Objective: Mucociliary clearance (MCC) is an important innate defense mechanism that is impaired in cystic fibrosis and several other airway diseases. MCC is an integrated system that requires coordinated regulation of three major processes, i.e., salt and water transport, mucin synthesis and secretion, and ciliary beat frequency (CBF). While individual components of MCC (e.g., the regulation of CBF, the regulation of ion transport) have frequently been studied in vitro, studies of MCC have been more limited due to the challenges of performing in vivo assays. For example, while the effects of many agents on CBF have been documented in the literature, there are few, if any, studies of the direct effects of agents that stimulate CBF on the rate of MCC. The objective of the studies reported here was to develop an in vitro system that is suitable for detailed studies of mucociliary transport (MCT) and its regulation. Method(s): Early passage human airway epithelial (HAE) cells were cultured in a modified air/liquid interface culture system (mucociliary transport device, MCTD, patent pending) that encourages the spontaneous development of continuous, directional, MCT. The device consists of a narrow track of defined width that allows mucus to be transported in a continuous path over the surface of the culture. HAE cells were cultured until fully differentiated (6-8 weeks) and monitored for the development of MCT. High speed videos were recorded from the central region of the MCTD track. Ciliary beat frequency was measured by phase contrast microscopy utilizing the SAVA system and the mucociliary transport rate was measured by recording the movement of endogenous mucous particles/debris. Alternatively, fluorescent micro-beads could be added to the airway surface liquid to visualize and quantify MCT. Ciliary beat frequency was modulated by varying the temperature or by treating the cultures with test agents and the corresponding change in MCT was determined. Result(s): In these experiments, HAE cells cultured at the air/liquid interface in the MCTD regularly developed continuous MCT that was maintained for several weeks. This simple culture system allowed for the simultaneous measurement of both CBF and MCT in the same culture under different conditions. Changes in temperature (~0-40degreeC) were used to alter CBF and the resulting change in MCT was measured. From these studies, it was determined that the rate of MCT increases linearly with increases in CBF over the range of 6-14 Hz and that the rate of MCT increased ~ 10 mum/s for every 1 Hz increase in CBF. CBF and MCT were also coordinately stimulated by treatment with the purinergic receptor agonist ATPgammaS. Conclusion(s):We have developed a novel in vitro method that allows for detailed studies of MCC using early passage HAE cells. Using this method we have systematically examined how changes in CBF directly affect the rate of MCT, and have shown that slight increases in CBF can lead to significant changes in MCT. Importantly, the system we describe will be used for in-depth studies of the integrated process of MCT and investigation of new therapeutic agents.

Sebastian Amar, G., et al. (2019). "Simulación y obtención de combustibles sintéticos a partir de la pirólisis de residuos plásticos." Ingeniería y Desarrollo **37**(2): 306-326.

The continuous demand for plastics has caused large accumulations of waste in landfills, contributing to environmental and public health problems. In Colombia, approximately 9.5 million tons of solid waste is generated annually, and 14% corresponds to plastic materials. Pyrolysis is a technique by which it is possible to remedy part of the problem, because energy and products are recovered in the form of liquid and gaseous fuel. This article presents the implementation and comparison of two models in Aspen Plus for the simulation of the pyrolysis process for the production of liquid fuels from different plastic waste. The models are based on the minimization of Gibbs free energy and reaction kinetic mechanisms. The simulation performed calculates the yields (% of weight) and the properties of each product flow according to the operating conditions. In comparison with data from the literature and experimental information collected in this research, the thermodynamic model showed deviations greater than 20%. The kinetic model presented good estimates obtaining errors ≤ 8%. According to the results obtained, the production of liquid fuel from plastic wastes is favored according to the raw material as follows: polystyrene > high density polyethylene ≈ low density polyethylene > polyethylene terephthalate.

Sebe, G., et al. (2019). "Cu²⁺-loaded cellulose micro-beads applied to the direct patterning of metallic surfaces using a fast and convenient process." Carbohydrate Polymers **207**: 492-501.

In this paper, we propose both a new application for cellulose micro-beads and a new concept in colloidal lithography to directly deposit and template a metal from ions transported by the organized colloidal particles, using the colloidal particles themselves. To do so, 5 mum-sized cellulose micro-beads (CmuBs) were first surface-functionalized by trimellitic anhydride to introduce carboxylate ligands before decorating them with Cu²⁺ ions by complexation of the carboxylate groups with a CuCl₂ solution. The Cu²⁺-loaded CmuBs, dispersed in an aqueous phase, were organized in compact monolayer at the vicinity of a planar electrode. The release of cupric ions and subsequent copper deposition were triggered by an electric field delivered by a tension generator. 2D non-close-packing arrays of copper dots assemblies displaying hexagonal symmetry were generated below or around the micro-beads - depending on the ions concentration in the aqueous phase - leading respectively to copper dots deposited circularly or concentrated in rings. The Cu²⁺-loaded cellulose beads allowed the covering of 2 cm2-surfaces by copper patterns in less than 45 min, using an easy and cheap process.

Segretin, F., et al. (2017). "Bracing and physical therapy in adult scoliosis." Revue du Rhumatisme Monographies **84**(1): 39-45.

Objective To describe and assess the place of brace and physical therapy in the treatment of idiopathic and degenerative adult scoliosis. Methods A literature review in Medline without blackout dates or language identified a few studies with a high level of evidence. We reported their results in addition to our clinical experience. Results In adults, the goal of these treatments is primarily to relieve pain and improve function. If lumbar and thoracolumbar scoliosis progress (increase of 5degree between two X-rays), wearing a custom-molded rigid lumbar-sacral orthosis 6 hours per day may slow the progression rate. If scoliosis does not progress but is painful, customized lumbar support corset or rigid lumbar-sacral orthosis (plastic, resin or plaster) on demand should be sufficient. Physical therapy is essential if the patient is symptomatic. It is based on exercises to correct sagittal and coronal balance, including core strengthening, stretching, lumbar traction, and on functional rehabilitation. Aerobic physical activity is also recommended. Conclusion Bracing and physical therapy have an important place in the treatment of adult scoliosis, whether idiopathic or degenerative, progressive or not. They are determined after a thorough clinical examination and after evaluation of patient expectations. Copyright © 2016 Societe francaise de rhumatologie

Seidensticker, S., et al. (2018). "A combined experimental and modeling study to evaluate pH-dependent sorption of polar and non-polar compounds to polyethylene and polystyrene microplastics." Environmental Sciences Europe **30**(1): 30.

Background: The contamination of aquatic ecosystems with both anthropogenic pollutants and particles in particular (microscopic) plastic debris items is of emerging concern. Since plastic

particles can accumulate contaminants and potentially facilitate their transport, it is important to properly investigate sorption mechanisms. This is especially required for a large variety of chemicals that can be charged under environmental conditions and for which interactions with particles may hence go beyond mere partitioning.

Results: In this study, sorption experiments with two types of microplastic particles (polyethylene and polystyrene) and 19 different contaminants (pesticides, pharmaceuticals, and personal care products) were performed at three different pH values. We could show that sorption to plastic particles is stronger for hydrophobic compounds and that neutral species usually contribute more to the overall sorption. Bulk partitioning coefficients were in the same order of magnitude for polyethylene and polystyrene. Furthermore, our results confirm that partition coefficients for polar compounds can only be accurately determined if the solid-to-liquid ratio in batch experiments is more than 6-7 orders of magnitude higher than any plastic concentration detected in the environment. Consequently, only a minor fraction of pollutants in water bodies is associated with microplastics.

Conclusions: Although neutral species primarily dominate the overall sorption, hydrophobic entities of ionic species cannot be neglected for some compounds. Notwithstanding, our results show that since microplastic concentrations as currently observed in the environment are very low, they are only a relevant sorbent for strongly hydrophobic but not for polar compounds.

Seidensticker, S., et al. (2017). "Shift in Mass Transfer of Wastewater Contaminants from Microplastics in the Presence of Dissolved Substances." Environmental Science & Technology **51**(21): 12254-12263.

In aqueous environments, hydrophobic organic contaminants are often associated with particles. Besides natural particles, microplastics have raised public concern. The release of pollutants from such particles depends on mass transfer, either in an aqueous boundary layer or by intrapartide diffusion. Which of these mechanisms controls the mass-transfer kinetics depends on partition coefficients, particle size, boundary conditions, and time. We have developed a semianalytical model accounting for both processes and performed batch experiments on the desorption kinetics of typical wastewater pollutants (phenanthrene, tonalide, and benzophenone) at different dissolved-organic-matter concentrations, which change the overall partitioning between microplastics and water. Initially, mass transfer is externally dominated, while finally, intrapartide diffusion controls release kinetics. Under boundary conditions typical for batch experiments (finitebath), desorption accelerates with increasing partition coefficients for intraparticle diffusion, while it becomes independent of partition coefficients if film diffusion prevails. On the contrary, under field conditions (infinite bath), the pollutant release controlled by intrapartide diffusion is not affected by partitioning of the compound while external mass transfer slows down with increasing sorption. Our results clearly demonstrate that sorption/desorption time scales observed in batch experiments may not be transferred to field conditions without an appropriate model accounting for both the mass-transfer mechanisms and the specific boundary conditions at hand. [ABSTRACT FROM AUTHOR]

Seidman, E. and S. Dionne (2016). "The influence of vitamin D on M1 and M2 macrophages in patients with Crohn's disease." Journal of Crohn's and Colitis **10 (Supplement 1)**: S123-S124.

Background: Macrophages play an important role in IBD possessing pro- and anti-inflammatory activities, depending on their phenotype. M1 polarised macrophages contribute to DSS colitis, whereas M2 macrophages attenuate colitis severity. Vitamin D is a potent modulator of both innate and adaptive immunity, but its effect on M1 and M2 macrophages in IBD has not been investigated. The aim of this study was to M1 and M2 macrophage function in CD and to determine the effect of 1,25D on monocyte-derived macrophages in CD patients. Method(s): PBMC were isolated from peripheral blood of 28 CD patients. Monocytes were isolated by negative selection or CD14 microbeads. Inflammatory M1 type macrophages were generated by culturing of monocytes in the presence of GM-CSF, whereas M-CSF with or without IL-4 was used to produce anti-inflammatory M2 macrophages. Cytokines were determined by ELISA following stimulation with 100 ng/ml LPS. Phagocytosis was determined by measuring uptake of FITC-latex beads using flow cytometry. Expression of M1 and M2 markers was determined by qPCR. Result(s): CD patients' M1 macrophages produced much more IL-12p40 compared with M2 macrophages (4 130 pg/ml vs 84.2 pg/ml production, $p < 0.0005$). There was a trend towards higher TNF-alpha in M1 macrophages compared with M2 macrophages ($p = 0.069$). CCL22 levels were very low in M2 cells generated with M-CSF alone, but were produced by M1 macrophages, as well as M2 macrophages generated in the presence of IL-4. M2 macrophages produced significantly higher amounts of IL-10 than M1 macrophages did (1 638 vs 152 pg/ml, $p < 0.005$). Preincubation with 1,25D greatly decreased IL-12p40 production by M1 macrophages (-68.2%, $p < 0.0005$), as well as that by M2 macrophages (-100%, $p < 0.05$). In addition,1,25D also inhibited TNF-alpha production by M1 macrophages (-36.0%, $p < 0.05$). IL-10 levels were decreased 32% by 1,25D ($p < 0.05$). CCL22 production was increased by 1,25D (+165%, $p < 0.05$). M2 macrophages displayed greater phagocytic activity compared with M1 macrophages (94.6% vs 81.1%). Phagocytosis was minimally enhanced when M1 macrophages were treated with 1,25D (84.4%). 1,25D decreased expression of M1 markers CCL7 and CD80 by 28-41% but had no effect on M2 markers CX3CR1 and CD206. Conclusion(s): M1 macrophages from CD patients displayed inflammatory activity/profiles with elevated production of the proinflammatory cytokines IL-12p40 and TNF-alpha, whereas enhanced anti-inflammatory IL-10 production characterised M2 macrophages. Moreover, 1,25D significantly inhibited pro-inflammatory cytokine production from M1 macrophages while increasing IL-10 production; 1,25D decreased M1 markers, enhanced phagocytosis, and CCL22 release, a chemokine that can promote tolerance.

Seif, S., et al. (2018). "Plastic and Non-plastic Debris Ingestion in Three Gull Species Feeding in an Urban Landfill Environment." Archives of Environmental Contamination & Toxicology **74**(3): 349-360.

Plastic debris is recognized as a widespread, common and problematic environmental pollutant. An important consequence of this pollution is the ingestion of plastic debris by wildlife. Assessing the degree to which different species ingest plastics, and the potential effects of these plastics on their health are important research needs for understanding the impacts of plastic pollution. We examined debris (plastic and other types) ingestion in three sympatric overwintering gull species (Herring gulls <italic>Larus smithsonianus</italic>, Great Black-backed Gulls <italic>Larus marinus</italic>, and Iceland Gulls <italic>Larus glaucoides</italic>) to understand how debris ingestion differs among species, age classes and sexes in gulls. We also assessed how plastic burdens were associated with body condition to investigate how gulls may be affected by debris ingestion. There were no differences among the species, age classes or sexes in the incidence of debris ingestion (plastic or otherwise), the mass or number of debris pieces ingested. We found no correlation between ingested plastics burdens and individual condition. Gulls ingested plastic debris, but also showed high levels of other debris types as well, including metal, glass and building materials, including a metal piece of debris found within an abscess in the stomach. Thus, when the health effects of debris ingestion on gulls, and other species that ingest debris, is of interest, either from a physical or chemical perspective, it may be necessary to consider all debris types and not just plastic burdens as is often currently done for seabirds. [ABSTRACT FROM AUTHOR]

Seigel, R. S., et al. (1982). "Potential complications in myelography: I. Technical considerations." AJR. American Journal of Roentgenology **138**(4): 705-708.

Scanning electron microscopy demonstrated starch powder contamination on the stylet tip from a spinal needle after it was lightly touched with nonwashed surgical gloves. A sterile solution of Pantopaque was injected through the spinal needle after the stylet was withdrawn and carried particulate contaminants to a 0.2 micrometer millipore filter. Using both scanning electron microscopy and energy dispersive x-ray analysis, particles of various sized (mostly 5-10 microns) and variable compositions, including starch, talc, and other elements, were identified. Also, glass particles from the Pantopaque vial and plastic particles from the plastic syringe and tubing used in drawing up the Pantopaque were seen. These observations indicate that strict attention to proper technique in myelography is essential in order to eliminate potential cerebrospinal fluid contamination.

Seitz, C., et al. (2016). "Transplantation of positive selected peripheral stem cells with add-back of T cells from unrelated donors in children: Favorable survival with low incidence of GvDH." Bone Marrow Transplantation **1)**: S260.

Introduction: Despite the use of ATG and pharmacological prophylaxis, there is still a significant risk for GvHD in transplantation of peripheral stem cells from matched unrelated donors. Especially in the case of young pediatric patients and adult donors, grafts with high numbers of stem cells but also extreme amounts of T cells can be obtained. T cell depletion does reduce the occurrence of GvHD but sets the patient at risk for graft failure, delayed immune reconstitution and consecutive increased risk for lifethreatening viral and fungal infections, lymphoproliferative disease and malignant relapse. Here we present long-term follow-up results on a clinical study for T cell reduced grafts in 22 patients receiving a clearly defined number of unselected T cell added back to their stem cell graft. Material (or patients) and methods: Positive selection of peripheral stem cells was performed using CD34 or CD133 coated magnetic microbeads and the CliniMACS device. Subsequently, an unselected aliquot of 10x10⁶/kg T cells was added to the purified stem cells resulting in a median T cell depletion of 2 log. The diagnoses were: acute lymphatic leukemia (n = 9; CR1 = 4, CR2 = 5), NHL (n = 1) acute (n=5; CR1 = 1, CR2 = 4), chronic myeloic leukemia (n = 3), MDS (n=3) and Wiskott-Aldrich (n = 1). Median age was 10 years (0.5-18). The donors were matched for HLA-A/B (medium resolution typing) and DRB1/DQB1 (high resolution). Sixteen patientdonor pairs were completely matched for HLA-A, -B, and -DRB1, and 6 were mismatched for 1 locus. A short course of MTX (2-3x10 mg/m²) and CSA (2-3 mg/kg, adjusted to blood levels) were given until day 100. Result(s): 21/22 patients had primary engraftment with a median time

to ANC >500 of 18 days (12-60). No G-CSF was given. One patient rejected his graft and was successfully retransplanted from another MUD. Platelet recovery was quick with a median time to reach independence from substitution of 20 days. Mean numbers of CD3+, CD3+CD4+ and CD3+CD8 + on day 180 (365) were 259/mul (868/mul), 98/mul (401/mul) and 146/mul (457/mul). 19/22 patients had GvHD grade 0-I (86%), one and two patients had grade II and III, (5%, 9%) respectively. Chronic GvHD occurred in only one patients (4,5%). 14/22 patients are alive with a median follow up of 9,8 years (range 5 to 11.5 years). Five year EFS was 64% (all patients), 50% (ALL/ NHL) and 73% (myeloic leukemias /MDS). Relapse probability at five years was 23%, probability of TRM at five years was 14%. Causes of death were relapse (n = 5) and infections (n = 3). Thus, stable and favorable survival rates with a low incidence of GvHD were achieved. Conclusion(s): The method allows the administration of clearly defined T cell numbers independent from the volume of the apheresis product. This may be of advantage in particular in small children and if the donor does not accept a bone marrow harvest. All available stem cells can be infused without the limitation of intolerable high T cell numbers.

Seligson, D. and L. Douglas (2010). "Experience with a large-frame, disposable external fixator." Orthopedics **33**(3).

External fixation is a temporizing measure that has a long history in the treatment of fractures. Thirty-eight newly designed large-frame external fixators were applied for acute lower-limb fractures and pelvis injuries in a level I trauma center. In 75% of cases, the frames were used for first-stage skeletal stabilization, followed by revision to plates or nails 1 to 2 weeks later. The external fixators remained in place from 4 to 28 days (median, 8 days). The fixator is composed of a low-cost plastic resin and uses modular, disposable components. The montage requires only 2 varieties of clamp, monotube rods, and fixation pins already in-house. The device is lighter than conventional fixators yet equal in rigidity. Cost analysis performed by our institution demonstrated cost savings of 20% to 25% compared to conventional external fixation. The new device is packaged sterilely and does not require autoclaving before application. Patient acceptance of the device was good. There were no complications or disadvantages associated with the use of this lower-cost device. Specifically, there were no pin tract infections, no loss of fixation, and no loosening or disassembly of the devices.

Selonen, S., et al. (2020). "Exploring the impacts of plastics in soil – The effects of polyester textile fibers on soil invertebrates." Science of the Total Environment **700**: N.PAG-N.PAG.

• The effects of polyester fibers on soil animals were studied for the first time. • Enchytraeid reproduction decreased up to 30% but only by long fibers in soil. • Isopod energy reserves and feeding activity were affected by fibers in soil. • Polyester fibers were not very harmful to soil invertebrates in 21–28-days exposure. • Polyester fibers can enter terrestrial food webs by ingestion by soil invertebrates. Polyester fiber is one of the most abundant types of microplastics in the environment. A major proportion of the fibers entering wastewater treatment plants end up in sewage sludge, which is used as a soil fertilizer in many countries. As their impacts in the terrestrial environment are still poorly understood, we studied the effects of polyester fibers on enchytraeids (Enchytraeus crypticus), springtails (Folsomia candida), isopods (Porcellio scaber) and oribatid mites (Oppia nitens), all playing an important role in soil decomposer food webs. We exposed these invertebrates in the laboratory to short (12 µm–2.87 mm) and long (4–24 mm) polyester fibers, spiked in soil or in food at five concentrations ranging from 0.02% to 1.5% (w/w) and using five replicates. Overall the effects of polyester fibers on the soil invertebrates were slight. Energy reserves of the isopods were slightly affected by both fiber types, and enchytraeid reproduction decreased up to 30% with increasing fiber concentration,

but only for long fibers in soil. The low ingestion of long fibers by the enchytraeids suggests that this negative impact arose from a physical harm outside the organism, or from indirect effects resulting from changes in environmental conditions. The short fibers were clearly ingested by enchytraeids and isopods, with the rate of ingestion positively related to fiber concentration in the soil. This study shows that polyester fibers are not very harmful to soil invertebrates upon short-term exposure. However, longer lasting, multigeneration studies with functional endpoints are needed to reveal the possible long-term effects on soil invertebrates and their role in the decomposition process. This study also shows that polyester fibers can enter terrestrial food web via ingestion of fibers by soil invertebrates. [ABSTRACT FROM AUTHOR]

Seltenrich, N. (2015). "New link in the food chain? Marine plastic pollution and seafood safety." Environmental Health Perspectives **123**(2): A34-41.

Seltzer, J. L., et al. (1977). "Plastic particulate contaminants in the medicine cups of disposable non-spinal regional anesthesia sets." Anesthesiology **47**(4): 378-379.

The authors have identified plastic particulate contaminants in the medicine cups of disposable epidural and nerve block trays. It is felt that the presence of these particles represents a possible hazard if they are injected with the anesthetic agent. This hazard is not associated with disposable spinal trays, because they do not contain medicine cups. Because of these findings, it is suggested these medicine cups not be used, and that an alternate method of containing the local anesthetic agent be used.

Selukar, N. B. (2014). "PETROL FROM WASTE PLASTIC." Journal of Environmental Research and Development **8**(3A): 741.

Due to its non-biodegradable nature, the plastic waste contributes significantly to the problem of municipal waste management. Waste plastics are mostly land filled or incinerated; however, these methods are facing great social resistance because of environmental problems such as air pollution and soil contamination, as well as economical resistance due to their increase of space and disposal costs. A pyrolysis of waste plastic has been carried out in presence of hydrocarbon liquid bed without catalyst. At 300 degrees C-400 degrees C all waste plastic undergoes decomposition and get converted to fuel which get recovered with liquid bed. The petrol, liquid bed and diesel fractions were separated during recovery section itself. This technique able to convert 100 gm waste plastic into more than 100 ml liquid fuel (56.1 ml petrol and 45.9 ml diesel). It requires less decomposition temperature than the common pyrolysis technique and recovered liquid bed can be used again and again. Hence this liquid bed technique is efficient, economical and eco-friendly.

Selvam, S., et al. (2020). "Microplastic presence in commercial marine sea salts: A baseline study along Tuticorin Coastal salt pan stations, Gulf of Mannar, South India." Marine Pollution Bulletin **150**: 110675.

The present baseline research infers that the salts present in the sea may contain microplastics (MPs), as the seawater is contaminated due to a number of anthropogenic activities. Herein, 25 types of sea salt samples were collected from salt pans located in the Tuticorin coastal region.

The MPs present in the samples were separated and identified by various methods such as handpicking, visual classification, and micro-Fourier transform infrared spectroscopy (mu-FT-IR) and atomic force microscopy (AFM). The MPs that measured less than 100mum formed the major part of the salts, accounting to 60% of the MPs among the total pollutants. The MPs that were found in abundance in the sea salts were polypropylene, followed by polyethylene, nylon, and cellulose. This study was conducted in salt pan areas and demarcated the percentage of MPs present in sea salts. Table salt, which is a prime edible commodity, was found to be contaminated with MPs through polluted seawater, which poses a threat to public health.

Semernya, L., et al. (2017). "Waste management outlook for mountain regions: Sources and solutions." Waste Management & Research **35**(9): 935-939.

Following the release of the global waste management outlook in 2015, the United Nations Environment Programme (UN Environment), through its International Environmental Technology Centre, is elaborating a series of region-specific and thematic waste management outlooks that provide policy recommendations and solutions based on current practices in developing and developed countries. The Waste Management Outlook for Mountain Regions is the first report in this series. Mountain regions present unique challenges to waste management; while remoteness is often associated with costly and difficult transport of waste, the potential impact of waste pollutants is higher owing to the steep terrain and rivers transporting waste downstream. The Outlook shows that waste management in mountain regions is a cross-sectoral issue of global concern that deserves immediate attention. Noting that there is no 'one solution fits all', there is a need for a more landscape-type specific and regional research on waste management, the enhancement of policy and regulatory frameworks, and increased stakeholder engagement and awareness to achieve sustainable waste management in mountain areas. This short communication provides an overview of the key findings of the Outlook and highlights aspects that need further research. These are grouped per source of waste: Mountain communities, tourism, and mining. Issues such as waste crime, plastic pollution, and the linkages between exposure to natural disasters and waste are also presented.

Sendra, M., et al. (2019). "Nanoplastics: From tissue accumulation to cell translocation into Mytilus galloprovincialis hemocytes. resilience of immune cells exposed to nanoplastics and nanoplastics plus Vibrio splendidus combination." Journal of Hazardous Materials: 121788.

Plastic litter is an issue of global concern. In this work Mytilus galloprovincialis was used to study the distribution and effects of polystyrene nanoplastics (PS NPs) of different sizes (50nm, 100nm and 1mum) on immune cells. Internalization and translocation of NPs to hemolymph were carried out by in vivo experiments, while endocytic routes and effects of PS NPs on hemocytes were studied in vitro. The smallest PS NPs tested were detected in the digestive gland and muscle. A fast and size-dependent translocation of PS NPs to the hemolymph was recorded after 3h of exposure. The internalization rate of 50nm PS NPs was lower when caveolae and clathrin endocytosis pathways were inhibited. On the other hand, the internalization of larger particles decreased when phagocytosis was inhibited. The hemocytes exposed to NPs had changes in motility, apoptosis, ROS and phagocytic capacity. However, they showed resilience when were infected with bacteria after PS NP exposure being able to recover their phagocytic capacity although the expression of the antimicrobial peptide Myticin C was reduced. Our findings show for the first time the translocation of PS NPs into hemocytes and how their effects trigger the loss of its functional parameters.

Sendra, M., et al. (2020). "Ingestion and bioaccumulation of polystyrene nanoplastics and their effects on the microalgal feeding of Artemia franciscana." Ecotoxicology & Environmental Safety **188**: 109853.

Nanoplastics (NPs) have become one of the most serious environmental problems nowadays. The environmental issues linked to NPs are attributed to the effects after ingestion in marine organisms. Due to the incipient and controversial information about the effects of PS NPs on the feeding of organisms, the aim of this work is to assess (i) digestion dynamics of Artemia franciscana when exposed to PS NPs as the lowest concentration of PS NPs reported in toxicity test [0 (control), 0.006 and 0.6mg.L-1] and possible interferences in the ingestion of microalgae and (ii) the accumulation and depuration of PS NPs by A. franciscana. Artemia were subjected to ingestion experiments [24 h and 3.5 h], in which the organisms were exposed to PS NPs or to PS NPs + microalgae. Post-exposure feeding (24 h exposure and 2 h feeding) and depuration (24 h exposure and 24 h of depuration) were also carried out. More than 90% of the PS NPs were ingested by Artemia and bioaccumulated in the mandible, stomach, gut, tail gut and appendages after 24 h. The ingestion of microalgae was not affected by the presence of the PS NPs. Data of post-exposure feeding indicated that Artemia previously exposed to plastic and/or microalgae presented similar microalgal ingestion (around 70%); the highest microalgal consumption (around 90%) was recorded in the treatment in which Artemia were previously starved (no plastic and no microalgae). The presence of PS NPs in the gut after the depuration experiments indicates that 24 h was not enough to eliminate the PS NPs.

Sendra, M., et al. (2019). "Are the primary characteristics of polystyrene nanoplastics responsible for toxicity and ad/absorption in the marine diatom Phaeodactylum tricornutum?" Environmental Pollution **249**: 610-619.

Nowadays, the occurrence of a large volume of plastic litter in oceanic and coastal zones has increased concern about its impacts on marine organisms. The degradation of plastic polymers leads to the formation of smaller fragments at both micro and nano scale (<5mm and <1mum respectively). Nanoplastics (NPs), due to their smaller size and high specific surface area can establish colloidal interactions with marine microalgae, therefore potential toxicity can be led. . To assess this hypothesis, the aim of the present study is to examine the behaviour of polystyrene nanoparticles (PS NPs) of different sizes (50 and 100nm) in marine water and their possible effects at different physiological and cellular levels in the marine diatom Phaeodactylum tricornutum. Different biomarkers and stress responses in P. tricornutum were analysed when organisms were exposed to environmentally relevant PS NPs concentrations between 0.1 and 50mgL⁻¹. Our results showed significant differences between controls and exposure microalgae, indicating toxicity. After 24h, an increase in oxidative stress biomarkers, damage to the photosynthetic apparatus, DNA damage and depolarization of mitochondrial and cell membrane from 5mgL⁻¹ were observed. Further after 72h the inhibition of population growth and chlorophyll content were observed. Examining effects the effects related to PS NPs size, the smallest (50nm) induced greater effects at 24h while bigger PS NPs (100nm) at72h. This bigger particles (100nm) showed more stability (in size distribution and spherical form) in the different culture media assayed, when compared with the rest of particles used. Strong adsorption and/or internalization of PS NPs was confirmed through changes in cell complexity and cell size as well as the fluorescence of 100nm fluoresbrite PS NPs after washing cell surface.

Senrong, F., et al. (2017). "Trophodynamics of Organic Pollutants in Pelagic and Benthic Food Webs of Lake Dianchi: Importance of Ingested Sediment As Uptake Route." Environmental Science & Technology **51**(24): 14135-14143.

Habitat is of great importance in determining the trophic transfer of pollutants in freshwater ecosystems; however, the major factors influencing chemical trophodynamics in pelagic and benthic food webs remain unclear. This study investigated the levels of p,p'-dichlorodiphenyldichloroethylene (p,p'-DDE), polycyclic aromatic hydrocarbons (PAHs), and substituted PAHs (s-PAHs) in 2 plankton species, 6 invertebrate species, and 10 fish species collected from Lake Dianchi in southern China. Relatively high concentrations of PAHs and s-PAHs were detected with total concentrations of 11.4-1400 ng/g wet weight (ww) and 5.3-115 ng/g ww, respectively. Stable isotope analysis and stomach content analysis were applied to quantitatively determine the trophic level of individual organisms and discriminate between pelagic and benthic pathways, and the trophodynamics of the detected compounds in the two food webs were assessed. P,p'-DDE was found to exhibit relatively higher trophic magnification rate in the pelagic food web than in the benthic food web. In contrast, PAHs and s-PAHs exhibited greater dilution rates along the trophic levels in the pelagic food web. The lower species differences of pollutants accumulated in benthic organisms compared to pelagic organisms is attributable to extra uptake via ingested sediment in benthos. The average uptake proportions of PAHs and s-PAHs via ingested sediment in benthic biotas were estimated to be 31-77%, and that of p,p'-DDE was 46%. The uptake routes are of importance for assessing the trophic magnification potentials of organic pollutants, especially in eutrophic freshwater ecosystems. [ABSTRACT FROM AUTHOR]

Seoane, M., et al. (2019). "Polystyrene microbeads modulate the energy metabolism of the marine diatom Chaetoceros neogracile." Environmental Pollution **251**: 363-371.

Due to the growing concern about the presence of microplastics (MP) in the environment, the number of studies evaluating the toxicity of these small persistent particles on different marine species has increased in recent years. Few studies have addressed their impact on marine phytoplankton, a subject of great concern since they are primary producers of the aquatic food web. The aim of this study is to unravel the cytotoxicity of 2.5mugmL⁻¹ unlabelled amino-modified polystyrene beads of different sizes (0.5 and 2mum) on the marine diatom Chaetoceros neogracile. In addition to traditional growth and photosynthesis endpoints, several physiological and biochemical parameters were monitored every 24h in C. neogracile cells by flow cytometry during their exponential growth (72h). Dynamic Light Scattering measurements revealed the strong aggregation and the negative charge of the beads assayed in the culture medium, which seemed to minimize particle interaction with cells and potentially associated impacts. Indeed, MP were not attached to the microalgal cell wall, as evidenced by scanning electron micrographs. Cell growth, morphology, photosynthesis, reactive oxygen species levels and membrane potential remained unaltered. However, exposure to MP significantly decreased the cellular esterase activity and the neutral lipid content. Microalgal oil bodies could serve as an energy source for maintaining a healthy cellular status. Thus, MP-exposed cells modulate their energy metabolism to properly acclimate to the stress conditions.

Sequeiros, O. E. (2008). Bedload transport, self acceleration, downstream sorting, and flow dynamics of turbidity currents.

The four chapters presented in this dissertation are self contained, yet related to each other. The first chapter of this dissertation reports on the first set of experiments which focus on bedload transport of granular material by density underflows. These underflows include saline density flows, hybrid saline/turbidity currents and a pure turbidity current. The use of dissolved salt is a surrogate for suspended mud that is so fine that it does not settle out readily. Thus all the currents can be considered to be model turbidity currents. The data cover four bed conditions: plane bed, dunes, upstream-migrating antidunes and downstream-migrating antidunes. The bedload transport relation obtained from the data is very similar to those obtained for open channel flows, and in fact is fitted well by an existing relation determined for open channel flows. In the case of dunes and downstream-migrating antidunes, form drag falls in a range that is similar to that due to dunes in sand-bed rivers. The second chapter presents novel results of self-accelerating turbidity currents. This chapter documents experimental turbidity currents composed of lightweight plastic particles ranging from 20 mu m to 200 mu m with a specific density between 1.3 and 1.5. These particles were either non-cohesive, or slightly cohesive. The experiments were performed in a 15 m long flume with a bottom of slope of 0.05. Self-acceleration of the head of the flow was achieved in some of the tests reported here. Measurements of velocity and suspended sediment taken at different stages of head evolution document this self-acceleration. In addition, these measurements are in agreement with previous empirical studies relating head thickness, concentration, velocity, and water depth. Stratigraphie analysis of the deposit shows the key role bed material plays in determining whether a given turbidity current will or will not accelerate. This factor ties the dynamics of a self-accelerating current to the existence of deposits laid down by antecedent currents. The conditions of the present tests appear to fulfill previous autosuspension criteria relating flow velocity, particle settling velocity and bed slope. Densimetric Froude number similarity analysis is used to estimate equivalent parameters for field scale turbidity currents. The third chapter focuses on a numerical model of turbidity currents with reversing buoyancy, i.e. flows which are rendered heavier than the ambient water due to the presence of suspended sediment, but lighter than the ambient water due to a difference in temperature or salinity. The numerical model, which is based in the Kappa - epsilon closure for turbulence, is verified with a unique set of experimental data intended to model sediment sorting associated with turbidity currents created by explosive undersea eruptions. Both cases with non-reversing buoyancy and reversing buoyancy are considered. As such, the model not only provides a detailed description of flows with reversing buoyancy, but also provides a tool to aid sedimentologists in back-calculating the flow emplaced by turbidity currents from the downstream variation in the grain size distribution of the bed deposit. The last chapter is the first part of a joint paper about the formation of internal deltas, or sediment wedges, by turbidity currents in submarine minibasins. The experiments reported here are performed in configuration to test the concept of an internal delta. Dissolved salt is used as a surrogate for the finer phase, and lightweight plastic particles are used as a surrogate for the coarser phase. The plastic particles are carried mostly as bedload. Succession sustained flows are allowed to create a deposit behind a barrier that simulates the downstream end of a minibasin. The flows are introduced in the supercritical regime; the downstream barrier forces an internal hydraulic jump to the subcritical regime. This chapter concentrates on (a) the flow pattern created by the barrier and (b) the evolution of this flow pattern as the bed evolved morphodynamically. he documentation of the internal delta itself is given in a companion paper. (Abstract shortened by UMI.)

