed to assess trends in this family of compounds. DDT concentrations at two sites were higher than previous records for southern Africa, but there is no evidence of a link to the ongoing use of DDT for malaria control. HCHs concentrations were lower than in pellets from the east coast of southern Africa, suggesting that this pesticide was mainly used in the eastern part of the region. Our study demonstrates the potential for International Pellet Watch to track temporal as well as geographical patterns in the abundance of POPs in marine environments. © 2012 Elsevier Ltd.

Ryan, P. G., et al. (1988). "Plastic ingestion and PCBs in seabirds: Is there a relationship?" Marine Pollution Bulletin **19**(4): 174-176.
Multivariate analyses were used to assess the independent determinants of four organochlorines (OCs) in the fat and eggs of breeding female Great Shearwaters Puffinus gravis . The amounts of polychlorinated biphenyls (PCBs), DDE, DDT, and dieldrin, in both adult fat tissue and in eggs were positively correlated. Positive correlations between the amounts of different OCs in adults and in eggs suggest that individual differences in non-breeding range, diet and age are determinants of pollutant levels within a species. The mass of ingested plastic was positively correlated only with PCBs, a group of chemicals commonly found in plastics. It is probable that seabirds assimilate PCBs and other toxic chemicals partly from ingested plastic particles.

Ryan, P. G., et al. (2019). "Rapid increase in Asian bottles in the South Atlantic Ocean indicates major debris inputs from ships." Proceedings of the National Academy of Sciences of the United States of

America **116**(42): 20892-20897.

Most plastic debris floating at sea is thought to come from land-based sources, but there is little direct evidence to support this assumption. Since 1984, stranded debris has been recorded along the west coast of Inaccessible Island, a remote, uninhabited island in the central South Atlantic Ocean that has a very high macrodebris load (~5 kg.m⁻¹). Plastic drink bottles show the fastest growth rate, increasing at 15% per year compared with 7% per year for other debris types. In 2018, we examined 2,580 plastic bottles and other containers (one-third of all debris items) that had accumulated on the coast, and a further 174 bottles that washed ashore during regular monitoring over the course of 72 d (equivalent to 800 bottles.km⁻¹.y⁻¹). The oldest container was a high-density polyethylene canister made in 1971, but most were polyethylene terephthalate drink bottles of recent manufacture. Of the bottles that washed up during our survey, 90% were date-stamped within 2 y of stranding. In the 1980s, two-thirds of bottles derived from South America, carried 3,000 km by the west wind drift. By 2009, Asia had surpassed South America as the major source of bottles, and by 2018, Asian bottles comprised 73% of accumulated and 83% of newly arrived bottles, with most made in China. The rapid growth in Asian debris, mainly from China, coupled with the recent manufacture of these items, indicates that ships are responsible for most of the bottles floating in the central South Atlantic Ocean, in contravention of International Convention for the Prevention of Pollution from Ships regulations.

Ryan, P. G. and S. Jackson (1987). "The lifespan of ingested plastic particles in seabirds and their effect on digestive efficiency." Marine Pollution Bulletin **18**(5): 217-219.

The assimilation efficiencies of fledgling Whitechinned Petrels Procellaria aequinoctialis artifically fed large quantities of plastic particles were assessed. No significant differences were detected in either assimilation efficiency or the rate of mass loss between experimental and control birds. Polyethylene pellets lost 1% of their mass after 12 days in the experimental birds' stomachs, suggesting a half-life of at least one year. No instances of plastic causing intestinal obstruction, and few cases of physical damage to te stomach lining, were found in over 400 individuals of 25 species of seabirds containing ingested plastic. These results suggest ingested plastic seldom impairs digestive efficiency in seabirds.

Ryan, P. G. and C. L. Moloney (1990). "Plastic and other artefacts on South African beaches: Temporal trends in abundance and composition." S. AFR. J. SCI./S.-AFR. TYDSKR. WET. **86**(7-10): 450-452.

Plastic debris has rapidly become one of the most abundant marine pollutants, with economic as well as ecological consequences. Surveys of 50 South African beaches in 1984 and again in 1989 show that the densities of all types of plastic objects have increased significantly. Floating plastic objects and other artefacts have three main impacts on the marine environment: 1) they are ingested by and entangle many marine animals; 2) they increase the amount of substratum available for epiphytic organisms; and 3) when stranded, they reduce the aesthetic appeal and tourism potential of beaches. The authors present preliminary measures of trends in plastic abundance off South Africa, estimated from sampling both micro- and macro-plastic particles stranded at a range of beaches over a five-year period.

Ryan, P. G., et al. (2019). "Sampling microfibres at the sea surface: The effects of mesh size, sample volume and water depth." Environmental Pollution: 113413.

Microfibres are one of the most ubiquitous particulate pollutants, occurring in all environmental compartments. They are often assumed to be microplastics, but include natural as well as synthetic textile fibres and are perhaps best treated as a separate class of pollutants given the

challenges they pose in terms of identification and contamination. Microfibres have been largely ignored by traditional methods used to sample floating microplastics at sea, which use 300-500mum mesh nets that are too coarse to sample most textile fibres. There is thus a need for a consistent set of methods for sampling microfibres in seawater. We processed bulk water samples through 0.7-63mum filters to collect microfibres in three ocean basins. Fibre density increased as mesh size decreased: 20mum mesh sampled 41% more fibres than 63mum, and 0.7mum filters sampled 44% more fibres than 25mum mesh, but mesh size (20-63mum) had little effect on the size of fibres retained. Fibre density decreased with sample volume when processed through larger mesh filters, presumably because more fibres were flushed through the filters. Microfibres averaged 2.5 times more abundant at the sea surface than in water sampled 5m sub-surface. However, the data were noisy; counts of replicate 10-L samples had low repeatability (0.15-0.36; CV=56%), suggesting that single samples provide only a rough estimate of microfibre abundance. We propose that sampling for microfibres should use a combination of <1mum and 20-25mum filters and process multiple samples to offset high within-site variability in microfibre densities.

S, A. N. (2019). "Preliminary study and first evidence of presence of microplastics and colorants in green mussel, Perna viridis (Linnaeus, 1758), from southeast coast of India." Marine Pollution Bulletin **140**: 416-422.

Pollution by microplastics (MPs) is currently a global problem in the coastal and marine environment. Transfer of MPs from land to sea and their inclusion in the food web has a significant adverse effect on the marine life and human health. The present study was carried out at the fishing harbour of Chennai, southeast coast of India. The possible MPs were isolated from the soft tissues of the commercially important bivalve Perna viridis and examined by microscopic and DXR Raman spectroscopic methods. The MPs were identified as to be polystyrene polymers in the soft tissues. This investigation revealed that size and color are the major factors affecting the bioavailability of MPs to bivalves in the study area. The presence of colorants in organisms revealed an anthropogenic origin through the use of a wide array of applications. Hence, coastal zones are a hotspot for pollution by MPs, and filter feeding bivalves are at the highest risk. Therefore, further studies are required to understand the accumulation rates and residence time of MPs across the food webs.

Sa, L. C. d., et al. (2015). "Effects of microplastics on juveniles of the common goby (Pomatoschistus microps): confusion with prey, reduction of the predatory performance and efficiency, and possible influence of developmental conditions." Environmental Pollution **196**: 359-362.

Microplastics (MP) are ubiquitous contaminants able to cause adverse effects on organisms. Three hypotheses were tested here: early Pomatoschistus microps juveniles can ingest MP; the presence of MP may reduce fish predatory performance and efficiency; developmental conditions may influence the prey selection capability of fish. Predatory bioassays were carried out with juveniles from two estuaries with differences in environmental conditions: Minho (M-est) and Lima (L-est) Rivers (NW Iberian coast). Polyethylene MP spheres (3 types) alone and in combination with Artemia nauplii were offered as prey. All the MP types were ingested, suggesting confusion with food. Under simultaneous exposure to MP and Artemia, L-est fish showed a significant reduction of the predatory performance (65%) and efficiency (up to 50%), while M-est fish did not, suggesting that developmental conditions may influence the prey selection capability of fish. The MP-induced reduction of food intake may decrease individual and population fitness.

Sa, L. C. d., et al. (2018). "Studies of the effects of microplastics on aquatic organisms: what do we know and where should we focus our efforts in the future?" Science of the Total Environment **645**: 1029-1039.

The effects of microplastics (MP) on aquatic organisms are currently the subject of intense research. Here, we provide a critical perspective on published studies of MP ingestion by aquatic biota. We summarize the available research on MP presence, behaviour and effects on aquatic organisms monitored in the field and on laboratory studies of the ecotoxicological consequences of MP ingestion. We consider MP polymer type, shape, size as well as group of organisms studied and type of effect reported. Specifically, we evaluate whether or not the available laboratory studies of MP are representative of the types of MPs found in the environment and whether or not they have reported on relevant groups or organisms. Analysis of the available data revealed that (1) despite their widespread detection in field-based studies, polypropylene, polyester and polyamide particles were under-represented in laboratory studies; (2) fibres and fragments (800-1600 micro m) are the most common form of MPs reported in animals collected from the field; (3) to date, most studies have been conducted on fish; knowledge is needed about the effects of MPs on other groups of organisms, especially invertebrates. Furthermore, there are significant mismatches between the types of MP most commonly found in the environment or reported in field studies and those used in laboratory experiments. Finally, there is an overarching need to understand the mechanism of action and ecotoxicological effects of environmentally relevant concentrations of MPs on aquatic organism health.

Saad, J. M. and P. T. Williams (2016). "Catalytic dry reforming of waste plastics from different waste treatment plants for production of synthesis gases." Waste Management **58**: 214-220.

Catalytic dry reforming of mixed waste plastics, from a range of different municipal, commercial and industrial sources, were processed in a two-stage fixed bed reactor. Pyrolysis of the plastics took place in the first stage and dry (CO<inf>2</inf>) reforming of the evolved pyrolysis gases took place in the second stage in the presence of Ni/Al<inf>2</inf>O<inf>3</inf> and Ni-Co/Al<inf>2</inf>O<inf>3</inf> catalysts in order to improve the production of syngas from the dry reforming process. The results showed that the highest amount of syngas yield was obtained from the dry reforming of plastic waste from the agricultural industry with the Ni/Al<inf>2</inf>O<inf>3</inf> catalyst, producing 153.67 mmol<inf>syngas</inf> g⁻¹ <inf>waste</inf>. The addition of cobalt metal as a promoter to the Ni/Al<inf>2</inf>O<inf>3</inf> catalyst did not have a major influence on syngas yield. Overall, the catalytic-dry reforming of waste plastics from various waste treatment plants showed great potential towards the production of synthesis gases. Copyright © 2016 Elsevier Ltd

Saavedra, J., et al. (2019). "Influence of nanoplastic surface charge on eco-corona formation, aggregation and toxicity to freshwater zooplankton." Environmental Pollution **252**(Part A): 715-722.

Concerns about possible environmental implications of nano- and micro-plastics are continuously raising. Hence, comprehensive understanding of their behaviour, bioaccumulation and toxicity potential is required. Nevertheless, systematic studies on their fate and possible effects in freshwaters, as well as the influence of particle-specific and environmental factors on their behaviour and impacts are still missing. The aims of the present study are thus two-fold: (i) to examine the role of the surface charge on nanoplastic stability and acute effects to freshwater zooplankton; (ii) to decipher the influence of the refractory natural organic matter (NOM) on the nanoplastic fate and effects. Amidine and carboxyl-stabilized polystyrene (PS) spheres of 200 nm diameter characterized by opposite primary surface charges and neutral buoyancy were selected as model nanoplastics. The results demonstrated that the surface functionalization of the polystyrene nanoplastics controls their aggregation behaviour. Alginate

or Suwannee River humic acid (SRHA) modified significantly the surface charge of positively-charged amidine PS nanoplastic and the aggregation state, while had no significant influence on the negatively-charged carboxyl PS nanoplastic. Both amidine and carboxyl PS nanoplastics were ingested by the zooplankton and concentrated mainly in the gut of water flea Daphnia magna and larvae Thamnocephalus platyurus, and the stomach of rotifer Brachionus calyciflorus. Amidine PS nanoplastic was more toxic than carboxyl one. The toxicity decreased in the order D. magna (48 h - immobilization) > B. calyciflorus (24 h - lethality) > T. platyurus (24 h - lethality). Alginate or SRHA reduced significantly the toxicity of both amidine and carboxyl PS nanoplastics to the studied zooplankton representatives. The implications of this laboratory study findings to natural environment were discussed.

Sabharwal, J., et al. (2017). "Elevated IOP alters the space-time profiles in the center and surround of both ON and OFF RGCs in mouse." Proceedings of the National Academy of Sciences of the United States of America **114**(33): 8859.

Glaucoma is a leading cause of blindness worldwide, and is characterized by progressive retinal ganglion cell (RGC) death. An experimental model of glaucoma has been established by elevating the intraocular pressure (IOP) via microbead occlusion of ocular fluid outflow in mice. Studies in this model have found visual dysfunction that varied with adaptational state, occurred before anatomical changes, and affected OFF RGCs more than ON RGCs. These results indicate subtle alterations in the underlying retinal circuitry that could help identify disease before irreversible RGC changes. Therefore, we looked at how RGC function was altered with elevated IOP under both photopic and scotopic conditions. We first found that responses to light offset are diminished with IOP elevation along with a concomitant decrease in receptive field center size for OFF RGCs. In addition, the antagonistic surround strength and size was reduced in ON RGCs. Furthermore, elevation of IOP significantly accelerated the photopic temporal tuning of RGC center responses in both ON and OFF RGCs. We found that some of the IOP-induced functional changes to OFF RGCs relied on ON cross-over pathways, indicating dysfunction in inner retinal circuitry. Overall, these results suggest that IOP alters multiple functions in the retina depending on the adaptational state. They provide a basis for designing multiple functional tests for early detection of glaucoma and for circuit-specific therapeutic targets in treatment of this blinding disease.

Saborowski, R., et al. (2019). "How to get rid of ingested microplastic fibers? A straightforward approach of the Atlantic ditch shrimp Palaemon varians." Environmental Pollution **254**(Part B).

Microplastic fibers represent a significant share of the global marine micrcroplastic pollution, particularly in coastal areas. In controlled laboratory experiments, we offered fluorescent microplastic fibers (40-4400 micro m lengths, median 150 micro m) and spherical microplastic beads (9.9 micro m O) together with commercial fish food to the Atlantic ditch shrimp Palaemonetes varians. The shrimps ingested fibers and beads along with the food. Upon ingestion, the beads and the shortest fibers (up to 100 micro m) passed from the stomach into the gut and were egested within the fecal strings. The longer fibers first remained in the stomach but were regurgitated, i.e. extruded through the esophagus, within 12-14 h. Regurgitation is an evolutionary adaptation of particular crustacean species and other invertebrates to remove large and indigestible food particles from the stomach. Accordingly, the process of regurgitation attained a new task nowadays, i.e. the elimination of anthropogenic filamentous microplastic debris from the stomach to avoid harm. This behavioral feature may represent a selective advantage in view of the continuously increasing environmental plastic pollution.

Sachithanantham, P., et al. (2016). "Effect of raw and re-engineered GFRP waste as an admixture in cement concrete." Journal of Chemical and Pharmaceutical Sciences **9**(2): E168-E172.

Recent Scientific developments led to tremendous progress in infrastructure development to mankind but also led to negative impact on the environment. Generation of glass fibre reinforced plastic (GFRP) waste has been a source of concern. The increase in GFRP waste pollutes not only land and water but also the air. If GFRP is dumped on land it chokes the soil making it infertile and useless. Dumping glass fibre reinforced plastics in water endangers the lives of the aquatic animals thus effectively disrupting the balance in nature. Disposal of GFRP waste by incineration generates toxic gases which are harmful not only to the flora and fauna but also to the atmosphere. The problem is more serious with thermo set plastic which is neither recyclable nor bio-degradable. In this paper an attempt is made to find an efficient way of utilizing the plastic waste as an admixture to cement concrete. To validate this, experimental investigations are carried out on concrete of M25 grade with raw GFRP and re-engineered GFRP in percentage ranging 0, 0.2, 0.3, and 0.4 which is designed as per IS standards. Tests on fresh concrete to determine the values of, compacting factor, Vee-Bee Consistency and slump are conducted. Compression, Tension and Flexure tests are conducted on hardened concrete. Conclusions are made from the results of fresh and hardened concrete properties by comparing with those of normal concrete. Copyright © 2018 SPB Pharma Society. All rights reserved.

Sadler, D. E., et al. (2019). "Temperature and clone-dependent effects of microplastics on immunity and life history in Daphnia magna." Environmental Pollution **255**(Pt 1): 113178.

Microplastic (MP) pollution is potentially a major threat to many aquatic organisms. Yet we currently know very little about the mechanisms responsible for the effects of small MPs on phenotypes, and the extent to which effects of MPs are modified by genetic and environmental factors. Using a multivariate approach, we studied the effects of 500nm polystyrene microspheres on the life history and immunity of eight clones of the freshwater cladoceran Daphnia magna reared at two temperatures (18degreeC/24degreeC). MP exposure altered multivariate phenotypes in half of the clones we studied but had no effect on others. In the clones that were affected, individuals exposed to MPs had smaller offspring at both temperatures, and more offspring at high temperature. Differences in response to MP exposure were unrelated to differences in particle uptake, but were instead linked to an upregulation of haemocytes, particularly at high temperature. The clone-specific, context-dependent nature of our results demonstrates the importance of incorporating genetic variation and environmental context into assessments of the impact of plastic particle exposure. Our results identify immunity as an important mechanism underpinning genetically variable responses to MP pollution and may have major implications for predicting consequences of MP pollution.

Saez, J., et al. (2016). Phantom microbeads chromatography column in microfluidics. 20th International Conference on Miniaturized Systems for Chemistry and Life Sciences, MicroTAS 2016.

Water pollution is one of the biggest concerns of society at the moment. Among all water pollutants, oils and surfactants are especially harmful for human health and the environment; therefore they should be continually monitored to avoid water contamination.[1] In this work we propose a new microfluidic device composed by packed microbeads invisible in water. This system enables an alternative methodology to detect polluting compounds in water samples.

Safarik, I., et al. (2008). "Hydrogen peroxide removal with magnetically responsive Saccharomyces cerevisiae cells." Journal of Agricultural & Food Chemistry **56**(17): 7925-7928.

Hydrogen peroxide (HP) is a promising chemical sanitizer for use in the food industry. Its residues have to be decomposed, usually using an enzyme process employing catalase. In order to offer an inexpensive biocatalyst and to simplify subsequent manipulation, we have prepared magnetically responsive alginate beads containing entrapped Saccharomyces cerevisiae cells and magnetite microparticles. Larger beads (2-3 mm in diameter) were prepared by dropping the mixture into calcium chloride solution, while microbeads (the diameter of majority of particles ranged between 50 and 100 microm) were prepared using the water in oil emulsification process. In general, microbeads enabled more efficient HP decomposition. The prepared microparticulate biocatalyst caused efficient decomposition of HP in water solutions (up to 2% concentration), leaving very low residual HP concentration after treatment (below 0.001% under appropriate conditions). The biocatalyst was stable; the same catalytic activity was observed after one month storage at 4 degrees C, and the microbeads could be used at least five times.

Safeukui, I., et al. (2013). "Surface Area Loss and Increased Sphericity Account for the Splenic Entrapment of Subpopulations of Plasmodium falciparum Ring-Infected Erythrocytes. e60150." PLoS ONE **8**(3).

Ex vivo perfusion of human spleens revealed innate retention of numerous cultured Plasmodium falciparum ring-infected red blood cells (ring-iRBCs). Ring-iRBC retention was confirmed by a microsphiltration device, a microbead-based technology that mimics the mechanical filtering function of the human spleen. However, the cellular alterations underpinning this retention remain unclear. Here, we use ImageStream technology to analyze infected RBCs' morphology and cell dimensions before and after fractionation with microsphiltration. Compared to fresh normal RBCs, the mean cell membrane surface area loss of trophozoite-iRBCs, ring-iRBCs and uninfected co-cultured RBCs (uRBCs) was 14.2% (range: 8.3-21.9%), 9.6% (7.3-12.2%) and 3.7% (0-8.4), respectively. Microsphilters retained 100%, 50% and 4% of trophozoite-iRBCs, ring-iRBCs and uRBCs, respectively. Retained ring-iRBCs display reduced surface area values (estimated mean, range: 17%, 15-18%), similar to the previously shown threshold of surface-deficient RBCs retention in the human spleen (surface area loss: >18%). By contrast, ring-iRBCs that successfully traversed microsphilters had minimal surface area loss and normal sphericity, suggesting that these parameters are determinants of their retention. To confirm this hypothesis, fresh normal RBCs were exposed to lysophosphatidylcholine to induce a controlled loss of surface area. This resulted in a dose-dependent retention in microsphilters, with complete retention occurring for RBCs displaying >14% surface area loss. Taken together, these data demonstrate that surface area loss and resultant increased sphericity drive ring-iRBC retention in microsphilters, and contribute to splenic entrapment of a subpopulation of ring-iRBCs. These findings trigger more interest in malaria research fields, including modeling of infection kinetics, estimation of parasite load, and analysis of risk factors for severe clinical forms. The determination of the threshold of splenic retention of ring-iRBCs has significant implications for diagnosis (spleen functionality) and drug treatment (screening of adjuvant therapy targeting ring-iRBCs).

Safeukui, I., et al. (2013). "Surface area loss and increased sphericity account for the splenic entrapment of subpopulations of Plasmodium falciparum ring-infected erythrocytes." PLoS ONE [Electronic Resource] **8**(3): e60150.

Ex vivo perfusion of human spleens revealed innate retention of numerous cultured Plasmodium falciparum ring-infected red blood cells (ring-iRBCs). Ring-iRBC retention was confirmed by a microsphiltration device, a microbead-based technology that mimics the mechanical filtering function of the human spleen. However, the cellular alterations underpinning this retention

remain unclear. Here, we use ImageStream technology to analyze infected RBCs' morphology and cell dimensions before and after fractionation with microsphiltration. Compared to fresh normal RBCs, the mean cell membrane surface area loss of trophozoite-iRBCs, ring-iRBCs and uninfected co-cultured RBCs (uRBCs) was 14.2% (range: 8.3-21.9%), 9.6% (7.3-12.2%) and 3.7% (0-8.4), respectively. Microsphilters retained 100%, ~50% and 4% of trophozoite-iRBCs, ring-iRBCs and uRBCs, respectively. Retained ring-iRBCs display reduced surface area values (estimated mean, range: 17%, 15-18%), similar to the previously shown threshold of surface-deficient RBCs retention in the human spleen (surface area loss: >18%). By contrast, ring-iRBCs that successfully traversed microsphilters had minimal surface area loss and normal sphericity, suggesting that these parameters are determinants of their retention. To confirm this hypothesis, fresh normal RBCs were exposed to lysophosphatidylcholine to induce a controlled loss of surface area. This resulted in a dose-dependent retention in microsphilters, with complete retention occurring for RBCs displaying >14% surface area loss. Taken together, these data demonstrate that surface area loss and resultant increased sphericity drive ring-iRBC retention in microsphilters, and contribute to splenic entrapment of a subpopulation of ring-iRBCs. These findings trigger more interest in malaria research fields, including modeling of infection kinetics, estimation of parasite load, and analysis of risk factors for severe clinical forms. The determination of the threshold of splenic retention of ring-iRBCs has significant implications for diagnosis (spleen functionality) and drug treatment (screening of adjuvant therapy targeting ring-iRBCs).

Safin, R. R., et al. (2019). THE STUDY OF THE DESTRUCTIVE PROPERTIES OF WOOD-FILLED COMPOSITES FOR THE PRODUCTION OF BIODEGRADABLE PACKAGING MATERIALS. Sofia, Surveying Geology & Mining Ecology Management (SGEM). **19:** 541-546.

Today it is difficult to imagine the area of human life, where polymeric materials are not used. However, the increasing consumption of polymers for packaging, as well as other household disposable products creates a problem of plastic waste and a threat to the environment. The chemical stability of polymers makes it possible to withstand the effects of physicochemical (solar radiation, heat, humidity, oxygen of the air) and biological (microorganisms) natural factors for many decades without noticeable destruction. In this connection, the development, production and use of new types of biodegradable composite materials for the packaging industry, which can biodegrade to environmentally friendly components under appropriate conditions, is relevant. This article discusses the possibility of using a biodegradable composite material, based on polylactide and filler, made of thermally modified wood flour, for packaging. It has been established that polylactide packaging with the addition of 60% thermo-modified wood filler would provide a high rate of biodegradation of the used packaging, thereby reducing the environmental stress on the environment. At the same time, the resulting composite will have acceptable physicomechanical and special characteristics intended for use as a package.

Sagar, K., et al. (2013). "Bio-degradation of 40 micron plastic bags by Aspergillus niger and optimization of pre-treatment methods." Environment Conservation Journal **14**(3): 61-68.

Lack of degradability and the closing of landfill sites as well as growing water and land pollution problems have led to concern about plastics. Among the various types of plastics, the most extensively used type is polyethylene bags. A survey on 40 micron polyethylene bags was done by obtaining the information from the City corporation office, Belgaum, Karnataka, India on the amount of plastic waste generated in the city. Polyethylene bags having a thickness less than 40 micron are not recycled, thus have to be degraded. In this work, Aspergillus niger is been employed to degrade the 40 micron plastic. Various pre-treatment methods are used which

include UV, nitric acid, thermal and UV+nitric acid treatments to effectively degrade the plastic. Different media having pre treated plastic as the carbon source are tested for the degradation of plastic along with the growth of the fungi. Incubation period was taken as 15 and 30 days. Optimization of pre-treatment methods was done to improve the degradation efficiency. Various analysis methods such as FTIR spectroscopy and dry-weight analysis were done to confirm the degradation of plastic.

Sagawa, N., et al. (2018). "Abundance and size of microplastics in a coastal sea: Comparison among bottom sediment, beach sediment, and surface water." Marine Pollution Bulletin **133**: 532-542.

Microplastics have adverse effects on marine life. This study examined the abundance and size of microplastics as well as their polymer types in the surface water and the bottom and beach sediments of Hiroshima Bay. The fragmentation process and sinking factors of foamed polystyrene (FPS) microplastics were also examined. Serious FPS pollution spread out not only in the beach sediments but also in the bottom sediments. The average size of FPS particles in the bottom sediments was significantly smaller than that of beached FPS particles. Field emission scanning electron microscopy images suggest that large amounts of microsized or nanosized FPS fragments are likely to be generated from the margins of beached FPS microplastics. X-ray computed tomography images show that FPS microplastics from the bottom sediments had tunnel-like structures inside the particle. Based on these images, FPS microplastics in the bottom sediments were susceptible to biofouling and soil deposition.

Sagis, L. M. C. (2019). "Coarse-grained models for diffusion in oil-filled hydrogel microbeads." Food Hydrocolloids **89**: 294-301.

Diffusion of digestive enzymes in oil-filled hydrogel microbeads is a highly complex process which is difficult to model, particularly for systems with high volume fractions of incorporated nano-droplets. In this paper coarse-grained models for this process are compared. The results show that the interplay between adsorption at the oil-water interface and diffusion through the matrix of the bead can lead to a front-like motion of the enzyme. This motion can be described by combining the mass balance for the enzyme with a Maxwell-Cattaneo type equation for the mass flux vector. Solutions of the resulting partial differential equation show that when tau << t_d (where tau and t_d are characteristic times for adsorption and diffusion) the time evolution of the enzyme concentration is identical to the profile calculated using Fick's law. For tau >>t_d and time t <= tau the enzyme migrates through the hydrogel as a sharp front. The position of the front changes linearly with time, and this corresponds well with findings of a recent experimental study (van Leusden et al. (2018), Food Hydrocolloids, 85, 242-247). The effects of poly-dispersity of the interior oil droplet phase were described using a multi-mode generalization of the Maxwell-Cattaneo model, and the results show that a widening of the droplet size distribution leads to smoothing of the front. The results show that this level of coarse-grained modelling can capture the dynamics of these complex systems quite accurately.

Sahay, N. (2018). "Plastic pollution, a study of knowledge, attitude and practices among students." Indian Journal of Public Health Research and Development **9**(10): 1014-1021.