Serban, M. A., et al. (2014). "Cross-linked gelatin microspheres with continuously tunable degradation profiles for renal tissue regeneration." Biotechnology & Applied Biochemistry **61**(2): 75-81.

Collagen and gelatin-based biomaterials are widely used in tissue engineering applications. Various methods have been reported for the cross-linking of these macromolecules for the purpose of delaying their biodegradation to prolong their in vivo residence (in tissue engineering applications) or tailoring their drug releasing capacity (when used as drug carriers). In this study, a carbodiimide-based cross-linking method, also used in the production of United States Food and Drug Administration-approved products, was employed to obtain differentially cross-linked gelatin beads. The colorimetric determination of the in vitro enzymatic susceptibility of the beads indicated that the resistance to degradation linearly correlated with the concentration of carbodiimide used for the cross-linking reaction. This result was also confirmed in vivo by the histological evaluation of the residence time of orthotopically injected cell-seeded beads. These data would indicate that the production of gelatin-based microbeads with tunable degradation profiles might be applicable toward the development of products that catalyze regeneration of kidney and other solid organs.

Serive, B., et al. (2012). "Development and optimization of a metabolite extraction process for the high throughput screening of microalgal chimiodiversity." Planta Medica. Conference: 8th Joint Meeting of AFERP, ASP, GA, PSE and SIF. New York City, NY United States. Conference Publication: **78**(11).

Since a decade, using microalgae for biofuel has become a major challenge worldwide. Several studies have evidenced that potent bioactive molecules can be purified from microalgae for cosmetic or health applications (e.g. antioxidants, immunostimulants, anticancer and antiviral compounds) in order to upgrade biomass. In some species, extraction of bioactive metabolites is tricky for the presence of highly resistant cell walls (Phaeodactylum tricornutum) or exopolysaccharidic barriers surrounding the cell membrane (Porphyridium purpureum). It was therefore essential to develop a process that preserves sensitive molecules. We optimized an extraction grinding process, the Mix Mill process, based on the use of vibrating microbeads. The process efficiency was assessed in pigments extraction experiments. It gave excellent extraction yields, and combined fidelity (no modification of analytes), compatibility with HPLC and LC-MS analysis, accuracy, simplicity, rapidity and safety. Moreover, it allowed to simultaneously extract all pigments, whatever their polarity or the strength that linked them to the cell structures. As a conclusion, the Mix Mill process is a general process for the total extraction of microalgal metabolites thought for high throughput screening of the microalgal chimiodiversity.

Serrano, D., et al. (2010). "Acid sphingomyelinase and membrane composition in CAM-mediated endocytosis." Arteriosclerosis, Thrombosis, and Vascular Biology **30 (11)**: e255.

Intercellular adhesion molecule 1 (ICAM-1) is a transmembrane glycoprotein overexpressed by endothelial cells (ECs), functionally involved in many cardiovascular pathologies, including inflammation and thrombosis. Targeting ICAM-1 using polymer nano-and microbeads coated with multiple copies of anti-ICAM provides a means to deliver therapeutic agents to ECs for treatment of such maladies. Binding of multivalent anti-ICAM carriers to ECs induces actin reorganization into stress fibers and subsequent endocytosis, leading to intraendothelial drug delivery. Cell adhesion molecule (CAM) endocytosis mediated by ICAM-1 differs from classical macropinocytosis and phagocytosis, and also from caveoli-and clathrin-mediated endocytosis, most abundant in endothelial cells. Intraendothelial delivery of micrometer-sized carriers via ICAM-1, shown in animal models, must require high plasmalemma plasticity. Hydrolysis of sphingomyelin into ceramide by sphingomyelinases is a proposed mechanism leading to cytoskeletal rearrangement and increased plasmalemma plasticity. We evaluated the potential crosstalk between ICAM-1 and the sphingomyelin/ceramide pathway. For this purpose, we coated polystyrene nano-and microbeads with anti-ICAM, and used fluorescence microscopy to trace plasmalemma lipid domains and acid sphingomyelinase (ASM) distribution upon binding of beads to human umbilical vein ECs (HUVECs). ICAM-1 engagement by anti-ICAM beads occurred in areas enriched in lipid raft components cholesterol and sphingomyelin. Cholesterol removal by methyl-beta-cyclodextrin affected engulfment of beads. Areas of ICAM-1 engagement by beads also became enriched in ceramide. Ceramide enrichment was prevented by imipramine, an ASM inhibitor, which also affected endocytosis of anti-ICAM beads by HUVECs. Redistribution of ASM from internal compartments to areas of ICAM-1 engagement by anti-ICAM beads was detected by immunofluorescence. These results indicate that the sphingomyelin/ceramide pathway may regulate intraendothelial delivery of drug carriers via CAM-mediated endocytosis. This also suggests a crosstalk between ICAM-1 and ASM signaling cascades, which have been both associated to a number of relevant vascular pathologies.

Serrano-Ruiz, H., et al. (2018). "Application of an in vitro plant ecotoxicity test to unused biodegradable mulches." Polymer Degradation and Stability **158**: 102-110.

Biodegradable plastics have emerged as an encouraging alternative to reduce the production of plastic waste, especially for agricultural mulches. However, degradation of these plastics in the field may involve the release of products from the mulch into the soil, before and during the in-soil biodegradation. The present work aims to assess the potential effects on two agricultural plant species (Lactuca sativa L. - lettuce, and Lycopersicon esculentum Mill. - tomato) of extracts from biodegradable (BDMs: Mater-Bi, Bioplast-SP4 and SP-6, BioFilm, BioFlex, Ecovio, Mirel, Paper) and Polyethylene mulch films. A previously designed highly sensitive in vitro ecotoxicity test was used. Some of the extracts from the biodegradable plastics had effects on plant development. Germination was reduced by Bioplast films treatments, both in lettuce (B-SP4) and in tomato (B-SP4 and B-SP-6). In lettuce, root development was notably reduced by all treatments except for Paper and Polyethylene. Plant aerial growth was also limited with Bioplast and BioFlex, but enhanced with Paper extracts. At a whole, tomato plants showed higher sensitivity than lettuce in the test. Tomato aerial plant part and root growth were reduced by all treatments with the exception of BioFlex and Polyethylene. For both plant species, inhibitory effects on development were associated to proline increases, a physiological marker for some plant stresses. It can be concluded that the contact of unused biodegradable films with a water solution may result in changes in plant development that depend on the nature of the biodegradable film. The in vitro used test revealed to be a highly sensitive tool for ecotoxicity studies. These results are to contribute to design safe materials for agricultural applications.

Serranti, S. and G. Bonifazi (2010). "Post-Consumer Polyolefins (PP-PE) Recognition by Combined Spectroscopic Sensing Techniques." Open Waste Management Journal **3**: 35-45.

The efficient large-scale recycling of plastic waste is of increasing interest from an ecological and economic point of view, but it represents a goal that has yet to be achieved by the recycling industry. The possibility offered by different spectroscopic sensing techniques in order to identify different plastic particles to be recycled, with particular reference to polyolefins from complex wastes, has been investigated. Representative samples of polyolefins (polyethylene and polypropylene) have been collected and analyzed for laboratory set-up and testing by FT-IR spectroscopy, by Raman spectroscopy and by hyperspectral imaging in two different wavelength fields, 400-1000 and 1000-1700 nm, respectively. The spectral signature obtained by the different techniques of the two plastic typologies have been detected, analysed and compared. The main parameters that allow to perform the recognition of the polyethylene (PE) and polypropylene (PP) have been defined, with particular reference to the hyperspectral imaging innovative technique. The analytical strategies can be utilised to define sorting and/or control logics to be applied in " on-line " control architectures to directly act at industrial plant level.

Serranti, S., et al. (2011). "Characterization of post-consumer polyolefin wastes by hyperspectral imaging for quality control in recycling processes." Waste Management **31**(11): 2217-2227.
In this paper new analytical inspection strategies, based on hyperspectral imaging (HSI) in the VIS-NIR and NIR wavelength ranges (400-1000 and 1000-1700 nm, respectively), have been investigated and set up in order to define quality control logics that could be applied at industrial plant level for polyolefins recycling. The research was developed inside the European FP7 Project W2Plastics "Magnetic Sorting and Ultrasound Sensor Technologies for Production of High Purity Secondary Polyolefins from Waste". The main aim of the project is the separation of pure polyethylene and polypropylene adopting an innovative process, the magnetic density separation (MDS). Spectra of plastic particles and contaminants resulting from post-consumer complex wastes and of virgin polyolefins have been acquired by HSI and by Raman spectroscopy. The classification results obtained applying principal component analysis (PCA) on HSI data have been compared with those obtained by Raman spectroscopy, in order to validate the proposed innovative methodology.

Serrati, S., et al. (2015). "Cancer associated fibroblast in multiple myeloma: The urokinase receptor system in tumor growth regulation." Haematologica **3)**: 98-99.
Background:Multiple myeloma is a B-cell malignancy with terminally differentiated plasma cells (PC). It is known that tumor progression is allowed by a favorable tumor microenvironment (TME) and fibroblasts represent the principal cellular component in TME. Recent findings indicate that the urokinase plasminogen activator (uPA), and its receptor (uPAR) are critical in tumor progression. Method(s): BM mononuclear cells (BMMCs) were isolated from 12 patients with relapse/refractory MM, 10 patients with asymptomatic MM, 10 with remission MM, 15 with MGUS. Cancer Associated Fibroblasts (CAFs) were purified through anti-fibroblasts-microbeads and they were analyzed and identified by FSP1 and -smooth muscle actin (alpha-SMA) expression on gated CD45- population. Expression of alpha-SMA in BM CAFs was also demonstrated by immunofluorescence staining. CAFs were cultured in DMEM medium, fixed and permeabilized according to routine methods. The primary antibodies were anti-uPAR, and anti-alpha-SMA. Fibroblast nuclei were stained with DAPI. The relative quantity of uPA, uPAR, MMP-2 and alpha-SMA messenger RNA were determined by the comparative Ct method using 18S ribosomal RNA as the normalization gene. Result(s): Flow cytometry analysis showed that CAFs were increased in patients with relapse-MM compared to patients with asymptomatic, remission MM and MGUS suggesting that CAFs expansion is involved in MM progression. The increased frequency of alpha-SMA in CAFs of relapsed MM patients was demonstrated by the immunofluorescence analysis. Overall, these results suggest that MM activation is associated with the overexpression of uPAR. CAFs activation was also demonstrated by Real Time PCR and the figure shows the overexpression of activation molecules as well as proinvasive systems in CAF of relapsed MM in comparison of MGUS and asymptomatic MM. Conclusion(s): In MM developement and progression the BM niche appears to play an important role in differentiation, migration, proliferation, and drug resistance of the malignant PCs. The main goal of this proposal was to globally approach the expression of CAFs' activation and proinvasive systems in the initiation and progression of MM. For the first time, we demonstrate that an activation of the fibrinolytic system occurs in relapsed/refractory MM compared to less active stages of the disease. Modulating uPAR expression on CAF could be an important key to understand the mechanisms involved in the progression of MM.

Setala, O., et al. (2014). "Ingestion and transfer of microplastics in the planktonic food web." Environmental Pollution **185**: 77-83.

Experiments were carried out with different Baltic Sea zooplankton taxa to scan their potential to ingest plastics. Mysid shrimps, copepods, cladocerans, rotifers, polychaete larvae and ciliates were exposed to 10 micro m fluorescent polystyrene microspheres. These experiments showed ingestion of microspheres in all taxa studied. The highest percentage of individuals with ingested spheres was found in pelagic polychaete larvae, Marenzelleria spp. Experiments with the copepod Eurytemora affinis and the mysid shrimp Neomysis integer showed egestion of microspheres within 12 h. Food web transfer experiments were done by offering zooplankton labelled with ingested microspheres to mysid shrimps. Microscopy observations of mysid intestine showed the presence of zooplankton prey and microspheres after 3 h incubation. This study shows for the first time the potential of plastic microparticle transfer via planktonic organisms from one trophic level (mesozooplankton) to a higher level (macrozooplankton). The impacts of plastic transfer and possible accumulation in the food web need further investigations.

Setala, O., et al. (2016). "Distribution and abundance of surface water microlitter in the Baltic Sea: A comparison of two sampling methods." Marine Pollution Bulletin **110**(1): 177-183.

Two methods for marine microlitter sampling were compared in the Gulf of Finland, northern Baltic Sea: manta trawl (333mum) and a submersible pump (300 or 100mum). Concentrations of microlitter (microplastics, combustion particles, non-synthetic fibres) in the samples collected with both methods and filter sizes remained <10particlesm(-3). The pump with 100mum filter gave higher microlitter concentrations compared to manta trawl or pump with 300mum filter. Manta sampling covers larger areas, but is potentially subjected to contamination during sample processing and does not give precise volumetric values. Using a submerged pump allows method controls, use of different filter sizes and gives exact volumetric measures. Both devices need relatively calm weather for operation. The choice of the method in general depends on the aim of the study. For monitoring environmentally relevant size fractions of microlitter the use of 100mum or smaller mesh size is recommended for the Baltic Sea.

Setala, O., et al. (2016). "Feeding type affects microplastic ingestion in a coastal invertebrate community." Marine Pollution Bulletin **102**(1): 95-101.

Marine litter is one of the problems marine ecosystems face at present, coastal habitats and food webs being the most vulnerable as they are closest to the sources of litter. A range of animals (bivalves, free swimming crustaceans and benthic, deposit-feeding animals), of a coastal community of the northern Baltic Sea were exposed to relatively low concentrations of 10 micro m microbeads. The experiment was carried out as a small scale mesocosm study to mimic natural habitat. The beads were ingested by all animals in all experimental concentrations (5, 50 and 250 beads mL⁻¹). Bivalves (Mytilus trossulus, Macoma balthica) contained significantly higher amounts of beads compared with the other groups. Free-swimming crustaceans ingested more beads compared with the benthic animals that were feeding only on the sediment surface. Ingestion of the beads was concluded to be the result of particle concentration, feeding mode and the encounter rate in a patchy environment.

Seth, C. K. and A. Shriwastav (2018). "Contamination of Indian sea salts with microplastics and a potential prevention strategy." Environmental Science & Pollution Research **25**(30): 30122-30131.

This study reports the contamination of Indian sea salts with different microplastic particles, as a consequence of using contaminated sea water. Samples from all eight brands of investigated sea

salts were found contaminated, and concentrations of these particles ranged from 103 +/- 39 to 56 +/- 49 particles kg⁻¹ of salt. Both fibers and fragments were observed with large variation in size. Eighty percent of the extracted fibers and the fragments were smaller than 2000 mum and 500 mum respectively. Extracted particles were mostly polyesters, polyethylene terephthalate (PET), polyamide, polyethylene, and polystyrene. Their total mass concentration was also estimated as 63.76 mug kg⁻¹ of salt. These results are significant, since India is a leading producer and exporter of sea salts. A simple sand filtration of artificially contaminated sea water could effectively (> 85% removal by weight and > 90% removal by number) remove these microplastics and has the potential for preventing the transfer of microplastics into the salt from contaminated sea waters.

Sethi, N., et al. (2014). "Bone marrow micrometastases in head and neck squamous cell carcinoma: A pilot study." European Journal of Surgical Oncology **40 (11)**: S121-S122.

Background: The survival of patients with head and neck squamous cell carcinoma (HNSCC) is catastrophically affected by locoregional recurrence and distant metastases. Despite the appearance of adequately treated disease recurrence and metastases occur. Disseminated tumour cells (DTCs) may be the cause for this. Developing techniques to detect DTCs and establishing their significance could enable clinicians to identify patients who could benefit from additional systemic therapy. This study aimed to determine whether bone marrow micrometastases (BMM) could be identified by immunocytochemical methods and if there was any correlation, in this small group, with histological characteristics of the tumour. Material(s) and Method(s): After obtaining ethical approval, patients diagnosed with primary T2-T4 HNSCC were recruited. All patients underwent bone marrow aspiration whilst under general anaesthetic for surgical treatment of their primary tumour. The bone marrow specimens underwent immunomagnetic separation with MACS CD45 microbeads and subsequent immunostaining with Rabbit antimouse Ig, Streptavidin AB complex and Fast Red TR/Naphthol AS dye. Result(s): Fourteen patients were included in the study (10 male, 4 female). All patients underwent tumour resection and neck dissection as primary treatment. Four patients had evidence of BMM. We found a strongly suggestive correlation between nodal extracapsular spread (ECS) and BMM. All 4 patients with BMM also had nodal ECS. Only 1 patient had nodal ECS without the presence of BMM. Conclusion(s): The correlation between BMM and ECS in this pilot study suggests that BMM could be of significance. ECS is well established as a significant negative prognosticator in HNSCC. Further study is required with larger numbers of patients. Developing the identification of BMM could help guide chemotherapeutic therapies in patients at risk of recurrence and distant metastases.

Setty, C. M., et al. (2014). "Hydrolyzed polyacrylamide grafted maize starch based microbeads: application in pH responsive drug delivery." International Journal of Biological Macromolecules **70**: 1-9.

The present study details the synthesis, characterization and pharmaceutical application of hydrolysed polyacrylamide grafted maize starch (HPam-g-MS) as promising polymeric material for the development of pH responsive microbeads. Different grades of graft copolymer were synthesized by changing the net microwave irradiation time, while keeping all other factors constant. Acute oral toxicity study performed in rodents ensured the bio-safety of graft copolymer for clinical application. Various batches of aceclofenac loaded microbeads were prepared by ionic gelation method using synthesized graft copolymers and evaluated for formulation parameters. FTIR spectroscopy confirmed the chemical compatibility between drug and graft copolymer.

Seuront, L. (2018). "Microplastic leachates impair behavioural vigilance and predator avoidance in a temperate intertidal gastropod." Biology Letters **14**(11).

Microplastics are a ubiquitous source of contaminations in marine ecosystems, and have major implications for marine life. Much effort has been devoted to assessing the various effects of microplastics on marine life. No evidence exists, however, on the effects of microplastic leachates on chemically mediated predator-prey interactions and the ability of prey to detect and avoid its predator. This study shows that microplastic leachates have direct biological effects by disturbing the behavioural response of the intertidal gastropod Littorina littorea to the presence of Carcinus maenas chemical cues, hence increasing their vulnerability to predation. Leachates from virgin and beached pellets respectively impaired and inhibited L. littorea vigilance and antipredator behaviours. These results suggest that the biological effects from microplastic leachates may have major implications for marine ecosystems on taxa that rely on chemosensory cues to escape predation.

Seval, G. C., et al. (2019). "Next generation sequencing may be helpful in designing novel combinations among heavily pretreated myeloma patients, refractory to all available approved anti-myeloma drugs." Blood. Conference: 61st Annual Meeting of the American Society of Hematology, ASH **134**(Supplement 1).

Introduction: Multiple genetic alterations that occur at diagnosis or relapse are not only prognostic characteristics of multiple myeloma (MM) but also provide evidence for clonal evolution. Uncovering and dissecting true driver events in MM might provide rational for new potential targets and therapeutic approaches. However, whereas genetic diagnostics in MM namely FISH and gene expression profiling are well-established prognostic tools, individual mutation profiling has not yet been adopted for this purpose. Herein, we aimed to analyze the Next Generation Sequencing (NGS) platform results investigating mutational profiling of patients with relapsed and refractory MM (RRMM). Also, the clinical results of those who had a targetable mutation and were treated "off label" will be presented. Material(s) and Method(s): A total of 14 consecutive patients with MM referred to our center between November 2018 and May 2019 were studied. Plasma cells were isolated from bone marrow samples using Selection Kit microbead specific for EasySepTM Human CD138 marker (StemCell Technologies). DNA extracted form magnetic bead enriched cells, bone marrow aspiration smears for bone marrow involved, from FFPE tissue samples for extramedullary-involved cases. NGS method was performed on llumina Miseq platform (USA) by using QIAseq targeted DNA panel (12)- Human myeloid neoplasm panel, covers all exons and exon-intron junctions of 141 target genes. For the data analysis QCI Analyze Universal 1,5.0 was performed. The PCL analysis was performed on CD138 and Ki67 double immune stained paraffin sections, and the quantification was done by using 3DHistech digital pathology platform. Result(s): We obtained 16 samples of DNA from 12 heavily pretreated and two newly diagnosed myeloma patients. Female/male: 5/9 with a median age of 57 years (range, 39-87) patients had received a median four lines (range; 1-13) of treatment. Out of a panel of 141 genes, 59 mutations in 26 genes were detected (Figure-1). Among these recurrent genomic abnormalities, concomitant missense protein coding alterations were detected in all patients. The PTEN mutation was the most frequently detected, followed by mutations of RAS/MAPK pathway genes. The hotspots of mutation in KRAS codon 61 and NRAS included codons 61 and 13 as well as codon 600 in BRAF. In addition, we detected novel ie myeloproliferative and myelodysplasia associated mutations previously undescribed in myeloma. A diverse range of recurrent gains and losses were detected in our cohort. Two patients at diagnosis also carried mutations of PTEN and KRAS. Based on these results three patients were able to obtain off-label approval for treatment with Everolimus (for PTEN)

(Patient-1) or Trametinib (for KRAS) (Patient 5 & 6) in combination with Pomalidomide (EvoPomDex) w/wo Daratumumab or Tra-PomDex. Patient-1 had extensive extramedullary disease (EMD) in the skin, which responded completely to Dara-EvoPomDex combination. Complete disappearance of initial lesions (presented in Figure-2) and VGPR duration was only two months. Subsequent refractoriness and appearance of new lesions lead to death of the patient, one year from the initiation of EMD. Patient-6, also presented with EMD, was treated with TraPomDex as the seventh treatment line. TraPomDex treatment was well tolerated, the most significant adverse event diarrhea, infections and pancytopenia. Her biochemical response was a transient VGPR, which was lost during interruption of treatment due to infection. She also died four months after initiation of TraPomDex. Patient-5, plasma cell leukemia, has been on Tra-PomDex for a month and his response is PR yet. Conclusion(s): The detection of mutations can improve our ability to treat multiple refractory patients who have ran out of all therapeutic options. Though the responses observed among such very heavily pretreated patients are not durable, they are highly promising. Also, of additional importance is detection of age-related cumulative mutations belonging to background bone marrow precursors. Detection of sub-clonal mutations is very helpful in depth analysis of clonal response to treatment and clonal evolution. In the coming years, the identification of actionable mutations in myeloma opens the way for targeted therapy. (Figure Presented).

Sevigne-Itoiz, E., et al. (2015). "Contribution of plastic waste recovery to greenhouse gas (GHG) savings in Spain." Waste Management **46**: 557-567.

This paper concentrates on the quantification of greenhouse gas (GHG) emissions of post-consumer plastic waste recovery (material or energy) by considering the influence of the plastic waste quality (high or low), the recycled plastic applications (virgin plastic substitution or non-plastic substitution) and the markets of recovered plastic (regional or global). The aim is to quantify the environmental consequences of different alternatives in order to evaluate opportunities and limitations to select the best and most feasible plastic waste recovery option to decrease the GHG emissions. The methodologies of material flow analysis (MFA) for a time period of thirteen years and consequential life cycle assessment (CLCA) have been integrated. The study focuses on Spain as a representative country for Europe. The results show that to improve resource efficiency and avoid more GHG emissions, the options for plastic waste management are dependent on the quality of the recovered plastic. The results also show that there is an increasing trend of exporting plastic waste for recycling, mainly to China, that reduces the GHG benefits from recycling, suggesting that a new focus should be introduced to take into account the split between local recycling and exporting.

Seymour, K., et al. (2000). "Extending the indications for curative liver resection by portal vein embolization." British Journal of Surgery **87**(3): 362-373.

AIMS: The aim of ipsilateral portal vein embolization is to induce hypertrophy of normal tissue when resection of a cancerous portion of the liver is contraindicated only by the volume of liver that would remain following surgery. This study reports its use in primary and metastatic liver tumours.

Sfriso, R., et al. (2016). "Growth hormone receptor knockout on porcine endothelial cells: Effect on complement and coagulation." Transplantation **100 (7 Supplement 1)**: S241.

Background: Growth hormone insensitivity (GHI) is a group of inherited disorders characterized by a reduction or absence of signaling triggered by growth hormone (GH). Laron syndrome - a classical example of GHI - is caused by mutations in the growth hormone receptor (GHR) gene

and it is characterized by dwarfism. GHR knockout (GHRKO) pigs have already been produced and due to the smaller size of their organs they might be suitable candidates for xenotransplantation. Furthermore, Laron syndrome affected people are protected from vascular diseases such as atherosclerosis and type II diabetes. For that reason this study aims to screen whether the GHRKO phenotype may help to prevent vascular disorders in the context of delayed xenograft rejection. Method(s): An immortalized porcine aortic endothelial cell line lacking alphaGal expression (PED GalTKO) was further modified by knocking out the GHR gene. The resulting cell line, PED GalTKO/GHRKO, was used in vitro to assess the effect of GHR deletion in a xenotransplantation setting. After transformation, cells were characterized by immunofluorescence (IF) for expression of endothelial cell markers such as CD31, VE-cadherin and von Willebrand Factor (vWF). Cell ELISA was carried out to screen the effect of the GHR deletion on deposition of complement (C3b/c and C4b/c) and immunoglobulins after incubation with pooled normal human serum. In order to evaluate whether GHRKO affects coagulation, a whole blood clotting assay was performed using endothelial cell-coated microcarriers. Result(s): PED GalTKO/GHRKO present a clear endothelial phenotype, undistinguishable from the original PED GalTKO. A strong expression of CD31, vWF, VE-cadherin, and heparan sulfate proteoglycans was observed by immunofluorescence. Cell ELISA after incubation with pooled normal human serum showed significantly lower IgM, IgG and C3b/c deposition compared to wild type porcine endothelial cells. Binding of immunoglobulins and complement were similar to the PED GalTKO cell line. Furthermore, PED GalTKO/GHRKO cells grown on microbeads significantly delayed the clotting time of freshly drawn, whole, non anticoagulated human blood as compared to wild type porcine endothelial cells (53 +/- 21 min vs. 19.8 +/- 7 min). These data are similar to the what was observed for the original PED GalTKO cell line (50 +/- 31.8 min). Conclusion(s): Our data show that GHR deficiency on porcine endothelial cells with GalTKO background preserved the endothelial phenotype. No differences in immunoglobulin binding, complement deposition or anticoagulant properties were observed as compared with the original PED GalTKO cell line. The used in vitro tests did not reveal a significant benefit of the growth hormone receptor knockout with respect to the anticoagulant properties of the endothelial cells and in vivo experiments may be needed to provide a better understanding of the long term effects of this phenotype on coagulation.

Sfriso, R., et al. (2016). "Activation of complement and coagulation in xenotransplantation: Effect of growth hormone receptor knockout on porcine aortic endothelial cells." Immunobiology **221 (10)**: 1174-1175.

Background: The phenotypic outcome of a mutation in the growth hormone receptor (GHR) gene - the Laron syndrome - is severe postnatal growth retardation and insulin-like growth factor-I deficiency despite high levels of serum GH. In the context of xenotransplantation the absence of GHR signaling might be beneficial because Laron pigs can be suitable donors due to their small organ sizes. In addition, people affected by the Laron syndrome have a reduced occurrence of cardiovascular diseases. This study therefore aimed at investigating whether the GHRKO phenotype may alter endothelial activation induced by pro-inflammatory stimuli in the context of delayed xenograft rejection. Method(s): Immortalized porcine aortic endothelial cells lacking alphaGal and GHR expression (PED GalTKO/GHRKO) were obtained after induction of a GHR gene mutation on the original PED GalTKO. The endothelial cell phenotype was assessed by immunofluorescence, assuring the expression of endothelial cell markers such as CD31, VE-cadherin and von Willebrand Factor (vWF). A cell ELISA was carried out in order to evaluate the effect of the GHR deletion on deposition of complement (C3b/c, C4b/c) and human antibodies (IgM, IgG) after incubation with pooled normal human serum. Effects on coagulation

were also assessed performing whole blood clotting assays using endothelial cell-coated microcarriers. Result(s): A strong expression of CD31, vWF, VE-cadherin, and heparan sulfate proteoglycans on PED GalTKO/GHRKO was observed by immunofluorescence. Significantly lower IgM, IgG, C3b/c and C4b/c deposition was observed on PED GalTKO and PED GalTKO/GHRKO compared to wild type porcine endothelial cells. Furthermore, growth hormone resistant cells grown on microbeads significantly delayed the clotting time of freshly drawn, whole, non anticoagulated human blood as compared to wild type porcine endothelial cells (53+/-21 min vs. 19.8+/-7 min). However, clotting times were not different from what was observed for the original PED GalTKO cell line (50+/-31.8 min). Conclusion(s): Our data show that the endothelial phenotype on GalTKO/GHRKO porcine aortic endothelial cells is preserved. So far the used in vitro tests did not reveal a significant benefit of the growth hormone receptor knockout with respect to the anticoagulant properties of the endothelial cells. Other experiments are ongoing in order to test the effect on endothelial activation induced by proinflammatory cytokines.

Sgier, L., et al. (2016). "Flow cytometry combined with viSNE for the analysis of microbial biofilms and detection of microplastics." Nature communications **7**: 11587.

Biofilms serve essential ecosystem functions and are used in different technical applications. Studies from stream ecology and waste-water treatment have shown that biofilm functionality depends to a great extent on community structure. Here we present a fast and easy-to-use method for individual cell-based analysis of stream biofilms, based on stain-free flow cytometry and visualization of the high-dimensional data by viSNE. The method allows the combined assessment of community structure, decay of phototrophic organisms and presence of abiotic particles. In laboratory experiments, it allows quantification of cellular decay and detection of survival of larger cells after temperature stress, while in the field it enables detection of community structure changes that correlate with known environmental drivers (flow conditions, dissolved organic carbon, calcium) and detection of microplastic contamination. The method can potentially be applied to other biofilm types, for example, for inferring community structure for environmental and industrial research and monitoring.

Shadfan, B., et al. (2013). "Multiplexed detection of early-stage ovarian cancer biomarkers using a microfluidic bead-based immunosensor." Cancer Research. Conference: 104th Annual Meeting of the American Association for Cancer Research, AACR **73**(8 SUPPL. 1).

The high mortality rate of ovarian cancer is directly related to the lack of an effective screening strategy, as up to 90% of cancers that have not metastasized beyond the ovaries can be treated effectively using current strategies. While the biomarker CA125 has been used with some success for detecting ovarian cancer, additional biomarkers can increase the sensitivity and specificity of an ovarian cancer diagnostic test. Here, a panel of 4 biomarkers, CA125, HE4, CA72-4 and MMP-7, has been multiplexed with the programmable Bio-Nano-Chip (p-BNC). A rapid, precise and multiplexable diagnostic system will more successfully validate these suspected biomarkers over traditional methods by utilizing less volume of precious clinical samples and significantly reducing assay times. Additionally, the p-BNC has potential to provide a method for the point-of-care analysis of patients' health, reducing costs and turn-around times for results. This system utilizes antibodies on nano-nets of agarose microbeads to capture protein biomarkers for a fluorescence-based sandwich immunoassay. By housing the microbeads in individual addressable wells that allow for the sample and reagents to pass through the porous agarose, multiple biomarkers can be analyzed in a single assay. The in-development disposable microfluidic card is utilized to control sample and reagent processing and allows the fluid to interact with the beads, as well as contains all biowaste for safer disposal.

Low limits of detection (LODs) and high precision have been achieved using the p-BNC with a short analysis time under an hour, confirming its ability to be used for measuring biomarker levels in the physiological rage. Dose response curves of the four individual biomarkers are performed on the p-BNC system and are compared to the multiplexed dose response curve to ensure minimal cross-reactivity between biomarker reagents. Additionally, all four biomarker assays are compared to EIA using late-stage clinical samples to validate the system's diagnostic value. Concurrently, samples from patients separated into blood, plasma and serum are being used to determine the feasibility of a finger-stick assay for the ovarian cancer biomarkers. A novel card for the p-BNC is now in development for analyzing finger-stick quantities of blood and is being demonstrated to work effectively with high concentrations as a proof of concept. The p-BNC shows strong promise to be an effective system capable of the multiplexed analysis of ovarian cancer biomarkers and now a retrospective trial in collaboration with MD Anderson and UKCTOCS is underway to create a risk of ovarian malignancy algorithm by utilizing pre-clinical sera from 50 patients destined to develop ovarian cancer.

Shah, A. A., et al. (2008). "Biological degradation of plastics: A comprehensive review." Biotechnology Advances **26**(3): 246-265.

Abstract: Lack of degradability and the closing of landfill sites as well as growing water and land pollution problems have led to concern about plastics. With the excessive use of plastics and increasing pressure being placed on capacities available for plastic waste disposal, the need for biodegradable plastics and biodegradation of plastic wastes has assumed increasing importance in the last few years. Awareness of the waste problem and its impact on the environment has awakened new interest in the area of degradable polymers. The interest in environmental issues is growing and there are increasing demands to develop material which do not burden the environment significantly. Biodegradation is necessary for water-soluble or water-immiscible polymers because they eventually enter streams which can neither be recycled nor incinerated. It is important to consider the microbial degradation of natural and synthetic polymers in order to understand what is necessary for biodegradation and the mechanisms involved. This requires understanding of the interactions between materials and microorganisms and the biochemical changes involved. Widespread studies on the biodegradation of plastics have been carried out in order to overcome the environmental problems associated with synthetic plastic waste. This paper reviews the current research on the biodegradation of biodegradable and also the conventional synthetic plastics and also use of various techniques for the analysis of degradation in vitro. Shah, S. K., et al. (2016). "Oral control release microparticulate drug delivery study of aceclofenac using natural polymer." Asian Journal of Pharmaceutical and Clinical Research **9**(3).

Objective: The present study was to prepare controlled release microsphere of aceclofenac using sodium alginate as a natural polymer. Method(s): Microspheres of the Aceclofenac sodium by ionotropic gelation technique using sodium alginate as hydrophilic carrier and three different cross-linking agent in various proportions and different condition drying, and examines the influences of various process such as drugs polymer ratio, different concentration of cross

linkage agents, drying condition, and cross-linking time on physicochemical properties of drug loaded microbeads. Result(s): Formulated drug loaded microbeads were investigated for physicochemical properties and drug release potential. All investigated properties showed satisfactory results. While increasing in the concentration of sodium alginate, and barium chloride cross-linking time increased sphericity, size distribution, flow properties, mean particle size, swelling ratio, and drug entrapment efficiency. No significant effect of drug polymer interactions was observed in Fourier transform infrared studies. The drug entrapment efficiency obtained in the range of 97.59-99.88. The particle size of drug loaded formulations was measured by an optical microscope. The mean particle size of drug-loaded microbeads was found to be in the range 948.555+/-1.673 to 998.41+/-0.428. The shape and surface characteristics were determined by scanning electron microscopy using gold sputter technique. In-vitro drug release profile of aceclofenac sodium from microbeads was examined in simulated gastric fluid pH 1.2 for initial 2 hrs mixed phosphate buffer pH 6.8 up to 6 hrs and simulated intestinal pH 7.4 at the end of 24 hrs studies. The release of drug from the microbeads was pH dependent, showed negligible drug release in pH 1.2. Under pH 7.4 conditions the beads will swell, and the drug release depends on the swelling and erosion process resulting the optimum level of drug released in a sustained manner and exhibited zero-order kinetics. Conclusion(s): Result of studies this system was able to prolong the drug release, minimizing the drug-related adverse effects and improve bioavailability in different GI-tract conditions. Shahar, E., et al. (2010). "Targeted microbeads for attraction and induction of specific innate immune response in the tumor microenvironment." Vaccine **28**(45): 7279-7287.

Antitumor activity of molecules and cells of the innate immune system has been reported. Here we propose a method for targeting preferred innate immune cells and magnifying their tumoricidal effect at the tumor microenvironment, by modular multiple-component complexes (termed TILTAN). As a model, micro-scale complexes were assembled carrying monoclonal anti-HER2 antibodies, lipopolysaccharide and/or mannose. The complexes showed high binding capacity to HER2-positive cancer cells in vitro, high induction of interleukin-1 RNA transcription by the activated monocytes and ability to mediate monocytes' attachment to HER2-positive cells. TILTAN treatment was found safe in in vivo testing and induced change in interleukin-1 RNA transcription in tumors xenografts. We thus present a new vision of targeting a desired innate immune response to the tumor microenvironment.

Shahnawaz, M., et al. (2016). "Rhizosphere of Avicennia marina (Forsk.) Vierh. as a landmark for polythene degrading bacteria." Environmental Science & Pollution Research **23**(14): 14621-14635.

Due to high durability, cheap cost, and ease of manufacture, 311 million tons of plastic-based products are manufactured around the globe per annum. The slow/least rate of plastic degradation leads to generation of million tons of plastic waste per annum, which is of great environmental concern. Of the total plastic waste generated, polythene shared about 64 %. Various methods are available in the literature to tackle with the plastic waste, and biodegradation is considered as the most accepted, eco-friendly, and cost-effective method of polythene waste disposal. In the present study, an attempt has been made to isolate, screen, and characterize the most efficient polythene degrading bacteria by using rhizosphere soil of Avicennia marina as a landmark. From 12 localities along the west coast of India, a total of 123 bacterial isolates were recorded. Maximum percent weight loss (% WL; 21.87 +/- 6.37 %) was recorded with VASB14 at pH 3.5 after 2 months of shaking at room temperature. Maximum percent weight gain (13.87 +/- 3.6 %) was reported with MANGB5 at pH 7. Maximum percent

loss in tensile strength (% loss in TS; 87.50 +/- 4.8 %) was documented with VASB1 at pH 9.5. The results based on the % loss in TS were only reproducible. Further, the level of degradation was confirmed by scanning electron microscopic (SEM) and Fourier transform infrared spectroscopy (FTIR) analysis. In SEM analysis, scions/crakes were found on the surface of the degraded polythene, and mass of bacterial cell was also recorded on the weight-gained polythene strips. Maximum reduction in carbonyl index (4.14 %) was recorded in untreated polythene strip with Lysinibacillus fusiformis strain VASB14/WL. Based on 16S ribosomal RNA (rRNA) gene sequence homology, the most efficient polythene degrading bacteria were identified as L. fusiformis strainVASB14/WL and Bacillus cereus strain VASB1/TS.

Shahul Hamid, F., et al. (2018). "Worldwide distribution and abundance of microplastic: How dire is the situation?" Waste Management and Research **36**(10): 873-897.

The widespread occurrence of microplastic has invaded the environment to an extent that it appears to be present throughout the globe. This review investigated the global abundance and distribution of microplastics in marine and freshwater ecosystems. Furthermore, the issues and challenges have been addressed for better findings in microplastics studies. Findings revealed that the accumulation of microplastics varies geographically, with locations, hydrodynamic conditions, environmental pressure, and time. From this review, it is crucial that proper regulations are proposed and implemented in order to reduce the occurrence of microplastics in the aquatic environment. Without appropriate law and regulations, microplastic pollution will eventually threaten human livelihood. Copyright © The Author(s) 2018.

Shahzad, M. I., et al. (2010). "Plasmid based DNA vaccines against tuberculosis." International Journal of Infectious Diseases **2)**: S22-S23.

TB is a pre-historic disease and it is a significant cause of morbidity and mortality in human and cattle, in many parts of world. The problem has further exacerbated due to emergence of increasingly more resistant strains of M. tb and failure of BCG vaccine. By keeping in view, DNA vaccination which is more efficacious and cost effective way to protect against TB, six M. tb genes (hspx, cfp10, ag85a, ag85b, ag85c and esat6) were selected and used in this study. The genes were cloned in pcDNA3.1 Topo (Invitrogen, USA) vector with Kozak sequences upstream the ATG and finally ligated in pND-a mammalian expression vector. The cell line expression of the conscructs were checked by Western blots analyses. All of the M. tb gene constructs in pND gave good expression under in vitro conditions except esat6 gene. The endotoxin free pND-M. tb gene constructs were subjected to eight weeks old female Balb/c mice @ of 50 mg DNA/leg intramuscularly and 25 mg interdermally. The animals were divided into six groups including positive and negative control groups. Eight animals were used for hspx-pND vaccine, eight for cfp10-pND vaccine, two for esat6-pND vaccine and two for equally mixed (ag85a, b and c)-pND vaccines. Blood collection was done by tail bleeding and cardiac puncture. The antibodies were confirmed by Western blots and Multiplex Microbead Assay (MMA). The best humoral response was shown by hspx-pND vaccinated animals both on Western blots and MMA. Fairly positive response was obtained in animals vaccinated with esat6-pND14 and (ag85 a, b and c)-pND vaccines. Whereas undetectable level of antibodies from cfp10-pND vaccinated animals were produced. In general the results of this study are promising but need more animal studies before the constructs go to clinical trials.

Shahzad, M. I., et al. (2013). "Cloning, expression and genetic immunization studies of Mycobacterium tuberculosis gene esat6." Pakistan Journal of Zoology **45**(3): 749-757.

Early secreted antigenic target protein 6 (esat6) is one of the genes present on region of difference 1 (RD1) of Mycobacterium tuberculosis (M. tb) genome. This RD1 is a characteristic of virulent strains of M. tb and Mycobacterium bovis and this is one of the major differences between the disease causing strains and Bacillus-Calmat Guerin (BCG) vaccine strains. Studies have proved the presence of large number of memory T cells in M. tb infected individuals and these memory cells are reactive towards Esat6 antigen, which highlighted the importance of this gene especially in early infections. In this study, numbers of esat6 gene constructs were made in order to get a suitable construct to be used as good DNA vaccine. First esat6 gene construct was made in pND vector without Kozak sequence upstream the gene, second construct was made in pcDNA3.1 vector with Kozak sequence upstream the gene, third construct was made again in pND vector with Kozak sequence, fourth construct was made with Kozak sequence upstream and GGG downstream the ATG as a second codon of gene first in pcDNA3.1 and later in pND vectors respectively which was designated as construct five. Sixth construct was a fusion and in pcDNA3.1 vector with Kozak upstream the gene and epitope V and poly histidine tail sequence provided by vector down stream the gene through inframe cloning of esat6 gene with sequences provided by vector by removing stop codon through PCR based primers. Seventh and final construct was prepared in pND14 vector also as a fusion construct and gene was cloned under tissue plasminogen activator sequence in an in-frame through PCR based primers. All these constructs were subjected to 293T human embryonic kidney cell lines to evaluate their level of expression. Although none of the constructs gave detectable level of expression in cultured cells when tested through Western blots (WB) but tpa-esat6-pND14 construct was selected as potential DNA vaccine candidate to inject intramuscularly and interadermally to balb/c mice along with controls to obtain detectable response in vivo. Animals were tested nine weeks post vaccination and found positive against tpa-esat6-pND14 vaccine through WB and multiplex micro bead immunoassay (MMIA).

Shahzadi, K., et al. (2018). "Synthesis of Bupropion HCl Loaded Microspheres Using Microencapsulation Technique and Various Polymers and In Vitro Evaluation." Latin American Journal of Pharmacy **37**(8): 1541.

The aim of this study was to formulate and evaluate sustained release microspheres of bupropion HCl by using various polymers. Ionic gelation method was used for the preparation of microbeads. Eleven formulations were prepared by using different concentrations of polymers. Prepared microbeads were evaluated for FTIR, entrapment efficiency, SEM, % yield, flow properties and drug release studies. Rheological studies showed that microbeads exhibited good flow properties. FTIR spectra confirmed compatibility between drug and polymers. XRD analysis of bupropion HCl showed that drug was in amorphous state in microbeads. SEM results, %age yield and percentage entrapment efficiency of sodium alginate (NaAlg) microbeads and sodium alginate- guar gum (NaAlg-GG) beads was satisfactory. The swelling study indicated that microspheres initially swelled then swelling decreased with the passage of time. Release kinetics studies showed that bupropion HCl microspheres followed Korsmeyer-Peppas kinetic model and release mechanism of drug from microbeads was non fickian diffusion. Among different formulations, F9 formulation is the best formulation. This formulation contains NaAlg 3.5% w/v and GG 0.5% w/v. This formulation has better sustained release effect as compared to other formulations.Alternate abstract:El objetivo de este estudio fue formular y evaluar microesferas de liberación sostenida de bupropion HCl mediante el uso de varios polímeros. El método de gelificación iónica se usó para la preparación de microperlas. Se prepararon once formulaciones usando diferentes concentraciones de polímeros. Las microesferas preparadas se evaluaron por FTIR, eficiencia de atrapamiento, SEM,% de rendimiento, propiedades de flujo y estudios de liberación de fármacos. Los estudios reológicos mostraron que las microperlas exhibían buenas

propiedades de flujo. Los espectros FTIR confirmaron la compatibilidad entre el fármaco y los polímeros. El análisis por XRD de bupropion HCl mostró que el fármaco estaba en estado amorfo en las microperlas. Los resultados de SEM,% de rendimiento por edad y porcentaje de atrapamiento de microperlas alginato de sodio (NaAlg) y alginato de sodio-goma guar (NaAlg-GG) fueron satisfactorios. El estudio de hinchamiento indicó que las microesferas inicialmente se hincharon y luego la hinchazón disminuyó con el paso del tiempo. Los estudios de cinética de liberación mostraron que las microesferas de bupropión HCl seguían el modelo cinético de Korsmeyer-Peppas y que el mecanismo de liberación del fármaco de las microperlas era una difusión no fickiana. Entre las diferentes formulaciones, la formulación F9 es la mejor. Esta formulación contiene NaAlg- al 3,5% p/v y GG al 0,5% p/v. Esta formulación tiene un mejor efecto de liberación sostenida en comparación con otras formulaciones.

Shamsi, R., et al. (2019). "Hopes Beyond PET Recycling: Environmentally Clean and Engineeringly Applicable." Journal of Polymers & the Environment **27**(11): 2490-2508.

Disposal of plastics in the environment has become a core of anxiety in developing countries, while in the developed countries the focus has additionally been placed on design and manufacture of emerging products from plastic wastes—a somewhat vague yet promising horizon. Central to environmental concerns are poly(ethylene terephthalate) (PET) wastes, mainly from post-consumer bottles. Because of a considerable drop in molecular weight in the course of recycling, recycled PETs are not suitable for engineering uses. An efficient yet reasonably green synthesis route is employed here to convert PET wastes into polyurethane, and then carbon nanotubes (CNTs) was added at different levels to obtain nanocomposites with high mechanical properties. The effects of isocyanate (NCO)/hydroxyl (OH) molar ratio and CNTs content on the morphology, physical and mechanical properties were discussed. Chemical/physical crosslink density was calculated from initial slope of stress–strain curves, Mooney–Rivlin plots, strain-hardening modulus, rubbery-plateau storage modulus and swelling data. High tensile strength (300 MPa) and breaking elongation (160%) of polyurethane/CNTs nanocomposites born from PET wastes seemed promising. Microscopic analyses by AFM, SEM, and TEM gave useful information about distribution of CNTs in polyurethane. Lastly, structural changes were correlated to mechanical properties improvement. [ABSTRACT FROM AUTHOR]

Shan, J., et al. (2018). "A novel way to rapidly monitor microplastics in soil by hyperspectral imaging technology and chemometrics." Environmental Pollution **238**: 121-129.

Hyperspectral imaging technology has been investigated as a possible way to detect microplastics contamination in soil directly and efficiently in this study. Hyperspectral images with wavelength range between 400 and 1000nm were obtained from soil samples containing different materials including microplastics, fresh leaves, wilted leaves, rocks and dry branches. Supervised classification algorithms such as support vector machine (SVM), mahalanobis distance (MD) and maximum likelihood (ML) algorithms were used to identify microplastics from the other materials in hyperspectral images. To investigate the effect of particle size and color, white polyethylene (PE) and black PE particles extracted from soil with two different particle size ranges (1-5mm and 0.5-1mm) were studied in this work. The results showed that SVM was the

most applicable method for detecting white PE in soil, with the precision of 84% and 77% for PE particles in size ranges of 1-5mm and 0.5-1mm respectively. The precision of black PE detection achieved by SVM were 58% and 76% for particles of 1-5mm and 0.5-1mm respectively. Six kinds of household polymers including drink bottle, bottle cap, rubber, packing bag, clothes hanger and plastic clip were used to validate the developed method, and the classification precision of polymers were obtained from 79% to 100% and 86%-99% for microplastics particle 1-5mm and 0.5-1mm respectively. The results indicate that hyperspectral imaging technology is a potential technique to determine and visualize the microplastics with particle size from 0.5 to 5mm on soil surface directly.

Shang, X., et al. (2019). "Microplastic (1 and 5 mum) exposure disturbs lifespan and intestine function in the nematode Caenorhabditis elegans." Science of the Total Environment **705**: 135837.

As an emerging environmental pollutant, microplastics (MPs) are increasingly viewed as a serious health concern to terrestrial and aquatic ecosystems. However, previous toxicological studies examining MPs on freshwater and terrestrial organisms provide contradictory results, possibly due to few investigations at environmentally relevant concentrations. Here, the nematode Caenorhabditis elegans (C. elegans), a model organisms with both aquatic and terrestrial free-living forms, was employed to investigate the effects of 1 and 5 mum MPs (10⁷-10¹⁰ particles/m²) on the intake, lifespan, defecation rhythm, defecation-related neurons and transcriptional expression of related genes (skn-1, mkk-4, pmk-1, cpr-1 and itr-1). We demonstrated that the percentage of MP-contaminated nematodes increased with increasing exposure concentrations and duration. The lifespan of nematodes in the lower concentration exposure groups (2.4 x 10⁷ and 2.4 x 10⁸ particles/m²) decreased more prominently than that of higher concentration groups (2.4 x 10⁹ and 2.4 x 10¹⁰ particles/m²) after a 72-h exposure period. Concomitantly, expression of the skn-1 gene, involved in detoxification and lifespan regulation, was significantly altered at lower MP concentrations. Physiologically, the defecation rhythm after a 72-h exposure period was most strongly affected by 1 mum MPs at 2.4 x 10⁸ particles/m². The significant up-regulation of related genes by 1 mum MPs appears responsible for the shortened defecation interval.

Shanks, K., et al. (2019). "An experimental analysis of the optical, thermal and power to weight performance of plastic and glass optics with AR coatings for embedded CPV windows." Solar Energy Materials & Solar Cells **200**: 110027-110027.

A low concentrator photovoltaic is presented and the optical losses within a double glazed window assembly are described. The use of plastic instead of glass is analyzed for its reduced weight and hence greater power to weight ratios. Although the transmittance of glass is higher, the power to weight ratio of the plastic devices was almost double that of the glass counterparts and even higher than the original non concentrating silicon cell. The plastic Topas material was found to be the best performing material overall. Crystal Clear, a plastic resin, had a higher average transmittance but had a lower optical efficiency due to the cold cast manufacturing process in comparison to injection moulding of the other materials. This proves the importance of considering both the materials and their associated manufacturing quality. External quantum efficiencies, optical properties, silicon cell temperatures and performance is analyzed for concentrating photovoltaic devices made of varying optical materials. The measurement methods for optical analysis are given in an attempt to separate the optical losses experimentally. The Silicon cells were found to gain higher temperatures due to the insulating plastic optics in comparison to glass but these effects are eliminated during vertical window orientation where instead the encapsulate dominates the insulation of the cell. The results presented here prove plastic optics to be a worthwhile alternative to glass for use in low concentration photovoltaic systems and have the significant effect of reversing the weight disadvantage concentrator photovoltaic technology has compared to standard flat plate solar panels. • New options for plastic materials, manufacturing processes and antireflection coatings are presented. • Practical methods for ascertaining the optical losses of manufactured optics are described. • Topas is the most suitable plastic material for refractive LCPV optics and gave the highest performance. • The Topas CPV prototype had a higher power to weight ratio than the flat plate Silicon cells used for comparison. [ABSTRACT FROM AUTHOR]

Shantha Kumara, M. C., et al. (2013). "Microarray analysis of T-lymphocyte gene expression after colorectal resection." Gastroenterology **1)**: S1134.

Introduction: Previous studies have established that surgical trauma is associated with significant transient alterations in cell-mediated immune function. Surgery-related immunosuppression may impact the patient's ability to deal with infection. Also, tumor growth has been shown in murine studies to be increased after surgical trauma. Cell-mediated immunosuppression after resection of a primary tumor may impair the host's ability to eradicate or contain residual tumors cells. This microarray study of perioperative T-lymphocyte (TLC) gene expression was undertaken in an effort to better understand the impact of colorectal resection (CR) on cell-mediated immune function. Method(s): Patients who underwent elective laparoscopic right hemicolectomy (RHC) for benign colonic disease (BCD) who had enrolled in an IRB approved blood/data bank for whom frozen pre- and postoperative TLC's were available were eligible for this study. Benign pathology patients were chosen in order to determine the impact of surgical trauma alone, independent of the potential effects of a cancer on immune function. Preoperative (PreOp) and postoperative day1 (POD1) blood samples were utilized. TLC's were isolated from the blood using a combination of gradient centrifugation and magnetic micro-bead separation. TLC's were subsequently lysed and total RNA extracted. cRNA was made from RNA hybridized to HG-U133APLUS oligonucleotide array. PreOp vs POD1 expression data was analyzed via Limma paired analysis to find differently expressed genes. (p>0.05 significant) and consistency of significance was analyzed via Empirical Bayes statistics (B>0 Sig.). Clinical data is presented as mean +/- SD. Result(s): Nineteen patients (12 males/7 female, mean age 65.8+/- 12.8 years) met the entry criteria. The mean incision length was 7.8+/- 3.5cm and mean length of stay was 6.3+/-2.6 days. All TLC expression data met the affymetrix data QC standards. A total of 39 genes showed significant changes on POD1; 21were up-regulated and 18 were down regulated (B=0.05- 5.3). The expression changes of 7 genes in this group were strongly significant (ABCG-1, TMEM49, FAM100B and PIM1 were upregulated and IFI44L, STAT1 and UCP2 were down regulated; P =0.02 and B =4.1-5.3). Enrichment analysis confirmed that these gene changes were likely to have significant effects on 7 signaling pathways and 3 functional categories i.e.; cell proliferation, hematological function and immune response. Conclusion(s): Surgical trauma affected gene expression of circulating TLC's in the immediate postoperative period. Altered gene expression may impact TLC growth and proliferation as well as immune

function. These changes must be validated at the protein level and additional patients studied. Also, the duration of these changes, after surgery, must be determined. Finally, a similar study in cancer patients is also needed.

Shao, F., et al. (2012). "Evaporative micro-particle self assembly influenced by capillary evacuation." Journal of Colloid & Interface Science **377**(1): 421-429.

As evaporation does not incur energy introduction, the droplet coffee-stain patterning approach is attractive for biochemical tests conducted in the field or in third world environments. A practical strategy uses chemically functionalized microbeads for the coffee stain deposition process. From an application perspective, it will be necessary to minimize the coffee stain deposition time, as evaporation, depending on the volume of the droplet, can be a slow process. The introduction of a porous media will generate a capillary flow (or wicking) that removes any remnant liquid in the droplet, thus permitting it to be done inexpensively and in the field. Using optical profilometry, we were able to establish that polystyrene microspheres developed more copious and defined single ring coffee depositions than silica of the same size and concentration in a suspension. In analyzing the droplet capillary evacuation process with a porous media, we found the liquid bridge formed during the later stages to rupture and leave behind some liquid material for a second stage evaporation process. This was responsible for a two ring structure that was more visible with silica microspheres. A high degree of hysteresis of the contact angle was found to develop at the contact line in which values below 5degree could be achieved. Dynamic observations showed the copious and dense packing of polystyrene particles to be more resistant to ring break up from the evacuation flow. Nevertheless, erosion of the back array portions of the ring was evident notwithstanding either type of microsphere used.

Shao, F., et al. (2012). "Bioparticles assembled using low frequency vibration immune to evacuation drifts." Review of Scientific Instruments **83**(8): 085115.

The use of low frequency vibration on suspensions of glass beads in a droplet has been shown to develop a strong degree of patterning (to a ring) due to the manner with which the surface waves are modified. Functionalized glass beads that serve as bioparticles permit for sensitive readings when concentrated at specific locations. However, a time controlled exposure with analytes is desirable. The replacement of the liquid medium with analyte through extraction is needed to conserve time. Nevertheless, we show here that extraction with a porous media, which is simple and useable in the field, will strongly displace the patterned beads. The liquid removal was found to be dependent on two mechanisms that affect the shape of the droplet, one of contact hysteresis due to the outer edge pinning, and the other of liquid being drawn into the porous media. From this, we developed and demonstrated a modified well structure that prevented micro-bead displacement during evacuation. An added strong advantage with this approach lies with its ability to require only analytes to be dispensed at the location of aggregated particles, which minimizes analyte usage. This was analytically established here.

Shao, H., et al. (2019). "Identification of signaling cascade in the insulin signaling pathway in response to nanopolystyrene particles." Nanotoxicology **13**(2): 174-188.

The molecular response of animals to nanoplastic particles is still largely unclear. In this study, we employed a modified prolonged exposure system to investigate the molecular response of Caenorhabditis elegans to nanopolystyrene particles. Exposure to nanopolystyrene particles (1 mug/L) significantly decreased expressions of daf-2 encoding an insulin receptor, age-1 encoding a PI3K, and akt-1 encoding an Akt/PKB, and increased expression of daf-16 encoding a FOXO transcriptional factor in insulin signaling pathway. Among these genes, mutation of daf-2, age-1,

or akt-1 induced a resistance to toxicity of nanopolystyrene particles, whereas mutation of daf-16 induced a susceptibility to the toxicity of nanopolystyrene particles. RNAi knockdown of daf-16 could further suppress the resistance of daf-2, age-1, or akt-1 mutant to the toxicity of nanopolystyrene particles. The insulin signaling pathway acted in intestinal cells to regulate the toxicity of nanopolystyrene particles. Moreover, sod-3 encoding a manganese superoxide dismutase, mtl-1 encoding a metallothionein, and gpd-2 encoding a glyceraldehyde-3-phosphate dehydrogenase were identified as downstream targeted genes for daf-16 in the regulation of toxicity of nanopolystyrene particles. Therefore, a signaling cascade of DAF-2-AGE-1-AKT-1-DAF-16-SOD-3/MTL-1/GPD-2 was identified in response to nanopolystyrene particles in nematodes. Additionally, this signaling cascade in the insulin signaling pathway may mediate a protective response for nematodes against the adverse effects from nanopolystyrene particles.

Shao, Z., et al. (2011). "Calcium-activated potassium channel KCa3.1 and chloride channels are involved in dendritic cell migration to lymph nodes." Journal of Allergy and Clinical Immunology **1)**: AB259.

RATIONALE: The role of ion channels is largely unknown in chemokineinduced migration in non-excitable cells such as dendritic cells (DC). In this study, the role of KCa3.1 and chloride channels was examined in DC migration to lymphatic chemokines. METHOD(S): Mouse CD11c-high and CD11c-low DCs were isolated from OVA-sensitized mouse lungs. Human DCs were obtained from peripheral blood mononuclear cells (PBMC) using anti-BDCA1 microbeads and AutoMACS, or derived from PBMC. KCa3.1 and CCR7 expression was determined using immunofluorescence and western blot. Labeled antigen was introduced into mouse lungs intranasally. Intracellular calcium was measured using flow cytometry. Chemotaxis in response to CCL19 and CCL21 was measured using Trans Well in the presence/absence of KCa3.1 blockers, TRAM-34 and charybdotoxin, or chloride channel blockers, NPPB and DIDS. RESULT(S): Mouse lung DC, human myeloid DC, and monocyte-derived DC expressed KCa3.1 protein. CCL19, CCL21, and KCa3.1 activator, 1-EBIO induced an increase in intracellular calcium. EBIO-induced calcium increase was abolished by TRAM-34 in mouse lung DCs. Ag-carrying lung DCs expressed significantly higher CCR7 than non-Ag-carrying DCs but KCa3.1 expression were similar. However, lung DCs from OVA-sensitized mouse expressed significantly higher KCa3.1 than those from non-sensitized mice. Blockade of KCa3.1 with TRAM-34 and/or charybdotoxin impaired CCL19/CCL21-induced transmigration with no toxicity observed. DIDS and NPPB impaired DC chemotaxis at a greater degree than KCa3.1 blockers but possibly caused remarkable changes in cell physiology. CONCLUSION(S): KCa3.1 is involved in DC migration through regulating membrane potential and calcium flux. Chloride channels regulate DC migration and may be predominantly involved in a broad range of cell functions.

Shao, Z., et al. (2013). "Increased population of myeloid-derived suppressor cells in patients with myelodysplastic syndromes overexpress ARG1 and mediate CD8+ T cell inhibition." Blood. Conference: 55th Annual Meeting of the American Society of Hematology, ASH **122**(21).

Objective To investigate the proportion and activation of myeloid- derived suppressor cells (MDSC) in bone marrow from patients with myelodysplastic syndromes (MDS). Methods The proportion of MDSC (Lin-HLA-DR-CD33+) in bone marrow of 30 MDS patients and 19 normal controls were measured by flow cytometry assay(FCM). MDSC and CD8+ T cell were isolated from bone marrow of 14 MDS patients and 14 normal controls among them by FCM and microbeads. The expressions of arginase 1(ARG1) and inducible nitric oxide synthase (iNOS) were analyzed by qPCR and western bolting. Co-cultures with CD8+ T cell were proved the MDSC-mediated inhibition of CD8+ T cell. Results MDS patient's median MDSC were 7.29%

which was higher than that of controls (2.91%). The expression of ARG1 and iNOS mRNA in MDSC of high-risk MDS patients was higher than that of low-risk MDS patients. But the protein of ARG1 was overexpressed rather than that of iNOS. After co-cultured, the apoptosis ratio of CD8+ T cells of MDS((64.17+/-4.86) %) was increased compared to pure CD8+ T cells ((54.58+/-9.95)%). Further more, the production of IFN-gammasecreted by CD8+ T cells co-cultured with MDSC ((551.94+/-47.39) pg/ml)was lower than that of pure CD8+ T cells ((586.04+/-46.65) pg/ml) There was no significant difference in level of TNF-betabetween co-cultured with MDSC and pure CD8+ cells. Conclusion The proportion of MDSC in bone marrow was increased significantly in MDS. MDSC overexpressed ARG1 in patients with MDS and correlated to the malignant degree of this disease. Further more, MDSC can increased the apoptosis ratio of CD8+ T cell, and inhibited the secretion of IFN-gamma. These findings suggested MDSC mediated the response of immunosuppression in MDS.

Sharifi, M., et al. (2017). "Identification and quantification of phthalate pollution in Holothuria atra: a sea cucumber from the Persian Gulf (Iran)." Jundishapur Journal of Natural Pharmaceutical Products **12**(4).

In recent years, microplastics have accumulated in oceans and sediments worldwide. Due to their small size, microplastics may be ingested by low trophic fauna, with uncertain consequences for the health of the organism. Sea cucumbers are one of the major echinoderms from the class Holothuroidea that ingest plasticizers in their mouth and filter the water. Regarding the recent interests on probable pollution of medicinal plants and other natural medicines, like marine organisms to phthalates, in this study a phthalate ester was isolated from Holothuria atra of Persian coasts for the first time. The structure of the compound was elucidated using spectroscopic data (IR, NMR and MS) and the compound was used as a standard for quantification of microplastic in H. atra, a marker of pollutant in the Persian Gulf. Quantification was done by high performance thin layer chromatography and the amount of bis (2-ethylhexyl) phthalate (BEHP) was 0.15+or-0.08 mg/g.

Sharma, H. K., et al. (2010). "Preparation and in vitro evaluation of enteric controlled release pantoprazole loaded microbeads using natural mucoadhesive substance from Dillenia indica L." International Journal of PharmTech Research **2**(1): 542-551.

Pantoprazole is a proton pump inhibitor prodrug used in the treatment of gastric ulcers and gastroesophageal disease. Pantoprazole must be absorbed in the gastrointestinal tract and because it is unstable under acidic conditions, enteric delivery systems are required. The purpose of this study was to prepare Pantoprazole loaded microbeads by ionotropic gelation technique using sodium alginate and natural Mucoadhesive substance from the fruit of Dillenia indica followed by a coating with Eudragit L100-55. The microspheres have been characterized in terms of their morphology, particle size, encapsulation efficiency, swelling ratio, mucoadhesivity and ability of stabilizing Pantoprazole in acidic media. Different formulation variables like polymer-polymer ratio, drug-polymer ratio and coating concentration were considered. Almost spherical microbeads were obtained with sufficient swelling, Mucoadhesive property and acid resistance. Dissolution study was followed at phosphate buffer (pH 7.4) for 8 hr.

Sharma, P. K. and R. Malviya (2015). "Effect of Calcium Chloride on Release Behavior of Babul (Acacia nilotica) gum Microbeads." Polimery W Medycynie **45**(2): 67-72.

BACKGROUND: Oral delivery of drugs is the most common method, but due to the inability of drugs to restrain and localize in the gastro-intestinal tract, oral administration of drugs in

conventional dosage forms have short-term limitations. Carrier technology may provide many approaches for the delivery of drugs by coupling the drug to a carrier particle, such as Microspheres, nanoparticles and liposomes, which modulate the release and absorption characteristics of the drug.

OBJECTIVES: The aim of this study was to prepare Diclofenac sodium microspheres using a natural polymer and show the effect of calcium chloride on the release behavior of microspheres. The microspheres of Diclofenac sodium were successfully developed by ionic gelation technique using natural polymer babul gum with sodium alginate.

MATERIAL AND METHODS: Diclofenac Sodium was received as a gift sample from Aegis Pharmaceuticals Pvt. Ltd., Roorkee. Acacia nilotica gum was purchased from Ghaziabad and purification was done in the laboratory. All other excipients used analytical grade method. The microspheres of diclofenac sodium were prepared by Ionic gelation method using a natural polimer, i.e. Acacia nilotica. Calcium chloride (5% solution) was used as a cross-linking agent. In this research article all the data was presented as averages and standard deviations.

RESULTS: Five formulations were successfully prepared, i.e. F1, F2, F3, F4 and F5. All the formulations were evaluated for micromeritic properties, particle size analysis, percentage yield, drug content, drug entrapment efficacy, percent moisture loss, swelling index and in vitro dissolution studies. The size of the microspheres varied between 14.55 +/- 0.29 to 20.18 +/- 0.15 mum and as high as 81.51 +/- 0.14% entrapment efficiency for babul gum was obtained.

CONCLUSIONS: Batch F1 and F5 was found to release the drug 91.35% and 75.48% respectively for 6 hrs. The formulations were found to be effective in providing controlled release of drug for a prolonged period of time.

Sharma, R. K., et al. (2010). "Bevacizumab therapy normalizes the pathological intraocular environment beyond neutralizing VEGF." Molecular Vision **16**: 2175-2184.

PURPOSE: Vascular endothelial growth factor (VEGF) plays a key role in neovascularization by stimulating the proliferation and migration of vascular endothelial cells. The anti-VEGF therapy bevacizumab acts by binding to VEGF and preventing its effects. However, this linear interaction represents only a partial view of the pathobiology of neovascular diseases and the anti-VEGF treatment. To obtain an integrated view of the processes involved in VEGF-related ocular pathologies, we applied a systems approach and investigated whether intravitreal bevacizumab injections have a global effect in normalizing the ocular physiology perturbed by the disease.

METHODS: We analyzed 90 analytes representing various pathophysiological processes in aqueous humor. The samples were obtained from eight patients receiving intravitreal bevacizumab injections for various ocular VEGF-related conditions. The samples were obtained before and after the injection and were analyzed using microbead technology developed by Luminex xMAP.

RESULTS: Forty-three analytes were detected above the sensitivity of the assay both in pre- and post-injection samples. Of these, normal values of 41 analytes were known and these analytes were further analyzed. The detected analytes included relevant markers such as VEGF, C reactive protein, glutathione, and cytokines. We identified 24 markers that were perturbed more than 1.5 fold in diseased samples (pre-injection) compared to normal levels. The levels of perturbed analytes were compared in post-treatment samples. The results demonstrated an unequivocal trend toward normalization in post-treatment samples.

CONCLUSIONS: Our results show intraocular bevacizumab injections change the perturbed physiologic environment of the eye toward normalization. Its effects reached beyond neutralizing VEGF. The results also demonstrate that large-scale analysis of the aqueous, using a systems approach, could provide useful insight regarding ocular diseases, their pathophysiologies, and treatment responses.

Sharma, S. and S. Chatterjee (2017). "Microplastic pollution, a threat to marine ecosystem and human health: a short review." Environmental Science & Pollution Research **24**(27): 21530-21547.