Over the years, plastic pollution has unquestionably surfaced as most pervasive pollution problem of the century afflicting land, waterways and seas. The intemperate interference of the mankind in the natural cycles has been wreaking havoc on natural environment. It is necessary to understand as to what extent the individuals are aware of these facts, what are their attitude and whether they are at all taking any step to address these issues. The objective of the study is

to have complete knowledge, attitude and practice among the students who are pursuing PhD, Post Graduate and Under Graduate studies. Students belonging to diverse academic background were the respondents. Area of study is the capital city of India i.e. Delhi and NCR. A structured questionnaire was prepared to assess the KAP of students towards plastic pollution. A Google Form was created and shared with the respondents. A total of 200 students participated in the survey. Both Male and female students were included in this research. Findings of the study show the Knowledge, Attitude and Practices existing among the students. Further an analysis was made of the findings. Recommendations to empower the students with knowledge and skill to curb this plastic pollution is also included in this research paper. © 2018, Indian Journal of Public Health Research and Development. Sahoo, S. K., et al. (2013). "Formulation, in vitro drug release study and anticancer activity of 5-fluorouracil loaded gellan gum microbeads." Acta Poloniae Pharmaceutica **70**(1): 123-127.

5-Fluorouracil loaded calcium-zinc-gellan and calcium-zinc-gellan-ethyl cellulose microbeads were successfully prepared by simple ionotropic gelation and oil in water ionotropic gelation technique, respectively. Prepared microbeads were characterized by scanning electron microscopy, Fourier transform infrared spectroscopy and evaluated for particle size, drug content, encapsulation efficiency, drug release and cell cytotoxicity study. Microbeads formed were spherical with rough surface. As concentration of gellan and ethyl cellulose has increased encapsulation efficiency, particle size and sustained drug release effect also increased. The release of 5-fluorouracil from microbeads has followed Hixson Crowell model suggesting the mechanism of drug release as dissolution controlled. Cytotoxicity analysis on HT-29 human colon cancer cell lines indicated that 5-FU loaded gellan gum/gellan in combination with ethyl cellulose microbeads leads to sustained releases of drug and thus delayed apoptosis over a long period of time. The formulation with drug:gellan:ethyl cellulose ratio 2.5:7.5:1 was found to be more effectual in terms of sustained drug release activity in addition to anti-cancer activity.

Sahoo, S. K., et al. (2015). "Microspheres embedded in microbeads: A novel approach to improve various controlled release characteristics of highly water soluble drug through ionic gelation method." Indian Journal of Pharmaceutical Education and Research **49**(2): 140-145.

The major hindrance behind the preparation of gellan microbeads by simple ionic gelation technique with aqueous soluble drugs is their low entrapment efficiency and sometimes its faster dissolution characteristics. This limits the employment of such a simple method for the preparation of microbeads of water-soluble drugs like stavudine. In the present study a novel attempt has been undertaken by embedding stavudine loaded Eudragit RSPO microspheres into gellan microbeads by ionotropic gelation method with an aim to improve its controlled drug delivery characteristics. The prepared microbeads were characterized by scanning electron microscopy, Fourier transform infrared spectroscopy, and optical microscopy for surface topography, drug polymer interaction and particle size analysis respectively. Other studies like drug content, encapsulation efficiency and drug release studies were also carried out. The resulting microspheres embedded in microbeads were free flowing in nature with mean particle size ranging from 544.2-564.2 micro m. SEM photomicrographs distinctly shows the microspheres embedded within the microbeads effectively with a smooth surface topography and the gellan microbeads containing D4T only are spherical in nature with rough surface. The FTIR study ascertained the compatibility of the drug within the formulation. The microspheres embedded in microbeads had enhanced percentage of drug content, drug entrapment efficiency and controlled release characteristics as compared to beads containing stavudine only. The mechanism of drug release from the formulations were found to follow non Fickian type diffusion with "n" value between 0.5 to 1but in case of stavudine loaded Eudragit RSPO microspheresit was found to be Fickian type. Sai, X., et al. (2013). "Isolation of hepatic stellate cells from mice infected with Schistosoma japonicum." China Tropical Medicine **13**(8): 915-917.

Objective: To explore a steady and effective method for isolation of hepatic stellate cells (HSCs) from mice infected with Schistosoma japonicum.

Said, T., et al. (2018). "Assessment of the impact of CryoFlex tubing on sperm, cryopreservation outcome." Human Reproduction **33 (Supplement 1)**: i174.

Study question: Does wrapping cryovials with CryoFlex tubing prior to immersion in liquid nitrogen (LN) impact sperm cryopreservation outcome and the post-thaw recovery of motile sperm? Summary answer: The use of CryoFlex tubing can negatively impact the out-come of sperm cryopreservation. The tubing should be removed prior to thawing to prevent such outcome. What is known already: Cryovials are widely used to store cryopreserved semen samples. Nevertheless, they are not considered to provide effective bio-containment. Thus, LN penetration in addition to contamination of samples and LN tanks remain a concern. It has been suggested that wrapping cryovials in heat-shrinkable tubing prior to immersion in LN could reduce these risks. The tubing is made of a safe plastic resin polymer, however it has a poor tem-perature capability, which could affect cryopreservation-thawing protocols. It is not yet known if the use of CryoFlex tubing will impact the outcome of sperm cryopreservation, specifically, cryosurvival rates. Study design, size, duration: Semen samples (n = 34) were included in this cross-sectional study. Following dilution with cryoprotectant media, each sample was split into 2 equal aliquots: 1) sample with CryoFlex wrapping, and 2) control without CryoFlex wrapping. The CryoFlex tubing remained wrapped during the thawing in 20 samples; while it was removed prior to thawing in 14 samples. All trials were conducted over the course of 3 months. Participants/materials, setting, methods: Samples were provided by healthy donors. All aliquots were cryopreserved in vials with internal threading and silicon gasket (Nunc CryoTubes, Thermo Scientific). Heat-sealable wrapping (Nunc CryoFlex, Thermo Scientific) was applied to the sample aliquots, vials without wrapping served as controls. Thereafter, aliquots were placed in liquid nitrogen vapor for 20 minutes followed by plunging in liquid nitrogen. Thawing was performed after a minimum of 24 hours by immersion in 37 C water bath for 4 minutes. Main results and the role of chance: Cryosurvival rates were calculated by dividing total motile sperm post-thaw by total motile sperm pre-freeze X 100. Statistical analysis was conducted using paired t-test with two-tailed test of sig-nificance. In samples thawed with the CryoFlex wrapping, the post-thaw sperm percentage motility and cryosurvival rates were significantly lower compared to controls (26.4 +/- 6.1 vs. 30.9 +/- 8.2, P = 0.003 and 60.6 +/- 11.7 vs. 70.2 +/- 12.8, P = 0.007, respectively). In samples where CryoFlex wrapping was removed prior to the thawing, no significant differences were noted in post-thaw sperm percentage motility and cryosurvival rates (32.1 +/- 12.9 vs. 32.9 +/- 12.8 and 69.0 +/- 20.4 vs. 71.0 +/- 12.5, respectively). Overall, the results showed that whenever the CryoFlex tubing is kept wrapped around the vials during the thawing process, a significant decline in the recovery of cryopreserved spermatozoa post-thaw will occur. No such decline was seen when the CryoFlex tubing was removed prior to thawing. Limitations, reasons for caution: Our results are solely based on the evalu-ation of semen samples from healthy donors with normal semen parameters using a single cryopreservation protocol. It cannot be assumed that semen samples with lower quality parameters or the use of other cryopreservation protocol will yield with the same

results. Wider implications of the findings: This pilot provides new insights into the impact on CryoFlex tubing on sperm cryopreservation outcome. While it may alleviate some of the safety concerns associated with the use cryovials in sperm cryopreservation, CryoFlex can also negatively impact the outcome of sperm cryopreservation unless removed prior to thawing.

Saido, K., et al. (2014). "New analytical method for the determination of styrene oligomers formed from polystyrene decomposition and its application at the coastlines of the North-West Pacific Ocean." Science of the Total Environment **473-474**: 490-495.

Abstract: The pollution caused by plastic debris is an environmental problem with increasing concern in the oceans. Among the plastic polymers, polystyrene (PS) is one of the most problematic plastics due to the direct public health risk associated with their dispersion, as well as the numerous adverse environmental impacts which arise both directly from the plastics and from their degradation products. Little is known about their potential distribution characteristics throughout the oceans. For the first time, we report here on the regional distribution of styrene monomer (SM), styrene dimers (SD; 2,4-diphenyl-1-butene, SD1; 1,3-diphenyl propane, SD2), and styrene trimer (2,4,6-triphenyl-1-hexene: ST1), as products of PS decomposition determined from samples of sand and seawater from the shorelines of the North-West Pacific ocean. In order to quantitatively determine SM, SD (=SD1+SD2), and ST1, a new analytical method was developed. The detection limit was $3.3\mu gL^{-1}$, based on a signal-to-noise ratio of three, which was well-suited to quantify levels of SM, SD, and ST1 in samples. Surprisingly, the concentrations of SM, SD, and ST1 in sand samples from the shorelines were consistently greater than those in seawater samples from the same location. The results of this study suggest that SM, SD, and ST1 can be widely dispersed throughout the North-West Pacific oceans. [Copyright &y& Elsevier]

Saifuddin, N., et al. (2011). "Chitosan-silver nanoparticles composite as point-of-use drinking water filtration system for household to remove pesticides in water." Asian Journal of Biochemistry **6**(2): 142-159.

Adsorption techniques are widely used to remove certain classes of pollutants from water and wastewater. Biosorbents such as natural and waste materials from industries and agriculture can be used as alternatives adsorbents which are inexpensive and easily obtainable. The objective of this study was to prepare silver nanoparticles embedded in chitosan, which is a non-toxic and biodegradable natural polymer, using microwave irradiation for the removal of pesticides from water. Cross-linked chitosan-silver nanoparticle composite bioadsorbent was prepared in order to investigate the adsorption and release behaviours of the pesticide, Atrazine. The concentration and time dependencies of the adsorbent for the pesticide were studied. The equilibrium time was found to be 65 min for 1, 5, 10, 20 and 25 ppm Atrazine concentration. A sharp increase in percent reduction of the pesticide content was observed in water as the adsorbent dose was increased from 0.5 to 2.0 g. At 2.0 g dosage of cross-linked chitosan-silver nanoparticle composite micro-beads, 98% removal was observed for 1 L of pesticide solution at 1 ppm concentration (1 mg L⁻¹). From the batch studies, the adsorbent capacity of the cross-linked chitosan-silver nanoparticle composite micro-beads toward Atrazine was 0.5 mg g⁻¹ of the adsorbent in 65 min. An on-line filter was

made using a column of cross-linked chitosan-silver nanoparticle composite micro-beads and the device was used for pesticide removal for extended periods. From the breakthrough curves, the results of breakthrough adsorption capacity and the total adsorption capacity were, respectively 115 and 360 micro g mL⁻¹ cross-linked chitosan-silver nanoparticles composite micro beads.

Saito, S., et al. (2012). "CD19-Specific T-Cell therapy for refractory philadelphia-chromosome-positive acute lymphoblastic leukemia using piggybac transposon-based gene modification and low autoserum-containing, but xeno-free and tumor cell line-free culture system." Molecular Therapy **1)**: S184-S185.

BCR-ABL tyrosine kinase inhibitors (TKIs) would improve the prognosis of patients with Philadelphia chromosome-positive (Ph+) ALL. However, TKI treatment often induces drug-resistance mutations. In particular, T315I mutation is refractory to second generation TKIs, dasatinib and nilotinib. Consequently, the prognosis of patients after TKI failure is very poor. Immunotherapy may be a promising strategy to overcome drug-resistant leukemic clones because Ph+ALL is subject to an apoptotic signal via TRAIL (Uno et al., 2003). We have previously demonstrated the nonviral piggyBac-transposon can efficiently and stably modify human T cells (Nakazawa et al., 2009), and cytotoxic T cells modified with piggyBac to express HER2-specific chimeric antigen receptor (CAR) directing towards HER2-positive tumors in vivo (Nakazawa et al., 2011). Aim of this study was to determine whether T cells modified to express CD19-specific CAR by piggyBac could induce potent cytotoxic effects in Ph+ALL. To generate CD19CAR expressing T cells, 1 x 107 peripheral blood mononuclear cells were nucleofected with a transposon encoding CD19CAR and a piggyBac. Nucleofected cells were stimulated with anti-CD3/CD28 antibodies, cultured in T-cell medium containing 2% autoserum and interleukin-15 for 7 days, and then selected with anti-CAR biotin-conjugated antibody followed by anti-biotin microbeads. The positively selected T cells were restimulated and further expanded for 14 days on UVB-irradiated negatively fractionated T cells as feeder cells in the G-Rex10 device. Generated T cells (CAR-T) were expanded up to 6 x 107 within 3 weeks of culture, and expressed CD19CAR at ~30%. To evaluate the anti-leukemia effect, we cocultured CAR-T with seven Ph+ALL lines (TKIs-resistant in 3 lines including a T315I mutatant) at effector/target ratios of 1:1, 1:5, 1:10, 1:50, and 1:100. In all cocultures from 1:1 to 1:10, CAR-T almost eradicated Ph+ALL cells on day 5, and in 5 of 7 cocultures even at effector/target ratios of 1:50 and 1:100, CAR-T enabled reducing Ph+ALL cells by day 10. By contrast, in control cocultures, non-transfected T cells did not show killing effect except cocultures at a 1:1 ratio. In conclusion, CD19CAR-T cells could develop superior cytotoxicity against Ph+ALL, even if the number is small for Ph+ALL cells. For transplant patients, the infusion of 1 x 106 cells/kg of recipient weight would not be great risk for graftversus- host disease. Additionally, our non-viral gene-transfer and T-cell culture system with 2% autoserum and without animal/tumorderived materials would be safe and cost-efficient for clinical use.

Sajdak, M. and K. Slowik (2014). "Use of plastic waste as a fuel in the co-pyrolysis of biomass: part II. Variance analysis of the co-pyrolysis process." Journal of Analytical and Applied Pyrolysis **109**: 152-158.

The aim of our study described in this article was statistical evaluation of the influence of process conditions on the chemical and physical properties of products obtained from biomass and plastic waste co-pyrolysis. To estimate the effects of the process conditions on the chemical and physical properties of products, analysis of variance (ANOVA) was used. Furthermore, a mathematical equation that can be used to determine the degree of change in chemical and physical properties of the solid, liquid and gaseous products from co-pyrolysis depending on

process conditions is presented in this article. In investigation were used alder wood (hardwood) and pine wood (softwood) with polypropylene addition which were carbonized in various thermal conditions. In the presented studied was described significant effect among char, liquid and gaseous fraction properties according to polymer addition. Analysis of variance (ANOVA) employed to exploratory analysis shows that the type of material has the most significant effect on the nitrogen concentration in the char, the nitrogen and sulphur concentration in the liquid fraction and the carbon mono- and dioxide, methane concentration in gaseous fraction.

Sakai, K., et al. (2011). "3-D collagen-dependent cell surface expression of MT1-MMP and MMP-2 activation regardless of integrin beta1 function and matrix stiffness." Biochemical & Biophysical Research Communications **412**(1): 98-103.

Matrix metalloproteinases (MMPs) play roles in spatially dynamic processes, including morphogenesis, wound healing, and tumor invasion. Three-dimensional (3-D) type I collagen stimulates cellular activation of MMP-2, however, the mechanisms underlying this are controversial. The present study investigated mechanisms for 3-D collagen-induced MMP-2 activation in highly invasive human malignant mesothelioma cells. MMP-2 was effectively activated by cells cultured in 3-D collagen but not in 2-D collagen, whereas MMP-2 activation was not regulated by the flexibility of collagen. The 3-D collagen did not largely increase the gene expression of MMP-2 and MT1-MMP. However, MT1-MMP exposed to the cell surface was much increased by 3-D collagen, and loss of MT1-MMP abolished MMP-2 activation in response to 3-D collagen. MT1-MMP and integrin beta1 translocated to pericellular regions interacting with collagen-coated microbeads, however their localization was different. Importantly, inhibition of integrin beta1 function and expression did not affect 3-D collagen-induced cell surface localization of MT1-MMP and MMP-2 activation. Our results strongly suggest that 3-D collagen scaffolding may provide opportunity for direct and multivalent interaction with MT1-MMP, by which MMP-2 activation occur in abundant cell surface MT1-MMP-dependent manner, rather than a manner regulated by matrix stiffness and integrin beta1 function.

Sakai, M. (2007). "Biomass Moves From "Biodegradable" To "Carbon Neutral"." BioCycle **48**(2): 54.

Voluntary industry standards for food containers are in place regarding use of PLA (Polylactic Acid) products, and standards are being examined for PBS (Poly Butylene Succinate) in Japan. Work is underway to use biomass plastics to improve heat proof, impact proof and crystallization speeds. The Biomass Nippon Strategy provides the strategic background for biomass use complete with specific goals and an action plan. In the strategy for biomass plastics, specific goals include a decrease in the price of biomass plastic resin to 200 yen in 2010, from a current price of 400 to 500 yen per kg. Registered products exceed 100 items as of the end of September 2006.

Sakudo, A., et al. (2007). "Recent developments in prion disease research: diagnostic tools and in vitro cell culture models." Journal of Veterinary Medical Science **69**(4): 329-337.

After prion infection, an abnormal isoform of prion protein (PrP^{Sc}) converts the cellular isoform of prion protein (PrP^C) into PrP^{Sc}. PrP^C-to-PrP^{Sc} conversion leads to PrP^{Sc} accumulation and PrP^C deficiency, contributing etiologically to induction of prion diseases. Presently, most of the diagnostic methods for prion diseases are dependent on PrP^{Sc} detection. Highly sensitive/accurate specific detection of PrP^{Sc} in many different samples is a prerequisite for attempts to develop reliable detection methods. Towards this goal, several methods have recently been developed to facilitate sensitive and

precise detection of PrP^{Sc}, namely, protein misfolding cyclic amplification, conformation-dependent immunoassay, dissociation-enhanced lanthanide fluorescent immunoassay, capillary gel electrophoresis, fluorescence correlation spectroscopy, flow microbead immunoassay, etc. Additionally, functionally relevant prion-susceptible cell culture models that recognize the complexity of the mechanisms of prion infection have also been pursued, not only in relation to diagnosis, but also in relation to prion biology. Prion protein (PrP) gene-deficient neuronal cell lines that can clearly elucidate PrP^C functions would contribute to understanding of the prion infection mechanism. In this review, we describe the trend in recent development of diagnostic methods and cell culture models for prion diseases and their potential applications in prion biology.

Šál, J. and P. Nováková (2019). APPLICATION OF PET BOTTLES FOR CONCRETE MASONRY BLOCKS. Sofia, Surveying Geology & Mining Ecology Management (SGEM). **19:** 19-24.

The production of cavity blocks, also referred to as concrete masonry blocks (CMU) or concrete lost formwork, takes place in a mobile or stationary press by extruding a special matrix through solid fresh concrete. This production is relatively cheap, simple and fast, provided we have the appropriate press. This article examines whether such concrete blocks can be manufactured without specialized equipment. This can be beneficial, for example, in slums or areas dependent on humanitarian aid, where there is not enough dwelling. On the contrary, in these areas there is a large amount of plastic waste, washed up from the oceans and landfilled in illegal dumps. Several methods of using PET bottles for forming cavities in concrete blocks are proposed in this article. PET bottles can save some of the concrete and create a closed air cavity that improves the thermal properties of the block. Moreover, it is a way to use plastic waste that needs to be recycled and which is a huge problem of the present.

Saleem, J., et al. (2015). "Combating oil spill problem using plastic waste." Waste Management **44**: 34-38.

Thermoplastic polymers (such as polypropylene, polyethylene, polyethylene terephthalate (PET) and high density polyethylene (HDPE)) constitute 5-15% of municipal solid waste produced across the world. A huge quantity of plastic waste is disposed of each year and is mostly either discarded in landfills or incinerated. On the other hand, the usage of synthetic polymers as oil sorbents, in particular, polyolefins, including polypropylene (PP), and polyethylene (PE) are the most commonly used oil sorbent materials mainly due to their low cost. However, they possess relatively low oil absorption capacities. In this work, we provide an innovative way to produce a value-added product such as oil-sorbent film with high practical oil uptake values in terms of g/g from waste HDPE bottles for rapid oil spill remedy.

Saleem, M., et al. (2019). "Fundamental investigation of solid waste generation and disposal behaviour in higher education institute in the Kingdom of Saudi Arabia." Indoor and Built Environment **28**(7): 927-937.

Waste characterization is a fundamental step for the development of solid waste management plan. In this regard, understanding the waste generation and disposal patterns plays a crucial role in developing realistic waste reduction strategies. Presently, there exists no solid waste management plan for higher education institutes in the Kingdom of Saudi Arabia. Hence, this article details the fundamental study related to the waste generation and disposal behaviour. The study also dwells into the existing practices of solid waste management and sheds light on the new polices that can be adopted for waste reduction, along with highlighting barriers to optimization of solid waste management. Through investigation, it was found that by adopting

E-learning system for examination and replacing paper towels with air dryers in washroom and by revising policy related to printing, considerable reduction in paper waste could be achieved. Furthermore, the adoption of the proposed sustainable drinking water solution led to 90% reduction in plastic pet bottle waste. The recommendations made by the presented investigation can be employed by other similar sized institutes in developing countries for the development of sustainable green campuses. Copyright © The Author(s) 2018.

Saley, A. M., et al. (2019). "Microplastic accumulation and biomagnification in a coastal marine reserve situated in a sparsely populated area." Marine Pollution Bulletin **146**: 54.

Toxic chemicals within and adsorbed to microplastics (0.05–5 mm) have the potential to biomagnify in food webs. However, microplastic concentrations in highly productive, coastal habitats are not well understood. Therefore, we quantified the presence of microplastics in a benthic community and surrounding environment of a remote marine reserve on the open coast of California, USA. Concentrations of microplastic particles in seawater were 36.59 plastics/L and in sediments were 0.227 ± 0.135 plastics/g. Densities of microplastics on the surfaces of two morphologically distinct species of macroalgae were 2.34 ± 2.19 plastics/g (Pelvetiopsis limitata) and 8.65 ± 6.44 plastics/g (Endocladia muricata). Densities were highest in the herbivorous snail, Tegula funebralis, at 9.91 ± 6.31 plastics/g, potentially due to bioaccumulation. This study highlights the need for further investigations of the prevalence and potential harm of microplastics in benthic communities at remote locations as well as human population centers.

Salih, B., et al. (1998). "Determination of inorganic and organic mercury compounds by capillary gas chromatography coupled with atomic absorption spectrometry after preconcentration on dithizone-anchored poly(ethylene glycol dimethacrylate-hydroxyethylmethacrylate) microbeads." Analytica Chimica Acta **371**(2-3): 177-185.

Poly(EGDMA-HEMA) microbeads were prepared by suspension polymerization of ethylene glycol dimethacrylate (EGDMA) and hydroxyethyl methacrylate (HEMA). Poly(vinyl alcohol), benzoyl peroxide and toluene were used as stabilizer, initiator, and diluent, respectively. A chelating ligand, dithizone, was then attached. The microbeads were characterized by FTIR spectrometers and elemental analysis. The affinity microbeads containing 118.9mumol dithizoneg⁻¹ polymer were used for the adsorption/desorption of inorganic mercury [Hg], methyl mercury chloride [CH<inf>3</inf>HgCl] and ethyl mercury chloride [C<inf>2</inf>H<inf>5</inf>HgCl] from aqueous media at concentrations in the range 5-1000mugl⁻¹ and various pH values (2.0-8.0). Adsorption rates were high, and adsorption equilibria were reached in about 30min. The maximum adsorption of mercury species onto the dithizone-anchored microbeads from their individual solutions was 138mgg⁻¹ for Hg(II), 221mgg⁻¹ for CH<inf>3</inf>HgCl and 207mgg⁻¹ for C<inf>2</inf>H<inf>5</inf>HgCl. The same behavior was observed during competitive adsorption in the case of the adsorption from their mixture. The affinity order of mercury species was CH<inf>3</inf>HgCl > C<inf>2</inf>H<inf>5</inf>HgCl > Hg(II). Dithizone-anchored microbeads are suitable for repeated use for more than 5 cycles without noticeable loss of adsorption capacity. Speciation of organomercurials was performed using a Gas chromatography-atomic absorption spectrometry coupled system. Detection limits were increased at least 120-fold with this preconcentration approach using the dithizone-anchored microbeads. Copyright (C) 1998 Elsevier Science B.V.

Saliu, F., et al. (2018). "Microplastic and charred microplastic in the Faafu Atoll, Maldives." Marine Pollution Bulletin **136**: 464-471.

Microplastics are recognized as a growing threat for the marine environment that may even affect areas generally considered pristine. In this work we surveyed the microplastic contamination in the Faafu Atoll (Maldives, Indian Ocean) across twelve sampling station, located either inside or outside the reef rim. Sediments and seawater samples were collected. Despite the remoteness of the atoll, the scarce local population and low touristic annual afflux, the detected average abundance were 0.32+/-0.15particles/m³ in the surface water and 22.8+/-10.5particles/m² in the beach sediments. Polymers identified through Fourier-Transform Infrared spectroscopy were mostly polyethylene, polypropylene, polystyrene, polyvinylchloride, polyethyleneterephtalate, and polyamide. Elastomeric residues and charred microparticles were also found. In particular, the charred microparticles were prevalently located nearby the inhabited island and they might be considered a peculiarity of the area, related to local practice of burning plastic waste at the shoreline.

Saliu, F., et al. (2020). "Biocompatible solid-phase microextraction coupled to liquid chromatography triple quadrupole mass spectrometry analysis for the determination of phthalates in marine invertebrate." Journal of Chromatography **A.**: 460852.

This paper describes the development and validation of a new procedure for the determination of phthalates in marine invertebrates, based on biocompatible solid-phase microextraction (BioSPME) followed by liquid chromatography coupled to mass spectrometry. The importance of this application relies on the current use of marine organisms as bioindicators for microplastic contamination through the detection of phthalates in their tissues. Challenges originate from the availability and/or possible restriction on the use of the biological materials, the need for user- friendly procedures for simplifying and speeding up operations in the marine environments, and the ubiquitous presence of phthalates in the laboratory environments that may cause background contamination. BioSPME served as an effective solution to all these issues, owing to the extreme minimization of the sample manipulation. Sampling operations were limited to the direct transfer of small amounts of the biological materials (150 mg) inside glass vials capped with aluminium lids; extractions were carried out by ultrasonication in acetone followed by dilution in ultrapure water and BioSPME clean-up; Electrospray (ESI) LC-MS/MS was employed for the final analytical determinations on the purified extracts. Tests were carried out on samples belonging to three different phyla, namely Cnidaria, Porifera, and Mollusca obtained from Maldivian coral reef environments and used for a current microplastic contamination biomonitoring project. Overall, very good sensitivity and repeatability, with negligible back contamination of the blanks were observed. The limits of detections were between 0.2 and 2.1 ng/g and precision, calculated as relative standard deviation (RSD), was below 14% for all the tested phthalates.

Saliu, F., et al. (2019). "Microplastics as a threat to coral reef environments: Detection of phthalate esters in neuston and scleractinian corals from the Faafu Atoll, Maldives." Marine Pollution Bulletin **142**: 234-241.

The impact of microplastics (MPs) on reef-building corals are still largely unknown. The scientific literature provides evidence from lab feeding trials that coral may ingest MPs. Several adverse effects, i.e., necrosis and bleaching, have also been highlighted. However, field studies are limited. Here, we investigated for the first time the possible correlation between MP seawater contamination and the presence of phthalic acid esters (PAEs), a class of MP-associated contaminants, in scleractinian corals. The survey was carried out in a remote coral reef atoll in the Indian Ocean located in the Maldivian archipelago, considered as a case study. MPs and PAEs were monitored in subsurface neustonic tow samples and scleractinian corals across twelve sampling sites. The results showed widespread MP contamination and the presence of appreciable levels of PAEs in the scleractinian corals sampled inside the atoll rim near an inhabited island, which correlated with the highest MP concentration. Salles-Loustau, G., et al. (2018). "Cytocoded passwords: BioMEMS based barcoding of biological samples for user authentication in microfluidic diagnostic devices." Biomedical Microdevices **20**(3): 1-9.

Smart and connected point-of-care (POC) medical devices are becoming ever more ubiquitous and have the potential to radically improve disease diagnosis and health monitoring. This emerging connectivity can potentially create serious security issues where patient privacy can be easily compromised. Protection of patient data from malicious cyber-physical attackers requires radical solutions at the BioMEMS level. Ideally, the information exchange between the patient and practitioner is an automated and transparent process for the patient. In practice, this exchange requires both the patient and the test results to be authenticated and validated respectively on the storage service to ensure that the medical diagnostic results are properly stored and their access is protected. This secure authentication phase is particularly critical for medical diagnostics: patient data exposure could lead to negative social effects. This work focuses on providing a transparent authentication mechanism for patient blood tests performed using impedance flow cytometry. The goal is twofold: first, to alleviate the user from security procedures, precisely an authentication step, while using the medical device; second, to provide a unique identifier for the test results when stored in a remote server. This paper describes a domain specific authentication method for impedance flow cytometry devices. We spike into the blood samples synthetic micro-beads of different sizes, at determined concentrations, to generate a unique authentication string that uniquely identify a test result on the remote storage service. These authentication strings are embedded in the test devices and can be used as a convenient alternative to generic authentication methods, such as logins and passwords. This alternative method removes the authentication burden from the user and protects patient's privacy further by preventing them from linking their personal information to their test results.