Human populations are using oceans as their household dustbins, and microplastic is one of the components which are not only polluting shorelines but also freshwater bodies globally. Microplastics are generally referred to particles with a size lower than 5 mm. These microplastics are tiny plastic granules and used as scrubbers in cosmetics, hand cleansers, air-blasting. These contaminants are omnipresent within almost all marine environments at present. The durability of plastics makes it highly resistant to degradation and through indiscriminate disposal they enter in the aquatic environment. Today, it is an issue of increasing scientific concern because these microparticles due to their small size are easily accessible to a wide range of aquatic organisms and ultimately transferred along food web. The chronic biological effects in marine organisms results due to accumulation of microplastics in their cells and tissues. The potential hazardous effects on humans by alternate ingestion of microparticles can cause alteration in chromosomes which lead to infertility, obesity, and cancer. Because of the recent threat of microplastics to marine biota as well as on human health, it is important to control excessive use of plastic additives and to introduce certain legislations and policies to regulate the sources of plastic litter. By setup various plastic recycling process or promoting plastic awareness programmes through different social and information media, we will be able to clean our sea dustbin in future.

Sharma, S., et al. (2014). "Role of neutrophils in visceral leishmaniasis in India." Allergy: European Journal of Allergy and Clinical Immunology **99)**: 38.

Background: Visceral leishmaniasis (VL), also know as Kala-azar, is a disease caused by Leishmania donovani in India. In this form of leishmaniasis the parasite spreads to visceral organs, and disease is fatal if left untreated. Isolated PBMCs from patients with VL lack antigen specific immune responses. Whether they play regulatory roles has yet to be unveiled. We found that PBMCs isolated from VL patients contained a distinct subset of low density granulocytes staining for neutrophil markers. Surprisingly, these cells stained for MHC II expression, and MHC II staining was more intense in cells from VL patients than cells from Endemic Healthy Controls (EHC). Method(s): Flow Cytometry was performed using BD Facs Calibur and analysed using FlowJO software (Treestar). Gene Expression: Human neutrophils were isolated from whole blood after RBC lysis using Militenyi CD66abce microbead kit to get highly pure neutrophils (>97%). Result(s): Neutrophils from patients with VL were examined for activation. A minimal increase CD11b high CD62L low neutrophils was observed in whole blood of VL patients than in EHC. Total blood neutrophils from patients with VL contain a subset of HLA DR expressing cells that stain as neutrophils. Low density granulocytes that co-purified with PBMCs contained a population expressing MHC II and CD66b (neutrophil marker). These cells were more abundant in VL patients than EHC. PMN in the RBC pellet separated by migration through the ficoll layer behave as 'classical neutrophils' and do not show appreciable MHC II expression in both VL patients and Endemic healthy groups.Differences were observed in expression of cytokine and chemokine mRNAs in the same subjects during active VL and after treatment. Conclusion(s): We observed a unique population of neutrophils like cells expressing MHC II in chronic VL. We need to determine if these cells are supressive as reported by Abebe et al. or function in antigen presentation.

Sharp, N. A., et al. (1998). "Hydrodynamic and mass transfer studies in an external-loop air-lift bioreactor for immobilized animal cell culture." Applied Biochemistry and Biotechnology - Part A Enzyme

Engineering and Biotechnology **73**(1): 59-77.

Air-lift bioreactors containing suspended or immobilized animal cells have been used for the production of a variety of high-value biologicals. In the bioprocessing industry, there is a need to study and quantify the relationships between bioreactor-system properties such as mixing, flow, mass transfer, and cell processes. In the present study, the performance of a 1-L external-loop air-lift bioreactor was investigated by studying gas-liquid oxygen transfer, mixing time, liquid velocity and gas hold-up at various aeration rates. These studies were performed over a range (0-25%) of loadings of small (500-800 mum) calcium alginate beads to investigate the effect of using various concentrations of cell immobilization matrices on the physical properties of the system. At an aeration rate of 0.5 vvm, the mixing time was decreased by 50%, from 75 s at 0% bead loading to 38 s at 10% bead loading. A minimum liquid velocity of 10 cm/s was required to keep the alginate beads in suspension. As bead loading increased, flow within the reactor went from turbulent conditions to the transition zone. At all bead loadings tested, the gas hold-up increased by only 2% with an increase in aeration rate from 0.1 to 1.0 vvm, regardless of whether the total reactor volume (i.e., liquid and beads) or the liquid volume was used in calculating the hold-up. A mathematical correlation was developed for expressing the dependence of the volumetric mass-transfer coefficient, k<inf>1</inf>a, on aeration rate (vvm) and microbead loading. With this equation it was possible to predict, within 20%, the k<inf>1</inf>a knowing the gas-flow rate and the volume percentage of microbeads present in the bioreactor. A theoretical study was also performed to calculate the oxygen transfer from the bulk liquid to the center of microcapsules containing animal cells using experimental k<inf>1</inf>a data. The results suggest that whereas there is no oxygen limitation at 10 to 15% microcapsule loading, there is a potential mass-transfer problem at 25% loading if the bioreactor is operated at an aeration rate of less than 1.06 vvm.

Sharuddin, S. D. A., et al. (2016). "A review on pyrolysis of plastic wastes." Energy Conversion & Management **115**: 308-326.

The global plastic production increased over years due to the vast applications of plastics in many sectors. The continuous demand of plastics caused the plastic wastes accumulation in the landfill consumed a lot of spaces that contributed to the environmental problem. The rising in plastics demand led to the depletion of petroleum as part of non-renewable fossil fuel since plastics were the petroleum-based material. Some alternatives that have been developed to manage plastic wastes were recycling and energy recovery method. However, there were some drawbacks of the recycling method as it required high labor cost for the separation process and caused water contamination that reduced the process sustainability. Due to these drawbacks, the researchers have diverted their attentions to the energy recovery method to compensate the high energy demand. Through extensive research and technology development, the plastic waste conversion to energy was developed. As petroleum was the main source of plastic manufacturing, the recovery of plastic to liquid oil through pyrolysis process had a great potential since the oil produced had high calorific value comparable with the commercial fuel. This paper reviewed the pyrolysis process for each type of plastics and the main process parameters that influenced the final end product such as oil, gaseous and char. The key parameters that were reviewed in this paper included temperatures, type of reactors, residence time, pressure, catalysts, type of fluidizing gas and its flow rate. In addition, several viewpoints to optimize the liquid oil production for each plastic were also discussed in this paper.

Shaw, D. G. and R. H. Day (1994). "Colour- and form-dependent loss of plastic micro-debris from the North Pacific Ocean." Marine Pollution Bulletin **28**(1): 39-43.

Floating plastic was collected with a neuston sampler at 27 locations in the North Pacific Ocean in 1987 and 1988. The plastic particles obtained were sorted according to size, physical form (e.g. pellet, line, fragment), and colour. Comparison of the size distribution of plastic observed with that predicted by a simple physical fragmentation model indicated that some forms, colours, and size fractions were significantly under-represented. We consider four possible explanations of these results and conclude that it is likely that marine organisms selectively remove plastic particles whose size, shape, and colour allow them to be mistaken for prey items. We further conclude that ingestion of small plastic objects by marine organisms occurs in substantial quantities.

Sheema, M., et al. (2011). "Rational use of antibiotics in gynaecology." Pharma Research **5**(1): 107-115.

Data was studied for evaluating rational use of antibiotics in gynaecology department and compare the data of public Vs private hospital on all the aspects, after so many efforts done by Delhi Society of promoting rational use of drugs (DSPRUD). The concurrent study was conducted in a 1276 bedded medical college hospital in Pt. B. D. Sharma University of Health Sciences, Rohtak and Shiv Hospital, Rohtak. The study was conducted on 100 outpatients from public and private hospital on equal population. Data was analyzed by applying statistical tools. A concurrent analysis on 100 patient's prescription was done in two groups and found that 41 (41%) prescriptions were probably appropriate, 18 (18%) prescriptions were inappropriate and 41 (41%) prescriptions were empirical. Inappropriate antibiotic therapy was due to inappropriate choice of antibiotics, having no efficacy for treatment and the cost inappropriate for the therapy prescribed, i.e. $p = 0.41 > 0.05$ (significant difference). Cost is the major factor for rational use of antibiotics. Cost comparison in two groups showed significant difference i.e. $p = 0.778 > 0.05$. The study concluded that 27% of the prescriptions were irrational and 73% of the prescriptions were empirical. Irrational use of antibiotics showed significant difference, $p = 0.27 > 0.05$. Comparing the two groups shows a significant difference i.e. $p = 0.61053$ (Chi-square test). The study was highly empirical and private practioners are giving completely empirical Vs public practioners. There are more chances of inappropriate prescriptions due to unavailability of investigation. © 2011 by Sudarshan Publication.

Sheikhi, A., et al. (2019). "Microfluidic-enabled bottom-up hydrogels from annealable naturally-derived protein microbeads." Biomaterials **192**: 560-568.

Naturally-derived proteins, such as collagen, elastin, fibroin, and gelatin (denatured collagen) hold a remarkable promise for tissue engineering and regenerative medicine. Gelatin methacryloyl (GelMA), synthesized from the methacryloyl modification of gelatin, mimicking the structure of extracellular matrix, has widely been used as a universal multi-responsive scaffold for a broad spectrum of applications, spanning from cell therapy to bioprinting and organoid development. Despite the widespread applications of GelMA, coupled stiffness and porosity has inhibited its applications in 3D cellular engineering wherein a stiff scaffold with large pores is demanded (e.g., at concentrations >10wt%). Taking advantage of the orthogonal thermo-chemical responsivity of GelMA, we have developed microfluidic-assisted annealable GelMA beads, that are first stabilized by temperature-mediated physical crosslinking, flowed to form a scaffold structure, and then chemically annealed using light to fabricate novel bead-based 3D GelMA scaffolds with high mechanical resilience. We show how beaded GelMA (B-GelMA) provides a self-standing microporous environment with an orthogonal void fraction and stiffness, promoting cell adhesion, proliferation, and rapid 3D seeding at a high polymer concentration (~20wt%) that would otherwise be impossible for bulk GelMA. B-GelMA, decorated with methacryloyl and arginylglycylaspartic acid (RGD) peptide motifs, does not

require additional functionalization for annealing and cell adhesion, providing a versatile biorthogonal platform with orthogonal stiffness and porosity for a myriad of biomedical applications. This technology provides a universal method to convert polymeric materials with orthogonal physico-chemical responsivity to modular platforms, opening a new horizon for converting bulk hydrogels to beaded hydrogels (B-hydrogels) with decoupled porosity and stiffness.

Shen, C., et al. (2015). "Neuroprotective effect of epigallocatechin-3-gallate in a mouse model of chronic glaucoma." Neuroscience Letters **600**: 132-136.

Epigallocatechin-3-gallate (EGCG) is a powerful antioxidant with suggested neuroprotective action. This study investigated the protective effects of EGCG against retinal ganglion cells (RGCs) degeneration in an animal model of glaucoma. C57BL/6J mice (n=54) were divided randomly into four groups: normal control group (group A, n=12); EGCG control group with EGCG in drinking water (group B, n=12); microbeads control group with anterior chamber microbeads injection to induce elevation in intraocular pressure (IOP) plus normal drinking water (group C, n=18); and EGCG study group receiving an anterior chamber microbeads injection plus EGCG in drinking water (group D, n=12). Animals were treated orally with either vehicle or EGCG (50 mg/kg x d). IOP was measured and animals were sacrificed at days 15 and 27. Neurons were retrograde-labeled by fluorogold and immnunolabeled by class III beta -tubulin to quantify RGCs in the retinal ganglion cell layer on flat mounts histologically and compared. All mice that received microbeads injections (groups C and D) developed IOP elevation higher than un-injected control mice. At days 15 and 27, progressive loss of RGCs was observed after microbeads injection in group C (P<0.01). In contrast, the fluorogold-labeled RGC density and class III beta -tubulin-positive RGC density were significantly higher in group D as compared to group C (P<0.01) but significantly lower than group B (P<0.01). These parameters did not differ significantly between groups A and B (P>0.05). The findings suggest the consumption of EGCG plays a neuroprotective role on RGCs in a mouse model of elevated IOP.

Shen, K., et al. (2014). "Microcavity substrates casted from self-assembled microsphere monolayers for spheroid cell culture." Biomedical Microdevices **16**(4): 609-615.

Multicellular spheroids are an important 3-dimensional cell culture model that reflects many key aspects of in vivo microenvironments. This paper presents a scalable, self-assembly based approach for fabricating microcavity substrates for multicellular spheroid cell culture. Hydrophobic glass microbeads were self-assembled into a tightly packed monolayer through the combined actions of surface tension, gravity, and lateral capillary forces at the water-air interface of a polymer solution. The packed bead monolayer was subsequently embedded in the dried polymer layer. The surface was used as a template for replicating microcavity substrates with perfect spherical shapes. We demonstrated the use of the substrate in monitoring the formation process of tumor spheroids, a proof-of-concept scale-up fabrication procedure into standard microplate formats, and its application in testing cancer drug responses in the context of bone marrow stromal cells. The presented technique offers a simple and effective way of forming high-density uniformly-sized spheroids without microfabrication equipment for biological and drug screening applications.

Shen, M., et al. (2020). "Can microplastics pose a threat to ocean carbon sequestration?" Marine Pollution Bulletin **150**: 110712.

Global climate change has attracted worldwide attention. The ocean is the largest active carbon pool on the planet and plays an important role in global climate change. However, marine

plastic pollution is getting increasingly serious due to the large consumption and mismanagement of global plastics. The impact of marine plastics on ecosystem responsible for the gas exchange and circulation of marine CO₂ may cause more greenhouse gas emissions. Consequently, in this paper, threats of marine microplastics to ocean carbon sequestration are discussed. Marine microplastics can 1) affect phytoplankton photosynthesis and growth; 2) have toxic effects on zooplankton and affect their development and reproduction; 3) affect marine biological pump; and 4) affect ocean carbon stock. Phytoplankton and zooplankton are the most important producer and consumer of the ocean. As such, clearly, further research should be needed to explore the potential scale and scope of this impact, and its underlying mechanisms.

Shen, M., et al. (2019). "Recent advances in toxicological research of nanoplastics in the environment: A review." Environmental Pollution **252**(Pt A): 511-521.

Nanoplastics have attracted increasing attention in recent years due to their widespread existence in the environment and the potential adverse effects on living organisms. In this paper, the toxic effects of nanoplastics on organisms were systematically reviewed. The translocation and absorption of nanoplastics, as well as the release of additives and contaminants adsorbed on nanoplastics in the organism body were discussed, and the potential adverse effects of nanoplastics on human health were evaluated. Nanoplastics can be ingested by organisms, be accumulated in their body and be transferred along the food chains. Nanoplastics showed effects on the growth, development and reproduction of organisms, and disturbing the normal metabolism. The toxic effects on living organisms mainly depended on the surface chemical properties and the particle size of nanoplastics. Positively charged nanoplastics showed more significant effects on the normal physiological activity of cells than negatively charged nanoplastics, and smaller particle sized nanoplastics could more easily penetrate the cell membranes, hence, accumulated in tissues and cells. Additionally, the release of additives and contaminants adsorbed on nanoplastics in organism body poses more significant threats to organisms than nanoplastics themselves. However, there are still knowledge gaps in the determination and quantification of nanoplastics, as well as their contaminant release mechanisms, degradation rates and process from large plastics to nanoplastics, and the transportation of nanoplastics along food chains. These challenges would hinder the risk assessment of nanoplastics in the environment. It is necessary to further develop the risk assessment of nanoplastics and deeply investigate its toxicological effects.

Shen, M., et al. (2019). "Micro(nano)plastics: unignorable vectors for organisms." Marine Pollution Bulletin **139**: 328-331.

Micro(nano)plastics, as emerging contaminants, have attracted worldwide attention. Nowadays, the environmental distribution, sources, and analysis methods and technologies of micro(nano)plastics have been well studied and recognized. Nevertheless, the role of micro(nano)plastic particles as vectors for attaching organisms is not fully understood. In this paper, the role of micro(nano)plastics as vectors, and their potential effects on the ecology are introduced. Micro(nano)plastics could (1) accelerate the diffusion of organisms in the environment, which may result in biological invasion; (2) increase the gene exchange between attached biofilm communities, causing the transfer of pathogenic and antibiotic resistance genes; (3) enhance the rate of energy, material and information flow in the environment. Accordingly, the role of microplastics as vectors for organisms should be further evaluated in the future research.

Shen, W., et al. (2018). "Fluorometric determination of zinc(II) by using DNAzyme-modified magnetic microbeads." Mikrochimica Acta **185**(10): 447.

A fluorometric assay for zinc ion is described that relies (a) on the use of an isothermal cycle to amplify the fluorescence signal, and (b) of magnetic beads (MBs) to completely remove unreacted DNA detection probes. Biotin and fluorophore-labeled substrate (Zn-Sub) strands acting as detection probes were first assembled on MBs. Next, Zn(II)-specific DNAzyme (Zn-Enz) strands were hybridized with the Zn-Sub strands. In the presence of Zn(II), the Zn-Sub strands are cleaved. This results in the release of the shorter DNA fragments (containing fluorescent label) and in the dissociation of Zn-Enz strands. The dissociated Zn-Enz strands then hybridize with the residual Zn-Sub strands and cleave them in a similar fashion. This leads to a target recycling amplification mechanism and in a cumulative signal amplification process. A strongly amplified signal is thus obtained in the presence of Zn(II). The use of MBs warrants that unreacted Zn-Sub strands can be magnetically separated from the solution. The method has a detection limit as low as 33 fM at a signal-to-noise ratio of 3 and a linear response in the 100 fM to 11 nM Zn(II) concentration range. It was applied to the determination of Zn(II) in spiked tap water and seawater samples, and the results compared well with data obtained by ICP-MS analysis. The method was also applied to the determination of Zn(II) in infant milk powder and breast milk. Graphical abstract Magnetic beads (MBs) carrying fluorescein-labeled substrate (Zn-Sub) strands were hybridized with Zn(II)-specific DNAzyme (Zn-Enz) and cleaved in the presence of Zn(II). After recycling, the unreacted Zn-Sub strands were removed with MBs and the released fluorescein tags are measured.

Shen, X. C., et al. (2018). "The effects of environmental conditions on the enrichment of antibiotics on microplastics in simulated natural water column." Environmental Research **166**: 377-383.

Concerns regarding the release of microplastics (MPs) into the environment led us to explore the relationship between the different environmental factors and physicochemical properties of MPs, as well as the change of interaction between MPs and organic pollutants. In this study, the effects of environmental factors (ageing conditions), such as pH, temperature, ionic strength, ageing time, and humic acid (HA) concentration, on the characteristics of MPs and their adsorption toward tetracycline (TC) were systematically investigated. The results showed that ageing factors such as pH, ionic strength, and temperature were found to have little impact on the adsorptive capacity of MPs for TC. However, MPs aged in HA solution exhibited a significant decreased adsorptive capacity for TC. HA, which has numerous functional groups, can cover the surface of MPs and change their hydrophobicity, thereby reducing the adsorption affinity to TC. The electrostatic repulsion between adsorbed HA and TC molecules may also decrease the adsorption of TC. In addition, the competing effect of HA for adsorption sites on the surface of MPs further reduces the adsorption of TC. The data presented in this work provide useful information for understanding the transfer of antibiotics by aged MPs, which is of fundamental importance to assess the environmental impact of MPs.

Objective: To study the inhibition of allergic asthma by adoptive transfer of dendritic cell (DC) subsets from mice infected with Schistosoma japonicum.

Shen, Y., et al. (2008). "Inhibitory effect on asthma by dendritic cells of Schistosoma japonicum-infected mice." Zhongguo Bingyuan Shengwuxue Zazhi / Journal of Pathogen Biology **3**(11): 832-834.

Objective: To study the inhibition of allergic asthma by adoptive transfer of dendritic cells (DC) from Schistosoma japonicum-infected mice and its mechanisms.

Shete, P. B., et al. (2017). "Evaluation of antibody responses to panels of M. tuberculosis antigens as a screening tool for active tuberculosis in Uganda." PLoS ONE [Electronic Resource] **12**(8): e0180122.

BACKGROUND: Improved systematic screening of high-risk groups is a key component of the tuberculosis (TB) elimination strategy endorsed by the World Health Organization (WHO). We used a multiplex microbead immunoassay to measure antibody responses to 28 M. tuberculosis (M.tb) antigens, and assessed whether combinations of antibody responses achieve accuracy thresholds required for a TB screening test.

METHODS: A random selection of plasma samples obtained from consecutive HIV-negative adults who were admitted to Mulago Hospital in Kampala, Uganda with cough >=2 weeks' but <6 months' duration were analyzed for serological response to 28 M.tb antigens using an in-house multiplex microbead immunoassay. We compared the median difference of the antibody response to each antigen between patients with and without culture-confirmed TB, ranked each antigen according to variable importance (VIM), and assessed the sensitivity and specificity of combinations of antibody responses using an advanced classification algorithm, SuperLearner.

RESULTS: Among the 237 patients included in the analysis, 119 (50%) were female, median age was 32 years (IQR 25, 46), and 113 (48%) had TB. Median antibody levels to eight antigens were significantly different between patients with and without TB. A panel including eight of the top ranked antigens had a sensitivity of 90.6% (95% CI 89.4, 93.8) and a specificity of 88.6% (95% CI 78.2, 97.6) (Ag85B, Ag85A, Ag85C, Rv0934-P38, Rv3881, BfrB, Rv3873, and Rv2878c). With sensitivity constrained to be >90%, specificity remained close to 70% with as few as 3 antigens included in the panels.

CONCLUSIONS: Measuring antibody responses to combinations of antigens could facilitate TB screening and should be further evaluated in populations being targeted for systematic screening.

Shetye, S. S., et al. (2019). "Anthropogenic spherules in Zuari estuary, south west coast of India." Marine Pollution Bulletin **143**: 1-5.

In this study we report silica rich anthropogenic spherules from the marine environment. We found spherical, dumbbell, teardrop and fused spherules in Zuari estuary (near the Dona paula jetty), south west coast of India. The spherules were composed of SiO<inf>2</inf> (69.8%), Na<inf>2</inf>O (13.2%), CaO (8.8%), MgO (3.8%), and traces of Al<inf>2</inf>O<inf>3</inf>, and FeO. Their high Na and Ca contents rules out the possibility of being an impact spherule or microtektite, or anthropogenic spherules coming from fly ash. Their elemental composition suggests that these are glass micro beads that have many applications including production of road and pavement marking materials, such as traffic paints. Considering that the glass micro beads are known to have high concentrations of Pb, As, and Sb that can leach into the marine environment, this study also raises questions regarding the impact of such spherules on marine biota, and highlights the need for further detailed study. Sheu, M. T., et al. (1986). "Entrapment of bioactive compounds within native albumin beads: II. Effects of rate and extent of crosslinking on microbead properties." Journal of Parenteral Science and Technology **40**(6): 253-258.

The rate of crosslinking of serum albumin is affected by several parameters such as pH, buffer concentration, and the ratio of serum albumin to glutaraldehyde concentration. Selection of experimentally controllable variables makes it possible to control crosslinking rate at room temperature to form a serum albumin microbead with an appropriate extent of crosslinking that

provides both structural integrity and biodegradability. It was confirmed that serum albumin concentrations of 200 mg/ml of sodium phosphate buffer solution (pH = 7.5, 10 mM) and 1% glutaraldehyde is a very favorable combination using a mixing time of around 20 sec before adding to oil phase to form an emulsion. A curing time of around 30 min is then used. Drug loading efficiency is crosslink rate-controlled. Mixing time also affects drug loading efficiency since it fixes the time for potential partitioning of drug out of the aqueous phase. The biodegradable character of the microbeads has been shown and it appears to be a function of the amount of serum albumin and glutaraldehyde used.

Shey, J., et al. (2006). "Properties of baked starch foam with natural rubber latex." Industrial Crops and Products **24**(1): 34-40.

Petroleum-based synthetic plastics used for making consumer articles constitute the largest non-renewable source of municipal solid waste in the United States. Containers and packaging products represent the largest group within plastic waste in municipal landfills. Efforts are being made worldwide to search for renewable and biodegradable substitutes for non-biodegradable plastics. Starch from surplus commodity crops has been investigated as a possible replacement, but it does have some disadvantages such as its susceptibility to water owing to its highly hydrophilic nature. To improve the water resistance of starch-based products, we incorporated natural rubber latex into baked starch foams based on wheat, potato, and waxy corn starches. While latex increases the density of the foam, it also improves the flexibility of the product. Stabilization of the latex with non-ionic additives helped prevent irregularities in the foam product. The flexural properties of these foams are comparable with commercial products and can be 'tuned' by varying the starch type and adjusting the latex concentration. Latex also decreases the equilibrium moisture content and decreases the effect of higher humidity on the foam products.

Shi, F., et al. (2014). "Heterogeneous solution NMR signal amplification by reversible exchange." Angewandte Chemie. International Ed. in English **53**(29): 7495-7498.

A novel variant of an iridium-based organometallic catalyst was synthesized and used to enhance the NMR signals of pyridine in a heterogeneous phase by immobilization on polymer microbead solid supports. Upon administration of parahydrogen (pH2) gas to a methanol mixture containing the HET-SABRE catalyst particles and the pyridine, up to fivefold enhancements were observed in the (1)H NMR spectra after sample transfer to high field (9.4 T). Importantly, enhancements were not due to any residual catalyst molecules in solution, thus supporting the true heterogeneity of the SABRE process. Further significant improvements may be expected by systematic optimization of experimental parameters. Moreover, the heterogeneous catalyst is easy to separate and recycle, thus opening a door to future potential applications varying from spectroscopic studies of catalysis, to imaging metabolites in the body without concern of contamination from expensive and potentially toxic metal catalysts or accompanying organic molecules.

Shibata, E., et al. (2012). "Investigation for the effect of the environmental contaminants exposure on the placental amino acid transport activity." Reproductive Sciences **1)**: 380A-381A.

Background Recent studies indicate that maternal exposure to environmental contaminants may decrease infant birth-weight. However, underlying mechanisms of fetal growth restriction caused by environmental contaminants is not understood. The aim of this study is to investigate in vivo levels of environmental contaminants in the mother and infant, and to clarify how those chemicals decreases the infant birth-weight. (Subjects and Methods) We measured in vivo levels of heavy metals including Lead, Arsenic, Cadmium, Mercury, and various pesticides in maternal and cord blood, and maternal urine of the time of delivery. Furthermore, we exposed villous fragments, and BeWo cell to Arsenic, Cadmium, Mercury, plastic resin; toluene diisocyanate, aldehyde analog; glutaraldehyde, acetaldehyde, and formaldehyde to mesure the placental system A transport activity, and system A and L amino acid transporter protein expression. (Result) In vivo experiments (n=9); All of environmental contaminants were under the Japanese environmental criteria. Total Mercury level was higher in cord blood than in maternal blood. Cadmium was detected in maternal specimens but not in the cord blood. In vitro experiments (n=6); Methyl-Mercury (0.5muM), Arsenic (5muM), Cadmium (20muM) were all found to decreased system A amino acid transport activity by 30 to 40% (P<0.001). Toluene diisocyanate and glutaraldehyde decreased system A amino acid transport activity significantly in a dose-dependent manner (1, 10, 100muM: P<0.001), but acetaldehyde (2.3, 23, 230muM) and formaldehyde (3.3, 33, 330muM) did not. Toluene diisocyanate and glutaraldehyde did not change expression of System A or L amino acid transporter protein in the cultured villous fragments or the BeWo cell line. All environmental contaminants tested did not increase the lactase dehydrogenase release into the culture media. (Conclusion) We suggest that the high concentration of Methyl-Mercury, Arsenic, and Cadmium decrease system A amino acid transport activity. Toluene diisocyanate and glutaraldehyde are thought to be environmental contaminants which may cause fetal growth restriction by decreasing placental system A amino acid transport activity.

Shibata, H., et al. (2010). "Injectable hydrogel microbeads for fluorescence-based in vivo continuous glucose monitoring." Proceedings of the National Academy of Sciences of the United States of America **107**(42): 17894-17898.

Fluorescent microbeads hold great promise for in vivo continuous glucose monitoring with wireless transdermal transmission and long-lasting activity. The full potential of fluorescent microbeads has yet to be realized due to insufficient intensity for transdermal transmission and material toxicity. This paper illustrates the highly-sensitive, biostable, long-lasting, and injectable fluorescent microbeads for in vivo continuous glucose monitoring. We synthesized a fluorescent monomer composed of glucose-recognition sites, a fluorogenic site, spacers, and polymerization sites. The spacers are designed to be long and hydrophilic for increasing opportunities to bind glucose molecules; consequently, the fluorescent monomers enable high-intensive responsiveness to glucose. We then fabricated injectable-sized fluorescent polyacrylamide hydrogel beads with high uniformity and high throughput. We found that our fluorescent beads provide sufficient intensity to transdermally monitor glucose concentrations in vivo. The fluorescence intensity successfully traced the blood glucose concentration fluctuation, indicating our method has potential uses in highly-sensitive and minimally invasive continuous blood glucose monitoring.

Shifu, C. and C. Gengyu (2005). "Study on the Photocatalytic Reduction of Dichromate and Photocatalytic Oxidation of Dichlorvos." Chemosphere **60**(9): 1308.

Dichromate and dichlorvos were used as model inorganic and organic pollutants, respectively, to investigate photocatalytic treatment involving titanium dioxide. Various operational parameters were considered in terms of their influence on the photocatalytic reduction of dichromate and the photocatalytic oxidation of dichlorvos, including the amount of

photocatalyst, the hydrogen peroxide concentration, pH, and the presence of metal ions, anions, and organic compounds. Titanium dioxide was supported on hollow glass microbeads. Results showed that both photoreduction and photooxidation efficiency increased rapidly with increasing TiO sub(2) concentration up to a limit of 6.0 g/dm super(3). Photoreduction efficiency decreased with increasing solution pH, while the opposite was observed for photooxidation. The photoreduction efficiency decreased gradually with an increase in the H sub(2)O sub(2) concentration, while the opposite was observed for photooxidation. Both reactions were accelerated in the presence of small amounts of trivalent iron or divalent copper. The presence of other anions did not influence the processes, but when toluene or methanol were added, the photoreduction efficiency was increased, while the photooxidation efficiency was decreased.

Shim, W. J. and R. C. Thomposon (2015). "Microplastics in the Ocean." Archives of Environmental Contamination & Toxicology **69**(3): 265-268.

Since their ubiquity in the ocean and marine organisms was first revealed, global concern about microplastics has grown considerably. The North Pacific Ocean and the adjacent marginal seas have high levels of microplastic contamination compared with the global average. This special issue on microplastics was organized by the North Pacific Marine Science Organization to share information on microplastic pollution in the North Pacific region. The special issue highlights high levels of contamination in the North Pacific both on shorelines and at the sea surface. Particularly high levels of contamination were reported on the western and southern coasts of Korea. Sources, including sewage discharge, aquaculture, and shipyards, were implicated. With the direction and energy of surface winds and currents have an important influence on shoreline patterns of distribution. The special issue also demonstrates potential for ingestion of microplastic by small planktonic organisms at the base of the food chain. A wide range of chemicals are associated with plastic debris and concerns are expressed about the potential for these chemicals to transfer to biota upon ingestion. As an introduction to the topic, this paper provides a brief background on microplastic contamination, highlights some key research gaps, and summarizes findings from the articles published in this issue.

Shima, Z., et al. (2018). "Environmentally relevant concentrations of polyethylene microplastics negatively impact the survival, growth and emergence of sediment-dwelling invertebrates." Environmental Pollution **236**: 425-431.

Microplastics are a widespread environmental pollutant in aquatic ecosystems and have the potential to eventually sink to the sediment, where they may pose a risk to sediment-dwelling organisms. While the impacts of exposure to microplastics have been widely reported for marine biota, the effects of microplastics on freshwater organisms at environmentally realistic concentrations are largely unknown, especially for benthic organisms. Here we examined the effects of a realistic concentration of polyethylene microplastics in sediment on the growth and emergence of a freshwater organism Chironomus tepperi. We also assessed the influence of microplastic size by exposing C. tepperi larvae to four different size ranges of polyethylene microplastics (1-4, 10-27, 43-54 and 100-126 micro m). Exposure to an environmentally relevant concentration of microplastics, 500 particles/kg_{sediment}, negatively affected the survival, growth (i.e. body length and head capsule) and emergence of C. tepperi. The observed effects were strongly dependent on microplastic size with exposure to particles in the size range of 10-27 micro m inducing more pronounced effects. While growth and survival of C. tepperi were not affected by the larger microplastics (100-126 micro m), a significant reduction in the number of emerged adults was observed after exposure to the largest microplastics, with the delayed emergence attributed to exposure to a stressor. While scanning electron microscopy

showed a significant reduction in the size of the head capsule and antenna of C. tepperi exposed to microplastics in the 10-27 micro m size range, no deformities to the external structure of the antenna and mouth parts in organisms exposed to the same size range of microplastics were observed. These results indicate that environmentally relevant concentrations of microplastics in sediment induce harmful effects on the development and emergence of C. tepperi, with effects greatly dependent on particle size.

Shimony, N., et al. (2006). "Fibrin microbeads (FMB) as a 3D platform for kidney gene and cell therapy." Kidney International **69**(3): 625-633.

Cell and gene therapy may alter the outcome of renal diseases, such as hereditary nephropathies, acute and chronic glomerulonephritis and allograft nephropathy. However, owing to blockade of many viral and cellular vehicles by the complex glomerular architecture, the exact nature of gene and cell delivery into specific renal compartments remains currently unknown. To study the interaction of viral vectors with a variety of renal cells and mesenchymal stem cells (MSCs), we employed a novel biological three-dimensional (3D) matrix comprised of fibrin microbeads (FMB) in comparison to monolayer cell culture. Our studies showed that renal cells of both established and primary lines can grow efficiently on FMB and differentiate into epithelial structures, as shown by electron microscopy. Gene delivery into renal cells in 3D was observed for several viral vectors and growth in 3D on FMB conferred resistance to renal cancer cells in the context of oncolytic adenoviruses. Finally, MSCs from various rodent species attached to FMB, grew robustly, survived for several weeks and could efficiently be transduced on FMB. Thus, on the basis of growth, differentiation and transduction of renal cells in 3D, FMB emerge as a novel 3D cellular microenvironment that differs substantially from monolayer cell cultures.

Shin, C. I., et al. (2019). "Delivery of Niacinamide to the Skin Using Microneedle-Like Particles." Pharmaceutics **11**(7): 11.

The stratum corneum is the outermost skin layer that obstructs the delivery of active ingredients found in cosmeceutical products. Chemical peels and microbeads have been used to overcome this layer, but these methods can cause side effects and are not environmentally friendly. While microneedles do not share the dangers mentioned above, they are currently only available as patches, which makes them unsuitable to be used with products that are usually applied onto a large area of the skin surface. Therefore, the aim of this study was to develop microneedle-like particles (MLP) whose needles would disrupt the skin during the rubbing process. A modified approach taken from conventional micromolding techniques was used to make the MLPs. The experimental results show that the fabricated structures had the required mechanical strength. Furthermore, after the application of the MLPs, the permeability of two fluorescent dyes, fluorescein sodium salt and sulforhodamine B increased to 217.6% +/- 25.6% and 251.7% +/- 12.8% respectively. Additionally, the permeability of a model drug, niacinamide, was shown to have increased to 193.8% +/- 29.9%. Cryosectioned porcine slices also confirmed the ability of MLPs to enhance skin permeability by revealing a deeper penetration of the applied fluorescent dye. Altogether, the results demonstrate the potential of MLPs to be used as safe skin permeability enhancers that can be applied all over the skin.

Shin, H. Y., et al. (2012). "Fluid Pressure Is a Magnitude-Dependent Modulator of Early Endothelial Tubulogenic Activity: Implications Related to a Potential Tissue-Engineering Control Parameter." Tissue Engineering, Part A: Tissue Engineering **18**(23-24): 2590-2600.

A significant barrier to the success of engineered tissues is the inadequate transport of nutrients

and gases to, and waste away from, cells within the constructs, after implantation. Generation of microtubular networks by endothelial cells in engineered constructs to mimic the in vivo transport scheme is essential for facilitating tissue survival by promoting the in vitro formation of microvessels that integrate with host microvasculature, after implantation. Previously, we reported that select pressures stimulate endothelial proliferation involving protubulogenic molecules such as fibroblast growth factor-2 (FGF-2) and vascular endothelial growth factor-C (VEGF-C). Based on this, we investigated fluid pressure as a selective modulator of early tubulogenic activity with the intent of assessing the potential utility of this mechanical stimulus as a tissue-engineering control parameter. For this purpose, we used a custom pressure system to expose two-dimensional (2D) and three-dimensional (3D) cultures of endothelial cells to static pressures of 0 (controls), 20, or 40mmHg for 3 days. Compared to controls, 2D endothelial cultures exposed to 20, but not 40 mmHg, exhibited significantly ($p < 0.05$) enhanced cell growth that depended on VEGF receptor-3 (VEGFR-3), a receptor for VEGF-C. Moreover, endothelial cells grown on microbeads and suspended in 3D collagen gels under 20 mmHg, but not 40 mmHg, displayed significantly ($p < 0.05$) increased sprout formation. Interestingly, pressure-dependent proliferation and sprout formation occurred in parallel with pressure-sensitive upregulation of VEGF-C and VEGFR-3 expression and were sensitive to local FGF-2 levels. Collectively, the results of the present study provided evidence that early endothelial-related tubulogenic activity depends on local hydrostatic pressure levels in the context of local growth factor conditions. In addition to relevance to microvascular diseases associated with interstitial hypertension (e.g., cancer and glaucoma), these findings provided first insight into the potential utility of hydrostatic pressure as a fine-tune control parameter to optimize microvascularization of tissue-engineering constructs in the in vitro setting before their implantation.

Shin, J., et al. (2013). "The proteomic profiling of TSLP-activated iNKT cells." Journal of Investigative Dermatology **1)**: S203.

In AD, innate immune mechanisms such as pattern recognition receptors and antimicrobial peptides have been investigated in detail, but recently, epidermis-derived cytokines, namely thymic stromal lymphopoietin (TSLP), IL-25 and IL-33, were shown to participate in innate immune reactions independently of adaptive immunity. In addition to conventional innate cells, such as mast cells, basophils and eosinophils, Th2 cytokine-producing invariant natural killer T (iNKT) cells, can participate in innate immune modulation in AD. To understand the role of iNKT cells in atopic dermatitis in the view of innate immunity, we used comparative approaches to analyze proteomic profiling of iNKT cells with and without stimulation of TSLP. In our study, iNKT cells were isolated from human PBMCs using the anti-iNKT MicroBeads (Microbeads conjugated to monoclonal anti-human Valpha24-Jalpha18 antibodies), a LS Column, and a Midi MACSTMSeparator. We used a quantitative mass spectrometry-based proteomics experiments with stable-isotope-containing isobaric tags (TMT), which produce differentially labeled peptide ions that are indistinguishable in full mass spectra. Initially, we identified about one thousand and four hundred proteins in TSLP-treated and TSLP-nontreated iNKT cells. Then we attempted to identify proteins that either increased or decreased depending on time after stimulation with TSLP. Finally, we identified 28 proteins for further investigation. We found 26 down regulated proteins and 2 up regulated proteins including chemokine receptors and others. Our method allows the quantitative comparison of biologically distinct data sets with high confidence and this can be utilized for differential protein expression analysis in the newly developing research field of innate immune system in atopic dermatitis.

Shirae, K., et al. (2016). "Microencapsulated rabbit adipose stem cells can initiate ectopic bone formation." Journal of Orthopaedic Research. Conference **34**(Supplement 1).

INTRODUCTION: Cell based therapies using adipose-derived stem cells (ASCs) provide one possible form of treatment for fractures or non-unions because they are multipotent (1), easily isolated, and readily available (2). Previously, we observed that when microbeads containing rat ASCs were pre-treated with chondrogenic media and implanted in a critical size chondral defect, new cartilage was formed (3). However, ectopic bone was observed following the implantation of microencapsulated rabbit ASCs (rbASCs) pretreated with chondrogenic media and implanted in a defect in rabbit ear cartilage. To begin to determine if this difference in outcome was due to inherent species differences, we investigated the multipotency of rbASCs and their ability to induce ectopic bone formation in rabbits following microencapsulation. Method(s): ASCs were isolated from inguinal fat pads of White New Zealand rabbits under an Institutional Animal Care and Use Committee (IACUC) approved protocol. To investigate the multipotency of rbASCs, cells were plated at 5000 cells/cm² and cultured in mesenchymal stem cell growth medium (GM) until confluent. rbASCs were treated with GM, osteogenic differentiation medium (OM), chondrogenic differentiation medium (CM) and adipogenic differentiation medium (AM) for 18 days. GM, OM, and AM were from Lonza; CM was made according to Lee et al. (3). mRNA levels were analyzed for ACAN, COL2, COL10, PPAR-y, LEPR RUNX2, and OCN. Statistical significance was determined by multi-way ANOVA with post hoc analysis by Bonferroni's correction to Student's t-test (n=6, per variable). First passage rbASCs were microencapsulated in low viscosity, high mannuronate (LVM) alginate in 75mM calcium crosslinker solution containing glucose at lxlO⁷ cells/ml alginate using a 6kV electrostatic potential (4,5). This method maintains viability of the encapsulated cells, reduces the amount of bound Ca++ and prevents dystrophic calcification of the alginate in vivo. Microencapsulated rbASCs were cultured in GM or OM for 7 days and ELISAs were used to analyze soluble factors in the conditioned media. To investigate the ability of microbeads containing rbASCs to induce bone formation, rbASCs were plated at 5000 cells/cm² and at confluence, cells were treated with GM or OM for 7 days then microencapsulated. rbASCs were also microencapsulated in degradable alginate microbeads, which were made by combining equal volumes of LVM alginate and alginate-lyase solution, resulting 0.22 U alginate lyase/g alginate. lOOul of microencapsulated cells were delivered in gelatin capsules into the gastrocenemius and rectus femoris of both legs for 6 weeks. As a positive control human demineralized bone matrix (DBM) was also implanted in gelatin capsules at the same location. MicroCT and histology were done to assess the amount of bone formed. Statistical significance was determined by Unpaired t-test (n=7, per variable). Result(s): rbASCs were multipotent: CM for 18 days caused higher COL2, ACAN, and COL10 mRNAs; OM increased RUNX2 and OCN mRNAs; AM increased LEPR but did not change PPAR-y mRNA. Microencapsulated rbASCs secreted comparable levels of VEGF and BMP2 regardless of pre-treatment. However, when implanted intramuscularly, pretreatment with OM caused a marked increase in new bone volume compared to rbASCs cultured in GM or compared to DBM. This stimulatory effect was reduced when rbASCs were encapsulated in degradable microbeads (FigureslA B). MicroCT analysis showed the formation of bone at the end of 6 weeks. Ectopic bone formation was observed in all samples; however the samples that were cultured in OM produced more bone (Figure 1C). Discussion(s): Our results show that rbASCs are able to differentiate along the osteogenic, adipogenic, and chondrogenic lineages based on mRNA expression. Increased expression of COL10 suggests CM induces endochondral differentiation. The rbASCs have also shown the ability to produce osteogenic growth factors after microencapsulation. As a result, ectopic bone formation was observed in all samples but amounts were greatest following pre-treatment with OM. This was not due to upregulation of VEGF or BMP2, however. Reduced ectopic bone following implantation of degradable beads may be due to reduced alginate Ca++, although the microbead processing technology prevents dystrophc calcification. SIGNIFICANCE: These microencapsulated rbASCs can induce ectopic bone formation in rabbits, and CM-treated rbASCs may not be suitable for regenerating hyaline cartilage.

Shivani, et al. (2019). "Seasonal variation, source apportionment and source attributed health risk of fine carbonaceous aerosols over National Capital Region, India." Chemosphere **237**: N.PAG-N.PAG.

Deteriorating air quality with high levels of fine particulate matter (PM 2.5) over National Capital Region (NCR) of India is one of the serious environmental and scientific issues. In this paper, PM 2.5 samples were collected for 24 h twice or thrice a week during December 2016–December 2017 at three sites [Delhi (IG), Modinagar (MN) and Mahendragarh (HR)] over NCR to analyse the carbonaceous aerosols. Source apportionment of PM 2.5 was attempted using Principal Component analysis (PCA) and Positive Matrix Factorization (PMF) based on the analysed carbonaceous fractions [Organic carbon, Elemental carbon, Secondary organic carbon (SOC)]. Organic compounds: alkanes, hopanes, steranes, polycyclic aromatic hydrocarbons (PAHs), phthalates, levoglucosan and n-alkanoic acids were analysed to distinguish the emission sources. Total Carbonaceous Aerosols (TCA) contributed significantly (∼26%) to PM 2.5 which revealed their importance in source apportionment. Estimated SOC contributed 43.2%, 42.2% and 58.2% to OC and 5.4%, 5.3% and 7.8% to PM 2.5 at IG, MN and HR sites respectively. PCA and PMF apportion five emission sources i.e., vehicular emissions (34.6%), biomass burning (26.8%), cooking emissions (15.7%), plastic and waste burning (13.5%) and secondary organic carbon (9.5%) for PM 2.5. Source attributed health risk has also been calculated in terms of Lung cancer risk (LCR) associated with PAHs exposure and concluded that vehicular emissions (40.3%), biomass burning (38.1%), secondary organic carbon (12.8%) contributed higher to LCR (503.2×10^{-5}; ∼503 cases in 1,00,000). Health risk assessment combined with source apportionment inferences signifies the immediate implementation of emissions reduction strategies with special target on transport sector and biomass burning over the NCR of India. • Carbonaceous aerosols contributed 26% to PM 2.5 over NCR of India. • Secondary organic carbon contributed 40–58% to Organic Carbon. • Source apportionment was performed to identify emission sources of PM 2.5 over NCR. • Source attributed health risk associated with PAHs was calculated. [ABSTRACT FROM AUTHOR]

Shivarov, M., et al. (2010). "Detection of mutations associated with chronic myeloproliferative disorders using bead-based liquid assay." Haematologica **2)**: 602.

Background: The JAK2 V617F mutation has recently been reported to be associated with the pathogenesis of chronic myeloproliferative disorders (CMPDs). Several techniques such as restriction fragment length polymorphism, direct sequencing analysis, pyrosequencing, real-time AS-PCR and a denaturing high-performance liquid chromatography have been developed for the detection of this kind of mutation. Aims. We aimed at the establishment and validation of a novel rapid, costeffective and moderate-throughput method for JAK2 V617F mutation identification using a multiplexed bead-based suspension array platform -

LuminexRxMAPTM. Method(s): A 354 bp region of spanning exon 14 of the human JAK2 gene was amplified using biotinylated primers and genotyping was performed by direct hybridization with 2 oligonucleotide probes, specific for the wild type and mutant alleles. The probes were synthesized with 5' amino group and 20 bases spacer oligonucleotides to allow covalent binding to carboxylated microbeads (Luminex Corp). Result(s): The method was validated by testing on different proportion mixtures of artificial plasmid construct harboring either the wild type and mutant JAK2 allele and a panel of DNA samples from patients with known CMPDs, genotyped by direct DNA sequencing. The sensitivity of this novel assay was approximately 5% mutant DNA in a wild-type Background: No discrepancies between the novel Luninex-based method and sequencing were observed. Conclusion(s): Our novel method could be successfully implemented in the diagnostic work-up for CMPDs. Additionally, the assay allows quantification of the JAK2 mutant allele burden and therefore is applicable for assessment of minimal residual disease in patients undergoing JAK2 targeted therapy or alloHSCT. Furthermore, this system would allow the design of multiplex assays for simultaneous testing for the presence of various mutations associated with CMPDs.

Shivarov, V., et al. (2013). "Novel Multiplex Bead-Based Assay for Detection of IDH1 and IDH2 Mutations in Myeloid Malignancies." PLoS ONE **8 (9) (no pagination)**(e76944).

Isocitrate dehydrogenase 1 and 2 (IDH) mutations are frequently found in various cancer types such as gliomas, chondrosarcomas and myeloid malignancies. Their molecular detection has recently gained wide recognition in the diagnosis and prognosis of these neoplasms. For that purpose various molecular approaches have been used but a universally accepted method is still lacking. In this study we aimed to develop a novel bead-based liquid assay using Locked nucleic acids (LNA)-modified oligonucleotide probes for multiplexed detection of the most frequent IDH1 (p.R132C, p.R132G, p.R132H, p.R132L, p.R132S) and IDH2 (p.R140Q, p.R172K) mutations. The method includes four steps: 1) PCR amplification of the targeted fragments with biotinylated primers; 2) Direct hybridization to barcoded microbeads with specific LNA-modified oligonucleotide probes; 3) Incubation with phycoerythrin coupled streptavidin; 4) Acquisition of fluorescent intensities of each set of beads on a flow platform (LuminexCorp., USA). We tested the performance of the assay on both artificial plasmid constructs and on clinical samples from 114 patients with known or suspected myeloid malignancies. The method appeared to be superior to direct sequencing having a much higher sensitivity of 2.5% mutant alleles. Applying this method to patients' samples we identified a total of 9 mutations (one IDH1 p.R132C, seven IDH2 p.R140Q and one IDH2 p.R172K). In conclusion, this method could be successfully implemented in the diagnostic work-up for various tumors known to harbor IDH1/2 mutations (e.g. myeloid malignancies, gliomas, etc.). International initiatives are needed to validate the different existing methods for detection of IDH1/2 mutations in clinical settings. © 2013 Shivarov et al.

Shojaei-Zadeh, S., et al. (2011). "Highly crosslinked poly(dimethylsiloxane) microbeads with uniformly dispersed quantum dot nanocrystals." Journal of Colloid & Interface Science **363**(1): 25-33.

This study demonstrates how luminescent semiconductor nanocrystals (quantum dots or QDs) can be dispersed uniformly in a poly(dimethylsiloxane) (PDMS) matrix by polymerizing a mixture of the prepolymer oligomers and the nanocrystals with a relatively large concentration of crosslinking molecules. A microfluidic device is used to fabricate PDMS microbeads embedded with the QDs by using flow focusing to first form monodisperse droplets of the prepolymer/crosslinker/nanocrystal mixture in a continuous aqueous phase. The droplets are subsequently collected, and heated to polymerize them into solid microbead composites. The degree of aggregation of the nanocrystals in the matrix is studied by measuring the nonradiative resonance energy transfer (RET) between the nanocrystals. For this purpose, two quantum dots are used with maxima in their luminescence emission spectrum at 560 nm and 620 nm. When the nanocrystals are within the Forster radius (approximately 10 nm) of each other, exciton energy cascades from the QDs which emit at the shorter wavelength to the QDs which emit at the longer wavelength. This energy transfer is quantified, for two concentration ratios of the prepolmer to the crosslinker, by measuring the deviation of the microbead luminescence spectrum from a reference spectrum obtained by dispersing the QD mixture in a solvent (toluene) in which the nanocrystals do not aggregate. For a low concentration of crosslinking molecules relative to the prepolymer (5:1 by weight prepolymer to crosslinker), strong RET is observed as the emission of the 620 nm QDs is increased and the 560 nm QDs is decreased relative to the reference. In the emission spectrum for a higher concentration of crosslinkers (2:1 by weight prepolymer to crosslinker), the resonance energy transfer is less relative to the case of the low concentration of crosslinkers, and the spectrum more closely resembles the reference. This result indicates that the increase in the crosslinker concentration has reduced the nanocrystal aggregation in the cured polymer. The use of crosslinking can serve as a general paradigm for forming, from a prepolymer/nanoparticle mixture, a composite in which the particles are not aggregated. Under the usual conditions the entropic cost to a linearly growing polymer chain of surrounding nanoparticles forces them to aggregate; crosslinking kinetically entraps the particles and circumvents this aggregation driving force. The QD/polymer composite microbeads fabricated in this study find applications in bead-based platforms for high-throughput, multiplexed screening, where the emission spectrum of the QD luminescence can be used as a spectral barcode to label the beads. For microbeads in which the nanocrystals are uniformly dispersed, this barcode is undistorted by energy transfer, and is easily read.

Shoji, K. and R. Kawano (2019). "Osmotic-engine-driven liposomes in microfluidic channels." Lab on a Chip **19**(20): 3472-3480.

Self-propelled underwater microrobots that locomote without external sources of energy have potential application as drug carriers and probes in narrow spaces. In this study, we focused on an osmotic engine model, which is a migration mechanism, and applied it as a negative chemotaxis mechanism to induce liposome displacement. First, we confirmed the osmotic flow across the lipid bilayer and calculated the osmotic flow velocity to be 8.5 fL min-1 mum-2 when a salt concentration difference was applied to the lipid bilayer. Next, we designed and fabricated a microchannel that can trap a giant liposome and apply a salt concentration difference to the front and rear of the liposome. Then, we demonstrated the movement of the liposome by flowing it to the microchannel. The liposome successfully moved in the direction of the lower ion concentration at a speed of 0.6 mum min-1 owing to the osmotic pressure difference. Finally, we visualized the inner flow in the liposome by encapsulating microbeads in the liposome and observed the movement of the microbeads to verify that an osmotic flow was generated on the liposome. As a result, we observed the circulation of the microbeads in the liposome when the concentration difference was applied to the front and rear of the liposome, suggesting that the movement of the liposome was driven by the osmotic flow generated by the osmotic pressure difference. These results indicate that the osmotic-pressure-based migration mechanism has the potential to be utilized as the actuator of molecular robots.

Shorie, M., et al. (2019). "Graphitic carbon nitride QDs impregnated biocompatible agarose cartridge for removal of heavy metals from contaminated water samples." Journal of Hazardous Materials **367**: 629-638.

Highly fluorescent, water-stable graphitic carbon nitride quantum dots (gCN QDs) synthesized by microwave assisted solvo-thermal technique and characterized via optical spectroscopy, XRD, HR-TEM, Fluorescence spectroscopy, FT-IR and Raman spectroscopy. Synthesized gCN were used for the removal of mercury ions from polluted water samples in a microcartridge format. Density functional theory (DFT) calculations revealed a possible interaction of mercury atoms, and embedment of mercury atom onto synthesized gCN surface lead to moderate structural distortion, reduced band gap and altered dielectric response. Experimentally, the excitation dependent fluorescence of QDs is highly compromised in presence of mercuric (Hg²⁺) and other ions, validating the theoretical findings, and establishing their use as metal sensor probes. Hg²⁺ binding ability with gCN QDs was further utilized in developing bioinspired micro-cartridge via covalent conjugation to Agarose microbeads. Micro-cartridge can remove heavy metal contamination from polluted water with a binding efficiency of 24.63 mg HgCl₂ for 10 mg of Agarose-gCN conjugate.

Shruti, V. C., et al. (2019). "Microplastics in freshwater sediments of Atoyac River basin, Puebla City, Mexico." Science of the Total Environment **654**: 154-163.

Microplastics (MPs) are contaminants of emerging concern in aquatic environments. The abundance, distribution and characteristics (color, morphology, texture) of MPs from Atoyac River basin, a highly urbanized river system located in Central Mexico were investigated in this study. The sediment samples were collected from 29 different sites along the Atoyac River basin in four different zones: Zahuapan River, Atoyac River, Confluence zone and Valsequillo dam and processed for MPs extraction using ZnCl₂ density separation method. The total number of MPs in Zahuapan River, Atoyac River, Confluence zone and Valsequillo dam was 1633.34+/-202.56, 1133.33+/-72.76, 833.33+/-80.79 and 900+/-346.12itemskg⁻¹ respectively. It was found that the concentration of MPs is higher in the downstream section of the river (confluence zone: 833.33+/-80.79 & Valsequillo dam: 900+/-346.12itemskg⁻¹), revealing significant impacts of dense population and industrial complex of Puebla City. Colored MPs were predominant accounting for 51% and white MPs for 49% of the total MPs. Films (25.9%) and fragments (22.2%) were the most abundant type followed by fibers (14.8%). Scanning electron microscope images revealed varying disintegration features and energy-dispersive X-ray spectra demonstrated the presence of different metal elements on the surface of MPs. The results highlighted the widespread distribution of MPs in the sediments of Atoyac River basin, Mexico.

Shyma, K. P., et al. (2011). "Latex agglutination test for detection of trypanosomosis in equines." Journal of Veterinary Parasitology **25**(2): 132-134.

A study was conducted to screen some horses in Haryana for trypanosomosis by monoclonal antibody based latex agglutination test (MAb-LAT). The latex reagent used in the present study contained suspension of latex microbeads, coated with anti-Trypanosoma evansi murine monoclonal antibody. Seventy one horse blood samples were screened initially by wet blood film (WBF) and their corresponding serum samples were subjected to MAb-LAT. Some of these samples (n=16) were also examined by microhaematocrit centrifugation technique (MHCT). None of the blood samples showed the presence of T. evansi by WBF, whereas MHCT could detect 1 (6.25%) sample positive. However, 33 samples (46.48%) were found positive by MAb-LAT. This study has revealed that MAb-LAT is more sensitive than the conventional parasitological examination for detection of trypanosomosis in horses. Moreover MAb-LAT is simple to perform, rapid, cost-effective and does not require sophisticated equipment for reading the results and hence can be used as a field-level test.

Si, L., et al. (2009). "Calcium pectinate gel bead intended for oral protein delivery: preparation improvement and formulation development." Chemical & Pharmaceutical Bulletin **57**(7): 663-667.

Calcium pectinate gel (CPG) micrometer-sized beads (microbeads) containing insulin, as a model amphoteric protein, were prepared by ionotropic gelation technique together with an air compressor. The influences of phosphate buffer, pH as well as calcium and pectin concentrations of cross-linking solution on the characteristics and release profiles of microbeads were investigated. With the aid of compressed air flow, the mean diameters of beads were successfully decreased to micron-sized. The results showed that all the factors investigated greatly affected the entrapment efficiencies and release profiles of the microbeads. Suitable formulation concentrations should be considered and great care should be taken to maintain the pH of working solutions at or close to isoelectric point of protein loaded during the whole preparation process. Hence, CPG microbeads of perfect spherical shape, uniform sizes, enhanced mechanical strength, good entrapment efficiencies and delayed release profiles were prepared for a load of amphoteric protein and peptide drugs, without any use of organic solvents or harsh ingredients. Therefore, CPG microbeads could be a promising carrier for oral controlled-release systems of amphoteric protein and peptide drugs.

Siddiqui, K. F., et al. (2011). "Understanding the biology of 16 kDa antigen of Mycobacterium tuberculosis: Scope in diagnosis, vaccine design and therapy." Critical Reviews in Microbiology **37**(4): 349-357.

Heat shock proteins (HSPs) are conserved and ubiquitous house keeping entities that act as molecular chaperones, which protect the cell from damage during stress. One such HSP, the 16kDa antigen, from Mycobacterium tuberculosis (Mtb) has received considerable attention due to its importance in tuberculosis latency and immunodominant property. In this article, we discuss about the potential role of 16kDa antigen of Mtb in latency, its expression, regulation, and implication in host immune response. We also highlight the scope of employing 16kDa in early diagnosis, development of vaccine and as a potential drug target. © 2011 Informa Healthcare USA, Inc.

Siddiqui, M. N., et al. (2009). "Determination of trace metals using laser induced breakdown spectroscopy in insoluble organic materials obtained from pyrolysis of plastics waste." Bulletin of environmental contamination and toxicology **83**(1): 141-145.

Laser induced breakdown spectroscopy (LIBS) was applied for the detection of trace elements in non-degradable part of plastics known as insoluble organic material, obtained from thermal and catalytic degradation of plastics. LIBS signal intensity for each metal measured in the test sample was unique and different. The capability of this technique is demonstrated by analyzing various trace metals present inside plastics and also compared with ICP results. The metal concentration (ppm) measured with LIBS and verified by ICP for Ag (901), Al (522), Fe (231), Co (628), V (275), Ni (558), Pb (325), Mn (167) and Cd (378) are higher than permissible safe limits. © 2009 Springer Science+Business Media, LLC.

Siddiqui, M. N., et al. (2008). "Identification of different type of polymers in plastics waste." Journal of Environmental Science & Health Part A-Toxic/Hazardous Substances & Environmental Engineering **43**(11): 1303-1310.

The main goal of this work was to develop and test advanced techniques for the instant identification of different type of polymers in post-consumer plastics. In order to accomplish this task, infrared (IR), X-ray diffraction (XRD), differential scanning calorimetric (DSC) and laser

induced breakdown spectroscopic (LIBS) techniques were applied. The following six model plastics were identified in this study. Low-density polyethylene (LDPE), High-density polyethylene (HDPE), Polypropylenes (PP), Polystyrene (PS), Polyethylene terephthalate (PET) and Polyvinyl chloride (PVC) along with few randomly selected plastics waste such as water bottle and cap, water cups, yogurt container and coke bottle were studied. IR has shown the fingerprinting of polymer types present in plastics waste. The XRD analysis helps to provide characteristic spectral lines whose intensities vary with the type of each constituent polymer. The DSC method provided the different crystalline melting temperature, glass transition, and onset temperature for the peaks and the percent crystallinity data single out different polymers. The ratio of LIBS signals intensities of carbon and hydrogen atoms were employed for the finger printing of the different family of plastics. The combined use of IR, XRD, DSC and LIBS techniques yielded very useful and effective results for plastic waste management.

Sieber, R., et al. (2020). "Dynamic probabilistic material flow analysis of rubber release from tires into the environment." Environmental Pollution **258 (no pagination)**(113573).

The release of rubber to the environment was quantified by dynamic probabilistic material flow analysis and proportions ending up in roadsides, water and soils were obtained. The presence of microplastics in the environment is currently receiving a lot of attention. Rubber particles from tire wear have been estimated in several mass emission inventories to be a major contributor to the total microplastic release. This work used dynamic probabilistic material flow analysis to quantify the flows of rubber particles from tires to roads and further onto soils and surface waters of Switzerland. The model considered the whole life-cycle of tires from import over the use phase to the end-of-life and the re-use of scrap tires. Uncertainties of model parameters and data variability were considered by using a probabilistic approach. Mass flows onto soils and through road drainage by both uncontrolled dispersal and engineered systems are considered. In addition, the release of rubber from artificial turfs was included. The accumulation of rubber particles in the environment was quantified over the time frame from 1988 to 2018. The results show that in 2018, 1.29 +/- 0.45 kg/capita of rubber was emitted from tire wear (97%) and rubber granules (3%). Street cleaning and waste water treatment removed around 26% of this rubber mass before finally reaching the receiving environmental compartment, resulting in an effective input of 0.96 +/- 0.35 kg/capita of rubber in 2018 into the natural environment. Most of this mass (74%) was deposited on roadside soils (up to 5 m distance from road), 22% flowed into surface waters and the remaining part (4%) was emitted to soils. The dynamic modeling showed an increase of the input into the environment by about 10% from 1990 to 2018. The ban of sewage sludge application on soils resulted in a marked decrease in the amount transferred to soils after the year 2000. In total, 219 +/- 22 ktonnes of rubber particles have accumulated in the environment since 1988 in Switzerland. Copyright © 2019 Elsevier Ltd

Siegel, C., et al. (2012). "Selective factor XIIa inhibition attenuates silent brain ischemia." Molecular Imaging and Biology **1)**: S861.

Objective - Silent brain ischemia (SBI) can be observed in up to 45% of patients who undergo invasive vascular procedures. Unlike acute stroke, the diffuse nature of SBI and its less tangible clinical symptoms make this disease difficult to diagnose and treat. Hence, there is a need to better understand the pathophysiology of SBI to a) improve its detection and b) explore therapeutic targets. Methods and Results - Here we use a murine model of SBI induced by injection of 500 microbeads of 43 mum diameter or 10 muL of fluorescently labeled fractionated clot (~10 mum size). Using sensitive molecular imaging, we found abnormal activation of the coagulation cascade (SPECT-CT of factor XIII activity) and inflammation (T1 weighted MRI of

myeloperoxidase activity) close to where emboli lodge in the brain. Injection of microbeads induced more MPO activity when compared to thromboemboli (contrast-to-noise-ratio, CNR, microbeads: 36 +/- 1, thromboemboli: 23 +/- 2, p<0.05) and larger lesions (number of MPO-Gd+ voxels in the brain, microbeads: 3162 +/- 1435, thromboemboli: 548 +/- 207; p = 0.05). A recombinant selective factor XIIa inhibitor derived from the hematophagous insect Triatoma infestans (rHA-Infestin-4) significantly reduced ischemic damage (54-66% reduction of TTC-negative area, p<0.05) and pathological coagulation (35-39% reduction of FXIII activity, p<0.05) without increasing hemorrhagic frequency. Ex vivo imaging and histopathology confirmed the in vivo data. Conclusion - Focal intracerebral clotting and inflammatory activity are part of the pathophysiology underlying SBI, and can be detected by SPECT-CT imaging of blood coagulation factor XII activity, as well as MPO-activated Gd compounds on MRI. Inhibiting factor XIIa with rHA-Infestin-4 may present a safe and effective treatment to decrease the morbidity from SBI.

Siegfried, M., et al. (2017). "Export of microplastics from land to sea. A modelling approach." Water Research **127**: 249-257.

Quantifying the transport of plastic debris from river to sea is crucial for assessing the risks of plastic debris to human health and the environment. We present a global modelling approach to analyse the composition and quantity of point-source microplastic fluxes from European rivers to the sea. The model accounts for different types and sources of microplastics entering river systems via point sources. We combine information on these sources with information on sewage management and plastic retention during river transport for the largest European rivers. Sources of microplastics include personal care products, laundry, household dust and tyre and road wear particles (TRWP). Most of the modelled microplastics exported by rivers to seas are synthetic polymers from TRWP (42%) and plastic-based textiles abraded during laundry (29%). Smaller sources are synthetic polymers and plastic fibres in household dust (19%) and microbeads in personal care products (10%). Microplastic export differs largely among European rivers, as a result of differences in socio-economic development and technological status of sewage treatment facilities. About two-thirds of the microplastics modelled in this study flow into the Mediterranean and Black Sea. This can be explained by the relatively low microplastic removal efficiency of sewage treatment plants in the river basins draining into these two seas. Sewage treatment is generally more efficient in river basins draining into the North Sea, the Baltic Sea and the Atlantic Ocean. We use our model to explore future trends up to the year 2050. Our scenarios indicate that in the future river export of microplastics may increase in some river basins, but decrease in others. Remarkably, for many basins we calculate a reduction in river export of microplastics from point-sources, mainly due to an anticipated improvement in sewage treatment.

Sierra, I., et al. (2019). "Identification of microplastics in wastewater samples by means of polarized light optical microscopy." Environmental Science & Pollution Research **28**: 28.

Many reports state the potential hazards of microplastics (MPs) and their implications to wildlife and human health. The presence of MP in the aquatic environment is related to several origins but particularly associated to their occurrence in wastewater effluents. The determination of MP in these complex samples is a challenge. Current analytical procedures for MP monitoring are based on separation and counting by visual observation or mediated with some type of microscopy with further identification by techniques such as Raman or Fourier-transform infrared (FTIR) spectroscopy. In this work, a simple alternative for the separation, counting and identification of MP in wastewater samples is reported. The presented sample preparation technique with further polarized light optical microscopy (PLOM) observation positively identified the vast majority of MP particles occurring in wastewater samples of Montevideo, Uruguay, in the 70-600 mum range. MPs with different shapes and chemical composition were identified by PLOM and confirmed by confocal Raman microscopy. Rapid identification of polyethylene (PE), polypropylene (PP) and polyethylene terephthalate (PET) were evidenced. A major limitation was found in the identification of MP from non-birefringent polymers such as PVC (polyvinylchloride). The proposed procedure for MP analysis in wastewater is easy to be implemented at any analytical laboratory. A pilot monitoring of Montevideo WWTP effluents was carried out over 3-month period identifying MP from different chemical identities in the range 5.3-8.2 x 10³ MP items/m³.

Sievert, W., et al. (2014). "Adhesion Molecule Expression and Function of Primary Endothelial Cells in Benign and Malignant Tissues Correlates with Proliferation." PLoS ONE **9**(3).

Background Comparative analysis of the cellular biology of the microvasculature in different tissues requires the availability of viable primary endothelial cells (ECs). This study describes a novel method to isolate primary ECs from healthy organs, repair blastemas and tumors as examples of non-proliferating and proliferating benign and malignant tissues and their functional characterization. Methodology/Principal Findings Single cell suspensions from hearts, lungs, repair blastemas and tumors were incubated consecutively with an anti-CD31 antibody and magnetic micro-beads, coupled to a derivative of biotin and streptavidin, respectively. Following magnetic bead separation, CD31-positive ECs were released by biotin-streptavidin competition. In the absence of micro-beads, ECs became adherent to plastic surfaces. ECs from proliferating repair blastemas and tumors were larger and exhibited higher expression densities of CD31, CD105 and CD102 compared to those from non-proliferating normal tissues such as heart and lung. The expression density of CD34 was particularly high in tumor-derived ECs, and that of CD54 and CD144 in ECs of repair blastemas. Functionally, ECs of non-proliferating and proliferating tissues differed in their capacity to form tubes in matrigel and to align under flow conditions. Conclusions/Significance This method provides a powerful tool to generate high yields of viable, primary ECs of different origins. The results suggest that an altered expression of adhesion molecules on ECs in proliferating tissues contribute to loss of EC function that might cause a chaotic tumor vasculature.

Sighicelli, M., et al. (2018). "Microplastic pollution in the surface waters of Italian Subalpine Lakes." Environmental Pollution **236**: 645-651.