Salma, N., et al. (1994). "Production of OKT3 monoclonal antibody at moderate scale by hybridoma encapsulation in calcium alginate." Biotecnologia Aplicada **11**(2): 131.

The entrapment of cells in calcium gel microbeads is a technique that is well adapted for use in biotechnology. One of the applications has been in the monoclonal antibody production field, in moderate of large scale. The encapsulation procedure takes advantage of the calcium-mediated gelation of sodium alginate. In this study, we encapsulated the OKT3 hybridoma at a concentration of 1.5 x 10 super(6) cells/mL of alginate, cultivated in a spinner vessel of 500 mL. The hybridoma showed a high cell density (reached a maximum of 11.7 x 10 super(6) cells/g alginate) and viability. The monoclonal antibody production was elevated, maintaining around 70 mg/mL of supernatant during the culture. The harvested supernatant was concentrated and purified without pyrogens. The results showed that the monoclonal antibody production was superior compared to conventional cultures. In this manner, the immobilization of hybridomas significantly promotes productivity.

Salvador Cesa, F., et al. (2017). "Synthetic fibers as microplastics in the marine environment: A review from textile perspective with a focus on domestic washings." Science of the Total Environment **598**: 1116-1129.

The ubiquity of plastic materials in the environment has been, for long, a matter of discussion. Smaller particles, named microplastics (<5mm), gained attention more recently and are now the focus of many studies, especially for their particularities regarding sources, characteristics and effects (e.g., surface-area-to-volume ratio which can increase their potential to transport toxic substances). Fibers from textile materials are a subgroup of microplastics and can be originated from domestic washings, as machine filters and wastewater treatment plants (WWTPs) are not specifically designed to retain them. Once in the environment, fibers can reach concentrations up to thousands of particles per cubic meter, being available to be ingested by a broad range of species. In this scenario, this review adds and details the textile perspective to the microplastics exploring nomenclature, characteristics and factors influencing emission, but also evidencing gaps in knowledge needed to overcome this issue. Preliminarily, general information about marine litter and plastics, followed by specific aspects regarding textile fibers as microplastics, were introduced. Then fiber sources to microplastic pollution were discussed, mainly focusing on domestic washings that pass through WWTPs. Studies that reveal domestic washing as microplastic sources are scarce and there is a considerable lack of standardization in methods as well as incorporation of textile aspects in experimental design. Knowledge gaps include laundry parameters (e.g., water temperature, use of chemicals) and textile articles characteristics (e.g., yarn type, fabric structure) orchestrated by consumers' choice. The lack of information on the coverage and efficiency of sewage treatment systems to remove textile fibers also prevent a global understanding of such sources. The search of alternatives and applicable solutions should come from an integrated, synergic and global perspective, of both environmental and textile area, which still need to be fostered.

Salvaggio, A., et al. (2019). "Biomarkers of Exposure to Chemical Contamination in the Commercial Fish Species Lepidopus caudatus (Euphrasen, 1788): A Particular Focus on Plastic Additives." Frontiers in Physiology **10**: 905.

In recent years, the Mediterranean Sea has become an accumulation zone for waste generated by the 22 countries bordering its shores. Although the effects of plastic litter on the marine environment and on organisms have recently been studied in other areas, further information is needed for the Mediterranean Sea and, in particular, about plastics additives inputs and interactions with the biota and the trophic network, such as phthalates and bisphenol A. Plastic material production, use and disposal contribute also to the release of heavy metals into the environment, such as mercury (Hg), often used during the production of chlorine, the primary ingredient in PVC, lead (Pb) and cadmium (Cd), which are used as stabilizers in PVC and leach out of products during use and disposal. Our research aims to evaluate phthalates, bisphenol A and heavy metals contamination in Lepidopus caudatus (Pisces, Trichiuridae), which could be considered as a potential sentinel species. For the evaluation of toxicological effects, we evaluated the expression of vitellogenin and metallothioneins 1. In all samples analyzed, we have not found microplastics in the gastrointestinal tract but chemical analysis revealed the presence of high content of phthalates, and in particular high quantities of DIDP, DEHP, bis-benzylester phthalate, bis-butyl ester phthalate and mono-N-butyl ester phthalate in different organs. Instead, trace elements detected in tissue revealed a trend of concentrations generally higher in liver and intestine than gill and muscle tissues. Immunohistochemical analysis for anti-metallothionein 1 antibody showed a strong positivity of liver cells, both in females and males. Analysis for the anti-vitellogenin antibody showed in females a strong positivity both in the liver cells and in the gonads, in male specimens was found to be always negative except for a specimen, in which it was highlighted a positivity in some areas of the liver and of the gonad.

Samaras, V. C. and D. P. Margaris (2010). "The Influence of a High Density Phase in a Multiphase Air-Lift Pump Performance." International Review of Chemical Engineering **2**(2): 240-245.

Pump performance of a lab-scale air-lift system for transporting solid particles is investigated experimentally. The internal diameter of the upriser varies between two values, 28 mm and 40 mm, while its total height is 4080 mm. Plastic particles of 3/8 in. are used as solid particles. The relation between the discharged liquid flux and the flux of injected air are obtained, varying injecting air flux, particles flux, type of upriser and submergence ratio. Experimental data are obtained, which represent the triangular relationship between the flow rate of air supplied and the flow rates of water and particles discharged. The results are presented on the flow-regime map. In addition, the particle motion in the upriser is investigated in detail by means of photographic observation. The physics of the phenomena is discussed from the practical viewpoint.

Samyuktha Rani, B., et al. (2012). "Mucoadhesive microbeads of metformin Hcl: A promising sustained drug delivery system." International Research Journal of Pharmacy **3**(5): 263-273.

The present work was investigated to reduce the dosing frequency, improve patient compliance, to improve gastric residence and to decrease GI side effects by designing and evaluating controlled Release Mucoadhesive (CRM) microbeads of Metformin hydrochloride for effective control of diabetes type-II. Microbeads were prepared by employing ionic gelation method by using various natural and synthetic polymers such as sodium alginate as main polymer and sodium carboxy methyl cellulose(SCMC), carboxy methyl cellulose(CMC), methyl cellulose (MC), poly vinyl pyrrolidine (PVP) as co-polymers which mainly containing mucoadhesive property.

These polymers are used with various proportions using calcium chloride as across linking agent. The mucoadhesive property of four polymers is in the following order (SCMC > CMC > MC > PVP).Twenty formulations were prepared. The mucoadhesive beads were characterized for micromeritic properties such as bulk density, tapped density, hausner's ratio, compressibility index, angle of repose, percentage drug content, entrapement effieciency, swelling index, In-vitro drug release, mucoadhesion test, drug kinetics and FT-IR studies. The drug entrapment efficiency increased progressively with increasing concentration of co - polymer resulting in the formation of larger microbeads entrapping greater amounts of the drug. No significant drug-polymer interactions were observed in FT-IR studies. The kinetics of drug release and their mucoadhesive nature in vitro using goat intestinal mucosa was also investigated at physiological pH 1.2 HcL. The effective mucoadhesion property with controlled release profile was observed from optimized mucoadhesive beads consisting of Sodium alginate and SCMC (1:5). The prepared microspheres exhibited prolonged drug release as the concentration of copolymer increased, as the SCMC polymer concentration increases the mucoadhesion increased and the drug release rate decreased at higher concentration of sodium alginate.

Sanchez, C. (2019). "Fungal potential for the degradation of petroleum-based polymers: An overview of macro- and microplastics biodegradation." Biotechnology Advances: 107501.

Petroleum-based plastic materials as pollutants raise concerns because of their impact on the global ecosystem and on animal and human health. There is an urgent need to remove plastic waste from the environment to overcome the environmental crisis of plastic pollution. This review describes the natural and unique ability of fungi to invade substrates by using enzymes that have the capacity to detoxify pollutants and are able to act on nonspecific substrates, the fungal ability to produce hydrophobins for surface coating to attach hyphae to hydrophobic substrates, and hyphal ability to penetrate three dimensional substrates. Fungal studies on macro- and microplastics biodegradation have shown that fungi are able to use these materials as the sole carbon and energy source. Further research is required on novel isolates from plastisphere ecosystems, on the use of molecular techniques to characterize plastic-degrading fungi and enhance enzymatic activity levels, and on the use of omics-based technologies to accelerate plastic waste biodegradation processes. The addition of pro-oxidants species (photosensitizers) and the reduction of biocides and antioxidant stabilizers used in the plastic manufacturing process should also be considered to promote biodegradation. Interdisciplinary research and innovative fungal strategies for plastic waste biodegradation, as well as ecofriendly manufacturing of petroleum-based plastics, may help to reduce the negative impacts of plastic waste pollution in the biosphere.

Sanchez, W., et al. (2014). "Wild gudgeons (Gobio gobio) from French rivers are contaminated by microplastics: preliminary study and first evidence." Environmental Research **128**: 98-100.

Marine ecosystem contamination by microplastics is extensively documented. However few data is available on the contamination of continental water bodies and associated fauna. The aim of this study was to address the occurrence of microplastics in digestive tract of gudgeons (Gobio gobio) from French rivers. These investigations confirm that continental fish ingested microplastics while 12% of collected fish are contaminated by these small particles. Further works are needed to evaluate the occurence of this contamination.

Sanchez-Moran, H., et al. (2019). "Oxime Cross-Linked Alginate Hydrogels with Tunable Stress Relaxation." Biomacromolecules **20**(12): 4419-4429.

Stress relaxation is an important design parameter of biomaterials that can provide an artificial microenvironment mimicking natural extracellular matrix (ECM). Here, we report a novel hydrogel platform based on sodium alginate (NaAlg) with tunable stress relaxation. We first developed a new synthesis route to introduce alkoxyamine functional groups into the alginate polymer backbone. By mixing the resulting polymer (NaAlg-AA) with aldehyde-containing oxidized alginate (NaAlg-Ald), oxime cross-linked alginate hydrogels were prepared. We demonstrate that highly tunable stress relaxation and mechanical properties can be achieved by systematically varying the composition (concentration, polymer mixing ratios, degree of oxidation of NaAlg-Ald) or environmental factors (pH, temperature, and use of catalyst). Combined with the natural capability of the alginate to be cross-linked by divalent cations, the developed hydrogel formations possess the unique capability of dual cross-linking mechanisms with different gelation kinetics. We demonstrated that this dual cross-linking capability can (i) be utilized for the creation of hydrogels in microbead or microthread geometries and (ii) be useful for biomedical applications that require both the fast encapsulation of cells in hydrogels (fast calcium cross-linking) and the provision of controlled viscoelastic environments to cultured cells for an extended period (durable oxime cross-linking). With biocompatibility confirmed by the culture of a B-cell line encapsulated within the developed hydrogel, this novel hydrogel platform provides a good prospect in various applications where stress relaxation plays a key role in cell-matrix interactions.

Sánchez-Nieva, J., et al. (2017). "A new analytical technique for the extraction and quantification of microplastics in marine sediments focused on easy implementation and repeatability." Analytical Methods **9**(45): 6371-6378.

A new analytical approach has been developed to extract and quantify HDPE microparticles from marine sediments. This is the first method that has been proposed using routine laboratory equipment that incorporates slow mixing and air flux for floatation in order to collect the supernatant by overflow, using NaCl saturated solutions. The technique developed in this study comprised the preparation of an HDPE standard of different sizes and calibration curves for artificial enrichment of sediments. Two different techniques were used and compared regarding quantification: (a) stereoscopic microscopy and visual sorting and (b) confocal microscopy and image-processing counting. Microplastics of different sizes were extracted and quantified in sediments with several total concentrations of particles, and different groups of sizes were identified ranging from 0.850 to 0.100 mm. Recoveries exceeding 90% for sediments with higher concentrations of microplastics and above 80% for those with lower concentrations emphasise the potential of this methodology. This is even more remarkable if it is taken into account that different sizes were also used in these experiments. The use of this technique will result not only in a more complete assessment of microplastic concentrations but also in higher repeatability in inter-laboratory comparisons. In addition, this methodology is also suitable for applying the extraction of different polymers of microplastics using other salt solutions such as NaI or ZnCl2.

Sancho, J. A., et al. (2008). "Catalytic Air Gasification of Plastic Waste (Polypropylene) in Fluidized Bed. Part I: Use of in-Gasifier Bed Additives." Industrial & Engineering Chemistry Research **47**(4): 1005-1010.

Gasification of 100 wt % polypropylene waste was carried out for this work. The main objective of this study was to compare the effectiveness of tar elimination by some additives in the gasifier bed with an inert bed. Dolomite and olivine were used as in-gasifier bed additives. Dolomite was more active than olivine when using the same amount in the gasifier bed (30 wt %). Tar content was reduced by 92% when dolomite was used, whereas the reduction of tar with olivine was 40% when compared with an inert bed. However, dolomite caused a few problems by plugging the gas cleaning devices because of the high amount of particulates; this did not happen with olivine. Therefore, olivine was used as the preferred gasifier bed material. The bed was then tested with 100 wt % olivine, which is a hard material. The results achieved were good and promising, obtaining from the gasifier a tar content of 2 g/nm3 at the exit, with an L.H.V. of 6 MJ/Nm3 and a gas yield of 6 Nm3/kgdaf.

Sander, M., et al. (2019). "Assessing the environmental transformation of nanoplastic through ¹³C-labelled polymers." Nature Nanotechnology **14**(4): 301-303.

To assess potential risks posed by plastic nanoparticles, we must study the way in which they transfer and transform in the environment. Using ¹³C-labelled nanoplastics could provide a safe and effective way to establish whether the plastic is mineralized or whether it persists in the environment. Copyright © 2019, Springer Nature Limited.

Sanderson, J. P., et al. (2009). "Enrichment of lipid specific immuneregulatory T lymphocytes with magnetic CD1d-microbeads." Rheumatology **1)**: i31.

Background: The highly conserved CD1d-restricted invariant Natural Killer T cells (iNKT) are key players of immunological tolerance and defects in the repertoire of iNKT cells are associated with autoimmune disease in animals and humans. Autologous adoptive transfer of human iNKT cells has been discussed as a possible future treatment option to restore normal tolerance in autoimmune patients. However, iNKT cells are often strongly reduced in peripheral blood of autoimmune patients, which poses challenges for their effective and sterile enrichement. The aim of this study was to design a new type of magnetic microbead coated with recombinant CD1d-molecules for effective ex vivo enrichement of human iNKT cells. Method(s): The extracellular alpha1-alpha3 domains of human CD1d were amplified from human dendritic cell cDNA and cloned into a pET expression vector, expressed in E.coli, and refolded with beta-2 microglobulin (B2m) and different glycolipids. Monomeric CD1d/B2m/lipid molecules were specifically biotinylated via an engineered BirA-motif at the COOH-terminus of the CD1d protein. After repurification of the biotinylated CD1d/B2m/lipid-complexes they could be conjugated to streptavidincoated magnetic microbeads at different molar ratios (biotin to streptavidin). Result(s): Dependent on the CD1d packaging density of the microbeads and the specific ligands bound to the CD1d molecules we were able to completely deplete human peripheral blood mononuclear cell (PBMC) samples of all iNKT cells. On the other hand the beads allowed for rapid strong enrichment of human iNKT cells (>90%) from PBMC samples, even when iNKT precursor frequencies were very low (<0.1%). Conclusion(s): Magnetic CD1d/B2m/Lipid-microbeads are a powerful tool to directly isolate human iNKT cells from peripheral blood and allow for effective enrichement of these immuneregulatory T cells. Compared to fluorescent activated cell sorter (FACS) based methods isolation of the rare iNKT lymphocyte populations from autoimmune patients using magnetic CD1d-microbeads should be both faster and cleaner.

Sangale, M. K., et al. (2019). "Potential of fungi isolated from the dumping sites mangrove rhizosphere soil to degrade polythene." Scientific Reports **9**(1): 5390.

Polythene is the most widely used plastic around the globe. Among the total plastic waste generated, polythene contributes the maximum share (64%). Various strategies/methods are being utilized to deal with the increasing rate of plastic waste, but among all the methods, bioremediation is regarded as the ecofriendly and widely accepted method. In the current investigation, we have attempted to discover the elite polythene deteriorating fungi (isolated from the rhizosphere soil of Avicennia marina). From 12 different eco-geographical locations along the West Coast of India, total 109 fungal isolates were recorded. The polythene deteriorating fungi were screened at varied pH (3.5, 7 and 9.5) based on changes in weight and tensile strength of the treated polythene at ambient temperature with continuous shaking for 60 days. BAYF5 isolate (pH 7) results in maximum reduction in weight (58.51 +/- 8.14) whereas PNPF15 (pH 3.5) recorded highest reduction in tensile strength (94.44 +/- 2.40). Surprisingly, we have also reported weight gain, with highest percent weight gain (28.41 +/- 6.99) with MANGF13 at pH 9.5. To test the reproducibility of the results, the elite polythene degrading fungal isolates based on weight loss and reduction in tensile strength were only used for repetition experiment and the results based on the reduction in tensile strength were found only reproducible. Polythene biodegradation was further confirmed using Scanning Electron Microscopy (SEM) and Fourier Transform Infrared Spectroscopy (FTIR) analysis. The most efficient polythene deteriorating fungal isolates were identified as Aspergillus terreus strain MANGF1/WL and Aspergillus sydowii strain PNPF15/TS using both morphological keys and molecular tools.

Sanganyado, E., et al. (2018). "Bioaccumulation of organic pollutants in Indo-Pacific humpback dolphin: a review on current knowledge and future prospects." Environmental Pollution **237**: 111-125.

Indo-Pacific humpback dolphin (Sousa chinensis) are chronically exposed to organic pollutants since they inhabit shallow coastal waters that are often impacted by anthropogenic activities. The aim of this review was to evaluate existing knowledge on the occurrence of organic pollutants in Indo-Pacific humpback dolphins, identify knowledge gaps, and offer recommendations for future research directions. We discussed the trends in the bioaccumulation of organic pollutants in Indo-Pacific humpback dolphins focusing on sources, physicochemical properties, and usage patterns. Furthermore, we examined factors that influence bioaccumulation such as gender, age, dietary intake and tissue-specific distribution. Studies on bioaccumulation in Indo-Pacific humpback dolphin remain scarce, despite high concentrations above 13,000 ng/g lw we previously detected for PFOS, Sigma PBDE and chlorinated paraffins. The maximum concentration of organochlorines detected was 157,000 ng/g wt. Furthermore, variations in bioaccumulation were shown to be caused by factors such as usage patterns and physicochemical properties of the pollutant. However, restrictions in sampling inhibit investigations on exposure pathway and toxicity of organic pollutants in Indo-Pacific humpback dolphin. We proposed the use of biopsy sampling, predictive bioaccumulation and toxicity modeling, and monitoring other emerging contaminants such as microplastics and pharmaceuticals for future health risk assessment on this critically endangered marine mammal species.

Santana, M. F. M., et al. (2016). "Microplastic contamination in natural mussel beds from a Brazilian urbanized coastal region: rapid evaluation through bioassessment." Marine Pollution Bulletin **106**(1/2): 183-189.

Microplastic pollution (particles <5 mm) is a widespread marine threat and a trigger for biological effects, especially if ingested. The mussel Perna perna, an important food resource, was used as bioindicator to investigate the presence of microplastic pollution on Santos estuary, the most urbanized area of the coast of Sao Paulo State, Brazil. A simple and rapid assessment showed that 75% of sampled mussels had ingested microplastics, an issue of human and environmental concern. All sampling points had contaminated mussels and this contamination had no clear pattern of distribution along the estuary. This was the first time that microplastic bioavailability was assessed in nature for the southern hemisphere and that wild P. perna was found contaminated with this pollutant. This is an important issue that should be better assessed due to an increase in seafood consumption and culture in Brazil and worldwide.

Santana, M. F. M., et al. (2018). "Continuous exposure to microplastics does not cause physiological effects in the cultivated mussel Perna perna." Archives of Environmental Contamination and Toxicology **74**(4): 594-604.

The environmental impact of microplastics is a challenging theme, especially under realistic experimental conditions. We investigated physiological responses to 0.1-1.0 micro m PVC particles intake by the mussel Perna perna after a relative long-term exposure (90 days) at a less extreme concentration compared with previous studies (0.125 g/L). Microplastic intake was inferred by the presence of PVC in the feces of mussels, and physiological damages were assessed through ingestion rate, assimilation efficiency, growth rate, cellular and molecular biomarkers (lysosomal integrity, lipid peroxidation, and DNA damage), and condition index. All physiological responses showed nonsignificant effects of the microplastics on the exposed mussels. We suggest that, despite the experimental concentration of microplastics, mussels were able to acclimate to the exposure through their abilities for long-term recovery and tolerance to stresses. These data have positive implications for environmental health and in terms of human food resource because mussel farming is a worldwide practice that heavily relies on plastic materials, increasing the chances of microplastic exposure and mussels contamination.

Santana, M. F. M., et al. (2017). "Trophic transference of microplastics under a low exposure scenario: insights on the likelihood of particle cascading along marine food-webs." Marine Pollution Bulletin **121**(1/2): 154-159.

Microplastics are emergent pollutants in marine environments, whose risks along food-web still need to be understood. Within this knowledge gap, MPs transference and persistence along trophic levels are key processes. We assessed the potential occurrence of these processes considering a less extreme scenario of exposure than used previously, with microplastics present only in the hemolymph of prey (the mussel Perna perna) and absent in the gut cavity. Predators were the crab Callinectes ornatus and the puffer fish Spheoeroides greeleyi. Transference of microplastics occurred from prey to predators but without evidences of particle persistence in their tissues after 10 days of exposure. This suggests a reduced likelihood of trophic cascading of particles and, consequently, a reduced risk of direct impacts of microplastics on higher trophic levels. However, the contact with microplastics along food-webs is still concerning, modulated by the concentration of particles in prey and predators' depuration capacity and rate.

Santana, M. F. M. and A. Turra (2020). Toxicity of microplastics in the marine environment. Wallingford, A handbook of environmental toxicology
CABI**:** 436-453 many ref.

Marine litter is one of the most expanding and devastating problems in the marine environment. Among several types of items and origins, microplastics have been drawing attention due to their small particle size (<5 mm), persistence and the potential to be ingested by a high variety of organisms and act as vectors of chemical pollutants. This chapter provides a broad and updated review of the ecotoxicological effects of microplastics on marine biodiversity. Effects of microplastics have been demonstrated from the biochemical to physiological, behavioural and even ecological levels of organization. Most information comes from a range of biomarkers on low levels of organization, such as oxidative stress (lipid peroxidation, DNA damage and the activation of antioxidant enzymes) and immunological responses (phagocytosis activity, signs of inflammation and enzyme/protein response).

However, the variety of experimental conditions, including plastic size and shape, polymer type, additives, concentration and period of exposure, and biological model, still does not allow a clear and wide understanding on the effects on the environment and, indeed, humans. This scenario calls for additional and coordinated efforts to improve scientific knowledge on this subject.

Santhi, K., et al. (2013). "Formulation and evaluation of Nifedipine microbeads using Guar gum as a release modifier." International Journal of Pharmaceutical Sciences Review and Research **21**(1): 270-275.

A great deal of attention has been given to the formulation of alginate micro beads which has potential as carrier in controlled drug delivery. The drug Nifedipine has low bioavailability, hence to improve its bioavailability; Nifedipine-loaded mucoadhesive microbeads were prepared by Ionotropic gelation and cross linking technique by using sodium alginate as the hydrophilic carrier in combination with Guar gum as release modifier. Micro beads with different ratio of sodium alginate and guar gum were formulated and evaluated for particle size, swelling ratio, and percentage yield. An optimized batch was selected from the previous study and four different concentrations of Nifedipine were loaded. The drug loaded batches were evaluated for drug entrapment, bio adhesiveness, in vitro release, and release kinetics. Particle size distribution of beads was measured by both optical microscopy and SEM. No significant drug-polymer interactions were observed in FT-IR studies. In-vitro drug release profile of Nifedipine micro beads in phosphate buffer pH 6.8 exhibited zero order release with kinetics of super case II-transport. The in vitro wash-off test using goat intestine revealed that the sodium alginate micro beads of Nifedipine possess good mucoadhesive properties. The drug loaded batches were found to have good drug loading. Hence the formulated Microbeads of Sodium alginate with guar gum as release modifiers could be used as an alternative and cost effective carrier for the development of oral controlled release capsules or tablets the of Nifedipine as once daily formulation.

Santillo, D., et al. (2017). "Microplastics as contaminants in commercially important seafood species." Integrated Environmental Assessment & Management **13**(3): 516-521.

The ingestion of microplastic fragments, spheres, and fibers by marine mollusks, crustaceans, and fish, including a number of commercially important species, appears to be a widespread and pervasive phenomenon. Evidence is also growing for direct impacts of microplastic ingestion on physiology, reproductive success and survival of exposed marine organisms, and transfer through food webs, although the ecological implications are not yet known. Concerns also remain over the capacity for microplastics to act as vectors for harmful chemical pollutants, including plastic additives and persistent organic pollutants, although their contribution must be evaluated alongside other known sources. The potential for humans, as top predators, to consume microplastics as contaminants in seafood is very real, and its implications for health need to be considered. An urgent need also exists to extend the geographical scope of studies of microplastic contamination in seafood species to currently underrepresented areas, and to finalize and adopt standardized methods and quality-assurance protocols for the isolation, identification, and quantification of microplastic contaminants from biological tissues. Such developments would enable more robust investigation of spatial and temporal trends, thereby contributing further evidence as a sound basis for regulatory controls. Despite the existence of considerable uncertainties and unknowns, there is already a compelling case for urgent actions to identify, control, and, where possible, eliminate key sources of both primary and secondary microplastics before they reach the marine environment. Santos, A. D. O., et al. (2015). "Marine Pollution: The Problematic of Microplastics." Journal of Marine Science. Research & Development **5**(3): 1.

Throughout the history of mankind and the of conquest of the seas and oceans these water masses were always seen as unlimited sinks of wastes since they were assumed as being able to disperse, dilute and redistribute natural and synthetic substances. However, in the last few decades the authors have finally realized that this capacity is not unlimited. The concern about the presence of plastics in marine environments comes from many years ago. The impacts of microplastics still remains unclear nevertheless some conclusions and suspicions were already raised by recent studies. Nevertheless, the contamination of marine environments by microplastics may have other types of impacts, indirectly affecting organisms. The ingestion of microplastics by small animals may cause a decrease in food consumption due to satiation feeling and/or intestinal blockage leading to death. Further, the permeability of the sand increases with the presence of microplastics.

Santos, D. C. M. d., et al. (2015). "Histological alterations in liver and testis of Astyanax aff. bimaculatus caused by acute exposition to zinc." Revista Ceres **62**(2): 133-141.

This study investigated the effect of acute exposition to zinc (Zn) on histology of the liver and testes of yellow tail lambari (Astyanax aff. bimaculatus). The exposure consisted of six concentrations of Zn (0, 3, 5, 10, 15, and 20 mg/L) for 96 hours of exposure. Fragments of liver and testis were routinely processed and embedded in plastic resin based on glycol methacrylate. Fragments of bones, muscles, liver and testis were dehydrated and digested to quantify the absorption levels of Zn in the tissue. Acute exposure to concentrations above 10 mg/L has produced structural changes in the liver and gonads. The changes found in the liver were vascular congestion; decrease of cellular volume; displacement of the hepatocyte nucleus; necrosis; disarrangement of cordon structure; leukocyte infiltrate and vacuolization. The changes found in the gonads were ruptured cyst, delayed development of germ cells, pyknotic nucleus, cell cluster, displacement of cyst wall and vacuolization. The histological changes observed were compatible with the increasing concentration of zinc in environment, compromising liver and reproductive functions, because there was an increase in relative frequency of hepatocytes and reduced sperm production.

Santos Ode, S., et al. (2015). "Manganese ore tailing: optimization of acid leaching conditions and recovery of soluble manganese." Journal of Environmental Management **147**: 314-320.

Manganese recovery from industrial ore processing waste by means of leaching with sulfuric acid was the objective of this study. Experimental conditions were optimized by multivariate experimental design approaches. In order to study the factors affecting leaching, a screening step was used involving a full factorial design with central point for three variables in two levels (2(3)). The three variables studied were leaching time, concentration of sulfuric acid and sample amount. The three factors screened were shown to be relevant and therefore a Doehlert design was applied to determine the best working conditions for leaching and to build the response surface. By applying the best leaching conditions, the concentrations of 12.80 and 13.64 %w/w of manganese for the global sample and for the fraction -44 + 37 mum, respectively, were found. Microbeads of chitosan were tested for removal of leachate acidity and recovering of soluble manganese. Manganese recovery from the leachate was 95.4%. Upon drying the leachate, a solid containing mostly manganese sulfate was obtained, showing that the proposed optimized method is efficient for manganese recovery from ore tailings.

Santos, R. G., et al. (2016). "Marine debris ingestion and Thayer's law - The importance of plastic color." Environmental Pollution **214**: 585-588.

In recent years marine plastic pollution has gained considerable attention as a significant threat to marine animals. Despite the abundant literature related to marine debris ingestion, only a few studies attempted to understand the factors involved in debris ingestion. Plastic ingestion is commonly attributed to visual similarities of plastic fragments to animal's prey items, such as plastic bags and jellyfish. However, this simple explanation is not always coherent with the variety of debris items ingested and with the species' main prey items. We assess differences in the conspicuousness of plastic debris related to their color using Thayer's law to infer the likelihood that visual foragers detect plastic fragments. We hypothesize that marine animals that perceive floating plastic from below should preferentially ingest dark plastic fragments, whereas animals that perceive floating plastic from above should select for paler plastic fragments. Santos-Oliveira, J. R., et al. (2011). "Evidence that lipopolisaccharide may contribute to the cytokine storm and cellular activation in patients with visceral leishmaniasis." PLoS Neglected Tropical Diseases [electronic resource] **5**(7): e1198.

BACKGROUND: Visceral leishmaniasis (VL) is characterized by parasite-specific immunosuppression besides an intense pro-inflammatory response. Lipopolisaccharide (LPS) has been implicated in the immune activation of T-cell deficient diseases such as HIV/AIDS and idiopathic lymphocytopenia. The source of LPS is gram-negative bacteria that enter the circulation because of immunological mucosal barrier breakdown. As gut parasitization also occurs in VL, it was hypothesized that LPS may be elevated in leishmaniasis, contributing to cell activation.

METHODOLOGY/PRINCIPAL FINDINGS: Flow cytometry analysis and immunoassays (ELISA and luminex micro-beads system) were used to quantify T-cells and soluble factors. Higher LPS and soluble CD14 levels were observed in active VL in comparison to healthy subjects, indicating that LPS was bioactive; there was a positive correlation between these molecules ($r = 0.61; p<0.05$). Interestingly, LPS was negatively correlated with CD4(+) ($r = -0.71; p<0.01$) and CD8(+) T-cells ($r = -0.65; p<0.05$). Moreover, higher levels of activation-associated molecules (HLA-DR, CD38, CD25) were seen on T lymphocytes, which were positively associated with LPS levels. Pro-inflammatory cytokines and macrophage migration inhibitory factor (MIF) were also augmented in VL patients. Consistent with the higher immune activation status, LPS levels were positively correlated with the inflammatory cytokines IL-6 ($r = 0.63; p<0.05$), IL-8 ($r = 0.89; p<0.05$), and MIF ($r = 0.64; p<0.05$). Also, higher plasma intestinal fatty acid binding protein (IFABP) levels were observed in VL patients, which correlated with LPS levels ($r = 0.57; p<0.05$).

CONCLUSIONS/SIGNIFICANCE: Elevated levels of LPS in VL, in correlation with T-cell activation and elevated pro-inflammatory cytokines and MIF indicate that this bacterial product may contribute to the impairment in immune effector function. The cytokine storm and chronic immune hyperactivation status may contribute to the observed T-cell depletion. LPS probably originates from microbial translocation as suggested by IFABP levels and, along with Leishmania antigen-mediated immune suppression, may play a role in the immunopathogenesis of VL. These findings point to possible benefits of antimicrobial prophylaxis in conjunction with anti-Leishmania therapy.

Santos-Oliveira, J. R., et al. (2011). "Evidence That Lipopolisaccharide May Contribute to the Cytokine Storm and Cellular Activation in Patients with Visceral Leishmaniasis: e1198." PLoS Neglected Tropical Diseases **5**(7): e1198.

Background Visceral leishmaniasis (VL) is characterized by parasite-specific immunosuppression besides an intense pro-inflammatory response. Lipopolisaccharide (LPS) has been implicated in the immune activation of T-cell deficient diseases such as HIV/AIDS and idiopathic lymphocytopenia. The source of LPS is gram-negative bacteria that enter the circulation because of immunological mucosal barrier breakdown. As gut parasitization also occurs in VL, it was hypothesized that LPS may be elevated in leishmaniasis, contributing to cell activation. Methodology/Principal Findings Flow cytometry analysis and immunoassays (ELISA and luminex micro-beads system) were used to quantify T-cells and soluble factors. Higher LPS and soluble CD14 levels were observed in active VL in comparison to healthy subjects, indicating that LPS was bioactive; there was a positive correlation between these molecules ($r = 0.61; p<0.05$). Interestingly, LPS was negatively correlated with CD4+ ($r = -0.71; p<0.01$) and CD8+ T-cells ($r = -0.65; p<0.05$). Moreover, higher levels of activation-associated molecules (HLA-DR, CD38, CD25) were seen on T lymphocytes, which were positively associated with LPS levels. Pro-inflammatory cytokines and macrophage migration inhibitory factor (MIF) were also augmented in VL patients. Consistent with the higher immune activation status, LPS levels were positively correlated with the inflammatory cytokines IL-6 ($r = 0.63; p<0.05$), IL-8 ($r = 0.89; p<0.05$), and MIF ($r = 0.64; p<0.05$). Also, higher plasma intestinal fatty acid binding protein (IFABP) levels were observed in VL patients, which correlated with LPS levels ($r = 0.57; p<0.05$). Conclusions/Significance Elevated levels of LPS in VL, in correlation with T-cell activation and elevated pro-inflammatory cytokines and MIF indicate that this bacterial product may contribute to the impairment in immune effector function. The cytokine storm and chronic immune hyperactivation status may contribute to the observed T-cell depletion. LPS probably originates from microbial translocation as suggested by IFABP levels and, along with Leishmania antigen-mediated immune suppression, may play a role in the immunopathogenesis of VL. These findings point to possible benefits of antimicrobial prophylaxis in conjunction with anti-Leishmania therapy.

Sanz, M., et al. (2017). "Compact, cost-effective and field-portable microscope prototype based on MISHELF microscopy." Scientific Reports **7**: 43291.

We report on a reduced cost, portable and compact prototype design of lensless holographic microscope with an illumination/detection scheme based on wavelength multiplexing, working with single hologram acquisition and using a fast convergence algorithm for image processing. All together, MISHELF (initials coming from Multi-Illumination Single-Holographic-Exposure Lensless Fresnel) microscopy allows the recording of three Fresnel domain diffraction patterns in a single camera snap-shot incoming from illuminating the sample with three coherent lights at once. Previous implementations have proposed an illumination/detection procedure based on a tuned (illumination wavelengths centered at the maximum sensitivity of the camera detection channels) configuration but here we report on a detuned (non-centered ones) scheme resulting in prototype miniaturization and cost reduction. Thus, MISHELF microscopy in combination with a novel and fast iterative algorithm allows high-resolution (mum range) phase-retrieved (twin image elimination) quantitative phase imaging of dynamic events (video rate recording speed). The performance of this microscope prototype is validated through experiments using both amplitude (USAF resolution test) and complex (live swine sperm cells and flowing microbeads) samples. The proposed method becomes in an alternative instrument improving some capabilities of existing lensless microscopes.

Saphirstein, R., et al. (2011). "The focal adhesion: A regulator of vascular stiffness?" Molecular Biology of the Cell. Conference: Annual Meeting of the American Society for Cell Biology, ASCB **22**(24).

Despite the fact that arterial stiffening with age is now known to be an independent and early predictor of cardiovascular disease, relatively little is known about the contributions of different tissue components to vascular stiffness. The extracellular matrix (ECM) has traditionally been regarded as the main determinant of vascular tissue stiffness, but a recent study (Qiu et al. Circ Res. 2010) implicates the actomyosin-based stiffness of vascular smooth muscle cells as a significant contributor. Here, we investigated the role of differentiated vascular smooth muscle cells in determining tissue stiffness. We measured the stiffness of vascular tissue strips in vitro and observed that stiffness increases unexpectedly when tissue strips are treated with PP2, a small molecule inhibitor of the master focal adhesion (FA) tyrosine kinase Src. This result suggests that FAs, which mechanically link the ECM to the internal actin CSK, may regulate vascular tissue stiffness. To further confirm FA involvement, we examined tyrosine phosphorylation as a biochemical signature of FA signaling and turnover. Phosphotyrosine screening of vascular tissue homogenates via Western blots reveals roles for the FA proteins Src, FAK, and CAS in vasoconstrictor-induced signaling. To directly confirm the role of FAs in the regulation of stiffness, we used optical tweezers to measure stiffness in A7r5 smooth muscle cells by applying piconewton forces localized directly to FAs via cell-bound RGD-coated microbeads. We found that A7r5 stiffness is modulated by FAs and by A7r5 activation state. Stimulation with the vasoconstrictor lysophosphatidic acid (LPA) increases stiffness in a PP2-attenuated manner. Cell immunofluorescence imaging suggests that A7r5 stiffness is related to FA size as well as FA stiffness, since FA size increases in a PP2-attenuated manner with LPA stimulation. Our findings indicate that the FA is a significant component of vascular stiffness.

Sappington, R. M., et al. (2010). "The microbead occlusion model: a paradigm for induced ocular hypertension in rats and mice." Investigative Ophthalmology & Visual Science **51**(1): 207-216.

PURPOSE. Elevated intraocular pressure (IOP) is an important risk factor for glaucoma. Animal models often involve techniques for IOP elevation that are surgically invasive. Here the authors describe a novel and relatively simple method for inducing a highly consistent, modest, and repeatable elevation in IOP for rats and mice. METHODS. IOP was elevated unilaterally by injection of polystyrene microbeads into the anterior chamber to occlude aqueous outflow in rats (2.5-7 micro L) and mice (1 micro L). The fellow eye received an equivalent saline injection as internal control. The authors used tonometry to measure microbead-induced IOP elevations. Optic nerves were processed histologically to determine axon loss. RESULTS. For rats, a single injection of microbeads raised IOP by 21% to 34%, depending on volume, for approximately 2 weeks, though they were not tracked to full recovery. IOP in the saline-injected eye was constant. An additional injection (5 micro L) extended the elevation to 8 weeks. Cumulative pressure exposure for both injections increased linearly. For mice, a single 1- micro L injection of microbeads elicited a highly regular 30% elevation in IOP that persisted for more than 3 weeks, with a linear rise in cumulative pressure exposure. For both rats and mice, interanimal variability on a given day was modest, approximately 5% of the mean IOP measurement. Extended elevations (4-5 weeks) induced approximately a 20% loss of axons in both rats and mice. CONCLUSIONS. These data support a novel and flexible model of modest ocular hypertension with axon loss. The maximal duration of IOP elevation will be further characterized in future studies.

Saputra, E., et al. (2015). "An edible film characteristic of chitosan made from shrimp waste as a plasticizer." Journal of Natural Sciences Research **5**(4): 118-124.

The edible film is expected to replace the plastic packaging, so it can reduce plastic waste used. Information about edible film as food packaging that is stored at room temperature is still very few found. The aims of research is to assess the characteristics of an edible film from chitosan for biodegradable packaging to substitute plastic in general that it could not be processed further. The results of characterization making edible film chitosan with the addition of a plasticizer from carrageenan produce the value of the thickness, and tensile strength film meet the criteria of standard value for characterization of edible film, while the transmission of water vapor and the percentage of lengthening is not yet meet the criteria of standard value for characterization of edible film. Packaging is the final part of a process for the production of foodstuffs or other products. Today, the packaging industry is dominated by packaging materials made from plastic. This resulted in the increase of plastic waste in the world. Plastic packaging commonly used type of polyethylene, polystyrene, polyvinylchloride (PVC) and resins that many impacts are not as good as the environmental damage can not be decomposed by microorganisms, expensive in recycling and contamination of foodstuffs was due to the presence of certain substances migrated into the food material. One alternative solution is the use of edible film which has several advantages, which are able to protect the product, the original appearance of the product can be maintained, safe for the environment and can be eaten.

Saraji, M., et al. (2015). "Sol-gel/nanoclay composite as a solid-phase microextraction fiber coating for the determination of organophosphorus pesticides in water samples." Analytical and bioanalytical chemistry **407**(4): 1241-1252.

Issue Title: A different way of looking at vibrational hyperspectral data/Micellar extraction for the analysis of Alzheimer's disease brain proteome/Quantification of polyolefin microplastics in personal-care products/Removal of Triton X-100 by microdialysis A novel solid-phase microextraction (SPME) fiber coated with a sol-gel/nanoclay composite was prepared by the sol-gel technique involving the hydrolysis reaction of alkoxysilanes and the subsequent condensation reaction with hydroxyl groups of the nanoclay on a stainless steel wire. A method based on direct immersion SPME and gas chromatography-corona discharge ion mobility spectrometry was developed for the determination of four organophosphorus pesticides in aqueous samples. The effect of different experimental parameters on the extraction efficiency of the method was investigated. The sol-gel/nanoclay fiber showed higher extraction performance for the organophosphorus pesticides compared with Ppy/nanoclay, sol-gel coating, and three commercial fibers (polydimethylsiloxane (PDMS), PDMS/divinylbenzene (DVB), and polyacrylate (PA)). Limits of detection (LOD) and quantitation (LOQ) of the method were in the range of 0.003-0.012 and 0.01-0.02 [mu]g L^sup -1^, respectively. The calibration curves were linear in a concentration range from 0.01 to 2.0 [mu]g L^sup -1^ (r ^sup 2^>0.995). The relative standard deviations for intra- and inter-day precision were 3.3-5.6 and 6.4-8.4 %, respectively. Fiber-to-fiber reproducibility for three prepared fibers was 7.4-10.2 %. Finally, the method was successfully applied for the extraction of the studied compounds from water samples. The relative recovery obtained for the spiked real-water samples were 86-104 %. [Figure not available: see fulltext.]

Saralidze, K., et al. (2003). "Injectable polymeric microspheres with X-ray visibility. Preparation, properties, and potential utility as new traceable bulking agents." Biomacromolecules **4**(3): 793-798.

The copolymer of methyl methacrylate (MMA) and 2-[2',3',5'-triiodobenzoyl]oxoethyl methacrylate (1), ratio 3:1 (mass:mass), was prepared via a free-radical polymerization in bulk. The copolymer (M<inf>w</inf> = 97.8 kD and M<inf>n</inf> = 41.5 kD was dissolved in chloroform and subsequently transformed into beads with a diameter in the micrometer range, using a solvent evaporation technique. The resulting microbeads were characterized by different

techniques, including NMR spectroscopy, differential scanning calorimetry, gel permeation chromatography, and scanning electron microscopy. The latter technique was used as the basis for statistical analysis of the bead size. Typically, an average diameter of 96 mum and a standard deviation of 21 mum were obtained. The beads were also subjected to some preliminary tests regarding cytotoxicity. The copolymer of MMA and 1 contains covalently bound iodine. Therefore, the material is intrinsically radiopaque, i.e., capable of absorbing X-radiation while no contrast additive is needed. Our interest in these microspheres stems primarily from their possible utility as injectable and afterward traceable (radiopaque) bulking agents, e.g., for use in urology for the treatment of female stress incontinence due to sphincter deficiency. As a first test into this direction, a sample of the microbeads was mixed with ethylene glycol, and the resulting suspension was studied with respect to injectability and radiopacity. The results suggest that the radiopaque microbeads may provide access to improved bulking agents. Further modification of the surface may be necessary in order to suppress the migratory aptitude of the radiopaque polymeric microspheres in vivo.

Sargin, I., et al. (2016). "Microfungal spores (Ustilago maydis and U. digitariae) immobilised chitosan microcapsules for heavy metal removal." Carbohydrate Polymers **138**: 201-209.

Designing effective chitosan-based biosorbents from unexploited biomass for heavy metal removal has received much attention over the past decade. Ustilago, loose smut, is a ubiquitous fungal plant pathogen infecting over 4000 species including maize and weed. This study aimed to establish whether the spores of the phytopathogenic microfungi Ustilago spores can be immobilised in cross-linked chitosan matrix, and it reports findings on heavy metal sorption performance of chitosan/Ustilago composite microcapsules. Immobilisation of Ustilago maydis and U. digitariae spores (from maize and weed) in chitosan microcapsules was achieved via glutaraldehyde cross-linking. The cross-linked microcapsules were characterised using scanning electron microscopy, FT-IR spectroscopy and thermogravimetric analysis. Sorption capacities of chitosan-U. maydis and chitosan-U. digitariae microcapsules were investigated and compared to cross-linked chitosan beads: Cu(II): 66.72, 69.26, 42.57; Cd(II): 49.46, 53.96, 7.87; Cr(III): 35.88, 49.40, 43.68; Ni(II): 41.67, 33.46, 16.43 and Zn(II): 30.73, 60.81, 15.04mg/g, respectively. Sorption experiments were conducted as a function of initial metal ion concentration (2-10mg/L), contact time (60-480min), temperature (25, 35 and 45degreeC), amount of the sorbent (0.05-0.25g) and pH of the metal solution. The microcapsules with spores exhibited better performance over the plain chitosan beads, demonstrating their potential use in water treatment.

Sari, M. M., et al. (2011). "Monosize microbeads for pseudo-affinity adsorption of human insulin." Colloids & Surfaces B: Biointerfaces **84**(1): 140-147.

Affinity adsorption technique is increasingly used for protein purification, separation and other biochemical applications. Therapeutic molecules such as antibodies, cytokines, therapeutic DNA and plasma proteins must be purified before characterization and utilization. The aim of this study was to prepare micronsized spherical polymeric beads and to investigate the extent of their human insulin adsorption capability. Monosize poly(ethylene glycol dimethacrylate-N-methacryloyl-(L)-histidine) [poly(EDMA-MAH)] beads were prepared by modified suspension copolymerization. Functional monomer (MAH) was synthesized using methacryloyl chloride and L-histidine. The beads were characterized using scanning electron microscopy (SEM), Fourier transform infrared spectroscopy, swelling test and elemental analysis. MAH incorporation into monosize polymeric beads, having an average size around 2-3 mum, was estimated as 55.3 mumol MAH/g bead. Equilibrium swelling ratios of poly(EDMA-MAH) and poly(EDMA) beads were 65% and 55%, respectively. Adsorption experiments were performed under different conditions (i.e., pH, temperature, protein concentration and ionic strength). It was found that adsorption characteristics are strongly depend on these conditions. Maximum insulin adsorption capacity was achieved as 24.7 mg insulin/g poly(EDMA-MAH) beads.

Sari, P. K., et al. (2017). "Utilization of banana pseudo stem as media grow with various source of nutrient to growth of Pre Nursery of palm oil (Elaesis guinensis Jacg)." Journal of Applied Agricultural Science and Technology **1**(1): 37-47.

This research objective is to examine how the effect of banana pseudo stems, as a substitute for polybags at the seedling stage of Pre Nursery of palm oil. Obtaining the best organic material on the growth of oil palm seedlings is an appropriate technology to reduce environmental pollution due to plastic waste, publication media and scientific articles, scientific journals. researching and doing field analysis on the object of research taken. Utilization of banana pseudo stem as media grow with various source of nutrient to growth of Pre Nursery of palm oil can be concluded that the best vegetative growth in utilization of banana pseudo stem as media grow on various element of nutrient to growth of Pre Nursery of palm oil by using media of polybag with planting medium consisting of a mixture of top soil with manure with a ratio of 1:1. With a leaf length of 9.545 cm and for leaf width of 2.933 cm. But the Utilization of banana pseudo stem as a medium grown with various sources of nutrients to the growth of Pre Nursery palm allow can be used as an alternative to polybag because the result of its growth shows that the seeds in the polybag not much different growth with the seeds in banana stems on the top soil planting medium + manure. It's just that the climate factor is very influential on the success in the implementation of Pre Nursery seedling of this oil palm. The result of this research is based on 3 aspects of consideration in breeding with the method of Utilization of banana pseudo stem as media grow with various sources of nutrients to the growth of Pre Nursery of palm oil that is economical, agronomic, and environmental use of banana pseudo stem better than polybag.

Sarkar, D., et al. (2014). "Ex Vivo Expanded Autologous Polyclonal Regulatory T Cells Suppress Inhibitor Formation in Hemophilia." Molecular Therapy Methods & Clinical Development **1**: 30.

Adoptive cell therapy utilizing ex vivo expanded polyclonal CD4⁺CD25⁺FOXP3⁺ regulatory T cells (Treg) is in use in clinical trials for the treatment of type 1 diabetes and prevention of graft vs host disease in bone marrow transplantation. Here we seek to evaluate this approach in the treatment of inherited protein deficiencies, i.e. hemophilia, which is often complicated by antibody formation against the therapeutic protein. Treg from mice that express GFP-marked FoxP3 were highly purified by two-step magnetic/flow sorting and ex vivo expanded 50- to 80-fold over a 2-week culture period upon stimulation with antibody-coated microbeads. FoxP3 expression was maintained in >80% of expanded Treg, which also expressed high levels of CD62L and CTLA-4. Transplanted Treg suppressed inhibitory antibody formation against coagulation factors VIII and IX in protein and gene therapies in strain-matched hemophilia A and B mice, including in mice with pre-existing antibodies. Although transplanted Treg became undetectable within two weeks, suppression persisted for >2 months. Additional studies suggested that antigen-specific suppression emerged due to induction of endogenous Treg. The outcomes of these studies support the concept that cell therapy with ex vivo expanded autologous Treg can be used successfully to minimize immune responses in gene and protein replacement therapies.

Sarkar, P. (2019). "Response of DNA damage genes in acrolein-treated lung adenocarcinoma cells."

Molecular & Cellular Biochemistry **450**(1-2): 187-198.

Acrolein is a alpha-beta-unsaturated aldehyde and is toxic to human upon its exposure from the environment. Sources of exposure to acrolein can be from heating cooking oil, automobile exhaust, tobacco smoke, and plastic waste. Acrolein exposure to lung is a major concern because of its volatile nature and due to its presence in the urban atmospheric air. Acrolein being highly reactive forms DNA and protein adducts, thereby making the cells vulnerable to long-term damage. Such long-term effect can lead to high susceptibility towards malignant transformation as has been reported in cigarette smokers. The response of DNA damaging genes by acrolein can perhaps give an insight to the cause of damage in the DNA by acrolein. The aim of this study was to examine the response of the DNA damage responsive genes by acrolein in A549 lung adenocarcinoma cells. Acrolein treatment at IC50 concentration showed a robust response of the DNA repair genes but eventually failed to rescue the cells from undergoing apoptosis. The cells pretreated with acrolein and followed by growing the same cells in fresh medium in the absence of acrolein did not help the cells to proliferate. These results conclude that exposure to acrolein marks long-lasting damage to DNA, irrespective of the DNA repair response.

Sarkar, S., et al. (2011). "Optical properties of breast tumor phantoms containing carbon nanotubes and nanohorns." Journal of Biomedical Optics **16**(5): 051304.

The degree by which optical properties of tumors are altered following introduction of carbon nanotubes (CNTs) of varying concentration and type is poorly understood, making it difficult to predict the impact of CNT inclusion on the photothermal response to laser therapies. Optical properties were measured of phantoms representative of breast tumor tissue incorporated with multiwalled carbon nanotubes (MWNTs), single-walled carbon nanotubes (SWNTs), and single-walled carbon nanohorns (SWNHs) of varying concentration (0.01-0.1 mg/ml). Tissue phantoms were made from sodium alginate (3 g/ml) incorporated with polystyrene microbeads (3 mum diam and 1 mg/ml) and talc-France powder (40 mg/ml). Absorption (mu(a)) and reduced scattering (mu's) coefficients of phantoms containing CNTs were determined by the inverse adding-doubling algorithm for the wavelength range of 400-1300 nm. Optical properties of phantoms without CNTs were in the range of mu(a) = 1.04-0.06 mm(-1) and mu's' = 0.05-0.07 mm(-1) at a wavelength of 900 nm, which corresponds with published data for human breast tumor tissue. Incorporating MWNTs, SWNTs, and SWNHs in phantoms with a concentration of 0.1 mg/ml increased (mu(a)) by 20- to 30-fold, 5- to 6-fold, and 9- to 14-fold, respectively, for the wavelength range of 800-1100 nm with minimal change in mu's (1.2- to 1.3-fold). Introduction of CNTs into tissue phantoms increased absorption, providing a means to enhance photothermal therapy.

Sarkar, S., et al. (2018). "Barrier Restitution Effects of Egcg Driven in Part by Its Effect on Il-10 Family Cytokines." Gastroenterology **154 (6 Supplement 1)**: S-1018.

Introduction: The anti-inflammatory properties of (-) epigallocatechin-3-gallate (EGCG), the major green tea polyphenol (GTP), have sparked considerable interest in its potential as a therapy for inflammatory bowel disease (IBD), including both Crohn's disease (CD) and ulcerative colitis (UC). In this study, we evaluated the effect of EGCG on IL-10 family members IL-10 and IL-22 in the epithelial Caco2 cell line in order to enhance our understanding of the role this compound plays in the treatment of IBD. IL-22 has demonstrated important effects on epithelial restitution and tight-junction protein (TJP) composition. Aim(s): Investigate the effect of EGCG on IL-10 family members IL-10 and IL-22 production by human Caco2 epithelial colon cells, evaluating its role in barrier restitution. Method(s): CaCo-2 cells were used in this

experiment. Untreated control cells were compared to cells treated with two concentrations of EGCG (5 or 10mug/ml), LPS, or both. Effects on production of IL-10 and IL-22 were measured by microbead ELISA and compared to effects on IL-12 family cytokines IL-12, IL-17A, and IL-23. RNA message for all cytokines was measured by real-time polymerase chain reaction. Specific claudins relevant to barrier function were measured by Western blot. Result(s): EGCG (5 or 10mug/ml) demonstrated striking effects on cytokine production and RNA message compared to basal production or LPS stimulated cells (Table1). EGCG significantly enhanced IL-10 and -22 production, while suppressing IL-12 family members. Interestingly, this pattern of cytokine modulation corresponded with a "tightening" effect as it modulated TJP composition in Caco-2 monolayers. LPS dramatically increased claudin-2 and down-regulated claudins-1 and 5. EGCG by itself enhanced occludin, ZO-1 and claudin-1 and -5, while decreasing claudin-2. EGCG co-administered with LPS reversed the decline in claudin-1 and -5, while suppressing claudin-2. These changes correlated with a reversal of LPS-induced changes in TER. Discussion(s): While initially considered to be proinflammatory and epithelial barrier disrupting, IL-22 has now been recognized as an important contributor to innate immune responses against enteric pathogens. In combination with IL-10, IL-22 promotes barrier restitution. We have now linked EGCG administration with both and IL-10 and IL-22 production, changes that correlate with favorable alterations in TJP composition. Particularly, we have confirmed that elevated IL-22 production contributes to an upregulation of claudins-1and -5, while suppressing claudin-2. The evidence linking EGCG administration to enhanced IL-10 and -22 production provides additional insight into the clinical benefits seen from EGCG on IBD and pouchitis. Sarker, M., et al. (2012). "Alternative Diesel Grade Fuel Transformed from Polypropylene (PP) Municipal Waste Plastic Using Thermal Cracking with Fractional Column Distillation." Energy and Power Engineering **4**(3): 165.