Plastic debris incidence in marine environment was already highlighted in the early 1970s. Over the last decade, microplastic pollution in the environment has received increasing attention and is now an emerging research area. Many studies have focused on quantifying microplastic abundance in the marine environment, while there are relatively few data on microplastic occurrence in freshwater environment. Recent studies have reported high concentrations of microplastics in lakes and rivers, although the understanding of several factors influencing source, transport and fate is still limited. This study compares different lakes and the common factors, which could influence the occurrence and distribution of microplastics. The three subalpine lakes monitored include Lake Maggiore, Iseo and Garda. The selected sampling transects reflect the hydrologic conditions, the morphometric characteristics of these lakes, and other factors influencing the release of plastics debris in lakes. Particles of microplastics (<5 mm) were found in all sampled surfaces. The particles collected were classified depending on their number, shape and composition. The shape distribution showed the dominating occurrence of fragments (73.7%). The chemical composition of all examined samples clearly shows dominating

presence of polyethylene (45%), polystyrene (18%) and polypropylene (15%). The results provide significant relations among the different contribution of direct and diffuse sources to the quantity of microplastics, highlighting the importance of understanding the spatial distribution dynamics of microplastics within a lake system that acts as a sink and source of plastic particles. The significant presence of microplastics in Italian freshwater systems and the spatial variation in microplastic concentration confirm the importance of the input sources. Copyright © 2018

Sigle, J. P., et al. (2013). "Anti-leucocyte antibodies in platelet apheresis donors with and without prior immunizing events: implications for TRALI prevention." Vox Sanguinis **105**(3): 244-252.

BACKGROUND AND OBJECTIVES: Transfusion-related acute lung injury (TRALI) prevention strategies in platelet (PLT) apheresis donors focus on identifying antileucocyte antibody-positive donors. The use of microbead based assays for screening purposes is hampered by the lack of a consensus cut-off for TRALI prevention and the undefined role of anti-leucocyte antibodies in never-alloexposed donors. This study evaluated anti-leucocyte antibody assays in PLT apheresis donors with and without prior immunizing events with special focus on microbead assay cut-offs, antibody specificities and their potential significance in never-alloexposed donors.

MATERIAL AND METHODS: Blood samples of male and female PLT apheresis donors with and without history of prior immunization were tested for anti-leucocyte antibodies.

RESULTS: Of 262 female and 118 male PLT apheresis donors, 37.4% had prior immunizing events. Fifty-eight of 238 (24.4%) donors without prior immunizing event had anti-HLA antibodies confirmed in microbead single antigen assay (mean fluorescence intensity (MFI) >500). Even with a cut-off MFI >3000, anti-HLA antibodies were detected in 10.6% of female and 4.3% of male donors without history of immunization. Of the antibody specificities found, 6 of 17 (35.3%) anti-HLA-A, 4 of 8 (50.0%) anti-HLA-B and 4 of 6 (66.6%) anti-HLA class II antibodies have been detected in donors associated with TRALI cases in the literature.

CONCLUSION: Platelet apheresis donors without history of immunization have anti-leucocyte antibodies that potentially can cause TRALI. In our opinion, this cohort should be included in screening strategies for TRALI prevention. As references and consensus cut-offs have not yet been established, it is premature to use microbead assays as standard for donor screening.

Sigler, M. (2014). "The effects of plastic pollution on aquatic wildlife: current situations and future solutions." Water, Air, and Soil Pollution **225**(11).

The majority of consumer products used today are comprised of some form of plastic. Worldwide, almost 280 million t of plastic materials are produced annually, much of which ends up in landfills or the oceans (Shaw and Sahni Journal of Mechanical and Civil Engineering 46-48, 2014). While plastics are lightweight, inexpensive, and durable, these same qualities can make them very harmful to wildlife, especially once they become waterborne. Once seaborne, plastics are most likely found circulating in one of five major ocean gyres: two in the Pacific, one in the Indian, and two in the Atlantic. These ocean garbage patches are not solid islands of plastic; instead, they are a turbid mix of plastics (Kostigen 2008; Livingeco 2011). Recent research conducted on the surfaces of the Great Lakes has identified similar problems (Erikson et al. Marine Pollution Bulletin, 77(1), 177-182, 2013). A growing concern is that once plastics reach the wild, they may cause entanglement, death from ingestion, and carry invasive species. Several cutting edge technologies have been piloted to monitor or gather the plastics already in our environments and convert them back into oil with hopes to reduce the damage plastics are causing to our ecosystems.

Silkenstedt, E., et al. (2019). "Interaction of mantle cell lymphoma with the microenvironment induces phospho AKT-mediated resistance against BTK inhibition and can be overcome by co-treatment with a specific AKT inhibitor (MK-2206)." Blood. Conference: 61st Annual Meeting of the American Society of Hematology, ASH **134**(Supplement 1).

Mantle cell lymphoma (MCL) is a distinct lymphoma subtype representing 6-8% of non-Hodgkin's lymphoma (NHL). Although with current standard therapy high initial response rates can be achieved, early relapses and rapid disease progression determine the clinical course of most MCL patients. Recently, Bruton's tyrosine Kinase (BTK) inhibitors have been introduced with highly promising clinical activity. Nevertheless, interindividual responsiveness is heterogenous and primary and secondary resistance has been reported. However, molecular mechanisms driving resistance to BTK inhibition are not well understood yet. Among other factors, interactions between the tumor and its microenvironment have been proposed to play an important role in response to targeted therapy. In this study, we investigated the influence of tumor cell interaction with its microenvironment on sensitivity to the BTK inhibitor CC292 in vitro. MCL cell lines JeKo-1, Z-138 and Granta-519 were treated with 5 muM of CC292 alone or in co-culture with human bone marrow stromal cells (HS-5) and cell death induction and proliferation were assessed. Expression of proteins involved in BCR signaling and other tumor-promoting pathways was analyzed by Western Blot. Co-cultured MCL cells settled within the stromal cell layer were separated using MACS Feeder removal microbeads prior to Western Blot analysis. In all cell lines, direct interaction with the microenvironment markedly reduced sensitivity towards CC292 treatment (by 22% (JeKo-1), 33% (Granta) and 64 % (Z-138)). Importantly, cell-cell contact was shown to play a crucial role for mediating resistance to CC292 as only those MCL cells settled within the stromal cell layer proved to be significantly less vulnerable to the inhibitor compared to MCL cells co-cultured with HS-5 but separated by a transwell insert. Western Blot analysis showed a reduction of protein levels of phBTK upon treatment with CC292 in both, mono- and co-cultured cells. Interestingly, direct interaction of MCL cells with the microenvironment strongly induced protein expression of phAkt. Accordingly, phosphorylation (inactivation) of the pro-apoptotic FoxO1, a downstream-target of phAkt, was increased and its translocation to the nucleus was decreased in those cells. We could show that the effect of microenvironment interaction on sensitivity towards CC292 is mediated by Akt as knockdown of Akt using siRNA restored sensitivity to the drug. Furthermore, co-treatment of MCL cells with CC292 and the specific Akt inhibitor MK-2206 hampered upregluation of phAkt in co-cultivated cells and prevented Akt-mediated sequestration of FoxO1 in the cytoplasm, resulting in translocation of FoxO1 to the nucleus. Thus, combination with MK-2206 could significantly overcome microenvironment-mediated protection from growth inhibition and apoptosis induction upon CC292 treatment. Moreover, combination of the BTK inhibitor CC292 and the Akt inhibitor MK-2206 proved to act synergistically in MCL cells in all dose combinations tested (Combination index 0,73-0,93 in Z-138; 0,47-0,78 in JeKo-1). Taken together, cell-cell-interaction of MCL cells with their microenvironment protected them from CC292-induced cell death. This effect was mediated by increased phAkt expression resulting in inhibition of pro-apoptotic signaling and could effectively be overcome by combination with the specific Akt inhibitor MK-2206. Furthermore, CC292 and MK-2206 acted synergistically in MCL cells. Our results indicate that co-targeting the PI3K/Akt-pathway might be a promising strategy to overcome resistance to BTK inhibition mediated by interaction with the microenvironment.

Sillanpaa, M. and P. Sainio (2017). "Release of polyester and cotton fibers from textiles in machine washings." Environmental Science & Pollution Research **24**(23): 19313-19321.

Microplastics are widely spread in the environment, which along with still increasing production

have aroused concern of their impacts on environmental health. The objective of this study is to quantify the number and mass of two most common textile fibers discharged from sequential machine washings to sewers. The number and mass of microfibers released from polyester and cotton textiles in the first wash varied in the range 2.1 x 10⁵ to 1.3 x 10⁷ and 0.12 to 0.33% w/w, respectively. Amounts of released microfibers showed a decreasing trend in sequential washes. The annual emission of polyester and cotton microfibers from household washing machines was estimated to be 154,000 (1.0 x 10¹⁴) and 411,000 kg (4.9 x 10¹⁴) in Finland (population 5.5 x 10⁶). Due to the high emission values and sorption capacities, the polyester and cotton microfibers may play an important role in the transport and fate of chemical pollutants in the aquatic environment.

Silva, C. J. M., et al. (2019). "Ingestion of small-sized and irregularly shaped polyethylene microplastics affect Chironomus riparius life-history traits." Science of the Total Environment **672**: 862-868.

Microplastics (MPs) are emerging contaminants of freshwater ecosystems. Once in aquatic systems, most of these plastic particles undergo processes of fragmentation, biofouling, and sedimentation, resulting in increased concentrations of smaller sized and irregularly-shaped particles in the sediment. High levels of MPs in freshwater sediments can denote a potential threat to benthic and sediment-dwelling organisms such as dipteran larvae. This study evaluates the ecotoxicological effect of three pools of irregularly-shaped polyethylene (PE) microplastics (pools containing 90% of the particles within 32-63 micro m (size-class A), 63-250 micro m (size-class B) and 125-500 micro m (size-class C)), with concentrations ranging from 1.25 to 20 g Kg⁻¹ sediment, on the dipteran Chironomus riparius life-history traits. After ten days of exposure, larvae ingested PE particles typically in the 32-63 micro m range, even when 90% of the particles possessed higher size (i.e., in size-classes B and C) and the larvae mandible allowed the ingestion of such bigger-sized particles. Thus, the number of ingested particles was higher in size-class A, followed by B and C, and led to a significant reduction with similar magnitude on larval growth (Lowest Observed Effect Concentrations (LOEC)=2.5 g Kg⁻¹ sediment DW) and a significant delay on imagoes emergence (e.g., LOEC=1.5 g Kg⁻¹ sediment DW for females). The results from this study show that the ingestion and persistence of small-sized polyethylene microplastics caused significant impairments on life-history traits of C. riparius. Considering their role on freshwater food-webs and the potential persistence of small-sized PE particles in their larval gut, these results also point for the potential adverse effects of small-sized microplastics at the community and ecosystem level.

Silva, J. D. B., et al. (2018). "Use of resources and microplastic contamination throughout the life cycle of grunts (Haemulidae) in a tropical estuary." Environmental Pollution **242**(Part A): 1010-1021.

The distribution, feeding ecology and microplastic contamination were assessed in different ontogenetic phases of Haemulidae species inhabiting the Goiana Estuary, over a seasonal cycle. Pomadasys ramosus and Haemulopsis corvinaeformis are estuarine dependent species that use habitats with specific environmental conditions each season. Pomadasys ramosus was found in the upper and middle estuaries during the rainy season, when salinity showed the lowest values. Haemulopsis corvinaeformis was found in the lower estuary during the dry season, when salinity increased in the estuary. Juveniles of P. ramosus are zooplanktivores, feeding mainly on calanoid copepods. Sub-adults and adults are zoobenthivores, feeding on invertebrates associated to the bottom, mainly Polychaeta. Juveniles of H. corvinaeformis were not found in the main channel, but sub-adults and adults showed a zoobenthivore habit, feeding mainly on Anomalocardia flexuosa (Mollusca: Bivalvia). Dietary shifts along the life cycle and the spatio-temporal

relationship between their distribution and the availability of microplastics along the estuary seem to have a strong influence in the ingestion of microfilaments. The highest average ingestion of microfilaments by P. ramosus coincided with the peak of ingestion of Polychaeta by sub-adults in the upper estuary during the late rainy season. For H. corvinaeformis the highest ingestion of microfilaments coincided with the peak of ingestion of A. flexuosa by adults in the lower estuary during the late dry season. Such contamination might be attributed to the time when these phases shifted to a more diverse diet and began to forage on benthic invertebrates. Research on microplastic contamination must consider species-specific behaviour, since the intake of microplastics is dependent on patterns of distribution and trophic guild within fish assemblages.

Silva, J. S., et al. (2008). "Flag items as a tool for monitoring solid wastes from users on urban beaches." Journal of Coastal Research **24**(4): 890-898.

An experiment was designed to test if the contamination of intensely used beaches by solid wastes could be correlated to the presence of users. Profiles perpendicular to the water line were marked on Boa Viagem Beach, Recife City, Pernambuco, Brazilian Northeast. The solid waste items collected within these profiles at days of high user frequency revealed that some items might be used as flags for the presence (and contribution to the contamination) of users on the beach. Such items especially abundant were plastic cups and drinking straws. The contamination of the beach has the same qualitative character at all sites at all times. However, the amount of flag items changes according to the more intense use of the beach, especially during summer weekends and sociocultural events, when use reaches its maximum intensity.

Silva, K. C. G., et al. (2018). "Symbiotic microencapsulation to enhance Lactobacillus acidophilus survival." LWT Food Science and Technology **89**: 503-509.

Lactobacillus acidophilus was microencapsulated in alginate-gelatin (AG) and alginate-gelatin-fructooligosaccharides (AGF) microbeads by external gelation, with the purpose of increasing the viability of the probiotic culture when exposed to gastrointestinal tract (GIT) and during storage when added to yogurt. The microencapsulation provided greater protection of cells when exposed to simulated GIT. Moreover the addition of fructooligosaccharide (FOS) to the matrix promoted the formation of a more interconnected network, which contributed to better protection of cells and controlled delivery. Microencapsulation process proved to not affect cell viability. Microbeads AG and AGF improved probiotic survival during the storage in yogurt compared to free L. acidophilus (FLA). This study showed that symbiotic microencapsulation provided greater viability of L. acidophilus during the storage in yogurt and in GIT, as well as providing functional characteristics of yogurt with added of AGF microbeads.

Silva, M. M., et al. (2019). "Dispersal of potentially pathogenic bacteria by plastic debris in Guanabara Bay, RJ, Brazil." Marine Pollution Bulletin **141**: 561-568.

Analyses of thermotolerant coliform and heterotrophic bacteria as well as Escherichia coli and Vibrio species were carried out on plastic samples and in the surrounding waters of Guanabara Bay to evaluate plastic debris as vehicles of bacterial dispersal. Chemical characterizations of plastics were performed using Fourier transform infrared spectroscopy (FTIR). Plastic debris with high coliform contents were found, while their respective water samples had only low titers. No correlations were observed, however, between the amounts of bacteria and the chemical compositions of the plastic debris. Forty-four bacterial strains were PCR-confirmed as E. coli pathotypes, and 59 strains of Vibrio spp. (with 12 being identified as Vibrio cholerae [6], Vibrio vulnificus [5], and Vibrio mimicus [1]). These findings suggest these plastics can function as a

substrate for bacterial biofilms (including pathogens). These debris, in turn, can be dispersed in aquatic environments not otherwise showing recent fecal bacterial contamination. Copyright © 2019 Elsevier Ltd

Silva-Cavalcanti, J. S., et al. (2017). "Microplastics ingestion by a common tropical freshwater fishing resource." Environmental Pollution **221**: 218-226.

Microplastics pollution is widespread in marine ecosystems and a major threat to biodiversity. Nevertheless, our knowledge of the impacts of microplastics in freshwater environments and biota is still very limited. The interaction of microplastics with freshwater organisms and the risks associated with the human consumption of organisms that ingested microplastics remain major knowledge gaps. In this study, we assessed the ingestion of microplastics by Hoplosternum littorale, a common freshwater fish heavily consumed by humans in semi-arid regions of South America. We assessed the abundance and diversity of both plastic debris and other food items found in the gut of fishes caught by local fishermen. We observed that 83% of the fish had plastic debris inside the gut, the highest frequency reported for a fish species so far. Most of the plastic debris (88.6%) recovered from the guts of fish were microplastics (<5 mm), fibres being the most frequent type (46.6%). We observed that fish consumed more microplastics at the urbanized sections of the river, and that the ingestion of microplastics was negatively correlated with the diversity of other food items in the gut of individual fish. Nevertheless, microplastics ingestion appears to have a limited impact on H. littorale, and the consequences of human consumption of this fish were not assessed. Our results suggest freshwater biota are vulnerable to microplastics pollution and that urbanization is a major factor contributing to the pollution of freshwater environments with microplastics. We suggest the gut content of fish could be used as a tool for the qualitative assessment of microplastics pollution in freshwater ecosystems. Further research is needed to determine the processes responsible for the high incidence of microplastics ingestion by H. littorale, and to evaluate the risk posed to humans by the consumption of freshwater fish that ingested microplastics.

Silva-Cote, I., et al. (2019). "Strategy for the Generation of Engineered Bone Constructs Based on Umbilical Cord Mesenchymal Stromal Cells Expanded with Human Platelet Lysate." Stem Cells International **2019 (no pagination)**(7198215).

Umbilical cord mesenchymal stromal cells (UC-MSC) are promising candidates for cell therapy due to their potent multilineage differentiation, enhanced self-renewal capacity, and immediate availability for clinical use. Clinical experience has demonstrated satisfactory biosafety profiles and feasibility of UC-MSC application in the allogeneic setting. However, the use of UC-MSC for bone regeneration has not been fully established. A major challenge in the generation of successful therapeutic strategies for bone engineering lies on the combination of highly functional proosteogenic MSC populations and bioactive matrix scaffolds. To address that, in this study we proposed a new approach for the generation of bone-like constructs based on UC-MSC expanded in human platelet lysate (hPL) and evaluated its potential to induce bone structures in vivo. In order to obtain UC-MSC for potential clinical use, we first assessed parameters such as the isolation method, growth supplementation, microbiological monitoring, and cryopreservation and performed full characterization of the cell product including phenotype, growth performance, tree-lineage differentiation, and gene expression. Finally, we evaluated bone-like constructs based on the combination of stimulated UC-MSC and collagen microbeads for in vivo bone formation. UC-MSC were successfully cultured from 100% of processed UC donors, and efficient cell derivation was observed at day 14+/-3 by the explant method. UC-MSC maintained mesenchymal cell morphology, phenotype, high cell growth

performance, and probed multipotent differentiation capacity. No striking variations between donors were recorded. As expected, UC-MSC showed tree-lineage differentiation and gene expression profiles similar to bone marrow- and adipose-derived MSC. Importantly, upon osteogenic and endothelial induction, UC-MSC displayed strong proangiogenic and bone formation features. The combination of hPL-expanded MSC and collagen microbeads led to bone/vessel formation following implantation into an immune competent mouse model. Collectively, we developed a high-performance UC-MSC-based cell manufacturing bioprocess that fulfills the requirements for human application and triggers the potency and effectivity of cell-engineered scaffolds for bone regeneration. Silvestris, E., et al. (2015). "Ovarian stem cells in perspective treatment of infertility: A preliminary isolation approach." Human Reproduction **1)**: i459.

Study question: Ovarian stem cells (OSC) have been detected in mice and postulated in human ovaries1. They typically expose Ddx-4 (DEAD box polypeptide 4), a stemness marker uniquely expressed by germ line cells as both OSCs and spermatogones. Thus, we tried to isolate OSCs from woman ovaries by immunoselection using anti-Ddx-4 antidodies. Summary answer: Although at low percentage, OSCs are located within the cortex of the human ovary and their isolation is possible by sorting with appropriate combined separation methodology. Once isolated, OSCs appear viable and can be further characterized and/or cultured for additional studies. What is known already: Despite the general opinion that postnatal mammalian ovaries of most species do not contain renewable germinal OSCs2, previous work by Tilly and co-workers showed the existence of OSCs in human ovaries since these cells were separated by Ddx-4 positive selection3. However, these finding were confuted for the major cytoplasmic expression of Ddx-4. The antigen, indeed, is expressed both on cell membrane and cytoplasm by OSCs, whereas mature oocytes contain only its cytoplasmic tale. Study design, size, duration: The study was aimed to verify the occurrence and tentatively separate the OSCs from a small number of human ovaries by using magnetic immunoselection and sorting with anti-Ddx-4 reagents and subsequent typing by flowcytometry with specific monoclonal antibodies (MoAb) to specific cell lineage markers. Participants/materials, setting, methods: Ovarian cortex fragments from three women undergoing ovariectomy in premenopausal age, were digested by collagenase, filtered, suspended in presence of rabbit anti-Ddx-4 antibody and then passed through a column including anti-rabbit IgG conjugated magnetic microbeads. The eluted cells were typed by flowcytometry and confocal microscopy to assess the Ddx-4 localization. Main results and the role of chance: Within the full cell suspension, we gated the putative OSC population in relation to the cell size and found that the double positive population including OCT4A+/Ddx-4+ cells, was poorly expressed, whereas a definite enrichment was observed after the immunomagnetic sorting. In fact, the enriched Ddx-4+ cell population was increased up to 24% from the original 2% value in the initial cortical suspension, with remarkable fluorescence intensity suggesting the high molecular expression of Ddx-4 molecule. By immunofluorescence under confocal microscopy, these cells appeared of small size with a large nucleus, few cytoplasm and highly FITC-fluorescent deposits on the cell membrane reflecting the consistent expression of Ddx-4 molecules. This result supports the suitability of the separation of OSCs by this simple methodology using the immunomagnetic cell sorting. Limitations, reason for caution: Major skepticism derives from using Ddx-4 as cell surface marker for the OSC sorting since its location in cytoplasm is still detectable in mature oocytes. However, only OSCs express the membrane associated Ddx-4 and further work investigating other membrane markers as OCT-4A and SSEA-4 may improve the OSC separation methods. Wider implications of the findings: The future applications of these findings to the infertility field will cover different and unrelated

conditions ranging from the endocrine defective ovarian reserve to the iatrogenic infertility associated to chemotherapy in cancer patients. On the other hand, besides the infertility treatment, OSCs can be further investigated in parallel studies aimed at restoring the woman endocrine physiology in postmeno-pausal age. However, this approach primarily requires animal experimental models to prove their efficacy in treating endocrine dysfunctions.

Silvia, A., et al. (2019). "Microplastic removal by Red Sea giant clam (Tridacna maxima)." Environmental Pollution **252**(Part B): 1257-1266.

This study assesses for the first time the ingestion of microplastics by giant clams and evaluates their importance as a sink for this pollutant. A total of 24 individuals of two size classes were collected from the Red Sea and then exposed for 12 days to 4 concentrations of polyethylene microbeads ranging from 53 to 500 micro m. Experiments revealed that clams actively take up microplastic from the water column and the average of beads retained inside the animal was ~7.55+or-1.89 beads individual ⁻¹ day ⁻¹ (5.76+or-1.16 MPs/g dw). However, the digestive tract itself cannot be considered the only sink of microbeads in Tridacnids. Indeed, shells play a key role as well. The abundance of microplastic adhering to the shells, which was estimated directly, was positively correlated to the concentration of beads found in the surrounding seawater. Therefore, clams' shells contribute to the removal of 66.03+or-2.50% of the microplastic present in the water column. Furthermore, stress responses to the exposure to polyethylene were investigated. Gross Primary Production:Respiration (GPP:R) ratio decreased throughout of the experiment, but no significant difference was found between treatments and controls.

Simon, J. C., et al. (1995). "Rapid purification of human Langerhans cells using paramagnetic microbeads." Experimental Dermatology **4**(3): 155-161.

Detailed studies on the biology of Langerhans cells (LC), which account for only 1-3% of all epidermal cells, require isolation from their cutaneous symbionts. Several techniques of LC isolation have been reported, including positive enrichment with mAb coupled to immunomagnetic beads. The disadvantage of this technique is the size of the beads (approximately 2-5 microns), which can interfere with subsequent phenotypic and functional analyses. This limitation prompted us to test whether paramagnetic microbeads (15 nm) employed by the MACS system could be used to purify LC from human skin. To isolate fresh LC (fLC), epidermal cell suspensions (EC) were stained with anti-CD1a mAb and with appropriate secondary reagents conjugated to microbeads and to FITC. They were then passed over a separation column and exposed to a strong magnetic field. Thereafter both CD1a-depleted and CD1a-enriched cells were collected. Cultured LC (cLC) were isolated by staining 72-h cultured EC with anti-HLA-DR mAb followed by the same isolation procedure. Using this technique, we could routinely isolate viable EC that were 45-88% CD1a+ or HLA-DR+ as determined by FACS. Two-color FACS analysis demonstrated the majority of MACS-purified cells to be CD1a+/HLA-DR+, indicating that they were indeed LC. By transmission electron microscopy (TEM), the MACS-purified CD1a+/HLA-DR+ cells showed typical ultrastructural characteristics of LC. Furthermore, MACS-purified fLC or cLC were functionally intact, because they stimulated the proliferation of alloreactive T cells in a primary, one-way, mixed epidermal cell leukocyte reaction (MECLR). We conclude that MACS-separation is an efficient and rapid method to isolate human fLC and cLC of high purity and unimpaired function.

Simon, M., et al. (2019). "Removal of >10 micro M microplastic particles from treated wastewater by a disc filter." Water **11**(9).

In this paper, we evaluate the performance of a disc filter that retains microplastic (MP) particles from treated wastewater. A focal plane array-based Fourier transform infrared imaging technique enabled MP quantification and an in-house-built software (MPhunter) facilitated automatic analysis of the obtained infrared spectra. The disc filter retained 89.7% of particles, and 75.6% of their mass. This removal efficiency is comparable to removal rates reported by previous studies. However, the presence of an unexpectedly large number of MP particles whose size substantially exceeded the pore size of the disc filter suggests that particles could either bypass or pass through the filter mesh, somewhat diminishing the performance of the filter. The concentration of MPs in the effluent was 3 MP/L, corresponding to an estimated mass concentration of 0.31 micro g/L. The annual MP discharge from the studied WWTP after the disc filter was estimated to be 1.1 kg in 2017. It was hence not a significant contributor to MP emissions in Denmark. Although the operation of the disc filter seems to have been disturbed, it nonetheless achieved a high MP removal rate. Therefore, we conclude that it is a suitable technology to decrease the concentration of discharged MPs in wastewater effluents.

Simon-Sanchez, L., et al. (2019). "River Deltas as hotspots of microplastic accumulation: the case study of the Ebro River (NW Mediterranean)." Science of the Total Environment **687**: 1186-1196.

Microplastics (MPs) are considered pollutants that are ubiquitously distributed in aquatic environments. One of the key hotspot areas to understand fluxes of MPs entering into the oceans are transitional systems, between fresh and marine waters, where river estuaries in particular play an important role. In this study we analyzed MPs occurrence in the Ebro River Delta, Northeastern Iberian Peninsula, one of the largest wetland areas in the NW Mediterranean Basin. Microplastic profile, abundance, distribution, and characteristics were screened across different environmental matrices. MPs were collected in sandy beaches on the northern edge of the delta, in estuarine benthic sediments, and in surface waters of the Ebro River, with a mean abundance of 422+or-119 MPs.kg⁻¹ DW, 2052+or-746 MPs.kg⁻¹ DW and 3.5+or-1.4 MPs.m⁻³, respectively. Fibers were found to be the largest class (70+or-22%) of the three different environmental matrices investigated. We estimated that the Ebro surface water represents an input of 2.14 x 10⁹ MPs.yr⁻¹ to the Mediterranean Sea. The main contribution of this study is a new insight on the distribution of MPs across different environmental matrices in river estuaries, where estuarine benthic sediments were identified as a potential important sink for MPs.

Simon-Sylvestre, G. and J. Chabannes (1975). "The effects of some cultural techniques on certain soil properties: effects on a maize crop." Annales Agronomiques **26**(1): 75-99.

In field trials in 1971-2, maize was given 1 application of 2.5 kg a.i. simazine/ha or was mulched with black plastic sheeting or was given a dark-coloured soil conditioner consisting of a suspension of plastic particles. Application of simazine did not significantly affect yield, growth or chemical composition of grain or vegetative organs. The plastic mulch increased growth and yield and increased N, P, K and S contents. The soil conditioner also increased yields and nutrient contents but the effect was less than that given by the plastic mulch.

Singh, N., et al. (2019). "Understanding the stability of nanoplastics in aqueous environments: effect of ionic strength, temperature, dissolved organic matter, clay, and heavy metals (Electronic supplementary information (ESI) available. See DOI: 10.1039/c9en00557a)." Environmental Science: Nano **6**(10): 2968-2976.

Nanoplastics (NPs) are one of the most dangerous fractions of plastics because of their possible eco-toxicological impacts. NP stability and transport are highly influenced by various

environmental factors, which warrants the necessity to understand their fate in ambient water systems. This study investigates the polystyrene (PS) NP stability under the effect of varying ionic strength, temperature, dissolved organic matter (DOM), inorganic soil colloids and heavy metal salts using the dynamic light scattering technique. Controlled studies were used to examine the aggregation of NPs in the presence of natural river water (RW), groundwater (GW), and seawater (SW). Results highlight that, at all studied temperatures, divalent cations had a greater influence on the aggregation rate of NPs as compared to monovalent cations whereas for the same salt, a drop in temperature tended to increase the stability. A rise in critical coagulation concentration (CCC) by 1.6 and 2.4 times for NaCl and CaCl2 was observed, respectively, at 15 °C as compared to 35 °C. Steric repulsion produced by DOM stabilizes NPs shifting the CCC value to a higher salt concentration for NaCl. However, faster aggregation with CaCl2 due to complexation was notable. The clay colloids participate in heteroaggregation with NPs under the influence of salts; this was confirmed using cryo-TEM. Heavy metal salts such as ZnCl2 and CdCl2 had interactions with PS NPs similar to that presented by CaCl2 but showed independent behaviour in the presence of HgCl2, due to metal speciation under different redox conditions. The concentration of salts and organic substances in the complex matrix of natural water results in the least stable NPs in SW > RW > GW. The results of this study contribute to the fundamental understanding of the fate of NPs in complex aquatic environments.

Singh, R. K., et al. (2019). "Thermal degradation of waste plastics under non-sweeping atmosphere: Part 1: Effect of temperature, product optimization, and degradation mechanism." Journal of Environmental Management **239**: 395-406.

Continuous generation of plastic waste has prompted substantial research efforts in its utilization as a feedstock for energy generation. Pyrolysis has emerged as one of the best waste management technique for energy extraction from the plastic waste. The objective of this work is to investigate the effect of operating temperature on the liquid product yields in the pyrolysis process by non-isothermal heating. Non-catalytic thermal pyrolysis of waste polyethylene (PE) [high density polyethylene (HDPE)], waste polypropene (PP), waste polystyrene (PS), waste polyethylene terephthalate (PET) and mixed plastic waste (MPW) was carried out in a non-sweeping atmosphere in a semi-batch reactor at four different temperatures 450, 500, 550, and 600 degreeC. The minimum degradation temperature of the mixed and individual plastics was obtained using a thermogravimetric apparatus (TGA) at a heating rate of 20^{degree}C/min. The TGA results show that all plastics degrade in a single step and the degradation temperatures of PS > PET > PP > HDPE, while mixed plastic degradation indicates two distinct degradation steps. Further, a waste polymer shows a lower degradation temperature than the virgin polymer. The degradation of HDPE is found to produce the maximum oil yield with minimum solid residue. The degradation of PET results in the highest amount of solid and benzoic acid as crystals and gas with no oil. Degradation of mixed plastic causes oil yield in the intermediate range of pyrolysis of individual plastic wastes. Overall, 500 degreeC is observed to be an optimum temperature for the recovery of low-density pyrolytic oil with the highest liquid yield. The degradation of PE and PP is found to be caused by random chain scission followed by inter and intramolecular hydrogen transfer. The degradation of PS occurs by side elimination or end chain scission followed by beta-scission mechanism. The degradation of mix plastics results from random chain scission followed by beta-scission mechanism. The effect of temperature on oil and gas recovery as well as recovery time was also assessed. Copyright © 2019 Elsevier Ltd

Singh, R. K., et al. (2020). "Waste plastic to pyrolytic oil and its utilization in CI engine: Performance

analysis and combustion characteristics." Fuel **262**: 1.

For application of pure plastic pyrolytic oil (PPO) several modifications in the engine is required which rejects the utilization of the existing engines while a blend of conventional fuel and PPO can be used with a slight change in engine without having a high impact on engine performance and hence the blends are preferred over the utilization of PPO as crude oil for diesel engines. In this study, the non-catalytic pyrolysis of mixed plastic waste at a temperature of 450 °C is done to obtain high-grade pyrolytic oil having a composition similar to petroleum fuels such as gasoline and diesel. Physical properties of the PPO were analysed, and the compound analysis was done with GC–MS. Further FTIR of PPO and diesel were analysed and compared. Five different ratios of 10, 20, 30, 40 and 50% PPO with diesel in blends were utilized as a fuel in a diesel engine to determine the engine performance and characteristics. The higher presence of PPO in blend increases the brake thermal efficiency (BTE) and reduces specific fuel consumption (SFC) with an increase in load as reported. The presence of PPO results in high heat release and delayed ignition resulting in high in-cylinder pressure. Further high amount of oxygenated compounds in PPO helps in reducing the emission from the combustion. The utilization of PPO with diesel upto 50% in the blend can be used in diesel engines with a slight increase in emission of CO at higher loads.

Singhal, U., et al. (2018). "Targeted gene expression profiling within circulating tumor cells in mCRPC." Journal of Urology **199 (4 Supplement 1)**: e1188.

INTRODUCTION AND OBJECTIVES: Moving from simple enumeration of circulating tumor cells (CTCs) to molecular characterization continues to be a critical need in order for CTC-based liquid biopsy approaches to move into the clinic. CTCs provide a unique avenue to assess tumor-specific RNA expression, and methods that replicate tissue-based approaches may help address key technical challenges. Tissue-based molecular risk classifiers, such as Prolaris and OncotypeDx, were previously developed by targeted expression profiling using the TaqMan Low Density Array (TLDA) platform. Here we describe the development of an approach to perform CTC-based, targeted gene expression profiling using the TLDA platform in patients with metastatic castrate resistant prostate cancer (mCRPC). METHOD(S): CTCs were isolated from 5 mL whole blood of mCRPC patients using an anti-EpCAM-microbead based protocol. Following cell lysis, mRNA from CTCs was captured using Oligo(dT)25 mRNA Dynabeads followed by reverse transcription. TLDA cards (Applied Biosystems) were used to perform simultaneous, singleplex qPCR detection of a custom panel of 48 prostate cancer related genes and controls, including AR, AR-V7, PCA3, PSMA, SChLAP1, TMPRSS2:ERG, and WNT5B. Blood processed from 22 healthy controls was used as a baseline referent to account for leukocyte contamination. Gene expression data from prostate cancer cells (VCaP, PC3, and LNCaP) spiked into normal control blood was used for CTC isolation assay development, and CTCs from 68 patients with mCRPC were subsequently evaluated. RESULT(S): CTC expression was assessed in 68 patients with mCRPC. We identified 46 (68%) that showed increased androgen signaling, including 27 (40%) with increased expression of AR and 19 (28%) with increased AR-V7, 27 (40%) with increased expression of KLK2, and 14 (21%) with increased TMPRSS2:ERG. Wnt signaling was upregulated in 29 (43%) patients, with increased expression of WNT5B in 21 (31%) and BMP7 in 14 (21%) patients. The prostate cancer specific long non-coding RNAs SChLAP1 and PCA3 were upregulated in 5 (7%) and 29 (43%) samples, respectively. 38 (56%) samples showed expression of epithelial-mesenchymal transition genes SOX2, SOX9, and TWIST1 and cell proliferation was upregulated in 51 (75%) as indicated by expression of GAS6, MDK, MET, and TSPAN8. CONCLUSION(S): CTC-based targeted gene expression profiling using TLDA cards allows RNA assessment on a platform that has shown analytic validity in the tissue-based setting. Additional

work will be required to assess the analytic and clinical validity of this approach when applied to CTCs. Further correlation of long-term, objective outcomes with CTC-based gene expression is ongoing and may inform prognosis in patients with advanced prostate cancer.