Day by day worldwide use of plastics is increasing because of their light weight and durable characteristics. Waste plas- tics are major environmental problems all over the world. Waste plastics are not bio-degradable, it remains in the land- fill for a long period of time causing vegetation and aquatic ecosystem dilemmas. Abandoned waste plastic thrown into the ocean causes friction of ocean waves and then broken down by sunlight into small pieces and takes the shape of plastic like soup. Aquatic organism mistakes the plastic soup as their food and can't digest, either they die or through food chain it affects human health. To avoid severe environmental degradation problems of waste plastics some coun- tries and big cities banned or restricted the use of plastic products. The worldwide generation of waste plastics is ap- proximately 280 million tons/year. All most all of these waste plastics are dumped either in land or ocean. City munici- palities spend huge amount of money each year just to dispose of these waste plastics into landfill because most waste plastics are not recycled. When the waste plastics are subjected to incineration, they release harmful toxic gas into the environment causing severe pollution. These waste plastics gradually enhance the hazardous environmental problems. Generally plastics are made from crude oil, however crude oil is a very limited natural resource and non-renewable. Every year millions of barrels of crude oil are to produce the waste plastics and when plastics are discarded after use the energy source is lost. A new developed technology plan minimizes the environment pollution problems simultaneously boost up energy sector by renovating the waste plastics into high energy content fuel. The produced fuel is obtained using a unique thermal degradation of waste plastics and converting them into hydrocarbon fuel like materials. Prelimi- nary tests proved that this fuel burns cleaner and the production cost is very low. Unique production setup demonstrated to produce 93% fuel from

waste plastic in the pilot scale. The Fuel produced has been tested and proven to work on majority types of internal combustion engines. This technology utilized can avoid waste plastic pollution problem worldwide by the implementation of newly developed technology. Through the utilization of the technology the use of reliable plastics won't need to be banned and serve as a very reliable alternate source of energy. The technology will also help reduce a significant amount of import oil from foreign countries and help provide a steady economy.

Sasaki, N., et al. (2017). "Molecular crowding improves bead-based padlock rolling circle amplification." Analytical Biochemistry **519**: 15-18.

Bead-based padlock rolling circle amplification (RCA), an ultrasensitive and accurate DNA detection technique, was conducted in a molecular crowding environment created by poly(ethylene glycol) (PEG). The number of RCA products generated increased and exhibited a bell-shaped dependence on PEG concentration. Experiments using magnetic beads suggested that facilitation of DNA ligation and hybridization is the main reason for the observed increase. Selectivity of the technique was retained in the presence of PEG. This technique is simple and can be utilized to detect target DNA with high accuracy and sensitivity in a variety of areas such as medical diagnosis and food analysis.

Sasso, L. A., et al. (2013). "Continuous Monitoring of Inflammation Biomarkers During Simulated Cardiopulmonary Bypass Using a Microfluidic Immunoassay Device-A Pilot Study." Artificial Organs **37**(1): E9-E17.

This work demonstrates the use of a continuous online monitoring system for tracking systemic inflammation biomarkers during cardiopulmonary bypass (CPB) procedures. The ability to monitor inflammation biomarkers during CPB will allow surgical teams to actively treat inflammation and reduce harmful effects on postoperative morbidity and mortality, enabling improved patient outcomes. A microfluidic device has been designed which allows automation of the individual processing steps of a microbead immunoassay to allow continuous tracking of antigen concentrations. Preliminary experiments have demonstrated that the results produced by the microimmunoassay are comparable to results produced from a standard enzyme-linked immunosorbent assay (r = 0.98). Additionally, integration of the assay with a simulated CPB circuit has been demonstrated with temporal tracking of C3a concentrations within blood continuously sampled from the circuit. The presented work describes the motivation, design challenges, and preliminary experimental results of this project.

Sasso, L. A., et al. (2012). "Automated microfluidic processing platform for multiplexed magnetic bead immunoassays." Microfluidics & Nanofluidics **13**(4): 603-612.

A microfluidic platform is presented which fully automates all incubation steps of a three-stage, multiplexed magnetic bead immunoassay, such as the Luminex xMAP technology. Magnetic actuation is used to transfer the microbeads between co-infused adjacent laminar flow streams to transport the beads into and out of incubation and wash solutions, with extended incubation channels to allow sufficient bead incubation times (1-30 min, commonly 5 min per stage) to enable high-sensitivity. The serial incubation steps of the immunoassay are completed in succession within the device with no operator interaction, and the continuous flow operation with magnetic bead transfer defines the incubation sequencing requiring no external fluidic controls beyond syringe pump infusion. The binding kinetics of the assay is empirically characterized to determine the required incubation times for specific assay sensitivities in the range 1 pg/ml to 100 ng/ml. By using a Luminex xMAP duplex assay, concurrent detection of IL-6 and TNF-alpha was demonstrated on-chip with a detection range 10 pg/ml to 1 ng/ml. This technology enables rapid automation of magnetic microbead assays, and has the potential to perform continuous concentration monitoring.

Sasso, L. A., et al. (2010). "Autonomous magnetically actuated continuous flow microimmunofluorocytometry assay." Microfluidics & Nanofluidics **9**(2-3): 253-265.

This article presents a microfluidic device which integrates autonomous serial immunofluorocytometry binding reactions of cytometric beads with fluorescence detection and quantification in a continuous flow environment. The microdevice assay is intended to alleviate the extensive benchwork and large sample volumes used when conducting traditional immunoassays, without requiring complex external controls. The technology is based on the miniaturization and automation of the serial processing steps of an antigen sandwich immunoassay, with integrated fluorescence detection using paramagnetic microbeads. The continuous flow design may enable temporal tracking of time-varying protein concentrations in a continuously infused sample for clinical applications, specifically for monitoring inflammation marker proteins in blood produced during cardiac surgeries involving cardiopulmonary bypass (CPB) procedures. The device operation was first validated via a single incubation device which measured the concentration of a fluorescently labeled biotin molecule using streptavidin-coated paramagnetic cytometric beads. Subsequently, a dual incubation device was tested with samples of the anaphylatoxin complement protein C3a, and was shown to be capable of differentiating between samples at typical systemic concentrations of the protein (1-5 mug/ml), with very low sample usage (<6 mul/h). It is believed that this continuous flow, automated microimmunosensor technology will be a platform for high sample rate immunoassays capable of tracking and more thoroughly characterizing the systemic inflammation process, and may aid in the development of better treatment options for systemic inflammation during and after CPB.

Sasso, L. A., et al. (2011). "Multiplexed real-time monitoring of systemic inflammation during mechanical circulatory support." Artificial Organs **35 (4)**: A24-A25.

Background: Mechanical circulatory support procedures such as cardiopulmonary bypass and extracorporeal life support are known to cause significant inflammatory responses, which lead to complications and diminished patient outcomes. The ability to thoroughly characterize the systemic inflammatory response is limited by the available assaying techniques, especially due to the limited blood volume available for testing. By combining microfluidic technology with a multiplexed microbead-based cytokine immunoassay, we are developing a system which will monitor and thoroughly characterize the inflammatory response at high sampling rates and with real-time output. Method(s): A multi-layer microfluidic chip is fabricated by conventional soft lithography. The device is infused with the reagents of the Bio-Rad Bio-Plex kit via syringe pump, which includes antibody coated magnetic microbeads, secondary labeling antibody, and fluorescent tagging solution. The microbead solution is pre-mixed to allow detection of between one and fifty cytokines simultaneously. The blood plasma sample is provided as a continuous stream from a microfil-tration device, and a flow controller ensures a steady stream of sample plasma into the immunoassay device. Upon reaching the outlet of the device, the microbeads are fluorescently labeled, having a fluorescence intensity which is proportional to concentration of each analyte in the blood. The incubated beads are currently being collected in fractions and interrogated by flow cytometry, and in future work they will flow directly into a flow cytometer for real-time, continuous measurements. Result(s): Preliminary results have shown that the microfluidic device is able to perform the necessary incubations with continuous flow operation. It has also been shown that that the assay incubation times can be reduced from the typical 30 minutes per stage to as low as 2 minutes, although the sensitivity is reduced. A trade-off must be chosen between assay lag time and minimum cytokine concentration sensitivity. Conclusion(s): The fully integrated assay will allow continuous measurement of inflammatory markers during mechanical circulatory support procedures with very high sampling rates and lag times likely below 20 minutes.

Sasso, P. d., et al. (2010). "The use of geographical information systems analysis for the detection of the use of protective plastic." Colture Protette **39**(2): 66-72.

The ever growing use of plastic materials in agriculture, whether on a seasonal basis or for several years, poses environmental problems related to their correct disposal, as well as their affect on the landscape. Plastic waste in agriculture mainly derives from the covering of greenhouses and small and large tunnels, mulching and the protection of fruit trees, including vines grown in overhead trellis and, to a lower extent, peach and cherry trees. Other plastic waste results from irrigation pipes, silage films, containers, boxes, etc. There is an urgent need to tackle the issues related to the disposal of this type of waste, which currently occurs only sporadically and without any consideration for specific applicable standards, with significant repercussions on the landscape and the environment. This phenomenon appears to be quire widespread, especially in the Bari metropolitan area, due to the presence of greenhouses, vines grown in trellis and many vegetable varieties that use plastic films for covering, protection and/or mulching. This study assessed the quantity of plastic films and nets used to protect the crops in the study area, identifying the location of those crops for which these are used through surveys conduced with the GIS.

Sasuga, Y., et al. (2006). "Development of a microscopic platform for real-time monitoring of biomolecular interactions." Genome Research **16**(1): 132-139.

We developed a new microscopic platform for the real-time analysis of molecular interactions by combining microbead-tagging techniques with total internal reflection fluorescent microscopy (TIRFM). The optical manipulation of probe microbeads, followed by photo immobilization on a solid surface, enabled us to generate arrays with extremely high density (>100 microbeads in a 25 mu m x 25 mu m area), and TIRFM made it possible to monitor the binding reactions of fluorescently labeled targets onto probe microbeads without removal of free targets. We demonstrated the high performance of this platform through analyses of interactions between antigen and antibody and between small compounds and proteins. Then, recombinant protein levels in total cellular lysates of Escherichia coli were quantified from the association kinetics using antibody-immobilized microbead arrays, which served as a model for a protein-profiling array. Furthermore, in combination with in vitro synthesis-coupled protein labeling, we could kinematically analyze the interaction of nuclear factor Kappa B (p50) with DNA. These results demonstrated that this platform enabled us to: (1) monitor binding processes of fluorescently labeled targets to multiple probes in real-time without removal of free targets, (2) determine concentrations of free targets only from the association kinetics at an early phase, and (3) greatly reduce the required volume of the target solution, in principle to subnanoliter, for molecular interaction analysis. The unique features of this microbead-based microarray system open the way to explore molecular interactions with a wide range of affinities in extremely small volumes of target solutions, such as extracts from single cells.

Satake, E., et al. (2017). "Resveratrol suppresses inflammatory responses of peritoneal macrophages in endometriosis." Journal of Obstetrics and Gynaecology Research **43 (12)**: 1900.

Objective Resveratrol is shown to control endometriosis in a mouse model but the mechanism is undetermined. Our group previously showed that resveratrol suppresses inflammatory responses in endometriotic stromal cells. This study was aimed at investigating whether resveratrol suppresses inflammatory responses of peritoneal macrophages in endometriosis patients. Methods Under IRB approval and informed consents, peritoneal fluid was collected from patients with endometriosis. Macrophages were isolated using CD14 MicroBeads, cultured at a density of 5.0x105 cells/ml, and exposed to resveratrol at doses of 25, 50, and 100 muM one hour before the stimulation. Stimulation was done by treatment with IL1beta(5 ng/ml)or LPS(100 ng/ml)to mimic local inflammation. After 24 hours, supernatants were collected and concentrations of IL6 and IL8 were measured by ELISA. Results Resveratrol significantly reduced IL1 betainduced IL6 and IL8 secretions to 96.7+/-46.0% and 81.0+/- 4.3%(25 muM), 89.0+/-13.2% and 67.3+/-10.8%(50 muM), and 62.0+/- 22.3% and 55.8+/-14.1%(100 muM), of that without any stimulation or treatment, respectively. Similarly, resveratrol significantly decreased LPSinduced IL6 and IL8 secretions to 48.9+/-3.8% and 60.2+/-8.7%(25 muM), 8.1+/-1.8% and 46.0+/-13.2%(50 muM), and 5.7+/-3.8% and 38.5+/-18.1%(100 muM), respectively(n=3, mean +/-SEM, p<0.05). Conclusion Resveratrol reduced the secretion of inflammatory cytokines from peritoneal macrophages, which may contribute to the therapeutic effects of resveratrol on endometriosis.

Sathe, T. R., et al. (2006). "Mesoporous silica beads embedded with semiconductor quantum dots and iron oxide nanocrystals: dual-function microcarriers for optical encoding and magnetic separation." Analytical Chemistry **78**(16): 5627-5632.

Mesoporous beads are promising materials for embedding functional nanoparticles because of their nanometer-sized pores and large surface areas. Here we report the development of silica microbeads embedded with both semiconductor quantum dots (QD) and iron oxide (Fe3O4) nanocrystals as a new class of dual-function carriers for optical encoding and magnetic separation. The embedding (doping) process is carried out by either simultaneous or sequential addition of quantum dots and iron oxide (Fe3O4) nanocrystals in solution. The doping process is fast and quantitative, but the incorporated iron oxide strongly attenuates the signal intensity of QD fluorescence. We find that this attenuation is not due to conventional fluorescence quenching but is caused by the broad optical absorption spectrum of mixed-valence Fe3O4. For improved biocompatibility and reduced nonspecific binding, the encoded beads are further coated with amphiphilic polymers such as octylamine poly(acrylic acid). The results indicate that the polymer-coated beads are well suited for target capturing and enrichment, yielding magnetic separation efficiencies higher than 99%. By combining the multiplexing capability of QDs with the superparamagnetic properties of iron oxide nanocrystals, this class of encoded beads is expected to find broad applications in high-throughput and multiplexed biomolecular assays.

Sathish, T. (2017). "Performance Measurement on Extracted Bio-Diesel from Waste Plastic." Journal of Applied Fluid Mechanics **10**: 41.

This paper presents an important analysis on the fuel extracted from waste plastic using the process of pyrolysis. Here, the plastics collected from local municipality are used for conversion of solid plastic waste to liquid fuel. The fuel prepared is blended with mixtures of oxygenated compounds to test the performance of the fuel. The bio-diesel or waste plastic oil (WPO) from the waste solid plastic is tested with other blended mixtures to find the mechanical efficiency, emission rate, brake test efficiency and total fuel consumption. Here, the efficiency between the pure diesel mixture and WPO with different blends that varied between 10-50% of pure diesel oil is tested. The performance of the produced WPO-diesel blended oil performs with better efficiency than the other fuels.

Sati, P. C., et al. (2012). "Oxidative status in workers engaged in recycling of plastic: occupational hazard." Indian Journal of Physiology & Pharmacology **56**(3): 234-238.

Recycling plastic industry is on rise. Plastic waste in environment is a pollutant so recycling of it can save environment and is economical too. However its recycling is associated with harmful effects on workers engaged in it. The present study was designed to elucidate the role of free radicals and cytochrome c in pathogenesis of polypropylene associated diseases. Thirty workers from plastic recycling factory occupationally exposed to polypropylene between the age of 18-40 years and working for atleast 8 hours a day for more than a year but less than 10 years were selected for the study. A trend in increase of FRAP and decrease of MDA was observed but they could not reach the level of significance. The level of serum cytochrome c, which is an indirect marker of oxidative stress, was also detectable in only two subjects. Since the number of subjects in the study was less, the result needs to be confirmed on larger number. More over cause of pulmonary dysfunction and carcinomas in these workers needs to be investigated.

Sato, K., et al. (2010). "Microbead-based rolling circle amplification in a microchip for sensitive DNA detection." Lab on a Chip **10**(10): 1262-1266.

The sensitive detection and quantification of DNA targets in the food industry and in environmental and clinical settings are issues of utmost importance in ensuring contamination-free food, monitoring the environment, and battling disease. Selective probes coupled with powerful amplification techniques are therefore of major interest. In this study, we set out to create an integrated microchemical chip that benefits from microfluidic chip technology in terms of sensitivity and a strong detection methodology provided jointly by padlock probes and rolling circle amplification (RCA). Here, we have integrated padlock probes and RCA into a microchip. The chip uses solid phase capture in a microchannel to enable washing cycles and decrease analytical area, and employs on-bead RCA for single-molecule amplification and detection. We investigated the effects of reagent concentration and amount of padlock probes, and demonstrated the feasibility of detecting Salmonella.

Sauer, J. J. and J. P. Schnydrig (1974). "Plastic waste separate collection and recycling. [French]." Iswa Informat.Bull **No. 14-15**: 17-27.

The inhabitants of the city of Morges, Switzerland, have been separating glass and paper from household refuse for over one year. The savings achieved by the municipality due to the lower incineration costs, the improvement of collection and the proceeds from the sale of recovered products have led to the segregation of plastic wastes as well. This additional separation was considered because of the important volume of plastic wastes, incineration problems and for the recovery of raw materials. The separate collection of plastic wastes was carried out 4 times in the autumn of 1973. As a result, 28% of the total plastic wastes containing 1 to 2% foreign matter could be collected. These results can be considered very satisfactory, since households do not have any home separating devices yet that would permit waste segregation into 4 components. Recovered plastics (3,600 kg) were sent to W. Germany for recycling experiments. Loose unprocessed plastics were replasticized in a mixer utilized by the rubber industry. From this process one can obtain either foils, by lamination, or granulated material, by grinding the replasticized mass. The granulated material could be used as foundation for roads or transformed into products by means of conventional machines used in plastics manufacturing. Processing and incineration problems created by plastic wastes are discussed and it is concluded that a separate collection and recycling are possible, but technical and economical aspects should be examined more thoroughly.

Savin, H., et al. (1987). "Digitalis hemoperfusion: increase of column binding capacity by pretreatment with ouabain." Biomaterials, Artificial Cells, & Artificial Organs **15**(3): 539-547.

Extracorporeal hemoperfusion through polyacrolein microsphere beads (APAMB) attached to antidigoxin antibodies is an effective treatment of digitalis intoxication. In order to increase the binding capacity of the APAMB columns the active sites of the antidigoxin antibodies were protected by ouabain during the binding to the microbeads. This brought about an 11-18 percent increase in digoxin binding capacity of the columns. It was also found that binding capacity does not increase with the rise of antibody concentration beyond a certain limit. Protection of antibody binding sites and determination of optimal concentration are, therefore necessary steps during preparation of antibody based hemoperfusion columns.

Savoca, M. S., et al. (2017). "Odours from marine plastic debris induce food search behaviours in a forage fish." Proceedings of the Royal Society B. Biological Sciences **284**(1860).

Plastic pollution is an anthropogenic stressor in marine ecosystems globally. Many species of marine fish (more than 50) ingest plastic debris. Ingested plastic has a variety of lethal and sublethal impacts and can be a route for bioaccumulation of toxic compounds throughout the food web. Despite its pervasiveness and severity, our mechanistic understanding of this maladaptive foraging behaviour is incomplete. Recent evidence suggests that the chemical signature of plastic debris may explain why certain species are predisposed to mistaking plastic for food. Anchovy (Engraulis sp.) are abundant forage fish in coastal upwelling systems and a critical prey resource for top predators. Anchovy ingest plastic in natural conditions, though the mechanism they use to misidentify plastic as prey is unknown. Here, we presented wild-caught schools of northern anchovy (Engraulis mordax) with odour solutions made of plastic debris and clean plastic to compare school-wide aggregation and rheotactic responses relative to food and food odour presentations. Anchovy schools responded to plastic debris odour with increased aggregation and reduced rheotaxis. These results were similar to the effects food and food odour presentations had on schools. Conversely, these behavioural responses were absent in clean plastic and control treatments. To our knowledge, this is the first experimental evidence that adult anchovy use odours to forage. We conclude that the chemical signature plastic debris acquires in the photic zone can induce foraging behaviours in anchovy schools. These findings provide further support for a chemosensory mechanism underlying plastic consumption by marine wildlife. Given the trophic position of forage fish, these findings have considerable implications for aquatic food webs and possibly human health.

Savoca, S., et al. (2019). "Microplastics occurrence in the Tyrrhenian waters and in the gastrointestinal tract of two congener species of seabreams." Environmental Toxicology & Pharmacology **67**: 35-41.
In this work it is reported for the first time the characterization of microplastics from sea water samples and in two congener species of seabreams: Pagellus erythrinus and P. bogaraveo, Mediterranean fish species of great commercial importance. An experimental survey was conducted on May–June 2017 in the southernmost part of the Tyrrhenian Sea. Microplastics found in the sea water and in the grastrointestinal tract of two teleosts were characterized by Raman and IR spectroscopies. Microplastics found in sea water samples appeared in the form of fragments made of plastics of low and high density (PVC and LPDE). All the microplastics found in fish belonged to Nylon 66, typical fibers used in industry and in fisheries. Our findings highlighted the importance of further studies along the food web chain for a better understanding of the diffusion and possible consequences of this terrible threat. [ABSTRACT FROM AUTHOR]

Savoca, S., et al. (2019). "Detection of artificial cellulose microfibers in Boops boops from the northern coasts of Sicily (Central Mediterranean)." Science of the Total Environment **691**: 455-465.
Pollution deriving from textile wastes, including industrial and household waste, is recently of great interest due to their environmental impacts. Anthropogenic and synthetic fibers are responsible for negative effects on the quality of water and soil, and, also, their presence damages plant and animal health. In this work, the authors revealed the occurrence of man-made cellulose fibers in specimens of Boops boops from the Northern Sicilian coasts. Bogue was chosen as target species as it has been used as an indicator within the European Marine Strategy Framework Directive (MSFD 2008/56/EC) in order to value the "microplastics status" in the stomach contents. Of the 30 specimens examined, 63.3% of these had ingested fibers items. The number of fibers ranged from 1 to 10 per specimens with an average of 2.7 items/specimen. Fibers length ranged from 0.5 to 30 mm, most of them were black (95%), and a small percentage was red (5%). The ingestion of man-made cellulose fibers, observed for the first time, in Boops boops in the Mediterranean Sea wake-up call and it should attract the attention of the EU for new guidelines where this new type of contaminant is classified harmful as well as plastics. Unlabelled Image • Microfibers were found in GIT of Boops boops (63%) from Northern Sicilian coasts (Central Mediterranean Sea). • The microfibers ranged from 1 to 10 per specimens with an average of 2.7 items/specimens. • Man-made fibers derived from regenerated cellulose were identified by the spectroscopic techniques SEM and μ-Raman. Sawitzke, A. L., et al. (2005). "Improvements in histological quality and signal retention following in situ hybridization in early chick embryos using plastic resin and recolorization." Biotechnic and Histochemistry **80**(1): 35-41.

We describe a novel method that allows reliable detection of in situ hybridization signals in thin sections of plastic embedded embryos. Sections from plastic embedded embryos are thinner and have superior histological quality compared to paraffin, gelatin, agarose embedded sections or cryosections; however, plastic resin traditionally has not been used as an embedding medium following in situ hybridization because of loss of signal. When signal is detected with alkaline phosphatase and NBT/BCIP, the resulting colored precipitate is subject to fading when samples are exposed to organic compounds. The colored precipitate can be redeposited by repeating the NBT/BCIP reaction following plastic sectioning. This recolorization shows no loss of specificity, because signal is detected only where the anti-digoxigenin/alkaline phosphatase conjugated antibody is bound to the riboprobe. Strong signals can be detected without recolorization; however, weaker signals require the recolorization step. This novel method of re-depositing colored precipitate after processing and sectioning allows accurate determination of the location of gene expression and study of this expression in high quality histological sections of early chick embryos. © Biological Stain Commission Biotechnic & Histochemistry 2005.

Say, R., et al. (2003). "Preconcentration of copper on ion-selective imprinted polymer microbeads." Analytica Chimica Acta **480**(2): 251-258.

Molecular recognition-based separation techniques have received much attention in various fields because of their high selectivity for target molecules. Molecular imprinting has been recognized as a promising technique for the preparation of such systems. In this study, we have prepared a novel molecular imprinted adsorbent to remove heavy metal ions with high selectivity. The Cu(II)-imprinted poly(ethylene glycol dimethacrylate-methacryloylamidohistidine/Cu(II)) (poly(EGDMA-MAH/Cu(II))) microbeads with an average size of 150-200mum were prepared by dispersion polymerization. These Cu(II) imprinted microbeads were used in the adsorption-desorption of copper(II) ions from metal solutions. Adsorption equilibria was achieved in about 1h. The maximum adsorption of Cu(II) ions onto imprinted microbeads was about 48mg/g. The pH significantly affected the adsorption capacity of imprinted microbeads. The observed adsorption order under competitive conditions was Cu(II) > Zn(II) > Ni(II) > Co(II) in mass basis. The imprinted microbeads can be easily regenerated by 0.1M EDTA solution with higher effectiveness. The imprinted microbeads showed excellent selectivity for the target molecule (i.e. Cu(II) ions due to molecular geometry). These features make imprinted microbeads very good candidate for selective removal of Cu(II) ions at high adsorption capacity. Detection limit was increased at least 1000-folds with the preconcentration approach using the imprinted microbeads. The method was also applied to certified reference and seawater samples. © 2003 Elsevier Science B.V. All rights reserved.

Saygin, D., et al. (2011). "Potential of best practice technology to improve energy efficiency in the global chemical and petrochemical sector." Energy **36**(9): 5779-5790.

The chemical and petrochemical sector is by far the largest industrial energy user, accounting for 30% of the industry's total final energy use. However, due to its complexity its energy efficiency potential is not well understood. This article analyses the energy efficiency potential on a country level if Best Practice Technologies (BPT) were implemented in chemical processes. Two approaches are applied and an improved dataset referring to Europe has been developed for BPT energy use. This methodology has been applied to 66 products in fifteen countries that represent 70% of chemical and petrochemical sector's energy use worldwide. The results suggest a global energy efficiency potential of 16% for this sector, excluding savings in electricity use and by higher levels of process integration, combined heat and power (CHP) and post-consumer plastic waste treatment. The results are more accurate than previous estimates. The results suggest significant differences between countries, but a cross-check based on two different methods shows that important methodological and data issues remain to be resolved. Further refinement is needed for target setting, monitoring and informing energy and climate negotiation processes. For the short and medium term, a combination of benchmarking and country level analysis is recommended.

Sayyed, R. Z., et al. (2020). "Production, purification and evaluation of biodegradation potential of PHB depolymerase of Stenotrophomonas sp. RZS7." PLoS ONE [Electronic Resource] **15**(1): e0220095.

There are numerous reports on poly-beta-hydroxybutyrate (PHB) depolymerases produced by various microorganisms isolated from various habitats, however, reports on PHB depolymerase production by an isolate from plastic rich sites scares. Although PHB has attracted commercial significance, the inefficient production and recovery methods, inefficient purification of PHB depolymerase and lack of ample knowledge on PHB degradation by PHB depolymerase have hampered its large scale commercialization. Therefore, to ensure the biodegradability of biopolymers, it becomes imperative to study the purification of the biodegrading enzyme system. We report the production, purification, and characterization of extracellular PHB depolymerase from Stenotrophomonas sp. RZS7 isolated from a dumping yard rich in plastic waste. The isolate produced extracellular PHB depolymerase in the mineral salt medium (MSM) at 30degreeC during 4 days of incubation under shaking. The enzyme was purified by three methods namely ammonium salt precipitation, column chromatography, and solvent purification. Among these purification methods, the enzyme was best purified by column chromatography on the Octyl-Sepharose CL-4B column giving optimum yield (0.7993 Umg-1mL-1). The molecular weight of purified PHB depolymerase was 40 kDa. Studies on the assessment of biodegradation of PHB in liquid culture medium and under natural soil conditions confirmed PHB biodegradation potential of Stenotrophomonas sp. RZS7. The results obtained in Fourier-Transform Infrared (FTIR) analysis, High-Performance Liquid Chromatography (HPLC) study and Gas Chromatography Mass-Spectrometry (GC-MS) analysis confirmed the biodegradation of PHB in liquid medium by Stenotrophomonas sp. RZS7. Changes in surface morphology of PHB film in soil burial as observed in Field Emission Scanning Electron Microscopy (FESEM) analysis confirmed the biodegradation of PHB under natural soil environment. The isolate was capable of degrading PHB and it resulted in 87.74% biodegradation. A higher rate of degradation under the natural soil condition is the result of the activity of soil microbes that complemented the biodegradation of PHB by Stenotrophomonas sp. RZS7.

Scanes, E., et al. (2019). "Microplastics detected in haemolymph of the Sydney rock oyster Saccostrea glomerata." Marine Pollution Bulletin **149**: 110537.

Plastic waste is ubiquitous in marine environments. Despite the sheer volume of plastic waste, it remains relatively unknown how marine invertebrates will interact with microplastics (plastic <1mm). Microplastics (<2mum) were ingested by the economically and ecologically significant Sydney rock oyster Saccostrea glomerata and translocated to the haemolymph, perhaps via phagocytosis. The presence of microplastics in the haemolymph indicates that filter feeding S. glomerata can ingest and accumulate microplastics which are prevalent in the environment. This research shows microplastics can enter marine molluscs and highlights the need to monitor microplastics in the marine environment and aquaculture to safeguard the seafood industry.