Singwe-Ngandeu, M., et al. (2010). "Diagnostic value of anti-cyclic citrullinated peptides and association with HLA-DRB1 shared epitope alleles in African rheumatoid arthritis patients." Arthritis Research & Therapy **12**(2): R36.

INTRODUCTION: The purpose of this study was to examine the diagnostic performance of autoantibodies against citrullinated peptides/proteins (ACPA) and to determine the prevalence of HLA-DRB1 shared epitope alleles (SE) in African patients with rheumatoid arthritis (RA).

METHODS: Serum levels of anti-cyclic citrullinated peptides antibodies (anti-CCP2, anti-CCP3), IgM and IgA rheumatoid factors (RF) were measured by enzyme-linked immunosorbent assay in the serum of 56 consecutive RA patients regularly followed in the Rheumatology Unit of the School of Medicine, University of Yaounde, Yaounde, Cameroon. Genotyping of HLA-DRB1 alleles was performed by polymerase chain reaction and hybridization with sequence-specific oligonucleotide probes on microbeads arrays. Fifty-one patients with other inflammatory rheumatic diseases and 50 healthy individuals were included as controls.

RESULTS: An anti-CCP2 assay showed the best diagnosis sensitivity (82%) and specificity (98%) with high positive predictive (PPV) (96%) and negative predictive values (NPV) (91%). Thirty percent of RA patients were carrying at least one copy of the HLA-DRB1 shared epitope (SE) compared to 10% and 14% of patients with other inflammatory rheumatic diseases and healthy individuals, respectively. The presence of the SE was associated with the production of ACPA.

CONCLUSIONS: Anti-CCP2 antibodies are useful markers of RA in African patients. In this cohort, the prevalence of the SE is higher in RA patients than in controls but lower than that reported in patient cohorts of European ancestry. The discrepancy between the high prevalence of ACPA-positive patients and the relatively low number of SE-positive cases suggest that, in addition to SE, other genetic factors control the development of ACPA in African RA patients.

Sintim, H. Y., et al. (2019). "Impacts of biodegradable plastic mulches on soil health." Agriculture, Ecosystems & Environment **273**: 36-49.

Plastic pollution in agricultural soils, caused by the incomplete removal of polyethylene mulch after usage, is a growing environmental concern. There has therefore been increased interest in biodegradable plastic mulches as alternative to polyethylene mulch; however, little is known about their impact on soil health. We evaluated the effects of four biodegradable plastic mulches on soil health at two sites (Knoxville, TN and Mount Vernon, WA) under pie pumpkin (Cucurbita pepo) production. Cellulosic paper, polyethylene, and no-mulch served as controls. Soil health was first assessed in May 2015, and then every six months until May 2017, by measuring 19 soil properties (physical, chemical, and biological). Soil properties were converted to index scores and aggregated into six soil health indicators and five soil functions. The results showed poor correlations and high spatial variations for most of the soil properties. We performed repeated measure analyses using raw values and change scores to account for the initial variations. The soil properties, soil health indicators, and soil functions were affected more by site and time than by the mulch treatments. Nonetheless, we did observe significant effects of some of the mulch treatments on six soil properties (aggregate stability, infiltration, soil pH, electrical conductivity, nitrate-N, and exchangeable potassium), four soil health indicators (hydraulic, biological, fertility, and salinity & sodicity), and one soil function (nutrient cycling). However, these effects were not consistent among all the biodegradable plastic mulches, across the two sites, and the sampling times. Overall, biodegradable plastic mulches

may be a viable alternative to polyethylene. However, evaluation under long-term studies is needed to better establish their effects on soil health.

Sintim, H. Y., et al. (2019). "Release of micro- and nanoparticles from biodegradable plastic during in situ composting." Science of the Total Environment **675**: 686-693.
Plastic is ubiquitous in modern life, but most conventional plastic is non-biodegradable and accumulates as waste after use. Biodegradable plastic is a promising alternative to conventional plastic. However, biodegradable plastics must be thoroughly evaluated to ensure that they undergo complete degradation and have no adverse impact on the environment. We evaluated the degradation of biodegradable plastics during 18-week full-scale composting, and determined whether additives from the plastics are released upon degradation. Two biodegradable plastic films—one containing polybutylene co-adipate co-terephthalate (PBAT) and the other containing polylactic acid/poly-hydroxy–alkanoate (PLA/PHA)—were placed into meshbags and buried in the compost. Degradation was assessed by image analysis, scanning electron microscopy, Fourier-transformed infrared spectroscopy, electrophoretic mobility, δ 13C isotope analyses, and single particle mass spectrometry of mulch fragments. The results showed >99% macroscopic degradation of PLA/PHA and 97% for PBAT film. Polymers in the biodegradable films degraded; however, micro- and nanoparticles, most likely carbon black, were observed on the meshbags. Overall, biodegradable plastics hold promise, but the release of micro- and nanoparticles from biodegradable plastic upon degradation warrants additional investigation and calls for longer field testing to ensure that either complete biodegradation occurs or that no long-term harm to the environment is caused. Unlabelled Image • Plastic pollution is a ubiquitous environmental problem. • Biodegradable plastic can help reduce plastic pollution. • Not all components in biodegradable plastics may degrade. • Non-biodegradable additives, such as carbon black, may be released upon degradation of plastic. [ABSTRACT FROM AUTHOR]

Sisavath, N., et al. (2015). "Taking Advantage of Electric Field Induced Bacterial Aggregation for the Study of Interactions between Bacteria and Macromolecules by Capillary Electrophoresis." Analytical Chemistry **87**(13): 6761-6768.
The quantification of interaction stoichiometry and binding constant between bacteria (or other microorganism) and (macro)molecules remains a challenging issue for which only a few adapted methods are available. In this paper, a new methodology was developed for the determination of the interaction stoichiometry and binding constant between bacteria and (macro)molecules. The originality of this work is to take advantage of the bacterial aggregation phenomenon to directly quantify the free ligand concentration in equilibrated bacteria-ligand mixtures using frontal analysis continuous capillary electrophoresis. The described methodology does not require any sample preparation such as filtration step or centrifugation. It was applied to the study of interactions between Erwinia carotovora and different generations of dendrigraft poly-L-lysines leading to quantitative information (i.e., stoichiometry and binding site constant). High stoichiometries in the order of 10(6)-10(7) were determined between nanometric dendrimer-like ligands and the rod-shaped micrometric bacteria. The effect of the dendrimer

generation on the binding constant and the stoichiometry is discussed. Stoichiometries were compared with those obtained by replacing the bacteria by polystyrene microbeads to demonstrate the internalization of the ligands inside the bacteria and the increase of the specific surface via the formation of vesicles.

Sitaram, J. and D. G. M. Purohit (2017). "Stabilization of bentonite soil with stone dust." International Journal for Research in Applied Science and Engineering Technology **5**(12): 1541-1545.

Bentonite soil has the tendency to swell or shrink depending on its water content variations. Due to such expansive characteristics of these soils, the structures constructed over this may develop some cracks in due course of time. It is there for essential to stabilize such soils, prior to any construction work carried out on this to improve its engineering properties. At present waste materials like stone dust from crushers, lime from industry and plastic waste are in abundance at various parts of our country. These wastes not only create health problems but also its disposal is a great problem for our society. This paper deals with a feasibility study carried out to find the suitability of using waste material i.e. stone dust as stabilizing material for improving the engineering properties of bentonite soil. Various tests like CBR, Standard Proctor Test and DFS were performed on the soil samples prepared by using stone dust (5%, 10%, 15% 20% and 25%) mixed with bentonite soil. On the basis of the results obtained from these tests, it may be concluded that the strength of bentonite soil can be substantially improved by mixing with stone dust as stabilized materials.

Situ, E., et al. (2010). "Influence of imatinib mesylate on bone marrow-derived dendritic cells." Journal of Investigative Medicine **58 (1)**: 193.

Purpose of Study: Primarily described as initiators and regulators of immune responses, dendritic cells (DC) may also be endowed with the capacity of directly triggering tumor cell death. This cytotoxic function is an atypical novel feature of these cells that may be used effectively in cancer immunotherapy. Imatinib mesylate has become the drug of choice for the majority of BCR-ABL+ leukemia patients. Although the direct effects of imatinib on cancer cells are well documented, the potential of imatinib to modulate anti-tumor immune responses remains poorly understood. The goal of this study was to evaluate whether imatinib may modulate the killing activity of dendritic cells. Methods Used: DC were generated from Balb/c mouse bone marrow cultured in complete RPMI medium (Gibco/BRL) with GM-CSF and IL-4 (10 ng/ml each). On day 6, DC were selected by Magnetic Activated Cell Sorting (MACS, Miltenyi) using anti-CD11c antibody conjugated with microbeads and subcultured. Imatinib (10⁻⁵M and 10⁻⁶M) was added to the culture on day 0, 6 or 7. On day 8, DC were collected and co-cultured with 4+/-1 breast cancer cells (tumor cell:DC ratio = 1:5) and with LPS, which triggers DC killing activity. Tumor cell killing was then assessed by crystal violet assays. Summary of Results: Exposure of DC to imatinib from day 7-8 does not affect their killing potential. Interestingly, reduced killing activity was observed when DC were pre-treated with imatinib (10⁻⁵M and 10⁻⁶M) from day 6 to day 8, resulting in a significant impairment of their tumoricidal activity. In addition, the presence of imatinib from day 0 and during the entire culture period resulted in the complete loss of DC killing potential. Conclusion(s): Imatinib may modulate DC killing potential in a dose- and time-dependent manner and may affect the differentiation of DC from bone marrow precursors, rendering them ineffective in eliminating tumor cells. Further studies are required to elucidate the molecular mechanisms underlying the modulation of DC by this drug and the possible significance of these findings in vivo as it relates to the promotion or inhibition of tumor growth.

Sivakumar, G., et al. (2015). "Formulation and evaluation of alginate microbeads of ondansetron by ionotropic gelation technique." International Journal of Research in Pharmaceutical Sciences **6**(3): 242-247.

Ondansetron is an anti emetic agent for the treatment of nasia and vomiting and also used chemotheraphy in cancer. Ondansetron drug is 5ht3 receptor antagonist. it has shorter biological half-life (3 - 4 hrs) necessitates that it to be administered in frequent doses of 4mg. The main objective of this study was to develop suitable micro particulate system of ondansetron for controlled release delivery system by varying the alginate, CaCl2 and HPMC concentrations. In the present work ondansetron microbeads were formulated using sodium alginate by ionotropic gelation technique. Prepared beads were evaluated for granulometric studies, micromeretic, scanning electron microscopy, drug entrapment efficiency and in-vitro dissolution studies etc. The prepared beads were free flowing and white in colour. The drug loaded beads showed 84.6-98.2 % drug entrapment, which was found to increase with increase in sodium alginate concentration. Scanning electron microscopy revealed that the beads were spherical and rough in structure. In vitro drug release study of these microbeads indicated controlled release for ondansetron 85.54 - 97.2 % released. Hence the observation of all results of the different batches third and fourth showed controlled release action and improved drug availability. The release of ondansetron was found to be affected by both concentration of polymers such as sodium alginate and HPMC. By the observation of accelerated stability studies second batch formulation was found to be best formulation. From this study, it could be concluded that the spherical and free flowing microbeads of ondansetron could be successfully prepared by ionotropic gelation technique with high entrapment efficiency and prolonged release characteristics. Sivakumar, R., et al. (2011). "Design of mucoadhesive hydropilic beads entrapped with ketoprofen for delivery into small intestine." Research Journal of Pharmaceutical, Biological and Chemical Sciences **2**(1): 706-713.

The purpose of this study was to develop and evaluate pH dependent multiparticles of ketoprofen loaded mucoadhesive beads to target the small intestine. The hydrogel beads were prepared by inotropic gelation method using sodium alginate, pectin and xanthan gum as polymers. The prepared gel beads were coated with 1 % chitosan. The obtained beads were filled into hard gelatin capsules and enteric coated with Eudragit L100. The beads were evaluated for particle size, morphology, encapsulation efficiency, in vitro release, and mucoadhesion. The size of microbeads ranged from 1mm to 2mm and the encapsulation of ketoprofen beads was between 60 to 70%. The release of ketoprofen from the gel beads at pH 6.8 was initially fast followed by a slower and more controlled release. The drug release from the beads was found to follow case II transport mechanism (n>0.85) and was independent of time, which corresponds with zero-order kinetics.

Sivan, A. (2011). "New perspectives in plastic biodegradation." Current Opinion in Biotechnology **22**(3): 422-426.

During the past 50 years new plastic materials, in various applications, have gradually replaced the traditional metal, wood, leather materials. Ironically, the most preferred property of plastics - durability - exerts also the major environmental threat. Recycling has practically failed to provide a safe solution for disposal of plastic waste (only 5% out of 1 trillion plastic bags, annually produced in the US alone, are being recycled). Since the most utilized plastic is polyethylene (PE; ca. 140 million tons/year), any reduction in the accumulation of PE waste alone would have a major impact on the overall reduction of the plastic waste in the

environment. Since PE is considered to be practically inert, efforts were made to isolate unique microorganisms capable of utilizing synthetic polymers. Recent data showed that biodegradation of plastic waste with selected microbial strains became a viable solution. © 2011 Elsevier Ltd.

Six, M., et al. (2016). "Different platelet concentrations impact on DC maturation." Transfusion Medicine and Hemotherapy **43 (Supplement 1)**: 75-76.

Introduction: This study shows the influence of platelets on the differentiation and maturation of dentritic cells (DCs) derived from monocytes, focusing on the influence of different platelet concentrations in the mononuclear cell culture. Method(s): Mononuclear cells (MNCs) were obtained by leukapheresis and CD14 positive monocytes were isolated with CD14 MicroBeads. The MNCs were cultivated in a culture medium with IL-4, GM-CSF and TNF-alpha (starting on day 4). The following culture preparations were performed supplementing platelets in different concentrations: Control without platelets added (baseline), TH10 with addition of 1.0 x 10e7 platelets, TH50 (5.0 x 10e7 platelets), TH150 (1.5 x 10e8 platelets) and TH250 (2.50 x 10e8 platelets). The different cell culture preparations were analyzed by flow cytometer on days 1 to 4 and on day 7. Result(s): On day 7, high platelets concentrations TH150 (24.0 +/- 10.9) and TH250 (24.3 +/- 14,0) showed a significantly (p = 0.036) lower ratio of CD1a positive cells than in the baseline (51.8 +/- 21.3%). The ratio of CD83 positive cells was significantly (p = 0.028) lower on day 1 for TH250 (4.5 +/- 4.1%) compared to baseline (9.3 +/- 7.1%). No significant difference (p = 0.139) could be found on day 7 between baseline (42.0 +/- 17.4) and TH250 (55.4 +/- 23.6). The difference between the baseline (42.0 +/- 17.4) and TH10 (52.0 +/- 12.6) was significant (p = 0.007). Regarding the measurement of cell viability, there was a significant correlation between the ratio of live cells and the platelets concentration analyzed (day 1: p = 0.021; day 2-7: p values < 0.001). On day 7, there was a significantly (p < 0.001) lower ratio of vital cells in the baseline (29.0 +/- 24.5) compared to TH250 (73.8 +/- 22.6). Negative correlations were seen between the ratio of dead cells and the platelets concentration regarding all days (p values < 0.001). Conclusion(s): Platelets show an inhibitory effect on premature DCs (CD1a positive cells) and apparently, in the further process, a boosting effect on the maturing process of DCs (CD83 positive cells) derived from monocytes. In addition, the part of Annexin V and 7AAD positive cells depends on platelet concentration. The higher the platelet concentration, the lower was the ratio of dead cells.

Sjollema, S. B., et al. (2016). "Do plastic particles affect microalgal photosynthesis and growth?" Aquatic Toxicology **170**: 259-261.

The unbridled increase in plastic pollution of the world's oceans raises concerns about potential effects these materials may have on microalgae, which are primary producers at the basis of the food chain and a major global source of oxygen. Our current understanding about the potential modes and mechanisms of toxic action that plastic particles exert on microalgae is extremely limited. How effects might vary with particle size and the physico-chemical properties of the specific plastic material in question are equally unelucidated, but may hold clues to how toxicity, if observed, is exerted. In this study we selected polystyrene particles, both negatively charged and uncharged, and three different sizes (0.05, 0.5 and 6mum) for testing the effects of size and material properties. Microalgae were exposed to different polystyrene particle sizes and surface charges for 72h. Effects on microalgal photosynthesis and growth were determined by pulse amplitude modulation fluorometry and flow cytometry, respectively. None of the treatments tested in these experiments had an effect on microalgal photosynthesis. Microalgal growth was negatively affected (up to 45%) by uncharged polystyrene particles, but only at high

concentrations (250mg/L). Additionally, these adverse effects were demonstrated to increase with decreasing particle size.

Sjöqvist, M. and A. Boldizar (2011). "Molecular Modification and Compatibilization of Collected Polyethylene." Journal of Polymers & the Environment **19**(2): 335-340.

The increasing use of plastics in packaging materials leads to growing amounts of plastic waste. Recycling material is generally regarded as advantageous. But in fact very few products are made from plastic waste, partly this can be explained by that little is known about the recycling process and the properties of collected materials. There is a need for injection moulding grades of recycled polyethylene, while large amounts of extrusion grades are available from packaging waste. A controlled way of de-branching or partly degrading PE would be desirable. Peroxides are commonly used to crosslink polyolefins, but under certain conditions a chain scission reaction occur. Another problem encountered with recycling of polyethylene are the poor miscibility of low amounts contaminations, i. e. polypropylene. A compatibilizer can improve properties of such polymer blends, in this work EPDM is used as compatibilzer. Studies of mechanical properties and viscosity measurements show that it is possible to partly degrade PE with peroxide exposing it to high temperature and oxygen. The properties of PE/PP blends were improved with EPDM as compatibilizer. [ABSTRACT FROM AUTHOR]

Skariyachan, S., et al. (2015). "Selection and screening of microbial consortia for efficient and ecofriendly degradation of plastic garbage collected from urban and rural areas of Bangalore, India." Environmental Monitoring & Assessment **187**(1): 4174.

Industrialization and urbanization have led to massive accumulation of plastic garbage all over India. The persistence of plastic in soil and aquatic environment has become ecological threat to the metropolitan city such as Bangalore, India. Present study investigates an ecofriendly, efficient and cost-effective approach for plastic waste management by the screening of novel microbial consortia which are capable of degrading plastic polymers. Plastic-contaminated soil and water samples were collected from six hot spots of urban and rural areas of Bangalore. The plastic-degrading bacteria were enriched, and degradation ability was determined by zone of clearance method. The percentage of polymer degradation was initially monitored by weight loss method, and the main isolates were characterized by standard microbiology protocols. These isolates were used to form microbial consortia, and the degradation efficiency of the consortia was compared with individual isolate and known strains obtained from the Microbial Type Culture Collection (MTCC) and Gene Bank, India. One of the main enzymes responsible for polymer degradation was identified, and the biodegradation mechanism was hypothesized by bioinformatics studies. From this study, it is evident that the bacteria utilized the plastic polymer as a sole source of carbon and showed 20-50% weight reduction over a period of 120 days. The two main bacteria responsible for the degradation were microbiologically characterized to be Pseudomonas spp. These bacteria could grow optimally at 37 degreeC in pH 9.0 and showed 35-40% of plastic weight reduction over 120 days. These isolates were showed better degradation ability than known strains from MTCC. The current study further revealed that the microbial consortia formulated by combining Psuedomonas spp. showed 40 plastic weight reduction over a period of 90 days. Further, extracellular lipase, one of the main enzymes responsible for polymer degradation, was identified. The computational docking studies suggested that polyethylene glycol and polystyrene present in the plastics might have good interaction towards the microbial lipase with stable binding and interacting forces which probably could be one of the reasons for the degradative mechanisms.

Skira, I. J. (1986). "Food of the short-tailed shearwater, Puffinus tenuirostris, in Tasmania." Australian Wildlife Research **13**(3): 481-488.

Food from stomachs of 396 short-tailed shearwaters collected at 3 colonies was analysed. The main food items found were the euphausiid (Nyctiphanes australis) and arrow squid (Notodarus sloani gouldi) with fish, other crustaceans and squids forming a minor part of the diet. Plastic particles were common particularly at the beginning of the breeding season but gradually decreased in frequency as the season progressed.

Skjermo, J. and O. Bergh (2004). "High-M alginate immunostimulation of Atlantic halibut (Hippoglossus hippoglossus L.) larvae using Artemia for delivery, increases resistance against vibriosis." Aquaculture **238**(1/4): 107-113.

A strategy for microbial management in marine juvenile production should include nonspecific immunostimulation to reduce losses caused by infectious diseases. Halibut (Hippoglossus hippoglossus L.) larvae (250 day degrees) were distributed into first-feeding tanks of 10.000 l, at a Norwegian halibut juvenile farm. Immunomodulatory high-M alginate was bioencapsulated in Artemia by use of alginate microbeads (2-30 micro m), and administered to halibut larvae at three stages during the first feeding period (days 7-9, 20-22 and 41-43). A fourth treatment was run after weaning, 5-3 days prior to a challenge test with two different doses of Vibrio anguillarum O2 that was started at day 90 after first feeding. After 15 days, the mortality at the highest dose was 45+or-1% in the control and 28+or-8% in the stimulated group, corresponding to 38% reduction in mortality, whereas no significant differences were measured at the low dose. It is concluded that feeding immunostimulants to halibut larvae for four short periods during 3 months enhanced resistance against vibriosis, and that high-M alginates are suitable as immunostimulants for marine larvae during first feeding and weaning.

Skolnick, A. and J. Johnson (2015). "sailing the plastic seas." Rodale's Organic Life **1**(3): 82-87.

The article reports on a voyage to the North Atlantic conducted by nonprofit the Surfrider Foundation that reveals the impact of trash on human health and the health of the oceans. Topics include the plastic smog that infests the bluest water in the North Atlantic Gyre, how the plastics end up in oceans like the Atlantic, and the two types of plastic waste that make up most of the plastic found at sea including polyethylene and polypropylene.

Skorupskaite, V. and G. Denafas (2004). "Investigation of particles size distribution and form of bottom and volant ash." Environmental Research, Engineering and Management **3**: 21-28.

A study was conducted to investigate the particle size distribution and form of volant ash of wood and peat bottom, ash of medical waste combustion and bottom ash of plastic waste and used lubricants combustion. The particle size distribution of the ash was determined by laser diffraction analysis and analysis of sieves, while the form of the particles was determined by scanning electron microscope. The laboratory investigations were performed in the Clausthal Technical University in Germany. Results showed that the greatest amount of small particles that can cause damage in airway was found in the bottom ash of plastic waste and used lubricants combustion. The bottom ash of medical waste combustion has the widest particle size distribution based on diameter. All kinds of ash particles, especially small particles, have relatively large surface area and high porosity resulting to increased absorption capacity.

Slater, N., et al. (2017). "Cardiac iron burden is correlated with innate immune markers, body mass index and labile plasma iron in seta-thalassemia major patients undergoing combined chelation therapy." American Journal of Hematology **92 (8)**: E380.

Introduction: beta-thalassemia major (TM) is an inherited anemia that is characterized by severe transfusion dependence which can lead to hepatic and extra-hepatic cardiac iron overload, causing cardiomyopathy, the leading cause of death. Despite improved chelation therapies, TM patients still endure cardiomyopathy as well as chronic inflammation, organ failure and infection. Innate immune cells are central to iron trafficking and response to organ injury. To travel to areas of iron-induced tissue injury, innate immune cells must extravasate from the vasculature using surface presentation of ligands such as LewisX (aka CD15). LewisX is a trisaccharide adhesion molecule, used by granulocytes to mediate endothelial attachment and phagocytosis. In this study, TM granulocyte LewisX expression was compared to iron-burden markers (such as cardiac T2*) and body mass index when undergoing combined chelation therapy with deferoxamine and deferasirox. A comparative healthy control group of subjects were also studied. LewisX surface presentation was also quantified on cultured THP-1 cells exposed to exogenous iron. Patients and Methods: TM patients were investigated at baseline and after 6 months and a year of combined chelation therapy with deferasirox and deferoxamine and analyzed for the expression of LewisX on peripheral-blood granulocytes. Eighteen transfusion dependent thalassemia patients (11 - 29 yrs old) participating in the combination trial of deferasirox and deferoxamine (Novartis sponsored CICL670AUS24T) were enrolled in a substudy investigating innate immunology (Novartis sponsored CICL670AUS42T). Fasting blood samples were obtained i) at baseline after a 72 hr. washout of chelator, and ii) at 6 and 12 months on study. Fourteen healthy controls (10 - 35 yrs old) were also enrolled. Peripheral blood mononuclear cells (PBMCs) were isolated from blood samples and granulocytes were separated from dilute blood using ficoll. Granulocytes were purified using antibody-linked magnetic microbeads (Miltenyi Biotec Inc). Highly enriched populations of LewisX+ (CD15+) granulocytes were verified by flow cytometry. The expression level of LewisX on purified granulocytes was determined and reported as the median fluorescent intensity (MFI). Result(s): A 5% decrease in LewisX positive granulocytes was observed in TM compared to healthy age and ethnically matched controls (TM = 90.19 +/- 7.14, control = 96.6 +/- 1.90, p = 0.034). LewisX expression was also decreased on THP-1 monocytic cells exposed to iron-citrate for greater than six weeks in vitro (p=0.04). In TM, LewisX expression correlated with labile plasma iron (r = -0.47 and p=0.015), T2* (myocardial iron, r= 0.69 and p=0.001), left ventricular ejection fraction (r = 0.49 and p=0.030) and body mass-index (r = -0.78 and p=0.002). Multiple regression analysis revealed that myocardial iron was best predicted by LewisX independently (r = 0.66, p = 0.001), whereas, LewisX expression was best predicted by BMI (r = 0.76, p = 0.002). 52 weeks of combined chelation therapy successfully restored TM expression of LewisX to the level of healthy controls (baseline = 90.19+/-7.14, 26 weeks = 96.10+/-3.44, 52 weeks = 96.61+/-3.10, p= 0.011). Conclusion(s): We found significant evidence that granulocyte LewisX surface presentation may be decreased in response to LPI and is predicted by BMI. Furthermore, LewisX and BMI appear to be predictive of cardiac iron loading and function, providing potential novel indicators for the leading cause of mortality in TM.

Sleight, V. A., et al. (2017). "Assessment of microplastic-sorbed contaminant bioavailability through analysis of biomarker gene expression in larval zebrafish." Marine Pollution Bulletin **116**(1/2): 291-297.

Microplastics (MPs) are prevalent in marine ecosystems. Because toxicants (termed here "co-contaminants") can sorb to MPs, there is potential for MPs to alter co-contaminant bioavailability. Our objective was to demonstrate sorption of two co-contaminants with different physicochemistries [phenanthrene (Phe), log₁₀K_{ow}=4.57; and 17 alpha -ethinylestradiol (EE2), log₁₀K_{ow}=3.67] to MPs; and assess whether co-contaminant bioavailability was increased after MP settlement. Bioavailability was indicated by gene expression in larval zebrafish. Both Phe and EE2 sorbed to MPs, which reduced bioavailability by a maximum of 33% and 48% respectively. Sorption occurred, but was not consistent with predictions based on co-contaminant physicochemistry (Phe having higher log₁₀K_{ow} was expected to have higher sorption). Contaminated MPs settled to the bottom of the exposures did not lead to increased bioavailability of Phe or EE2. Phe was 48% more bioavailable than predicted by a linear sorption model, organism-based measurements therefore contribute unique insight into MP co-contaminant bioavailability.

Sloane, H. S., et al. (2016). "Hybridization-Induced Aggregation Technology for Practical Clinical Testing: KRAS Mutation Detection in Lung and Colorectal Tumors." Journal of Molecular Diagnostics **18**(4): 546-553.

KRAS mutations have emerged as powerful predictors of response to targeted therapies in the treatment of lung and colorectal cancers; thus, prospective KRAS genotyping is essential for appropriate treatment stratification. Conventional mutation testing technologies are not ideal for routine clinical screening, as they often involve complex, time-consuming processes and/or costly instrumentation. In response, we recently introduced a unique analytical strategy for revealing KRAS mutations, based on the allele-specific hybridization-induced aggregation (HIA) of oligonucleotide probe-conjugated microbeads. Using simple, inexpensive instrumentation, this approach allows for the detection of any common KRAS mutation in <10 minutes after PCR. Here, we evaluate the clinical utility of the HIA method for mutation detection (HIAMD). In the analysis of 20 lung and colon tumor pathology specimens, we observed a 100% correlation between the KRAS mutation statuses determined by HIAMD and sequencing. In addition, we were able to detect KRAS mutations in a background of 75% wild-type DNA-a finding consistent with that reported for sequencing. With this, we show that HIAMD allows for the rapid and cost-effective detection of KRAS mutations, without compromising analytical performance. These results indicate the validity of HIAMD as a mutation-testing technology suitable for practical clinical testing. Further expansion of this platform may involve the detection of mutations in other key oncogenic pathways.

Slootmaekers, B., et al. (2019). "Microplastic contamination in gudgeons (Gobio gobio) from Flemish rivers (Belgium)." Environmental Pollution **244**: 675-684.

Plastic pollution is continuously growing on a global scale and emerging as a major environmental hazard. Smaller-sized plastics, so-called microplastics (<5 mm), are considered as being omnipresent throughout the aquatic environment, yet freshwater ecosystems have received little attention so far and are still largely unstudied. Present study aims to expand the current knowledge on microplastics in freshwater systems by documenting the occurrence in the digestive system of fish from 15 rivers at 17 locations in Flanders, Belgium. To increase inter-study comparability and identification accuracy, a more standardized protocol was combined with a conservative approach towards acceptance of microplastic particles. Four rivers were found to have fish containing microplastics. However, no significant differences could be established between the sampling sites. In total 78 specimens of gudgeon (Gobio

gobio) have been investigated, 9% of which had ingested at least one microplastic item, thus showing that contamination appears to be limited. Microscopic and spectroscopic analysis showed the microplastics to be from various sources with a diverse range of physical characteristics. Out of the eight items identified as microplastics, seven different polymer types were identified. Although further detailed research is necessary, this preliminary study shows that gudgeons from several Flemish rivers are contaminated with microplastics.

Smedes, F., et al. (2017). "Partitioning of hydrophobic organic contaminants between polymer and lipids for two silicones and low density polyethylene." Chemosphere **186**: 948-957.

Polymers are increasingly used for passive sampling of neutral hydrophobic organic substances (HOC) in environmental media including water, air, soil, sediment and even biological tissue. The equilibrium concentration of HOC in the polymer can be measured and then converted into equilibrium concentrations in other (defined) media, which however requires appropriate polymer to media partition coefficients. We determined thus polymer-lipid partition coefficients (K_{PL}) of various PCB, PAH and organochlorine pesticides by equilibration of two silicones and low density polyethylene (LDPE) with fish oil and Triolein at 4 degreeC and 20 degreeC. We observed (i) that K_{PL} was largely independent of lipid type and temperature, (ii) that lipid diffusion rates in the polymers were higher compared to predictions based on their molecular volume, (iii) that silicones showed higher lipid diffusion and lower lipid sorption compared to LDPE and (iv) that absorbed lipid behaved like a co-solute and did not affect the partitioning of HOC at least for the smaller molecular size HOC. The obtained K_{PL} can convert measured equilibrium concentrations in passive sampling polymers into equilibrium concentrations in lipid, which then can be used (1) for environmental quality monitoring and assessment, (2) for thermodynamic exposure assessment and (3) for assessing the linkage between passive sampling and the traditionally measured lipid-normalized concentrations in biota. LDPE-lipid partition coefficients may also be of use for a thermodynamically sound risk assessment of HOC contained in microplastics.

Smirnova, S., et al. (2017). "CD8+ T-cell clones persistent in bone marrow and peripherial blood during course of CD4+ angioimmunoblastic lymphoma." Haematologica **102 (Supplement 2)**: 575-576.

Background: Angioimmunoblastic T-cell lymphoma (AITL) - peripheral T-cell lymphoma, characterized by polymorphous infiltration of the lymph nodes, proliferation of high endothelial venules (HEV) and follicular dendritic cells (FDC). In addition to the lymph nodes, AITL affects spleen, liver, skin and bone marrow. The disease is almost always associated with Epstein-Barr virus (EBV), suggesting its role in the etiology of AITL. Neoplastic T cells in most cases are CD4+ and express pan T-cell antigens CD3, CD2, CD5, markers of normal follicular Thelper cells - CD10, CXCL13, PD-1. To confirm the diagnosis and assess disease dissemination combined morphological, immunohistochemical and molecular studies of affected tissues are being used. We have found that T-cell clones detected in the tissue of the lymph node (LN), often differ in T-cell receptor gene rearrangements from those detected in the bone marrow (BM), peripheral blood (PB) and other tissues. T-cell clonality testing itself may not distinguish between neoplastic or reactive lymphoproliferation in the BM and PB. Therefore, T-cell clonality of CD4+ and CD8+ populations of peripheral blood lymphocytes in patients with AITL had been tested during the course of disease. Aim(s): To determine immunological characteristics of persisting in the PB and BM T-cell clones in AITL patients. (Figure presented). Method(s): The study included 26 patients (15 males and 11 females; age 36-92, median 67) with the diagnosis of AITL established on the basis of WHO 2008 diagnostic criteria. LN, BM and peripheral blood lymphocytes were tested for Tcell clonality according to BIOMED-2 protocol with subsequent fragments analysis on ABI PRISM 3130 (Applied Biosystems). The material was examined at the diagnosis and at various stages of patient's treatment. In 5 patients selection of CD8+ and CD4+ populations of PB lypmphocytes was performed with MidiMACS and MiniMACS Separators using CD4+, CD8+ MicroBeads (Miltenyi Biotec). Result(s): Clonal TCRG and TCRB gene rearrangements in the LN of all AITL patients were found. In 6 of the 26 patients (23%) clonal products found in LN matched those from PB and BM. In 8 patients (30%) at least one of the clonal products isolated from the BM and/or PB mismatched the clonal products isolated from LN. In 12 patients (46%) clonal rearrangements found in the PB and BM were completely different from those identified for LN. Thus, at the diagnosis 20 patients (76%) had PB and BM T-cell clones distinct from LN T-cell clones. In 14 of 20 patients T-cell clones of PB and BM were tested repeatedly during the course of disease treatment. In 7 of 14 patients (50%) clonal products persisted for a long time and do not disappear upon reaching the remission of the disease. The observation period averaged 12 months (1 to 44 months). No correlation of T-cell clones persistence and the activity of EBV infection in the PB was found. Selection of CD4+ and ?D8+ T-lymphocyte populations was performed for 4 patients in remission with persistent T-cell clones. In all cases, clonal products, which were originally identified in the BM and PB were shown to belong to the CD8+ population of cells (Fig.). In one case BM and PB derived- CD4+ cells also shared a clonal product with LN cells tested at at the diagnosis. In one case CD4+ population selected from PB cells at the diagnosis carried clonal rearrangements, fully consistent with that of LN. Summary/Conclusions: One may conclude that CD8+ T-cell clones identified in BM and PB, do not match those identified in LN for the majority of patients with AITL (76%). These clones can persist for a long time (the period of observation from 1 to 40 months), may not disappear in remission and probably have reactive nature. Therefore exclusive T-cell clonality in PB and/or BM should not be threated as minimal disease or relapse in AITL.