Scarascia-Mugnozza, G., et al. (2010). "Technical characteristics of regenerated plastic profiles produced through recycling agricultural plastic material." International Conference on Agricultural Engineering AgEng.

The use of plastics for agricultural use is steadily increasing in the world thanks to the significant increases in production that it is able to obtain. This causes a high and growing volume of plastic waste that is not usually enough well managed, causing heavy consequences to the environment and loss of energy and material. The mechanical recycling of post-consume plastic is a suitable system for the recovery of these materials, that could determine new economic profit deriving by the re-use of agricultural plastic waste as secondary raw material. With the aim to evaluate the mechanical properties of rigid profiles obtained by the recycling of agricultural plastic film, experimental tests were performed by recycling different blends of plastic material, adding specific additives in the waste stream. These profiles were analyzed by bending, compression and tensile tests and their mechanical characteristics were determined in order to estimate their new possible use.

Schefzyk, M., et al. (2009). "Eosinophil granulocytes: functional differences of a new isolation kit compared to the isolation with anti-CD16-conjugated MicroBeads." Experimental Dermatology **18**(7): 653-655.

BACKGROUND/PURPOSE: Using a new eosinophil isolation kit, we were not able to confirm our previous findings of a delayed apoptosis of eosinophils in atopic dermatitis. Thus, we investigated whether this new isolation kit modulates the functional activity of eosinophils.

METHODS: Peripheral blood eosinophils were isolated with the new isolation kit as well as conventionally with anti-CD16-conjugated MicroBeads. We analysed viability, apoptosis, CD69 and CD95 expression, streptavidin binding and superoxide anion release.

RESULTS: Purity of eosinophils was higher using the new isolation kit ($P < 0.05$). However, these eosinophils had a decreased survival ($P < 0.05$-0.01), presented morphological features of apoptosis, showed an increased percentage of apoptotic nuclei ($P < 0.01$), an increased release of superoxide anions ($P < 0.05$), a higher expression of CD69 and CD95 ($P < 0.05$) and an increased binding to streptavidin compared to eosinophils isolated with anti-CD16 conjugated MicroBeads.

CONCLUSION: The new eosinophil isolation kit should not be used for the investigation of eosinophils as it potently affects their functional activity.

Schepky, A., et al. (2009). "Development of an in vitro sensitization assay based on monocyte-derived dendritic cells." Toxicology Letters **1)**: S66.

Dendritic cells, including Langerhans cells, forming a sentinel network for pathogen detection are the most abundant antigen presenting cells in the skin. Through their ability of hapten uptake, processing and presentation to T-cells they play a critical role in the induction of contact allergies. In this process dendritic cells undergo fundamental changes, e.g. surface marker expression. Their observance marks a potential endpoint in the experimental set-up of a predictive in vitro skin sensitization assay. Thus, CD1a-/CD14+ peripheral blood monocytes from donors where purified by density centrifugation and positive selection of anti-CD14-Ig coupled magnetic microbeads. CD1a-/CD14+ monocytes were differentiated into immature dendritic cells by 5-day culture in the presence of IL4 and GM-CSF. Substance treatment for 48h was followed by FACS analysis of HLA-DR; CD86; CD80; CD14; CD1a and CD83. In this assay all strong

sensitizers tested as well as non-sensitizers where identified correctly referring to their allergic potential in the LLNA, whereas moderate sensitizers (according to the LLNA) showed surface marker changes only close to cytotoxic concentrations. Limitations, e.g. donor variability and work intensiveness are widely discussed. However, this assay leads to results that reflect the reaction of a healthy donor population in contrast to single individuals of cell lines. Moreover, after interpretation of comprehensive investigation we assume that a classification of the sensitizing potential of substances may be possible, marking a clear advantage over an all-or-none interpretation of cell line based assays already established. Therefore this assay provides a basic application in assessing the allergic potential of active components.

Scherer, C., et al. (2017). "Feeding type and development drive the ingestion of microplastics by freshwater invertebrates." Scientific Reports **7**(1).

Microscopic plastic items (microplastics) are ubiquitously present in aquatic ecosystems. With decreasing size their availability and potential to accumulate throughout food webs increase. However, little is known on the uptake of microplastics by freshwater invertebrates. To address this, we exposed species with different feeding strategies to 1, 10 and 90 micro m fluorescent polystyrene spheres (3-3 000 particles mL⁻¹). Additionally, we investigated how developmental stages and a co-exposure to natural particles (e.g., food) modulate microplastic ingestion. All species ingested microplastics in a concentration-dependent manner with Daphnia magna consuming up to 6 180 particles h⁻¹, followed by Chironomus riparius (226 particles h⁻¹), Physella acuta (118 particles h⁻¹), Gammarus pulex (10 particles h⁻¹) and Lumbriculus variegatus (8 particles h⁻¹). D. magna did not ingest 90 micro m microplastics whereas the other species preferred larger microplastics over 1 micro m in size. In C. riparius and D. magna, size preference depended on the life stage with larger specimens ingesting more and larger microplastics. The presence of natural particles generally reduced the microplastics uptake. Our results demonstrate that freshwater invertebrates have the capacity to ingest microplastics. However, the quantity of uptake depends on their feeding type and morphology as well as on the availability of microplastics.

Scherer, C., et al. (2019). "Toxicity of microplastics and natural particles in the freshwater dipteran Chironomus riparius: Same same but different?" Science of the Total Environment: 134604.

Microplastics (MP) are contaminants of emerging concern in aquatic ecosystems. While the number of studies is rapidly increasing, a comparison of the toxicity of MP and natural particulate matter is largely missing. In addition, research focusses on the impacts of hydrophobic chemicals sorbed to plastics. However, the interactive effects of MP and hydrophilic, dissolved chemicals remain largely unknown. Therefore, we conducted chronic toxicity studies with larvae of the freshwater dipteran Chironomus riparius exposed to unplasticised polyvinyl chloride MP (PVC-MP) as well as kaolin and diatomite as reference materials for 28 days. In addition, we investigated the effects of particles in combination with the neonicotinoid imidacloprid in a multiple-stressor experiment. High concentrations of kaolin positively affected the chironomids. In contrast, exposure to diatomite and PVC-MP reduced the emergence and mass of C. riparius. Likewise, the toxicity of imidacloprid was enhanced in the presence of PVC-MP and slightly decreased in the co-exposure with kaolin. Overall, parallel experiments and chemical analysis indicate that the toxicity of PVC-MP was not caused by leached or sorbed chemicals. Our study demonstrates that PVC-MP induce more severe effects than both natural particulate materials. However, the latter are not benign per se, as the case of diatomite highlights. Considering the high, environmentally irrelevant concentrations needed to induce adverse effects, C. riparius is insensitive to exposures to PVC-MP.

Schettini, E., et al. (2005). "Physical properties of innovative biodegradable spray coating for soil mulching in greenhouse cultivation." Acta Horticulturae **691**(Vol 2): 725-732.

To overcome with the serious drawback of huge quantities of plastic waste obtained at the end of the life of agricultural plastic mulching films, research on innovative biodegradable materials have been developing. The paper examines a new sustainable approach in which a water solution of natural biodegradable polymers is sprayed on a cultivation area to form a mulch coating. The material used is a blend of two polysaccharides, such as guar gum and locust bean gum added with glycerol. A protected field experiment was conducted to test the effectiveness of spray black biodegradable mulching coating in a tomato crop in Southern Italy. Field performance and physical properties, evaluated by means of laboratory tests, are compared to those of commercial low density polyethylene and biodegradable starch based mulch films. The spray mulching coating is opaque in the solar radiation range and behaved as a black body. The tested spray coating showed much lower values of tensile stress and elongation at break in comparison with the values of commercial low density polyethylene and biodegradable starch based mulch films. Such innovative coatings were characterized by functionality during their use in field. Results indicate that the biodegradable spray coatings could be a sustainable alternatives to plastic films based on fossil raw materials.

Scheurer, M. and M. Bigalke (2018). "Microplastics in Swiss Floodplain Soils." Environmental Science & Technology **52**(6): 3591-3598.

Microplastics (MPs) are small (<5 mm diameter) but have clear implications for the environment. These artificial particles are found in and pose threats to aquatic systems worldwide. MPs have terrestrial sources, but their concentrations and fates in the terrestrial environment are poorly understood. While global plastic production continues to increase, so do the environmental concentrations and impacts of MPs. In this first study of MPs in floodplain soils, we developed a method for identifying, quantifying, and measuring the sizes of most commonly produced MPs in soil by FT-IR microscopy. For small MP (<1 mm) analysis, MP were separated by density separation and oxidation of organic matter. In this study we analyzed 29 floodplains in Swiss nature reserves associated with catchments covering 53% of Switzerland. We found evidence that 90% of Swiss floodplain soils contain MPs. The highest MP concentrations were associated with the concentration of mesoplastics (5 mm - 2.5 cm diameter), indicating plastic waste as source. Furthermore, MP concentration was correlated with the population of the catchment. The wide distribution of MPs, their presence in remote unsettled high mountain areas, decoupling of MEP and MP compositions, and the dominance of MPs by small (<500 mum diameter) particles, indicate that MPs enter soils via diffuse aeolian transport.

Scheytt, T. and J. v. Freyberg (2015). "A comparison of different methods for sampling of solid material for microbial studies." Grundwasser **20**(4): 253-261.

Sediment sampling for microbial characterization is often associated with cross-contamination. The aim of this study was to assess the suitability of widely used sediment-sampling techniques for obtaining microbially uncontaminated samples from the saturated zone. Three different methods were applied: Continuous percussion drilling, discontinuous drilling with Direct-Push technology and a freeze corer using liquid nitrogen for cooling. Microbial contamination was monitored with dye tracers and fluorescent micro beads. It was assumed that microbial contamination would take place mainly at the ground surface. The results show that the sediment cores in the liners from both the conventional core driver and from Direct-Push yielded little to no contamination if the uppermost 30 cm and the outer part of the sediment core were discarded. A broken core resulted in a high degree of contamination. The freeze corer did not meet the expectations and lead to unsatisfactory results.

Scheytt, T. and F. Jana von (2015). "Vergleich unterschiedlicher Methoden zur Entnahme von Feststoffproben für mikrobielle Untersuchungen." Grundwasser **20**(4): 253-261.

Bei der Probennahme von Feststoffproben für die mikrobielle Charakterisierung kann es zu einer Verunreinigung des Feststoffmaterials durch Einschleppen von Fremdmaterial kommen. Das Ziel dieser Studie ist eine Bewertung von allgemein gebräuchlichen Probennahmeverfahren für Feststoffe im Hinblick auf die Gewinnung mikrobiell unkontaminierter Proben aus dem Grundwasserleiter. Hierfür wurden Feststoffproben mittels konventioneller Kleinrammbohrverfahren (kontinuierlich mittels Rammkernsondierung, diskontinuierlich mittels Direct-Push-Verfahren) und Stickstoff-Gefrierkernverfahren aus dem wassergesättigten Bereich gewonnen. Zur Ermittlung der mikrobiellen Verunreinigung wurden Farbstoffe und Partikeltracer eingesetzt, wobei eine mikrobielle Verunreinigung von der Geländeoberfläche aus angenommen wurde. Die mit der Rammkernsondierung und der Direct-Push-Sondierung gewonnenen Bohrkerne zeigen gute Ergebnisse hinsichtlich einer mikrobiell einwandfreien Beprobung, wenn der obere Teil des Bohrkerns (ca. 30 cm) und der äußere Bereich verworfen werden. Das Zerbrechen des Sedimentkerns ist eine wichtige Ursache für Kontaminationen des inneren Bohrkerns, wobei das Ausmaß nur schwer abzuschätzen ist. Das hier benutzte Gefrierkernverfahren erwies sich als untauglich für die Gewinnung mikrobiell unkontaminierter Proben.Alternate abstract:Sediment sampling for microbial characterization is often associated with cross-contamination. Schildgen, B. (2014). "How to Handle Microbeads." Sierra **99**(4): 1-2.

The article focuses on the management of microbeads and their harmful effects on humans and the environment. Topics discussed include the description an overview of microbeads, the components of the beads, their presence in cosmetics,their disposal, and the efforts in banning microbeads and replaced with safer materials.

Schirinzi, G. F., et al. (2017). "Cytotoxic effects of commonly used nanomaterials and microplastics on cerebral and epithelial human cells." Environmental Research **159**: 579-587.

Plastic wastes are among the major inputs of detritus into aquatic ecosystems. Also, during recent years the increasing use of new materials such as nanomaterials (NMs) in industrial and household applications has contributed to the complexity of waste mixtures in aquatic systems. The current effects and the synergism and antagonisms of mixtures of microplastics (MPLs), NMs and organic compounds on the environment and in human health have, to date, not been well understood but instead they are a cause for general concern. The aim of this work is to contribute to a better understanding of the cytotoxicity of NMs and microplastics/nanoplastics (MPLs/NPLs), at cell level in terms of oxidative stress (evaluating Reactive Oxygen Species effect) and cell viability. Firstly, the individual cytotoxicity of metal nanoparticles (NPs) (AgNPs and AuNPs), of metal oxide NPs (ZrO₂NPs, CeO₂NPs, TiO₂NPs, and Al₂O₃NPs), carbon nanomaterials (C₆₀fullerene, graphene), and MPLs of polyethylene (PE) and polystyrene (PS) has been evaluated in vitro. Two different cellular lines T98G and HeLa, cerebral and epithelial human cells, respectively, were employed. The cells were exposed during 24-48h to different levels of contaminants, from 10ng/mL to 10micro g/mL, under the same conditions. Secondly, the synergistic and antagonistic relationships between fullerenes and other organic contaminants, including an organophosphate insecticide (malathion), a surfactant (sodium dodecylbenzenesulfonate) and a plasticiser (diethyl phthalate) were assessed. The obtained results confirm that oxidative stress is one of the mechanisms of cytotoxicity at cell level, as has been observed for both cell lines and contributes to the current knowledge of the effects of NMs and MPLs-NPLs.

Schirmel, J., et al. (2018). "Plasticulture changes soil invertebrate assemblages of strawberry fields and decreases diversity and soil microbial activity." Applied Soil Ecology **124**: 379-393.

In agriculture, the use of plastic mulch (plasticulture) is globally increasing. Besides beneficial effects on crop yield and quality, possible adverse environmental effects associated with plastic mulch are currently under debate. Aside from the obvious disadvantages of substantial amounts of (micro)plastic waste, adverse effects on soil quality and biodiversity might be assumed. We compared the effect of plastic mulch and organic mulch (straw) systems in strawberry cultivation on soil invertebrates and biological activity in an observational field study in the Upper Rhine valley, Germany. Soil invertebrates were collected using pitfall traps and Berlese-Tullgren-funnels, earthworms by hand sorting. Soil biological activity was determined using bait-lamina sticks and the MicroResp^{TM} system. Soil samples from test fields were analysed for physicochemical and microbial parameters. Despite minor effects on soil physicochemical parameters, our results showed that the mulch system had a significant effect on the community structure of soil invertebrates. In strawberry fields with plastic mulch we found a decreased taxonomic richness and taxonomic richness decreased with increasing soil temperature. About 50% of the analysed taxa had significantly lower abundances in plastic mulched fields compared to fields with organic mulch. No investigated taxon had a higher abundance in plastic mulched fields. Soil moisture was the most important environmental variable in explaining invertebrate abundances. The soil microbial activity was significantly lower in plastic mulched fields than in fields with organic mulch. Our results indicate that even little shifts in abiotic (e.g. temperature, water content) and biotic (e.g. food availability) conditions associated with the plastic mulch system can have strong effects on soil invertebrates and soil microbial activity. Hence, plastic mulch might pose a threat to soil biodiversity and related ecosystem functions in agroecosystems. We call for further studies analysing the influence of plasticulture, to better evaluate the long-term consequences on agrobiodiversity and soil quality as well as sustainability.

Schirmer, D., et al. (2016). "Therapeutic potential of GPR64 specific CAR T cells in pediatric ewing sarcoma." Monatsschrift fur Kinderheilkunde **164 (12)**: 1176.

Background: Ewing Sarcoma (ES) is the second most common bone malignancy in children and young adolescents with a high potential of dissemination into lung and bones. Patients with localized disease receiving current treatment, have an approximate long-term survival of >65 %.

Patients with disseminated disease into the bone have an approximate longterm survival rate of only 10 %, compelling the search for new therapeutic treatment modalities like engineered T cell therapy. Here the therapeutic potential of chimeric antigen receptor (CAR) transgenic T cells directed against G-protein coupled receptor 64 (GPR64), an orphan receptor with normal expression restricted to human epididymis and significant overexpression in ES, was examined. Method(s): Therefore, two different monoclonal antibodies (mAb) directed against the extracellular region of GPR64 were generated and characterized. Subsequently, retroviral constructs containing second generation CARs together with the scFv fragments of the respective mAbs were designed. Primary lymphocytes were transduced and tested in vitro via flow cytometry, ELISpot and xCelligence assay. Result(s): Antibodies specifically stained ES cells as determined by flow cytometry. The signal intensity was reduced after RNAi mediated down-regulation of GPR64 in ES cell lines confirming specificity of mAbs. Following sequence determination of those mAbs two different CAR constructs were designed. Retroviruses containing such CARs transduced primary lymphocytes with good efficiency. The CAR transgenic T cells could be enriched for CD8+CAR+ cells via microbead isolation and showed strong proliferative capacities in vitro. Furthermore, target structures were specifically recognized as determined by ELISpot and xCelligence assays. Conclusion(s): CAR transgenic T cells targeting GPR64 show a promising approach to transfer the success of CARs in hematological malignancies to solid tumors. The cells generated in this study show strong specificity towards GPR64 and are able to control tumor cell growth in vitro. Since GPR64 expression is not restricted to ES but also up-regulated in a number of carcinomas derived from prostate, kidney or lung, GPR64-specific CARs may also be a future treatment option for other tumor entities.

Schleser, A., et al. (2016). "The impact of disposables towards more eco-friendly and less costly haemodialysis." Nephrology Dialysis Transplantation **1)**: i494.

Introduction and Aims: In Europe, over 50 million dialysis treatments are carried out annually, producing substantial amounts of contaminated and eco-damaging plastic waste. As part of the green dialysis concept, we examined the impact of 3 types of haemodialysis (HD)-disposables on the amount of plastic waste produced per treatment and the associated costs of disposal. Method(s): In a standard 3-times per week double-needle HD-setting, the weight of disposables (bloodlines and dialysers) was analysed after reinfusion for 3 haemodialysis machines: Gambro Artis (in HD mode), Fresenius Medical Care 5008 and Fresenius Medical Care 6008 (both in HDF mode). The weights were then correlated with the average costs of disposal of contaminated waste (mean of 17 European countries: 1.56 /kg; range: 0.47 - 9.08 /kg). Result(s): Conclusion(s): The weight of disposable waste differs considerably for the 3 HD-machine systems. The unused CareSet blood-cassette of the Fresenius Medical Care 6008 system is the lightest in weight; further, after treatment and reinfusion, it weighs 0.2 kg less than its precursor, the Fresenius Medical Care 5008 AV-Set. In comparison, the weight of disposable waste for Gambro Artis in HD-mode is below that of Fresenius Medical Care 5008 in HDF-mode. Application of Gambro Artis in HDF-treatments would necessitate the usage of the ArtiSet ULTRA, which is ca. 120 gr heavier than the standard ArtiSet and therefore even more costly to dispose. Projecting the difference between the Fresenius Medical Care 5008 and 6008 machines (0.2 kg less disposable waste per treatment for 6008) to 10,000 treatments/year (typical number of treatments for many clinics), approx. 2,000 kg less waste would be produced annually and costs would be reduced by ~ 3120 (at a mean of 1.56 /kg). As part of the environmentally-conscious development concept, the new automatic blood-cassette drainage-feature of the Fresenius 6008 system will further lead to a reduction of disposable weight by approx. 30 gr/treatment. The provision of healthcare, particularly dialysis, is associated with substantial usage of energy,

water and plastic materials, adding to the carbon footprint of dialysis. Sustainable and cost effective dialysis practices, aiming at a reduced consumption of energy, water and plastic materials are a responsibility of the entire dialysis community and should be an important global goal towards making dialysis more eco-friendly1,2. 1 Agar JWM. Personal viewpoint: hemodialysis-water, power, and waste disposal: rethinking our environmental responsibilities. (Table Presented).

Schlosser, O., et al. (2015). "Extension of the sorting instructions for household plastic packaging and changes in exposure to bioaerosols at materials recovery facilities." Waste Management **46**: 47-55.

The aim of this study was to assess how extending the sorting instructions for plastic packaging would affect the exposure of workers working at materials recovery facility (MRF) to dust, endotoxins, fungi and bacteria, taking into consideration other factors that could have an influence on this exposure. Personal sampling was carried out at four MRFs during six sampling campaigns at each facility, both in sorting rooms and when the workers were involved in "mobile tasks" away from the rooms. The data was analysed by describing the extension of sorting instructions both using a qualitative variable (after vs before) and using data for the pots and trays recycling stream, including or excluding plastic film. Overall, before the extension of the sorting guidelines, the geometric mean of personal exposure levels in sorting rooms was 0.3mg/m(3) for dust, 27.7 EU/m(3) for endotoxins, 13,000 CFU/m(3) for fungi and 1800 CFU/m(3) for bacteria. When workers were involved in mobile tasks away from the rooms, these averages were 0.5mg/m(3), 25.7 EU/m(3), 28,000 CFU/m(3) and 5100 CFU/m(3) respectively.The application by households of instructions to include pots, trays and film with other recyclable plastic packaging led to an increase in exposure to endotoxins, fungi and bacteria at MRFs. For an increase of 0.5 kg per inhabitant per year in the pots, trays and film recycling stream, exposure in sorting rooms rose by a factor of 1.4-2.2, depending on the biological agent. Exposure during mobile tasks increased by a factor of 3.0-3.6. The age of the waste amplified the effect of the extension of sorting instructions on exposure to fungi, bacteria and endotoxins. Factors that had a significant influence on the exposure of workers to dust and/or bioaerosols included the presence of paper, newspapers and magazines in the sorted waste, the order in which incoming waste was treated and the quality of the ventilation system in the sorting rooms. The levels of exposure observed in this study highlight the need to implement appropriate preventive measures against bioaerosols at MRFs for dry waste. There are grounds to justify these preventive measures, both inside sorting rooms and for the MRF as a whole, regardless of whether the decision to extend sorting instructions for household plastic waste is adopted.

Schmaelzlin, E., et al. (2006). "Monitoring hormone-induced oxygen consumption in the salivary glands of the blowfly, Calliphora vicina, by use of luminescent microbeads." Sensors and Actuators B: Chemical **119**(1): 251-254.

The salivary glands of the blowfly were injected with luminescent oxygen- sensitive microbeads. The changes in oxygen content within individual gland tubules during hormone-induced secretory activity were quantified. The measurements are based on an upgraded phase-modulation technique, where the phase shift of the sensor phosphorescence is determined independently from concentration and background signals. We show that the combination of a lock-in amplifier with a fluorescence microscope results in a convenient setup to measure oxygen concentrations within living animal tissues at the cellular level.

Schmalzlin, E., et al. (2005). "An optical multifrequency phase-modulation method using microbeads for

measuring intracellular oxygen concentrations in plants." Biophysical Journal **89**(2): 1339-1345.

A technique has been developed to measure absolute intracellular oxygen concentrations in green plants. Oxygen-sensitive phosphorescent microbeads were injected into the cells and an optical multifrequency phase-modulation technique was used to discriminate the sensor signal from the strong autofluorescence of the plant tissue. The method was established using photosynthesis-competent cells of the giant algae Chara corallina L., and was validated by application to various cell types of other plant species.

Schmetterer, K. G., et al. (2009). "Generation of allergen-specific T regulatory cells by multicistronic vector based retroviral transfer of T cell receptor alpha and beta chains and Foxp3 or TGF-beta." European Journal of Immunology **1)**: S413.

Background: Ectopic overexpression of transgenes in T-cells can modify T-cell function. Recently, we have shown that transfer of T-cell receptor (TCR) alpha and beta chains specific for allergen-derived epitopes can transfer allergen-specificity to peripheral blood T-cells. Similarly, retro- and lentiviral overexpression of Foxp3 has been shown to generate T-cells with regulatory function. Our aim is to combine these two approaches to generate allergen-specific regulatory T-cells (Treg) that might become useful in immunotherapeutic approaches. Method(s): Multicistronic expression constructs containing the respective alpha and beta chains of two TCRs specific for the Artv1<inf>25-36</inf> (TRAV17/TRBV18) and Betv1<inf>142-153</inf> (TRAV6/TRBV20) and the cDNAs encoding human Foxp3 and TGF-beta1 (TGFb) were generated by using internal ribosomal entry sites (IRES) and picornaviral 2A sequences. Subsequently, retrovirally transduced peripheral blood T-cells of non-allergic individuals were assessed for their regulatory capacity using either transfected HEK-293 as artificial antigen presenting cells or anti-CD3/CD28 coated microbeads as polyclonal stimulus. Result(s): Both Foxp3⁺ and TGFb⁺ T-cells showed the typical characteristics of Treg: hyporesponsiveness to polyclonal and antigen-specific activation, low cytokine secretion and proliferation in response to exogenous IL-2. Furthermore, TCR⁺Foxp3⁺ transgenic T-cells could inhibit T-cell proliferation of antigen-specific responder T-cells in a dose-dependent fashion both in response to antigen-specific and polyclonal activation. Importantly, Foxp3⁺ transgenic T-cells expressing their endogenous or a non-specific T-cell receptor could only inhibit activation of antigen-specific responder T-cells after polyclonal activation, supporting the view that Foxp3-mediated regulation is an active mechanism requiring activation of the regulatory T-cell. In contrast, both in an activated and resting state TGFb⁺ T-cells produced sufficient amounts of TGFb to inhibit T-cell activation. Conclusion(s): Our results show the feasibility to generate T regulatory cells, which exert their function only in response to allergen-specific activation. Such approaches might become useful for tolerance induction in allergic and other immune-mediated diseases.

Schmid, S., et al. (2010). "Real-time particle mass spectrometry based on resonant micro strings." Sensors **10**(9): 8092-8100.

Micro- and nanomechanical resonators are widely being used as mass sensors due to their unprecedented mass sensitivity. We present a simple closed-form expression which allows a fast and quantitative calculation of the position and mass of individual particles placed on a micro or nano string by measuring the resonant frequency shifts of the first two bending modes. The method has been tested by detecting the mass spectrum of micro particles placed on a micro string. This method enables real-time mass spectrometry necessary for applications such as personal monitoring devices for the assessment of the exposure dose of airborne nanoparticles.

Schmidt, C., et al. (2017). "Export of Plastic Debris by Rivers into the Sea." Environmental Science and Technology **51**(21): 12246-12253.

A substantial fraction of marine plastic debris originates from land-based sources and rivers potentially act as a major transport pathway for all sizes of plastic debris. We analyzed a global compilation of data on plastic debris in the water column across a wide range of river sizes. Plastic debris loads, both microplastic (particles <5 mm) and macroplastic (particles >5 mm) are positively related to the mismanaged plastic waste (MMPW) generated in the river catchments. This relationship is nonlinear where large rivers with population-rich catchments delivering a disproportionately higher fraction of MMPW into the sea. The 10 top-ranked rivers transport 88-95% of the global load into the sea. Using MMPW as a predictor we calculate the global plastic debris inputs form rivers into the sea to range between 0.41 and 4 x 10⁶ t/y. Due to the limited amount of data high uncertainties were expected and ultimately confirmed. The empirical analysis to quantify plastic loads in rivers can be extended easily by additional potential predictors other than MMPW, for example, hydrological conditions. Copyright © 2017 American Chemical Society.

Schmidt, J., et al. (2016). "Effect of Tris, MOPS, and phosphate buffers on the hydrolysis of polyethylene terephthalate films by polyester hydrolases." FEBS Open Bio **6**(9): 919-927.

The enzymatic degradation of polyethylene terephthalate (PET) occurs at mild reaction conditions and may find applications in environmentally friendly plastic waste recycling processes. The hydrolytic activity of the homologous polyester hydrolases LC cutinase (LCC) from a compost metagenome and TfCut2 from Thermobifida fusca KW3 against PET films was strongly influenced by the reaction medium buffers tris(hydroxymethyl)aminomethane (Tris), 3-(N-morpholino)propanesulfonic acid (MOPS), and sodium phosphate. LCC showed the highest initial hydrolysis rate of PET films in 0.2 m Tris, while the rate of TfCut2 was 2.1-fold lower at this buffer concentration. At a Tris concentration of 1 m, the hydrolysis rate of LCC decreased by more than 90% and of TfCut2 by about 80%. In 0.2 m MOPS or sodium phosphate buffer, no significant differences in the maximum initial hydrolysis rates of PET films by both enzymes were detected. When the concentration of MOPS was increased to 1 m, the hydrolysis rate of LCC decreased by about 90%. The activity of TfCut2 remained low compared to the increasing hydrolysis rates observed at higher concentrations of sodium phosphate buffer. In contrast, the activity of LCC did not change at different concentrations of this buffer. An inhibition study suggested a competitive inhibition of TfCut2 and LCC by Tris and MOPS. Molecular docking showed that Tris and MOPS interfered with the binding of the polymeric substrate in a groove located at the protein surface. A comparison of the K i values and the average binding energies indicated MOPS as the stronger inhibitor of the both enzymes.

Schmidt, L. K., et al. (2018). "Multi-temporal surveys for microplastic particles enabled by a novel and fast application of SWIR imaging spectroscopy - Study of an urban watercourse traversing the city of Berlin, Germany." Environmental Pollution **239**: 579-589.

Following the widespread assumption that a majority of ubiquitous marine microplastic particles originate from land-based sources, recent studies identify rivers as important pathways for microplastic particles (MPP) to the oceans. Yet a detailed understanding of the underlying processes and dominant sources is difficult to obtain with the existing accurate but extremely time-consuming methods available for the identification of MPP. Thus in the presented study, a novel approach applying short-wave infrared imaging spectroscopy for the quick and semi-automated identification of MPP is applied in combination with a multitemporal survey concept. Volume-reduced surface water samples were taken from transects at ten points along

a major watercourse running through the South of Berlin, Germany, on six dates. After laboratory treatment, the samples were filtered onto glass fiber filters, scanned with an imaging spectrometer and analyzed by image processing. The presented method allows to count MPP, classify the plastic types and determine particle sizes. At the present stage of development particles larger than 450 mum in diameter can be identified and a visual validation showed that the results are reliable after a subsequent visual final check of certain typical error types. Therefore, the method has the potential to accelerate microplastic identification by complementing FTIR and Raman microspectroscopy. Technical advancements (e.g. new lens) will allow lower detection limits and a higher grade of automatization in the near future. The resulting microplastic concentrations in the water samples are discussed in a spatio-temporal context with respect to the influence (i) of urban areas, (ii) of effluents of three major Berlin wastewater treatment plants discharging into the canal and (iii) of precipitation events. Microplastic concentrations were higher downstream of the urban area and after precipitation. An increase in microplastic concentrations was discernible for the wastewater treatment plant located furthest upstream though not for the other two. Short-wave imaging spectroscopy automatizes and accelerates the analysis of microplastic particles >450 mum extracted from environmental samples and thus opens the door for extensive (spatial and/or temporal) sampling surveys. Schmidt, R., et al. (1983). "Fast and efficient purification of yeast plasma membranes using cationic silica microbeads." Biochimica et Biophysica Acta **732**(2): 421-427.

A fast and efficient procedure for the purification of plasma membranes of Saccharomyces cerevisiae is described. Protoplasts served as starting material. They were coated with cationic silica microbeads. After lysis, the plasma membranes were washed free from debris and cell organelles. This procedure resulted in a high yield (about 85%) of plasma membranes, as judged by measuring vanadate-sensitive ATPase as a plasma membrane marker. The enzyme was enriched 12-fold relative to the homogenate after lysis. Its specific activity was 1.5--2.0 micromol/min per mg protein, the pH optimum was 6.5, and 10 microM vanadate was sufficient to obtain maximum inhibition. Based on the assay of internal markers and electron microscopic studies, we found our preparation essentially free of contamination from other cell organelles.

Schmidt, R., et al. (1985). "High-yield purification of plasma membranes from transformed human keratinocytes in culture." Journal of Investigative Dermatology **85**(1): 50-53.

The density pertubation technique with cationic silica microbeads was applied to prepare highly purified plasma membranes from cultured human keratinocytes. Trypsinized cells were coated successively with the beads (diameter approximately 50 nm, gravity greater than 2 g/cm3) and polyacrylic acid before they were lysed by osmotic shock and mechanical shear. The plasma membranes remained in the form of large open sheets which could easily be separated from other cell organelles and the cytosol by low-speed centrifugation. The membrane preparation was characterized by scanning and transmission electron microscopy, marker enzyme activities, one-dimensional sodium dodecyl sulfate polyacrylamide electrophoresis, and the specific beta-adrenergic receptor count. A yield of 79 +/- 9% was calculated by comparing the amount of beta-adrenoceptors in the purified membrane preparation with that of a crude cellular particulate fraction. The specific beta-adrenoceptor count of these two preparations was 1.2 +/- 0.02 and 0.2 +/- 0.05 pmol/mg protein, respectively, indicating a 6-fold improved purification with this microbead technique. The purified membranes were essentially free from contamination of other cell organelles.

Schmidt-Hieber, M., et al. (2012). "Cytogenetic heterogeneity in clonal plasma cell disorders: A study in highly purified aberrant plasma cells." Blood. Conference: 54th Annual Meeting of the American Society of Hematology, ASH **120**(21).

Background: Recurrent immunoglobulin heavy chain (IGH) translocations - t(14q32) - such as t(4;14) or t(11;14) are considered to be primary cytogenetic events which play an important role in the pathogenesis of clonal plasma cell (PC) disorders. However, previous cytogenetic studies in these diseases have mainly been done in whole bone marrow or CD138+ microbead-enriched PC; the latter technique has several pitfalls such as coexistence of CD138+ and CD138- aberrant PC or apoptotic loss of CD138. Design and Methods: Overall, highly-purified aberrant PC (purity >=98%) from 217 patients with either multiple myeloma (MM; n=155) or monoclonal gammopathy of undetermined significance (MGUS; n=62) were analyzed for the presence of different cytogenetic alterations such as del(13q14), del(17p13) and t(14q32) by multicolor interphase fluorescence in situ hybridization (iFISH). Purity of sorted PC populations was further confirmed by iFISH studies of residual normal - i.e. polyclonal - PC fractions in a subgroup of 10 exemplarily cases with clonal PC disorder. Additionally, analysis of IGH gene arrangements and complementarity determining region 3 (CDR3) sequencing was carried out in a subset of patients (n=9) and simultaneous application of iFISH and immunofluorescent protein staining (FICTION) was performed in selected cases to confirm the clonal relationship between different fractions of tumor PC from individual patients and specific cytogenetic findings. Result(s): At diagnosis, 96% of all MM vs. 77% of MGUS cases (p<0.001) showed >=1 cytogenetic alteration and/or hyperdiploidy. Interestingly, among cases with t(14q32), in 24% of MM vs. 62% of MGUS patients (p=0.02) aberrant PC with and without IGH translocation - e.g. t(4;14) or t(11;14) - coexisted in the same patient. Furthermore, longitudinal cytogenetic studies in a subset of MM patients at different stages of the disease showed that an aberrant PC subclone lacking a recurrent t(14q32) might even expand during disease evolution. PCR and sequencing studies confirmed the existence of only one unique CDR3 sequence - in the absence of an oligo-/polyclonal background - in all tested samples indicating clonal relationship of cytogenetically-defined aberrant PC subclones. These observations together with FICTION analyses performed in selected cases, led further to assume that our findings are not due to contaminating residual normal PC. Finally, MM and MGUS cases frequently showed different but related cytogenetic profiles when other cytogenetic alterations which were presumably sequentially acquired by the PC, such as deletions/gains of IGH, FGFR3, CCND1 and MAF, as well as the DNA ploidy status determined by multiparameter flow cytometry were additionally considered. Conclusion(s): Our findings using highly-purified aberrant PC suggest that also recurrent IGH translocations might evolve secondarily during disease evolution in a significant fraction of MGUS and MM cases, which raises the question about their precise role in the pathogenesis of clonal PC disorders. Our data further supports the existence of a high intratumoral cytogenetic heterogeneity in MM and MGUS, challenging individualized treatment approaches in these diseases.

Schneck, N. A., et al. (2015). "Current trends in magnetic particle enrichment for mass spectrometry-based analysis of cardiovascular protein biomarkers." Nanomedicine **10**(3): 433-446.

Magnetic particles have traditionally been utilized to isolate and enrich various cardiovascular protein biomarkers for mass spectrometry-based proteomic analysis. The application of functionalized magnetic particles for immunocapture is attractive due to their easy manipulation, large surface area-to-volume ratios for maximal antibody binding, good recovery and high magnetic saturation. Magnetic particle enrichment coupled with mass spectrometry can act as a complementary tool for clinical sandwich-immunoassay development since it can provide improved target specificity and true metrological traceability. The purpose of this review is to summarize current separation methods and technologies that use magnetic particles to enrich protein biomarkers from complex matrices, specifically focusing on cardiovascular disease-related proteins and the advantages of magnetic particles over existing techniques.

Schnurr, R. E. J., et al. (2018). "Reducing marine pollution from single-use plastics (SUPs): A review." Marine Pollution Bulletin **137**: 157-171.

Single-use plastics, or SUPs (plastic bags, microbeads, cutlery, straws and polystyrene) are substantial sources of plastic marine pollution, yet preventable via legislative and non-legislative interventions. Various international legislative strategies have been reported to address plastic marine pollution from plastic bags and microbeads, but these have since been accompanied by recent increasing public awareness triggered by international agencies and organizations. The Sixth International Marine Debris Conference highlighted increasing intervention strategies to mitigate SUP pollution. This study presents new multi-jurisdictional legislative interventions to reduce SUPs since 2017 and incorporates emergence of new non-legislative interventions to mitigate other types of SUPs at individual and private-sector levels that complement or influence legislative interventions. Further, effectiveness of SUP bag interventions (e.g., bans vs. levies) to help reduce SUP marine pollution are presented and range between 33 and 96% reduction in bag use. Schoeman, J. J. and J. F. van Staden (1991). "Evaluation of Sealed-Cell Electrodialysis for Industrial Effluent Treatment." Water S. A. **17**(4): 307.

Sealed-cell electrodialysis (SCED) involves the use of membranes sealed together at their edges to form membrane bags, which can be placed between a pair of electrodes in a simple membrane stack. The performance of a SCED unit for industrial effluent treatment is described. The ion-exchange membranes used in the demonstration were composed of microbeads of styrene-divinyl benzene copolymer that were modified to cation- and anion-exchange particles. The desalination/concentration of sodium chloride, ammonium nitrate, ammonium sulfate, sodium sulfate, sodium nitrate, and calcium chloride solutions as a function of time at constant cell pair voltage are presented. SCED was shown to effectively treat dilute NH sub(4)NO sub(3) and to moderately treat (NH sub(4)) sub(2)SO sub(4) . Calcium sulfate treatment was not possible, because of membrane scaling.

Schoenberger, T., et al. (2016). "Forensic examination of electrical tapes using high resolution magic angle spinning ^sup 1^H NMR spectroscopy." Analytical and bioanalytical chemistry **408**(1): 123-129.

Issue Title: Quo vadis, analytical chemistry?/E-Health - a topic for analytical chemists?/Precision mixology challenge/Advances in explosives analysis The application of high resolution magic angle spinning (HR-MAS) ^sup 1^H NMR spectroscopy is ideally suited for the differentiation of plastics. In addition to the actual material composition, the different types of polymer architectures and tacticity provide characteristic signals in the fingerprint of the ^sup 1^H NMR spectra. The method facilitates forensic comparison, as even small amounts of insoluble but swellable plastic particles are utilized. The performance of HR-MAS NMR can be verified against other methods that were recently addressed in various articles about forensic tape comparison. In this study samples of the 90 electrical tapes already referenced by the FBI laboratory were used. The discrimination power of HR-MAS is demonstrated by the fact that more tape groups can be distinguished by NMR spectroscopy than by using the combined evaluation of several commonly used analytical techniques. An additional advantage of this robust and quick method is the very simple sample preparation.

Schoenholzer, F., et al. (1999). "Origins and fate of fungi and bacteria in the gut of Lumbricus terrestris L. studied by image analysis." FEMS Microbiology Ecology **28**(3): 235-248.

The effect of the passage through the gut of the earthworm Lumbricus terrestris L. on fungi and bacteria ingested with decomposing leaves of Taraxacum officinale and with soil was quantified using image analysis tools. Both leaf and soil material were labeled with fluorescent latex microbeads to allow a quantification of the food sources in the fore-, mid-, and hindgut of the earthworms. The content of leaf material in the gut varied in a range between 4 and 59% of the total gut content in different earthworms and the different parts of the intestine of individual animals. Filamentous fungi in the gut compartments were found to originate mainly from leaf material (7700 plus or minus 1800 mu g (g leaf (dry wt.)) super(-1)), however, the major part was disrupted before arriving in the intestine. Remaining hyphae in the foregut with a biomass of up to 900 plus or minus 150 mu g (g gut content (dry wt.)) super(-1) were completely digested during passage through the earthworm gut. Spores of fungi were not detected in our studies. Bacterial cell numbers in the gut compartments ranged from 63 plus or minus 5 x 10 super(8) to 327 plus or minus 16 x 10 super(8) (g gut content (dry wt.)) super(-1) and were significantly higher than the numbers found in the soil (50 plus or minus 1 x 10 super(8) cells (g soil (dry wt.)) super(-1)). Cell numbers usually increased from fore- to hindgut. This increase was not correlated to contents of organic material and only partially due to a multiplication of bacterial cells. Numbers of dividing cells accounted in total for approximately 12% of all bacteria, increasing significantly from fore- to hindgut, counts were from 10 plus or minus 1 x 10 super(8) to 25 plus or minus 2 x 10 super(8) (g gut content (dry wt.)) super(-1), respectively. Average cell volumes of bacteria calculated from cell size distributions in leaf and soil material differed significantly, being 0.197 and 0.063 mu m super(3), respectively. In the gut compartments, average cell volumes ranged from 0.043 to 0.070 mu m super(3), which may indicate the disruption of large cells originating from the leaves before arriving in the foregut.

Scholz, M., et al. (2017). "In vitro chlorhexidine release from alginate based microbeads for periodontal therapy." PLoS ONE [Electronic Resource] **12**(10): e0185562.

Periodontitis is one of the most common infectious diseases globally that, if untreated, leads to destruction of the tooth supporting tissues and finally results in tooth loss. Evidence shows that standard procedures as mechanical root cleaning could be supported by further treatment options such as locally applied substances. Due to gingival crevicular fluid flow, substances are commonly washed out off the periodontal pockets. The evaluation of administration techniques and the development of local drug releasing devices is thus an important aspect in periodontal research. This study describes the development and examination of a new alginate based, biodegradable and easily applicable drug delivery system for chlorhexidine (CHX). Different micro beads were produced and loaded with CHX and the release profiles were investigated by high performance liquid chromatography (HPLC). The in vitro-demonstrated release of CHX from alginate based beads shows comparable releasing characteristics as clinically approved systems. Yet many characteristics of this new delivery system show to be favourable for periodontal therapy. Easy application by injection, low production costs and multifunctional adaptions to patient related specifics may improve the usage in routine care.

Schonau, A., et al. (1998). "A one-step solid phase immunoassay for simultaneous detection of serum IgG and IgM antibodies to Borrelia burgdorferi." Journal of Immunological Methods **218**(1-2): 9-17.

A one-step immunoassay for simultaneous detection of serum IgG and IgM antibodies to

Borrelia burgdorferi has been developed. The assay is based on C1q, which binds to immune complexes containing IgG and/or IgM antibodies. Micro-beads pre-coated with antibodies to human C1q are mixed with human serum samples and fluorochrome-labelled B. burgdorferi flagellum antigen. In the presence of serum IgG and/or IgM antibodies to B. burgdorferi, fluorochrome-labelled antigen/antibody complexes are formed. These are then bound by serum C1q and are subsequently captured on the anti-C1q-coated beads. The sample is analysed on a flow cytometer and the presence of fluorescent beads is, thus, indicative of a positive test result. In the present study the sensitivity and specificity of the assay are compared to those of the indirect IDEIA B. burgdorferi IgG and the mu-chain capture IDEIA B. burgdorferi IgM ELISAs for separate determination of IgG and IgM. Detection using a flow cytometer can be performed without separation of the beads from the reaction mixture, which means that in practice, the method is carried out as a one-step assay and it is, thus, very suitable for automation. Other advantages of this kind of assay includes an antibody/antigen reaction which occurs in solution and the potential of using the method for the detection of antibodies against several antigens from the same or different infectious agents (multi-parameter screening).

Schönholzer, F., et al. (1999). "Origins and fate of fungi and bacteria in the gut of <i>Lumbricus terrestris</i> L. studied by image analysis." FEMS Microbiology Ecology **28**(3): 235-248.

The effect of the passage through the gut of the earthworm Lumbricus terrestris L. on fungi and bacteria ingested with decomposing leaves of Taraxacum officinale and with soil was quantified using image analysis tools. Both leaf and soil material were labeled with fluorescent latex microbeads to allow a quantification of the food sources in the fore-, mid-, and hindgut of the earthworms. The content of leaf material in the gut varied in a range between 4 and 59% of the total gut content in different earthworms and the different parts of the intestine of individual animals. Filamentous fungi in the gut compartments were found to originate mainly from leaf material (7700±1800 μg (g leaf (dry wt.))−1), however, the major part was disrupted before arriving in the intestine. Remaining hyphae in the foregut with a biomass of up to 900±150 μg (g gut content (dry wt.))−1 were completely digested during passage through the earthworm gut. Spores of fungi were not detected in our studies. Bacterial cell numbers in the gut compartments ranged from 63±5×108 to 327±16×108 (g gut content (dry wt.))−1 and were significantly higher than the numbers found in the soil (50±1×108 cells (g soil (dry wt.))−1). Cell numbers usually increased from fore- to hindgut. This increase was not correlated to contents of organic material and only partially due to a multiplication of bacterial cells. Numbers of dividing cells accounted in total for approximately 12% of all bacteria, increasing significantly from fore- to hindgut, counts were from 10±1×108 to 25±2×108 (g gut content (dry wt.))−1, respectively. Average cell volumes of bacteria calculated from cell size distributions in leaf and soil material differed significantly, being 0.197 and 0.063 μm3, respectively. In the gut compartments, average cell volumes ranged from 0.043 to 0.070 μm3, which may indicate the disruption of large cells originating from the leaves before arriving in the foregut.

Schoof, R. A. and J. DeNike (2017). "Microplastics in the context of regulation of commercial shellfish aquaculture operations." Integrated Environmental Assessment & Management **13**(3): 522-527.

ABSTRACT Shellfish aquaculture in the Salish Sea (encompassing the Strait of Juan de Fuca, Puget Sound, and the Georgia Strait) is a major source of clams, oysters, and mussels in the United States and Canada. Plastic gear is necessary for the viability of many of these operations. During the past few years, shellfish farm permits issued in Washington State have been challenged on various bases that have included allegations that the plastic gear is releasing microplastics, commonly defined as particles less than 5 mm in diameter. Published survey data

on sources of marine plastic debris demonstrate the very limited contribution of aquaculture gear. Both permits and industry codes of practice provide procedures to minimize loss of gear to the marine environment. Plastic gear is also designed specifically to maintain its integrity and not degrade in the marine environment. Plastic degradation is greatest on beaches with high UV exposure, whereas aquaculture gear is mostly underwater and/or covered by biofoulants. Available data for microplastics in water, sediment, and biota of the Salish Sea do not suggest significant release of microplastics from shellfish aquaculture operations. Schrank, I., et al. (2019). "Effects of microplastic particles and leaching additive on the life history and morphology of Daphnia magna." Environmental Pollution **255**(Part 2).
Plastic waste is continuously introduced not only into marine, but also freshwater environments, where it fragments into microplastics. Organisms may be affected by the particles themselves due to ingestion and indirectly via incorporated additives such as plasticizers, since these substances have the ability to leach out of the polymer matrix. Although it has been indicated that the likelihood of additives leaching out into the gut lumen of organisms exposed to microplastics is low, studies distinguishing between the effects of the synthetic polymer itself and incorporated additives of the same polymer are scarce. Since this is obligatory for risk assessment, we analyzed the chronic effects of flexible polyvinylchloride (PVC), a widely used polymer, containing the plasticizer diisononylphthalate (DiNP) on morphology and life history of the freshwater crustacean Daphnia magna and compared these effects with the effects of rigid PVC, lacking DiNP, as well as a glass bead control. After up to 31 days of exposure, rigid PVC and glass beads did not affect body length and relative tail spine length of D. magna, whereas flexible PVC led to an increased body length and a reduced number of offspring. None of the treatments increased the mortality significantly. We were able to show that 2.67 micro g/L DiNP leached out of the flexible PVC into the surrounding medium using GC-MS. Yet, we were not able to measure leachate inside the gut lumen of D. magna. The effects emerged towards the end of the experiment, due to the time dependent process of leaching. Therefore, the results highlight the relevance of long-term chronic exposure experiments, especially as leaching of additives takes time. Further, our study shows the importance to distinguish between microplastics containing leachable additives and the raw polymer in ecotoxicological testing.

Schroder, H., et al. (2017). "Immuno-PCR with digital readout." Biochemical & Biophysical Research Communications **488**(2): 311-315.
Immuno-PCR (IPCR) combines the versatile ELISA antigen detection with ultrasensitive PCR signal amplification, thereby enabling the highly sensitive detection of a broad range of targets with a typically very large dynamic detection range. The quantification of the antigen is usually achieved by real-time PCR, which provides a correlation between the target concentration and amplified DNA marker. We here report on the implementation of digital droplet PCR as a means for direct quantification of DNA copies to enable the highly sensitive detection of protein biomarkers. To this end, two alternative approaches, based on either magnetic microbead-based IPCR or a microplate-release IPCR were tested. The latter format worked well

and revealed an extraordinary high robustness and sensitivity. While rtIPCR already fulfills typical immunoassay acceptance criteria, ddIPCR enables improved accuracy and precision of the assay because signal response and analyte concentrations are directly correlated. The utility of the novel ddIPCR technology is demonstrated at the example of two cytokines, interleukin 2 and interleukin 6 (IL2, IL6, respectively), with an overall average CV% of 5.0 (IL2) and 7.4 (IL6).

Schuldt, U., et al. (2019). "Characterization of mechanical parameters of microbeads by means of analytical centrifugation. (Special Issue: Gums and stabilisers.)." Food Hydrocolloids **86**: 201-209.

Microcapsules, microspheres and microbeads are widely used in the food industry, pharmacy, agriculture, cosmetics, construction, textile industry and printing to protect immobilized substances against harsh conditions or to mask bad taste, as well as to enable and control the release of substances e.g. active pharmaceutical ingredients. The knowledge of the mechanical properties is a key parameter in development, application and control of processing. The paper focuses on the experimental determination of the stiffness of alginate beads (about 400 micro m) in terms of bulk compressional behaviour by using a commercial available multisample analytical centrifuge (LUMiSizer). The basic principle consists in applying an increasing centrifugal force on an alginate bead column in a measuring cell and to record the height of the bead column (volume) in dependence on the applied force during centrifugation. The packing/compression of beads is quantified by the decreased column volume in relation to the applied force. It was shown that beads made of alginate of high alpha -L-guluronic acid (G) content are more stable compared to alginate types of high beta -D-mannuronic acid (M) content. In contrast, gelling cations and their concentrations have less influence on the mechanical behaviour. The described ensemble method is sensitive, reproducible, easy to perform and, due to the simultaneous analysis of up to 12 samples, time saving. The new method is especially suitable for quality control during microsphere production.

Schulte-Uebbing, C., et al. (2017). "Endocrine disruptors in drinking water. Do plastic particles, softeners, pesticides and heavy metals in drinking water stimulate (hormone-dependent) tumors?. [German]." Pravention und Rehabilitation **29**(1): 1-13.

Compared, e.g., with water in Africa, Asia, or South America, our drinking water is still acceptable. But some new scientific studies have shown that there are a lot of endocrine disruptors in our drinking water: (micro-and nano-) plastic particles, pesticides, heavy metals, radioactive substances (uranium, radon) etc. These substances can interfere with the hormone system, possibly leading to the development, growth, and metastasis of (hormone-dependent) tumors, e.g., ovarian, corpus, and female breast cancer. By applying modern (direct-flow) drinking water cleaning and finishing systems, endocrine disruptors can be removed from the drinking water. This can be a very important and effective preventive and therapy-accompanying measure. Copyright © 2017 Dustri-Verlag Dr. Karl Feistle.

Schultz, P., et al. (2008). "[Reconstruction of the anterior mandibule using a porous titanium implant: a case report]." Revue de Laryngologie Otologie Rhinologie **129**(3): 201-205.

OBJECTIVE: Anterior mandibular arch reconstruction.

PATIENT AND METHOD: A 55-year-old immuno-depressed female underwent resection of the lower third of the face subsequent to extensive mucormycosis-related necrosis. Reconstruction of the anterior part of the mandible and adjacent soft tissue was carried out with a mandibular prosthesis and a latissimus dorsi flap. The mandibular prosthesis was made of titanium T40 micro-beads, consolidated by two parallel plates of titanium. The porous structure is intended to enhance cellular and bone integration.

RESULTS: The tolerance of the prosthesis was still excellent after 36 months. Labial continence was restored in a second procedure. Unrestricted diet was allowed from the third month. Radiological investigations confirm the good stability of the prosthesis.
CONCLUSION: This original prosthesis design offers an alternative to the reconstruction of an anterior mandibular arch by plate or by vascularised free osseous tissue transfer that is sometimes associated with significant morbidity.

Schultz, S. (2017). "Reducing Plastic Pollution." Alternatives Journal **43**(2): 68-69.
Plastic is made to last so that people can use it repeatedly. Ironically, the average plastic bag is used for only 5 to 12 minutes. It's not biodegradable, which means bacteria can't decompose it like food waste. Instead, it slowly degrades into tiny pieces that still cause harm to the environment. Imagine that plastic pollution isn't a problem. There is no plastic in oceans. Landfills aren't mountains in the distance. There is more wildlife that isn't getting choked by plastic poison. Here, Schultz discusses ways how to reduce plastic pollution.

Schulz, U., et al. (2017). "Evaluation of a new microbeads assay for granulocyte antibody detection." Transfusion **57**(1): 70-81.
BACKGROUND: To reduce the risk of transfusion-associated acute lung injury (TRALI), a high number of plasma donors were tested for human leukocyte antigen (HLA) and human neutrophil antigen (HNA) antibodies. For HNA antibody detection, the gold standard is a combination of the granulocyte immunofluorescence test (GIFT) and the granulocyte agglutination test (GAT). However, these tests are not suitable for a high-throughput of samples.
STUDY DESIGN AND METHODS: To evaluate the new generation of the LABScreen MULTI assay (One Lambda, Inc.), which has special new beads for all the known HNA specificities, including HNA-3a, 97 sera samples containing well-defined HNA antibodies were used. For background testing, we used 91 samples from plasma donors previously identified by GAT, GIFT, and the monoclonal antibody-specific immobilization of granulocyte antigens (MAIGA) assay.
RESULTS: Compared with previous tests, the new LABScreen MULTI assay was highly specific for the HNA-1a, HNA-1b, HNA-2, and HNA-3a antibody specificities required to prevent TRALI. Ninety-eight percent of the HNA-1a, HNA-1b, and HNA-2 antibodies could be detected as true positive; and 90% of the HNA-3a antibodies were recognized correctly as positive. False-positive reactions were identified in 5.5% of samples that previously tested negative.
CONCLUSION: The detection of HNA-3a antibody specificities could be integrated into the new LABScreen MULTI assay; however, we detected only 90%. In addition, we detected further HNA antibodies, such as HNA-1c, HNA-1d, and some HNA-3b and HNA-4a antibodies. The new generation of LABScreen MULTI is a great step toward feasible high-throughput testing for HNA antibodies. Nevertheless, GIFT and GAT remain the gold-standard methods for the differentiation of rare and currently unknown HNA specificities.

Schulz, U., et al. (2015). "Evaluation of the microbeads assay labscreen multi for granulocyte antibody detection." Transfusion **3)**: 122A.
Background/Case Studies: In order to reduce the risk of TRALI, a high number of plasma donors were tested for HLA- and HNA-Abs. For HNA-Ab detection, the gold standard is a combination of the granulocyte immunofluorescence test (GIFT) and the granulocyte agglutination test (GAT). However, these tests are not suitable for a high sample throughput. By introducing the LabScreen Multi as a pre-screening test for HNA-1 and -2 Ab in our lab in 2009, we were able to significantly reduced the number of GIFTs used. HNA-3a Abs were exclusively detected by GAT. With the clarification of the molecular structure of HNA-3, it was possible to extend the test to

HNA-3a and -3b Abs. Here, we report the results of our initial study evaluating the new generation of LabScreen Multi, including special new beads coated with recombinant antigens for HNA-1a, -1b, -1c, -2 and additional beads for the detection of HNA-3a, -3b, and -4a, focusing on confirmation of well-defined HNA-Abs. Study Design/Methods: For evaluation of the new generation of LabScreen Multi, 98 sera containing well-defined HNA-Abs were used. The Abs were identified during routine testing in the involved labs by GIFT, GAT, and MAIGA. The test procedure for LabScreen Multi was carried out according to the manufacturer's instruction. The cutoff was set for the beads HNA-1a, -1b, -1c, -3a, -3b, and -4a to a ratio >5. The bead for HNA-2 was evaluated with ratios of >10 and >20. Results/Findings: Compared to the previous tests, the new LabScreen Multi reacts highly specifically for the specificities HNA-1a, -1b, -2, and -3a that are required to prevent TRALI, as shown in the Table. 100% of the HNA-1a, -1b, -1c, -1d, and -2 Abs could be detected as true-positives; 92% of the HNA-3a Abs (35/38) were correctly recognized as positive. Conclusion(s): The detection of HNA- 3a specificities was integrated in the new LabScreen Multi, without performing additional testing of samples by GAT. However we found that not 100% of the HNA-3a-positive sera were detected. In addition, we are able to detect new and rare HNA-Abs, such as HNA-1c, -1d and some HNA-3b and -4a Abs, although their importance is still unclear in terms of TRALI. The new generation of LabScreen Multi is a great step toward feasible highthroughput testing for HNA-Ab. Nevertheless, GIFT and GATremain the gold standard methods for the differentiation of rare and currently unknown HNA specificities, because of the use of granulocytes with their unmodified natural structures.

Schulz Vicentini, D., et al. (2019). "Toxicological Evaluation and Quantification of Ingested Metal-Core Nanoplastic by <i>Daphnia magna</i> Through Fluorescence and Inductively Coupled Plasma-Mass Spectrometric Methods." Environmental Toxicology and Chemistry **38**(10): 2101-2110.

There are few studies on nanoplastic that propose quantification of the amount ingested combined with evaluation of the toxic effects on aquatic organisms. We propose 2 methods to quantify the amount of polystyrene nanoplastic (PSNP) ingested by Daphnia magna: fluorescence intensity, where a fluorescent monomer (F) is added to the PSNP and quantified through fluorescence light microscopy, and total aluminum quantification, where PSNP is synthesized with Al2O3 metal-core nanoparticles and used for quantification of the nanoplastic ingested by the organism Daphnia magna using inductively coupled plasma-mass spectrometry. In addition, the PSNP was functionalized with palmitic acid to simulate the environmental conditions leading to biological and chemical transformations. Acute and chronic toxicity tests were performed with fluorescent PSNP (PSNP/F) and palmitic acid-functionalized PSNP/F (PSNP/F-PA). The ingestion quantified was higher by factors of 2.8 and 3.0 for PSNP/F-PA and 1.9 and 1.7 for PSNP/F applying the fluorescence intensity and total Al quantifying methods, respectively, when compared to PSNP. These results are consistent with the data obtained in the toxicity tests, which showed an approximately 3 times increase in the adverse effect of PSNP/F-PA on the mobility and reproduction of the organisms. Thus, the strong inhibition of D. magna reproduction caused by PSNP/F-PA in the chronic toxicity tests could be associated with a greater amount of this nanoplastic being ingested by the organisms. Schunck, T. and P. Poulet (2000). "Oxygen consumption through metabolism and photodynamic reactions in cells cultured on microbeads." Physics in medicine and biology **45**(1): 103-119.

Oxygen consumption by cultured cells, through metabolism and photosensitization reactions, has been calculated theoretically. From this result, we have derived the partial oxygen pressure PO<inf>2</inf> in the perfusion medium flowing across sensitized cultured cells during photodynamic experiments. The PO<inf>2</inf> variations in the perfusate during light irradiation are related to the rate of oxygen consumption through photoreactions, and to the number of cells killed per mole of oxygen consumed through metabolic processes. After irradiation, the reduced metabolic oxygen consumption yields information on the cell death rate, and on the photodynamic cell killing efficiency. The aim of this paper is to present an experimental set-up and the corresponding theoretical model that allows us to control the photodynamic efficiency for a given cell-sensitizer pair, under well defined and controlled conditions of irradiation and oxygen supply. To demonstrate the usefulness of the methodology described, CHO cells cultured on microbeads were sensitized with pheophorbide a and irradiated with different light fluence rates. The results obtained, i.e. oxygen consumption of about 0.1 muM s⁻¹ m⁻³ under a light fluence rate of 1 W m⁻², 10⁵ cells killed per mole of oxygen consumed and a decay rate of about 1 h⁻¹ of living cells after irradiation, are in good agreement with the theoretical predictions and with previously published data.

Schur, C., et al. (2019). "When Fluorescence Is not a Particle: The Tissue Translocation of Microplastics in Daphnia magna Seems an Artifact." Environmental Toxicology & Chemistry **38**(7): 1495-1503.

Previous research reported the translocation of nano- and microplastics from the gastrointestinal tract to tissues in Daphnia magna, most prominently of fluorescent polystyrene beads to lipid droplets. For particles >300 nm, such transfer is biologically implausible as the peritrophic membrane retains these in the daphnid gut. We used confocal laser scanning microscopy to study tissue transfer applying the setup from a previous study (neonates exposed to 20 and 1000 nm polystyrene beads at 2 micro g L⁻¹ for 4 and 24 h), the same setup with a fructose-based clearing, and a setup with a 1000-fold higher concentration (2 mg L⁻¹). We used passive sampling to investigate whether the beads leach the fluorescent dye. Although the 1000 nm beads were visible in the gut at both exposure concentrations, the 20 nm beads were detectable at 2 mg L⁻¹ only. At this concentration, we observed fluorescence in lipid droplets in daphnids exposed to both particle types. However, this did not colocalize with the 1000 nm beads, which remained visible in the gut. We further confirmed the leaching of the fluorescent dye using a passive sampler, a method that can also be applied in future studies. In summary, we cannot replicate the original study but demonstrate that the fluorescence in the lipid droplets of D. magna results from leaching of the dye. Thus, the use of fluorescence as a surrogate for particles can lead to artifacts in uptake and translocation studies. This highlights the need to confirm the stability of the fluorescence label or to localize particles using alternative methods. Schussler, O., et al. (2015). "Collagen foam membranes colonized by human mesenchymal stromal cells efficiently inhibit allogenic T lymphocyte proliferation in vitro." Bone Marrow Transplantation **1)**: S322-S323.

Introduction: Human mesenchymal stromal cells (MSC) can be expanded in vitro from most vascularized tissues. These cells are able to differentiate in multiple lineages and to control various inflammatory processes, including steroidresistant graft versus host disease that may occur after grafting patients with allogenic hematopoietic stem cells. MSC thus represent a great hope as a therapeutic tool for either tissue reconstruction or anti-inflammatory therapies. In general MSC are injected as single cell suspensions and tend to vanish from the injection site when injected locally, and are very difficult to localize after systemic infusion. We therefore investigated in vitro whether MSC immobilized on a biocompatible scaffold retained their ability to inhibit allogenic T lymphocyte activation. Materials (or patients) and methods: MSC precursors were harvested from femoral head remains after informed consent of patients undertaking hip surgery, and amplified with platelet lysate (PL). Amplified MSC (1xE5 cells in 10 mul, passage 2 or 3) were seeded on 6 mm-diameter collagen foam membranes (CFM) (ultrafoam collagen hemostat, Bard Limited, UK) for 2 hours. The seeded CFM were transferred in new wells and cultured for 19 to 120 days in PL. Mean CFM surface was estimated using a square grid as reference. CFM were then either fixed for microscopic examination, disrupted with collagenase type II for cell count and phenotype determination by FACS, or cocultured with allogenic T lymphocytes stimulated with anti-CD3 and CD28 mAb immobilized on microbeads (A3-28) to determine their immunomodulatory potency. Result(s): MSC-seeded CFM transiently released cells during the first week of culture. From day 9 on CFM decreased in shape, increased in opacity and exhibited a much smoother surface than unseeded CFM. After 65 days the mean surface of the seeded CFM was half of the value prior to seeding (n=9, P<E- 4, t-test). In one case, the CFM totally dissolved and MSC formed an adherent layer in the dish. Microscopic examination of CFM slides stained with Goldner's dye obtained after 19 days of culture showed that MSC were localized both within CFM and on its surface where they formed a well-organized layer that was multicellular in some areas. Collagenase digestion of the membranes released viable cells in numbers corresponding to 50% of the seeded value. These cells were CD45-, CD105+, CD54+, CD73+, and CD106 and HLADRlow. MSC-seeded CFM prevented A3-28-induced allogenic T lymphocyte proliferation. T cell inhibition was effective even after 3 consecutive incubations of membranes with 3 different T lymphocyte preparations, whereas empty

membranes never inhibited T lymphocyte proliferation. Conclusion(s): These data show that MSC efficiently colonize CFMs, are long-lived in these structures and express similar markers than these observed in 2D-culture. Moreover MSC residing in CFM maintain their in vitro immunomodulatory properties, suggesting that MSC-loaded CFM could be used in vivo to control local inflammation. However before undertaking any clinical application several points require answers such as how cell colonization progresses in the membrane, whether MSC develop a proteolytic activity that could explain membrane shrinkage, and what is the cell cycle and differentiation status of cells in regard to their localization within the membrane. These issues are presently under investigation.

Schuyler, Q. A., et al. (2016). "Risk analysis reveals global hotspots for marine debris ingestion by sea turtles." Global Change Biology **22**(2): 567-576.

Plastic marine debris pollution is rapidly becoming one of the critical environmental concerns facing wildlife in the 21st century. Here we present a risk analysis for plastic ingestion by sea turtles on a global scale. We combined global marine plastic distributions based on ocean drifter data with sea turtle habitat maps to predict exposure levels to plastic pollution. Empirical data from necropsies of deceased animals were then utilised to assess the consequence of exposure to plastics. We modelled the risk (probability of debris ingestion) by incorporating exposure to debris and consequence of exposure, and included life history stage, species of sea turtle and date of stranding observation as possible additional explanatory factors. Life history stage is the best predictor of debris ingestion, but the best-fit model also incorporates encounter rates within a limited distance from stranding location, marine debris predictions specific to the date of the stranding study and turtle species. There is no difference in ingestion rates between stranded turtles vs. those caught as bycatch from fishing activity, suggesting that stranded animals are not a biased representation of debris ingestion rates in the background population. Oceanic life-stage sea turtles are at the highest risk of debris ingestion, and olive ridley turtles are the most at-risk species. The regions of highest risk to global sea turtle populations are off of the east coasts of the USA, Australia and South Africa; the east Indian Ocean, and Southeast Asia. Model results can be used to predict the number of sea turtles globally at risk of debris ingestion. Based on currently available data, initial calculations indicate that up to 52% of sea turtles may have ingested debris.

Schwabl, P., et al. (2019). "Detection of Various Microplastics in Human Stool: A Prospective Case Series." Annals of Internal Medicine **03**: 03.

Background: Microplastics are ubiquitous in natural environments. Ingestion of microplastics has been described in marine organisms, whereby particles may enter the food chain.

Objective: To examine human feces for the presence of microplastics to determine whether humans involuntarily ingest them.

Design: Prospective case series in which participants completed a food diary and sampled stool according to step-by-step instructions.

Setting: Europe and Asia.

Participants: Eight healthy volunteers aged 33 to 65 years.

Measurements: After chemical digestion, Fourier-transform infrared microspectroscopy was used to analyze the presence and shape of 10 common types of microplastic in stool samples.

Results: All 8 stool samples tested positive for microplastics. A median of 20 microplastics (50 to 500 micro m in size) per 10 g of human stool were identified. Overall, 9 plastic types were detected, with polypropylene and polyethylene terephthalate being the most abundant.

Limitations: There were few participants, and each provided only 1 sample. The origin and fate of

microplastics in the gastrointestinal tract were not investigated.

Conclusion: Various microplastics were detected in human stool, suggesting inadvertent ingestion from different sources. Further research on the extent of microplastic intake and the potential effect on human health is needed.

Primary Funding Source: None.

Schwabl, P., et al. (2018). "Assessment of microplastic concentrations in human stool-preliminary results of a prospective study." United European Gastroenterology Journal **6 (8 Supplement)**: A127.

Introduction: Microplastic is defined as plastic particles with a size of 5mm to 1mm. The world plastic production has been growing exponentially within the past years, reaching up to 300 megatons/year. Pollution causes plastic to accumulate in the sea, where it is ingested by sea animals, thus integrating plastic into the food chain. Significant amounts of microplastic have been detected in tuna, lobster and shrimp. Microplastic may harm via bioaccumulation (especially when the intestinal barrier is damaged) and can serve as a vector for toxic chemicals or pathogens. Moreover, ingested plastic may affect intestinal villi, nutritional uptake and can induce hepatic stress. Since human data is very scarce, we are the first to quantify and characterize microplastic in human stool. Aims and Methods: In this prospective pilot study, 8 healthy participants from Finland, Italy, Japan, the Netherlands, Poland, Russia, United Kingdom and Austria were included. Exclusion criteria were: gastrointestinal disease, recent dental treatment, medical diets, alcohol abuse and intake of drugs affecting stool frequency, consistency or resorption. The participants documented daily food intake for a week before sampling ~100g of stool. After clearing samples from liquids and natural organic solids (e.g., bacterial biomass, undigested plant matter, proteins, and fats), the remaining particles of 50-500 micrometer size were characterized using Fourier-transform infrared (FT-IR) micro-spectroscopy. The data analysis consisted of screening for 11 plastic types: PS, PU, PE, PP, PVC, PET, PA, PC, PMMA, POM and MF. Result(s): Exposure to plastic was frequent among the 8 participants (age 46+/-12 years; 37% male). In the week before sampling 21+/-12 dishes with plastic wrapping were consumed and daily 740+/-580ml water were drunk from plastic bottles (11% fizzy drinks). None was vegetarian and sea fish was consumed by 6 participants (2.6x/week). 3 participants used polyethylene glycol (PEG) containing tooth-paste. 5/8 samples have been analyzed so far. The analytical screening identified polystyrene (PS) and polyurethane (PU) plastics in 2 of 5 samples, while in the other samples no definite results are yet obtainable due to high residual cellulose and fat content masking the presence of microplastic. Conclusion(s): Increased plastic pollution can cause plastic contamination of foods, which may affect the GI-tract. We are the first to detect presence of polystyrene and polyurethane microparticles in human stool samples. Currently, we are optimizing the stool-sample separation technique of clearing non-plastic particles to further improve quantification and characterisation of microplastic load by FTIR micro-spectroscopy.

Schwaferts, C., et al. (2019). "Methods for the analysis of submicrometer- and nanoplastic particles in the environment." TrAC - Trends in Analytical Chemistry **112**: 52-65.

Nanoplastic is an emerging topic of relevance in environmental science. The analytical methods for microplastic have a particle size limit of a few micrometers so that new methods have to be developed to cover the nanometer range. This contribution reviews the progress in environmental nanoplastic analysis and critically evaluates which techniques from nanomaterial analysis may potentially be adapted to close the methodological gap. A roadmap is brought forward for the whole analytical process from sample treatment to particle characterization. This includes a critical review of (i) methods for analyte extraction and preconcentration from

various environmental matrices; (ii) methods for the separation of the nanoplastic into specific size fractions; (iii) light scattering techniques and various types of microscopy to characterize the particle fractions; (iv) chemical identification of particles to validate the obtained data. For these methods, we will discuss prospects and limitations to develop analytical protocols for specific sampling scenarios. Copyright © 2019 Elsevier B.V.

Schwartz, A., et al. (2002). "Quantitating Fluorescence Intensity from Fluorophore: The Definition of MESF Assignment." Journal of Research of the National Institute of Standards & Technology **107**(1): 83-91.

The quantitation of fluorescence radiance may at first suggest the need to obtain the number of fluorophore that are responsible for the measured fluorescence radiance. This goal is beset by many difficulties since the fluorescence radiance depends on three parameters 1) the probability of absorbing a photon (molar extinction), 2) the number of fluorophores, and 3) the probability of radiative decay of the excited state (quantum yield). If we use the same fluorophore in the reference solution and the analyte then, to a good approximation, the molar extinction drops out from the comparison of fluorescence radiance and we are left with the comparison of fluorescence yield which is defined as the product of fluorophore concentration and the molecular quantum yield. The equality of fluorescence yields from two solutions leads to the notion of equivalent number of fluorophores in the two solutions that is the basis for assignment of MESF (Molecules of Equivalent Soluble Fluorophore) values. We discuss how MESF values are assigned to labeled microbeads and by extension to labeled antibodies, and how these assignments can lead to the estimate of the number of bound antibodies in flow cytometer measurements.

Schwarz, A. E., et al. (2019). "Sources, transport, and accumulation of different types of plastic litter in aquatic environments: A review study." Marine Pollution Bulletin **143**: 92-100.

Types of plastic waste in different aquatic environments were assessed to obtain a global framework of plastic waste transport and accumulation, relevant for plastic pollution mitigation strategies in aquatic environments. Packaging and consumer products were the most encountered product categories in rivers, while fishery items dominated in the oceanic environment. Plastics from electronics, building and construction, and transport were barely observed. For polymers, polyethylene and polypropylene contributed most to pollution in all environments. The highest diversity in polymer composition was found in oceanic and freshwater sediments. It is therefore argued that a large fraction of plastic waste accumulates here. This confirms that plastic waste transport and accumulation patterns were most affected by the density, surface area, and size of plastics. Only thick-walled, larger plastic debris from low-density polymers are transported through currents from rivers to ocean, while the larger fraction of plastic litter is likely retained in sediments or beaches.

Schwarz, T., et al. (2015). "The antimicrobial peptide human beta-defensin 3 induces regulatory T cell." Journal of Investigative Dermatology **1)**: S89.

Antimicrobial peptides (AMPs) are responsible for antibacterial defense and released by a variety of cells including keratinocytes. AMPs exert additional activities beyond their antimicrobial capacities, e.g. influencing the adaptive immune system by modulating antigen presenting cells. We observed that the UV-inducible murine AMP beta-defensin 14 (mBD14) induces regulatory T cells (Treg). To clarify whether this applies also for the human system, we studied whether human beta-defensin 3 (hBD3), the human orthologue of mBD14, exerts similar features. Human peripheral blood mononuclear cells were separated into

CD4⁺CD25⁺ (Treg) and CD4⁺CD25⁻ T cells by magnetobead separation. The non-regulatory CD4⁺CD25⁻ fraction was incubated with hBD3. FACS analysis revealed significant upregulation of the Treg characteristic molecules Foxp3, neuropilin, CTLA-4 and GARP. To address the functional relevance, CD4⁺CD25⁻ T cells were treated with hBD3 for 48 hours and cocultured with CD4⁺CD25⁻ responder T cells in the presence of anti-CD2-, anti-CD3- and anti-CD28-loaded microbeads. hBD3-treated CD4⁺CD25⁻ T cells significantly suppressed the antibody triggered proliferation of the responder cells, indicating induction of suppressive features of T cells upon incubation with hBD3. These data provide evidence that hBD3 similar to its murine analogue may change phenotypic and functional properties of non-regulatory T cells towards suppressive Treg. Through this ability, human AMP may protect the host from microbial attacks on the one hand, but tame T-cell-driven reactions on the other hand, thereby enabling an antimicrobial defense without collateral damage by the adaptive immune system.

Schymanski, D., et al. (2018). "Analysis of microplastics in water by micro-Raman spectroscopy: Release of plastic particles from different packaging into mineral water." Water Research **129**: 154-162.
Microplastics are anthropogenic contaminants which have been found in oceans, lakes and rivers. Investigations focusing on drinking water are rare and studies have mainly been using micro-Fourier Transform Infrared Spectroscopy (mu-FT-IR). A major limitation of this technique is its inability to detect particles smaller than 20 mum. However, micro-Raman spectroscopy is capable of detecting even smaller particle sizes. Therefore, we show that this technique, which was used in this study, is particularly useful in detecting microplastics in drinking water where particle sizes are in the low micrometer range. In our study, we compared the results from drinking water distributed in plastic bottles, glass bottles and beverage cartons. We tested the microplastic content of water from 22 different returnable and single-use plastic bottles, 3 beverage cartons and 9 glass bottles obtained from grocery stores in Germany. Small (-50-500 mum) and very small (1-50 mum) microplastic fragments were found in every type of water. Interestingly, almost 80% of all microplastic particles found had a particle size between 5 and 20 mum and were therefore not detectable by the analytical techniques used in previous studies. The average microplastics content was 118 +/- 88 particles/l in returnable, but only 14 +/- 14 particles/l in single-use plastic bottles. The microplastics content in the beverage cartons was only 11 +/- 8 particles/l. Contrary to our assumptions we found high amounts of plastic particles in some of the glass bottled waters (range 0-253 particles/l, mean 50 +/- 52 particles/l). A statistically significant difference from the blank value (14 +/- 13) to the investigated packaging types could only be shown comparing to the returnable bottles (p < 0.05). Most of the particles in water from returnable plastic bottles were identified as consisting of polyester (primary polyethylene terephthalate PET, 84%) and polypropylene (PP; 7%). This is not surprising since the bottles are made of PET and the caps are made of PP. In water from single-use plastic bottles only a few micro-PET-particles have been found. In the water from beverage cartons and also from glass bottles, microplastic particles other than PET were found, for example polyethylene or polyolefins. This can be explained by the fact that beverage cartons are coated with polyethylene foils and caps are treated with lubricants. Therefore, these findings indicate that the packaging itself may release microparticles. The main fraction of the microplastic particles identified are of very small size with dimensions less than 20 mum, which is not detectable with the mu-FT-IR technique used in previous studies.

Scopetani, C., et al. (2019). "Assessment of microplastic pollution: occurrence and characterisation in

Vesijarvi lake and Pikku Vesijarvi pond, Finland." Environmental Monitoring and Assessment **191 (11) (no pagination)**(652).

In the last few years, several studies have investigated microplastics (MPs) in marine ecosystems, but data monitoring and assessing the occurrence in freshwater environments are still scarce. The present study aims to investigate the occurrence, distribution, and chemical composition of MP pollution in Vesijarvi lake and Pikku Vesijarvi pond close to the city of Lahti (Finland) in winter. Sediment, snow, and ice core samples were collected near the shore of these two aquatic systems. MPs were analysed and identified by a non-destructive method using Fourier transform infrared spectroscopy (FTIR) 2D imaging. The mean concentrations of MPs detected in sediment, snow, and ice samples were 395.5 +/- 90.7 MPs/kg, 117.1 +/- 18.4 MPs/L, and 7.8 +/- 1.2 MPs/L, respectively. FTIR results showed the predominant abundance of microplastics, such as polyamides (up to 53.3%), polyethylene and polypropylene (up to 17.1%), and natural fragments such as cellulose (up to 45.8%) and wool (up 18.8%) in the same size range. The potential release of MPs arising from stormwaters and sport and recreational activities was evidenced. Copyright © 2019, The Author(s).

Scopetani, C., et al. (2018). "Ingested microplastic as a two-way transporter for PBDEs in Talitrus saltator." Environmental Research **167**: 411-417.

The presence and accumulation of plastic waste into the marine environment are well known environmental issues. Microplastics (MPs) end up in sea waters and, due to their hydrophobicity and high surface/volume ratio, POPs tend to sorb and accumulate to their surface. The supralittoral amphipod Talitrus saltator (T. saltator) was selected to study the role of MPs in the transfer of organic pollutants and to investigate if ingested MPs could either transfer contaminants to biota or clean it adsorbing pollutants taken from the diet. T. saltator is an established POPs (Persistent Organic Pollutants) biomonitor in coastal environments and it is able to swallow microplastics in natural condition. Two laboratory experiments were performed and T. saltator was exposed to a labelled polybrominated diphenyl ether (¹³C-labelled BDE-47) to investigate the opposite gradient role of MPs. X Ray Micro-CT (Micro-Computed Tomography) analyses were also performed on sandhopper samples to evaluate the uptake of MPs via digestive tract. The results showed that MPs ingestion could whether transfer and remove contaminants from T. saltator, indicating a partial balance among positive and negative effects. This study has underlined MP potential double role demonstrating that MP can act both as a carrier and scavenger for the bioaccumulation of organic pollutants (i.e. PBDEs), suggesting that chemicals leaching from MPs could have a limited impact to biota.

Scopetani, C., et al. (2020). "Self-contamination from clothing in microplastics research." Ecotoxicology & Environmental Safety **189**: 110036.

Self-contamination should not be underestimated when quantifying microplastics (MPs) in environmental matrices. Standardised and validated methodologies for MP sampling, extraction, and analysis are lacking. The various applications of plastics in our society have made them ubiquitous, even in clothing, rendering MP self-contamination inevitable. In the present study, we sampled lake sediment, snow, and ice, purposefully wearing red overalls composed of cotton; fibres from which we could quantify using Fourier-Transform Infrared Spectroscopy (FTIR), serving as an indication of possible self-contamination from clothes. The suitability of cotton as a representation of MP contamination was also evaluated. For all detected fibres, 25 +/- 1%, 20 +/- 7%, and 8 +/- 6% for snow, ice, and sediment, respectively, originated from sampling attire. These findings demonstrate that self-contamination can play a significant role when quantifying MP pollution, highlighting that sampling conducted to date might have

overestimated the presence of MP or even contaminated MP-free samples.

Scott, I. C., et al. (2013). "Large-scale isolation of human skeletal muscle satellite cells from post-mortem tissue and development of quantitative assays to evaluate modulators of myogenesis." Journal of Cachexia, Sarcopenia and Muscle **4**(2): 157-169.

BACKGROUND: During aging, there is a decreased ability to maintain skeletal muscle mass and function (sarcopenia). Such changes in skeletal muscle are also co-morbidities of diseases including cancer, congestive heart failure and chronic obstructive pulmonary disease. The loss of muscle mass results in decreased strength and exercise tolerance and reduced ability to perform daily activities. Pharmacological agents addressing these pathologies could have significant clinical impact, but their identification requires understanding of mechanisms driving myotube formation (myogenesis) and atrophy and provision of relevant assays. The aim of this study was to develop robust in vitro methods to study human myogenesis.

METHODS: Satellite cells were isolated by digestion of post-mortem skeletal muscle and selection using anti-CD56 MicroBeads. CD56(+) cell-derived myotubes were quantified by high content imaging of myosin heavy chains. TaqMan-polymerase chain reaction arrays were used to quantify expression of 41 selected genes during differentiation. The effects of activin receptor agonists and tumour necrosis factor alpha (TNFalpha) on myogenesis and gene expression were characterised.

RESULTS: Large-scale isolation of CD56(+) cells enabled development of a quantitative myogenesis assay with maximal myotube formation 3 days after initiating differentiation. Gene expression analysis demonstrated expression of 19 genes changed substantially during myogenesis. TNFalpha and activin receptor agonists inhibited myogenesis and downregulated gene expression of muscle transcription factors, structural components and markers of oxidative phenotype, but only TNFalpha increased expression of pro-inflammatory markers.

CONCLUSIONS: We have developed methods for large-scale isolation of satellite cells from muscle and quantitative assays for studying human myogenesis. These systems may prove useful as part of a screening cascade designed to identify therapeutic agents for improving muscle function.

Scott, N., et al. (2019). "Particle characteristics of microplastics contaminating the mussel Mytilus edulis and their surrounding environments." Marine Pollution Bulletin **146**: 125-133.

We investigated the environmental partitioning and particle characteristics of macro-, meso- and microplastics and their uptake into the mussel, Mytilus edulis. Sediment samples, overlying seawater and mussels from 9 intertidal locations in the South West of England were analysed for abundance and type of microplastic. Micro- and mesoplastic-like particles were found in 88.5% of the 269 mussels sampled, ranging from 1.43 to 7.64 items per mussel. Of these plastic particles, 70.9% were identified as semi-synthetic (mainly modified-cellulose). Mussel microplastic abundance, but not polymer type, was correlated with that of their surrounding sediment, but not with sea-surface microplastic concentration or mussel size for our study sites. We found significant differences in the relative abundance of polymer types and particle sizes between seawater, sediment, and mussels, with mussels over-representing modified-cellulose fibre abundance but under-representing polyvinyl. Mussels contained significantly smaller plastic fragments than their surrounding sediment and shorter fibres than their overlying seawater.

Sears, P. R., et al. (2013). "A novel in vitro system for studying mucociliary clearance: Relationship between ciliary beat frequency and mucociliary transport." Pediatric Pulmonology **36)**: 235.