Smiroldo, G., et al. (2019). "Anthropogenically altered trophic webs: alien catfish and microplastics in the diet of Eurasian otters." Mammal Research **64**(2): 165-174.

With the aim of examining how Eurasian otters (Lutra lutra) face human-mediated environmental alterations, we assessed their diet by spraint analysis on the River Ticino (NW Italy), where this mustelid has been reintroduced in 1997. From March 2016 to March 2017, a total of 101 spraints was found in 50% of 32 sampling stations (mean length+or-SD=567+or-263 m). Fish formed the bulk of otter diet (95% of the estimated mean percent volume, mV%). Cyprinids were the most preyed fish (mV%=44.9), followed by European catfish Silurus glanis (mV%=24.9%) and eel Anguilla anguilla (mV%=8.5). Introduced European catfish is an invasive species, which can deeply alter the composition and structure of local fish communities and accumulate large amounts of metals and pollutants through the trophic chain. We also recorded for the first time microplastic particles (<5 mm) in otter spraints. Suspected particles were analysed by Fourier transform infrared (FTIR) spectroscopy and two polymer types were identified: polyethylene terephthalate (PET) and polyamide (PA). Although otters showed to be able to adapt to anthropogenic changes, these results point out new potential threats to otter conservation and ask for further studies.

Smith, D., et al. (2014). "Cohort analysis of FISH testing of CD138+ cells in relapsed multiple myeloma: Implications for prognosis and choice of therapy." Blood. Conference: 56th Annual Meeting of the American Society of Hematology, ASH **124**(21).

Introduction: Interphase FISH on CD138-selected bone marrow cells enables genetic risk stratification in newly diagnosed multiple myeloma (MM), however as MM remains incurable, most centres still treat newly diagnosed MM uniformly, utilising the most active regimens available. At relapse an increasing choice of regimens, coupled with co-morbidities and treatment-emergent toxicities, means no uniform approach is possible. Instead, therapy is tailored to disease and patient related risk factors. In this setting, FISH testing may be particularly useful if not done at diagnosis and to identify progression events that may alter prognosis. Aim(s): To evaluate the outcome of FISH analysis in consecutive patients with relapsed MM undertaken at our centre: success rate, frequency of abnormalities, incidence of progression events and correlation of FISH abnormalities with treatment outcomes. Method(s): FISH analysis was performed on 192 samples from 154 relapsed patients (2012-13). Plasma cells were selected using magnetic CD138 MicroBeads and interphase FISH carried out using probes as recommended by the EMN (Ross et al, 2012). If patients had no prior results, a full FISH MM panel was performed, using probes for t(4;14), t(14;16), t(11;14), deletion 17p (17p-), Chr 1 abnormalities (1p-/1q+) and deletion 13q (13q-). If patients had been previously tested for an IgH translocation (Tx), a progression event panel was used: 1p-/1q+, 17p- and 13q-. Patients underwent FISH testing prior to starting the next line of therapy. Result(s): 79% of samples were successfully analysed, with analysis limited in 16% and failed in 5%. Common reasons for failure were poor quality/aged slides, insufficient material and poor hybridisation. 17% of patients had no cytogenetic abnormality. The most common abnormality was 13q- (43.1%), followed by 1q+ (41.4%), t(11;14) (18.3%), t(4;14) (12.4%), 17p- (12.0%) 1p- (8.9%), and t(14;16) (5.6%) Progression events were more common in t(14;16) and t(4;14) groups. All patients with t(14;16) and 82% with t(4;14) had an additional genetic lesion. Only 21% of patients with t(11;14) and 54% with no IgH Tx had an additional event. 80 patients (51.3%) had prior FISH results and 13 (16.3%) had developed a new abnormality on the later test. In 9 cases the progression event was 17p-, in 2 it was 1q+ and 2 cases developed 17p- and 1q+. The patients developing 1q+ were previously standard risk, so repeat testing altered risk group. Acquisition of 17p- indicates especially poor outcome, thus in all 13 cases repeat FISH analysis altered risk. Among patients with progression events none harboured t(11;14), 8 (64%) had no IgH Tx, 3 had t(14;16) and 2 had t(4;14). FISH results were correlated with clinical outcome. Patients were stratified as having high risk genetics [t(4;14), t(14,16), 17p- in >=50% cells, 1p-/1q+] or standard risk [t(11;14), normal cytogenetics]. 63 (41%) patients were high risk, 83 (54%) standard risk, with no information available for 8 (5%). Both groups had received a median of 2 prior lines of therapy. Response rates (>=PR) to the next line of therapy were similar (60.4% standard risk vs 56.0% high risk). PFS from time of FISH was significantly longer in the standard risk group (9.8 months vs 5.9, p<0.01) as was OS (not reached vs 17.1 months, p<0.01, Fig. 1). In the high risk group, PFS was significantly longer in patients receiving a proteasome inhibitor (PI) as the next line of treatment versus those receiving other therapies (9.6 months vs 4.6, p=0.01) as was OS (not reached vs 9.7 months, p<0.01, Fig. 2). In the standard risk group, PFS was similar if patients received PI or not (9.5 months PI vs 9.8 other) as was OS (not reached both groups, Fig. 2). Conclusion(s): FISH analysis on MM patients at relapse was achievable. 74/154 patients had no prior results and a further 13 developed new poor prognostic markers, thus FISH at relapse provided new information in 56% of patients. Progression events were more common in patients harbouring t(4;14) or t(14;16). FISH at relapse was prognostic with high risk abnormalities associated with significantly shorter PFS and OS. The use of PI appeared to abrogate this poor prognosis, suggesting FISH at relapse could be a predictive and prognostic marker. Given the availability of second generation PI and the option of bortezomib re-treatment, results of FISH testing at relapse could directly influence clinical practice.

Smith, D. H., et al. (1999). "Comparisons of the effects of different long-acting delivery systems on the pharmacokinetics and pharmacodynamics of diltiazem." American Journal of Hypertension **12**(10 Pt 1):

1030-1037.

The benzothiazepine calcium channel antagonist diltiazem is a short-acting drug. To achieve effective 24-h blood pressure control with once-daily dosing, it relies on various extended drug-delivery systems that have grown in importance as a result of the recent reports relating the use of short-acting calcium channel antagonists to increased cardiovascular morbidity. This study examines the pharmacokinetics and resulting pharmacodynamics of two different delivery systems, each loaded with 240 mg of diltiazem and administered to 40 moderately hypertensive patients in a randomized, double-blind crossover trial. After a 4-week, single-blind placebo lead-in, patients with a clinical diastolic blood pressure of > or =100 mm Hg were randomized to either the single or dual microbead diltiazem delivery system for a 4-week period. At the end of this period, each subject was evaluated with 24-h ambulatory blood pressure monitoring and subjected to 24-h inpatient pharmacokinetic analysis on separate days. This was followed by a similar 4-week period in which each subject was treated with the alternative delivery system. For diltiazem, the area under the curve for plasma concentration versus time and the maximum plasma concentration attained by the single microbead system exceeded the values achieved by the dual bead system by 15% and 25%, respectively. These differences were greatest from the 3rd through the 13th h after dosing. During this period, both systolic and diastolic ambulatory blood pressure was significantly lower when the single microbead system was used. When compared with baseline blood pressure, blood pressure reductions achieved with the single microbead system exceeded reductions achieved with the dual microbead system by at least 2 mm Hg for 10 of the 24 postdose hours. Heart rates were slightly reduced but not significantly different. This improved blood pressure control at higher plasma levels of diltiazem suggests that a more efficient delivery system could provide better blood pressure control for identical doses of diltiazem.

Smith, E., et al. (2019). "Microplastics: what drinking water utilities need to know." Journal American Water Works Association **111**(11): 26-37.

Consumers are becoming more concerned with microplastics in water, so utilities should start thinking about methods to identify and address them. Although there is a lot of research on microplastics in marine environments, there isn't much research yet with drinking water. To address microplastics, utilities should establish sampling and analytical techniques, identify treatment methods, and implement communications strategies.

Smith, J., et al. (2010). "Measurement of multiple drugs in urine, water, and on surfaces using fluorescence covalent microbead immunosorbent assay." Toxicology Mechanisms & Methods **20**(9): 587-593.

There are a range of applications that require the measurement of multiple drugs such as urine analysis, drug determination in water, and screening for drug contamination on surfaces. Some of the procedures used such as enzyme-linked immunosorbent assay (ELISA) are simple but can only determine one drug at a time, and others such as GC-MS or LC-MS are complex, time-consuming, and expensive. In this study, fluorescence covalent microbead immunosorbent assay (FCMIA) was investigated as a simple method for the measurement of multiple drugs simultaneously in three matrices: diluted urine, water, and on surfaces. Five different drugs of abuse or their metabolites (methamphetamine, caffeine, benzoylecgonine (a metabolite of cocaine), tetrahydrocannabinol (THC), the active ingredient in marijuana, and oxycodone) were studied over the range 0-15 ng/ml. There was no measureable cross-reactivity among the drugs at the concentrations studied. Urine dilutions from 1/50 to 1/2.5 were studied and dilutions less than 1/20 had a significant effect on the methamphetamine assay but limited effects on the benzoylecgonine and oxycodone assays and almost no effect on the THC assay. For assays performed in 1/20 urine dilution, water, and diluted surface sampling buffer, least detectable doses (LDD) were 1 ng/ml or less for the drugs. Surfaces spiked with drugs were sampled with swabs wetted with surface sampling buffer and recoveries were linear over the range 0-100 ng/100 cm(2) surface loading for all drugs. FCMIA has potential to be used for the measurement of multiple drugs in the matrices studied.

Smith, J. P., et al. (2016). "Detection and measurement of surface contamination by multiple antineoplastic drugs using multiplex bead assay." Journal of Oncology Pharmacy Practice **22**(1): 60-67.

OBJECTIVES: Contamination of workplace surfaces by antineoplastic drugs presents an exposure risk for healthcare workers. Traditional instrumental methods to detect contamination such as liquid chromatography-mass spectrometry/mass spectrometry (LC-MS/MS) are sensitive and accurate but expensive. Since immunochemical methods may be cheaper and faster than instrumental methods, we wanted to explore their use for routine drug residue detection for preventing worker exposure.

METHODS: In this study we examined the feasibility of using fluorescence covalent microbead immunosorbent assay (FCMIA) for simultaneous detection and semi-quantitative measurement of three antineoplastic drugs (5-fluorouracil, paclitaxel, and doxorubicin). The concentration ranges for the assay were 0-1000 ng/ml for 5-fluorouracil, 0-100 ng/ml for paclitaxel, and 0-2 ng/ml for doxorubicin. The surface sampling technique involved wiping a loaded surface with a swab wetted with wash buffer, extracting the swab in storage/blocking buffer, and measuring drugs in the extract using FCMIA.

RESULTS: There was no significant cross-reactivity between these drugs at the ranges studied indicated by a lack of response in the assay to cross analytes. The limit of detection (LOD) for 5-fluorouracil on the surface studied was 0.93 ng/cm(2) with a limit of quantitation (LOQ) of 2.8 ng/cm(2), the LOD for paclitaxel was 0.57 ng/cm(2) with an LOQ of 2.06 ng/cm(2), and the LOD for doxorubicin was 0.0036 ng/cm(2) with an LOQ of 0.013 ng/cm(2).

CONCLUSION: The use of FCMIA with a simple sampling technique has potential for low cost simultaneous detection and semi-quantitative measurement of surface contamination from multiple antineoplastic drugs.

Smith, L. D. and P. Sainsbury (2007). "UK needs to better realise value from recovered plastics." Materials Recycling Week **190**(23): 8-8.

The article focuses on the report "Realising the value of recovered plastics" from the Waste & Resources Action Programme (WRAP) in Great Britain. The report analyzes the opportunities and risks for the country’s recovered plastics market as recycling demand grows from consumers. It states that a key challenge facing the recovered plastics sector is how to maintain quality, as a larger proportion of the material is being recovered from post-consumer rather than post-industrial sources. It also mentions that the demand from households for mixed plastics collections is a big challenge but represents a major opportunity to increase plastic recycling rates.

Smith, L. E. (2018). "Plastic ingestion by Scyliorhinus canicula trawl captured in the North Sea." Marine Pollution Bulletin **130**: 6-7.

The ingestion of plastic debris by marine organisms has been documented across a variety of taxa including; marine mammals, sea birds, sea turtles and some fish species. Fewer reports have described ingestion by sharks, in this study the gastrointestinal tracts of 20 small spotted catsharks (Scyliorhinus canicula) trawl captured in the North Sea were investigated.

Macroplastics (>20 mm) were found in 2 individuals and microplastic (<5 mm) was found in one other individual, this is the first time that plastic ingestion has been reported in this species. These observations suggest that gastrointestinal analysis of commonly landed elasmobranch species is worthwhile, to further understanding on the organisms and habitats impacted by plastic pollution. Copyright © 2018 Elsevier Ltd

Smith, M. (2013). "Baling Plastics -- density or throughput, what matters more?" Local Authority Waste & Recycling **21**(12): 21-21.

The article discusses the challenges in plastic polymers recycling. In Great Britain, some 5 million tonnes of waste plastics are produced every year and 2.4 million tonnes of it are related to packaging waste. The author cites monitoring bale weight as an essential part in overcoming the challenges in plastic polymers recycling as well as machine choice and bale size.

Smith, M. and J. Blackburn (2015). "Identifying novel cancer antigens using immunoproteomics." Annals of Oncology **8)**: viii9.

Aim: The Blackburn lab has developed a highly sensitive and selective native cancer-antigen (CT100+) microarray, housing 123 tumour-specific antigens (TSA), for cancer diagnosis using patient blood. Although technically advanced, the microarray has biological limitations as we observed a random antibody response in 10-20% of patients. Our aim is therefore to use immunoproteomics to identify TSAs which can reproducibly be used for cancer diagnosis and prognosis. Method(s): We have an archive of 67 cancer and normal tissues, with corresponding autologous sera, from patients with colorectal cancer (CRC) (Groote Schuur Hospital, South Africa) for identifying novel TSAs. For each patient, we have a range of clinical information including their MSI status, inflammation status, cancer stage, family CRC history, etc. We have, thus far, developed an immuno-pulldown assay, in which Protein A and Protein G magnetic microbeads are used to selectively capture antibodies from the patient sera. The Ig-bound microbeads were incubated with native cancer and control tissue lysates to capture antigens. After performing an on-bead tryptic digestion, the peptides were eluted and proteins were identified by mass spectrometry, using a QExactive mass analyser. Result(s): In total, 1276 proteins were identified of which 360 were unique to cancer. Eight of the 360 cancer-unique proteins were matched to the Tantigen database, a data source and analysis platform for cancer vaccine target discovery focusing on human tumour antigens that contain HLA ligands and T cell epitopes. Furthermore, we found the most abundant cancer-specific protein to be elongation factor 2, a protein previously reported in CRC patients to result in an antibody response, supporting evidence that the IP assay developed captured cancer antigens. Conclusion(s): In conclusion, we have optimised an immuno-pulldown assay to capture and identify cancer antigens from CRC tissues using autologous sera. Our next step is to assay the remaining samples to identify additional TSAs associated with disease diagnosis and prognosis. The newly identified TSAs will then be fabricated on the CT100+ microarray, and validated with patient sera to confirm the presence of cancer-specific antibody response.

Smith, M. and J. M. Blackburn (2017). "Identifying serum biomarkers for colorectal cancer using immunoproteomics." Cancer Research. Conference **77**(22 Supplement 1).

The Blackburn lab has developed a highly sensitive and selective native cancer-antigen (CT100+) microarray, which has been used to detect autoantibodies in the blood samples of cancer patients. Although technically advanced, the microarray has biological limitations as we observe a random antibody response in 10-20% of patients with various cancer-types. Our aim is therefore to use immunoproteomics to identify tumor specific antigens (TSAs) which can

reproducibly be used for cancer diagnosis and prognosis. We have an archive of 67 cancer and paired normal tissues, with corresponding autologous blood plasma samples, from patients with colorectal cancer (CRC) (Groote Schuur Hospital, South Africa) for identifying novel TSAs. For each patient, we have a set of clinical information which can be used to identify cancer antigens associated with disease pathogenesis. To identify novel cancer antigens, we have developed an immuno-pulldown assay, in which Protein A and Protein G magnetic microbeads are used to selectively capture antibodies from the patient blood plasma. The Ig-bound microbeads were incubated with native cancer and control tissue lysates to capture antigens. After performing an on-bead tryptic digestion, the peptides were eluted and proteins were identified by mass spectrometry, using a Q-Exactive mass analyser. Using the MaxQuant proteomics software, we were able to identify a total of 1276 proteins, of which 360 were unique to the cancer samples. Eight of the 360 cancer-unique proteins were matched to the Tantigen database, a data source and analysis platform for cancer vaccine target discovery. Furthermore, 3 of the 8 proteins identified have been reported to induce antibody responses in cancer patients. In conclusion, we have developed an immuno-pulldown assay that captures and identifies proteins which are unique to cancer tissues, of which several have shown to induce a T- and B-cell response in cancer patients. Although we are able to identify protein candidates of interest, we observe several limitations with the assay, for which we are currently troubleshooting. Once the method is optimized, the newly identified TSAs will be fabricated on to the CT100+ microarray, and validated with patient sera to confirm the presence of cancer-specific antibody response.

Smith, M., et al. (2018). "Microplastics in Seafood and the Implications for Human Health." Current Environmental Health Reports **5**(3): 375-386.

PURPOSE OF REVIEW: We describe evidence regarding human exposure to microplastics via seafood and discuss potential health effects.

RECENT FINDINGS: Shellfish and other animals consumed whole pose particular concern for human exposure. If there is toxicity, it is likely dependent on dose, polymer type, size, surface chemistry, and hydrophobicity. Human activity has led to microplastic contamination throughout the marine environment. As a result of widespread contamination, microplastics are ingested by many species of wildlife including fish and shellfish. Because microplastics are associated with chemicals from manufacturing and that sorb from the surrounding environment, there is concern regarding physical and chemical toxicity. Evidence regarding microplastic toxicity and epidemiology is emerging. We characterize current knowledge and highlight gaps. We also recommend mitigation and adaptation strategies targeting the life cycle of microplastics and recommend future research to assess impacts of microplastics on humans. Addressing these research gaps is a critical priority due to the nutritional importance of seafood consumption.

Smith, S. and J. F. Parr (1972). "Chemical stability of DDT and related compounds in selected alkaline environments." Journal of Agricultural and Food Chemistry **20**(4): 839-841.

DDT was stable in soil treated with anhydrous ammonia (pH > 10.0) and in sterile, buffered, glass microbeads up to pH 124 The threshold pH for dehydrochlorination of DDT to DDE in microbeads was 12E, with extensive conversion (> 70%) at pH 13.0 where the amount of applied DDT unaccounted for increased from 2OV at 140 hr to approximately SOX after 30 days. suggesting the formation of intermediates that were lost during extraction or not detectable by electron capture. Applied DDE was relatively stable in microbeads even at pH 13.0 where nearly complete recovery was obtained after 7 days. However, extended incubation to 28 days allowed a gradual disappearance of DDE with only 88 and IVL accounted for at pH 10.0 and 13.0, respectively, suggesting a time dependent pH relationship for transformation under these conditions. Similar observations were observed in studying the effect of pH on the dehydrochlorination of DDD to DDMU. While DDD was stable for extended periods at pH 10.0, it converted rapidly to DDMU at pH 13.0 and then tended to disappear with time.

Smith, S. L., et al. (2019). "Life cycle analysis: end of life analysis of two contact lens replacement modalities." Contact Lens and Anterior Eye **42 (6 Supplement 1)**: e21.

Purpose: There is growing evidence of an increase in microplastic pollution of the aquatic environment, and wider environmental concerns regarding use and disposal of resources. This study examines the annualised waste produced by two representative contact lens systems and the end of life disposal of contact lenses and packaging. Method(s): Waste audits for a representative daily disposable system (somofilcon A) versus a reusable monthly replacement system (somofilcon A with MPS) were conducted to quantify and characterise the materials that would enter household waste or recycling during normal use. Calculations for the reusable system included all lens care products; 12 solution bottles and 12 lens cases. Once weighed (after dehydration, where appropriate) and categorised, annualised figures were calculated assuming compliant, full-time use, with lenses worn in both eyes. Result(s): Four categories of material were identified: liquid; paper and cardboard; metal; plastics (high-density polyethylene, polypropylene and hydrogel plastic). The reuseable system generated 0.8 kg of material solid waste (MSW) over a year, the daily disposable system 1.1 kg. Plastics accounted for the most significant proportion of MSW by mass for both systems. The annualised mass of somofilcon A was 0.3 g and 10 g for reusable and daily disposable lenses respectively. 89 % by mass of MSW generated by the monthly replacement system could be recycled, compared to 35 % of the daily disposable system. Polypropylene trays generated 700 g of waste over a year for the daily disposable system; such material is not commonly accepted for household recycling. Conclusion(s): In the UK, household waste generated per person is approximately 390 kg per year. Contact lens use accounts for only a small percentage of household waste, 0.2-0.3 % and a significant proportion of this can be recycled. Contact lens wearers should be encouraged to dispose of worn lenses in the bin, rather than the sink or lavatory to avoid microplastic contamination of the marine environment. Copyright © 2019

Smits, A. I., et al. (2012). "A mesofluidics-based test platform for systematic development of scaffolds for in situ cardiovascular tissue engineering." Tissue Engineering - Part C: Methods **18**(6): 475-485.

Recently, in situ tissue engineering has emerged as a new approach to obtain autologous, living replacement tissues with off-the-shelf availability. The method is based on the use of an instructive biodegradable scaffold that is capable of repopulation with host cells in situ and subsequent tissue formation. This approach imposes high demands on scaffold properties. For cardiovascular grafts, the repopulation with endogenous cells from the circulation is further hypothesized to be influenced by the hemodynamic environment of the scaffold. To systematically study the effect of scaffold properties on the response of circulating cells, we aimed to develop a mesofluidics-based in vitro test platform that enables on-stage investigation of the interaction of circulating cells with three-dimensional (3D) synthetic scaffolds under physiologic hemodynamic conditions. The test platform consists of a custom-developed cross-flow chamber that houses small-scale 3D scaffolds. The cross-flow chamber is incorporated into a flow-loop to drive a cell suspension along the scaffold with physiological wall shear stress and perfusion pressure. The fluidics system is validated numerically and experimentally using a computational fluid dynamics model and real-time microbead tracing studies, demonstrating a fully developed flow profile with a homogeneous shear stress

distribution over the scaffold. Wall shear stresses and pressure can be controlled independently, well within the target physiological range (0-8 Pa and 0-100 mmHg, respectively). Bench-top evaluation is performed using electrospun poly(e-caprolactone) scaffolds with varying fiber diameter, exposed to a suspension of human peripheral blood mononuclear cells in pulsatile flow for 72 h. Cell adhesion and infiltration are monitored using time-lapsed confocal laser scanning microscopy. In conclusion, we have successfully developed a mesofluidics platform to study cell-scaffold interactions under hemodynamic conditions in vitro. This platform not only enables us to systematically screen and develop potential scaffolds for future in situ cardiovascular tissue engineering approaches, but also acts as a tool to further elucidate processes as observed in vivo.

Smol, T., et al. (2016). "Combination of t(4;14), del(17p13), del(1p32) and 1q21 gain fish probes identifies clonal heterogeneity and enhances detection of adverse cytogenetic profiles in 233 newly diagnosed multiple myeloma." Haematologica **101 (Supplement 1)**: 514.

Background: Cytogenetic analyses play a leading part in the risk stratification of MM due to the prognostic and therapeutic impacts of cytogenetic abnormalities. However, with a metaphase cytogenetic approach only 35% of patients present abnormal karyotypes, often associated with an advanced stage of the disease. Practice guidelines now recommend interphase fluorescence in-situ hybridization (FISH) on isolated CD138-expressing plasma cells (PC) as the initial cytogenetic analysis for MM. The most pertinent markers target the deletion of 17p13 (TP53 deletion) and the t(4;14)(p16;q32) FGFR3-IGH translocation, and partial aneuploidies of chromosome 1 (1q21 gain and 1p32 deletion) are retained as more relevant additional markers. Aim(s): Our aim was to fix the FISH combination of del(17p13), t(4;14), 1q21 gain and del(1p32) in a prospective study of 233 newly diagnosed MM with an analysis of the association between abnormalities and the number of clones. Method(s): Between January 2013 and August 2015, 233 BM samples were collected from 233 patients during diagnostic at the Cytogenetic Laboratories in Valenciennes General Hospital, and Versailles General Hospital. The institutional ethics committee approved the study. PC were enriched from BM mononuclear cells, using a magnetic cell sorting CD138 MicroBeads kit (Miltenyi Biotec; BergischGlabach, Germany). The FISH panel included TP53/CEP17 probe (Amplitech, Compiegne, France), 1p32/CDKN2C-FAF1-1q21/CKS1B probe (Amplitech), t(4;14)(p16;q32) probe (MetaSystems, Altlussheim, Germany), and IGH break-apart probe (MetaSystems). Technical thresholds were determined for each probe using isolated CD138-expressing PC from patients without MM, on the basis of the same method as patients with MM. Thresholds were assessed after counting 200 cells for each negative sample, and established by "mean+3 DS" calculation. Result(s): Cytogenetic abnormalities were identified in 79.0% of cases, with one or more adverse abnormalities in 51.9%. We observed a del(17p13) in 15.0%, a t(4;14) translocation in 11.5%, a 1q21 gain in 37.8%, and a del(1p32) in 8.7% of patients with statistically significant associations between 1q21 gain and t(4;14) (p=0.001), and del(1p32) and del(17p13) (p=0.01). Adding 1p32/1q21 FISH probe has enabled us to identify one or more adverse abnormalities in 39.0% of patients with absence of TP53 deletion or t(4;14). Clonal heterogeneity was observed in 51.1% of cases. Adverse abnormalities were significantly more frequent when the number of clones was greater than or equal to 2, with a frequency of 85.1% against 45.6% when 1 single clone was identified (p<0.0001). We observed a greater number of MM with 1q21 gain when clonal heterogeneity was present (>=2 clones): 81.6% versus 18.4% when 1 single clone was identified (p<0.0001). In the case of marked clonal heterogeneity (>=3 clones), a higher involvement of del(1p32) was found with a frequency of 28.0% against 5.8% when only 2 related clones were present (p=0.002). In the subgroup t(4;14)+/1q21+ with 2 or more identified clones (n=14), 1q21 gain

was found to be significantly more often present in the minor clone compared to the clone with t(4;14) (10/14) (p=0.01). Summary/Conclusions: We were able to identify adverse abnormalities or derivative anomalies, and related clones or clonal evolution by FISH analysis. We confirm the presence of clonal heterogeneity and accumulation of adverse abnormalities in the first diagnostic analysis. The prognostic impact of these parameters should be evaluated, and could be included in cytogenetic classifications.

Snider, E. J., et al. (2020). "A flexible, robust microbead-based assay for quantification and normalization of target protein concentrations." Analytical Biochemistry **590**: 113510.

Although there are many methods for quantifying the concentration of specific proteins in samples, current techniques are technically challenging or do not easily lend themselves to normalization. Here, we describe a microbead-based assay for quantifying specific protein concentration(s) that is high-throughput, inexpensive, simple-to-use, and intrinsically incorporates normalization against the sample total protein content. This assay, termed the FRANC assay, exploits high affinity biotin-streptavidin binding to couple sample proteins to streptavidin-labelled magnetic microbeads. Proteins are then antibody-probed, followed by labeling of proteins on the microbead with fluorescent dye, and flow cytometry-based analysis. The FRANC assay demonstrates detection limits for target proteins in the femtogram range, with a linear range up to as much as 10 ng. Normalization of target protein concentrations resulted in an 80% reduction in variability as compared to non-normalized measurements. We conclude that the FRANC assay offers attractive advantages over current methods for quantifying specific protein(s) in samples.

Snow, D. D., et al. (2019). "Detection, occurrence, and fate of emerging contaminants in agricultural environments (2019)." Water Environment Research **91**(10): 1103-1113.

A review of 82 papers published in 2018 is presented. The topics ranged from detailed descriptions of analytical methods, to fate and occurrence studies, to ecological effects and sampling techniques for a wide variety of emerging contaminants likely to occur in agricultural environments. New methods and studies on veterinary pharmaceuticals, microplastics, and engineered nanomaterials in agricultural environments continue to expand our knowledge base on the occurrence and potential impacts of these compounds. This review is divided into the following sections: Introduction, Analytical Methods, Fate and Occurrence, Pharmaceutical Metabolites, Anthelmintics, Microplastics, and Engineered Nanomaterials. Practitioner points: New research describes innovative new techniques for emerging contaminant detection in agricultural settings. Newer classes of contaminants include human and veterinary pharmaceuticals. Research in microplastics and nanomaterials shows that these also occur in agricultural environments and will likely be topics of future work. Copyright © 2019 Water Environment Federation

So, W. K., et al. (2018). "Abundance of plastic microbeads in Hong Kong coastal water." Marine Pollution Bulletin **133**: 500-505.

To address the rising concern over the use of plastic microbeads in personal care and cosmetic products, countries worldwide have started taking legislative actions to ban microbeads. Yet, the degree of contamination of coastal waters by plastic microbeads is rarely reported. Surface manta trawls were conducted to investigate the presence of microbeads in the southern coastal waters of Hong Kong. Considering only the size fraction of 0.3 to 1mm, 60% of samples were found to contain microbeads. Microbeads accounted for 3.6% of the total microplastics collected and microbead abundance ranged from 0 to 380,129pcs/km². The shapes, sizes, colours, and composition of microbeads found in our samples were similar to those from tested facial scrubs, suggesting that pelagic microbeads collected in this study very likely originated from the cosmetic products available locally. Microbeads represent a non-negligible part of the microplastics found in surface coastal waters.

Soares, R. R. G., et al. (2019). "Silica bead-based microfluidic device with integrated photodiodes for the rapid capture and detection of rolling circle amplification products in the femtomolar range." Biosensors & Bioelectronics **128**: 68-75.

The rapid and sensitive detection of specific nucleic acid sequences at the point-of-care (PoC) is becoming increasingly in demand for a variety of emergent biomedical applications ranging from infectious disease diagnostics to the screening of antimicrobial resistance. To meet such demand, considerable efforts have been invested towards the development of portable and integrated analytical devices combining microfluidics with miniaturized signal transducers. Here, we demonstrate the combination of rolling circle amplification (RCA)-based nucleic acid amplification with an on-chip size-selective trapping of amplicons on silica beads (~8 nL capture chamber) coupled with a thin-film photodiode (200x200micro m area) fluorescence readout. Parameters such as the flow rate of the amplicon solution and trapping time were optimized as well as the photodiode measurement settings, providing minimum detection limits below 0.5 fM of targeted nucleic acids and requiring only 5muL of pre-amplified sample. Finally, we evaluated the analytical performance of our approach by benchmarking it against a commercial instrument for RCA product (RCP) quantification and further investigated the effect of the number of RCA cycles and elongation times (ranging from 10 to 120min). Moreover, we provide a demonstration of the application for diagnostic purposes by detecting RNA from influenza and Ebola viruses, thus highlighting its suitability for integrated PoC systems.

Sobhani, Z., et al. (2019). "Identification and visualisation of microplastics by Raman mapping." Analytica Chimica Acta **1077**: 191-199.

Recently, microplastics (MP) have emerged as global contaminants of serious concern to human and ecological health. However, identification and visualisation of MP are still a challenge, whether from wastewater, oceans, sediment or soil. Particularly when MP are mapped to visualise their distribution, the background signal from sediment and soil might be high and shield the MP signal from the analysis. Raman has recently received increasing attention, as the complementary spectrum of infrared (IR), because it can overcome the drawbacks of IR analysis including water interference, low lateral resolution and a complex spectrum. Here we show that Raman can identify and visualise MP from a soil/sand background, with almost no sample preparation, no dye, no destruction of the sample and no interference from water/organic matter/fluorescence background signals as well. By mapping image via their characteristic and fingerprint peaks, MP including polystyrene (PS), polyethylene terephthalate (PET), polyethylene (PE), polyvinyl chloride (PVC) and polypropylene (PP) can be individually identified and visualised. The lateral resolution along the focal plane is 1mum/pixel to catch small MP down to 1mum.

Sobrova, P., et al. (2012). "Capillary electromigration based techniques in diagnostics of prion protein caused diseases." Electrophoresis **33**(24): 3644-3652.

Transmissible spongiform encephalopathies are a group of fatal neurodegenerative diseases with long incubation time. This group includes Creutzfeld-Jakob disease, kuru, scrapie, chronic wasting disease, and bovine spongiform encephalopathy. Sensitive and specific detection of abnormal prion protein as "a source agent" of the above-mentioned diseases in blood could provide a diagnostic test or a screening assay for animal and human prion protein diseases diagnostics. Therefore, diagnostic tests for prion protein diseases represent unique challenge requiring development of novel assays exploiting properties of prion protein complex. Presently, diagnostic methods such as protein misfolding cyclic amplification, conformation-dependent immunoassay, dissociation-enhanced lanthanide fluorescent immunoassay, fluorescence correlation spectroscopy, and/or flow microbead immunoassay are used for abnormal prion protein (PrP(Sc)) detection. On the other hand, using of CE for PrP(Sc) detection in body fluids is an attractive alternative; it has been already applied for the blood samples of infected sheep, elk, chimpanzee, as well as humans. In this review, assays for prion protein detection are summarized with special attention to capillary electromigration based techniques, such as CE, CIEF, and/or CGE. The potential of the miniaturized and integrated lab-on-chip devices is highlighted, emphasizing recent advances of this field in the proteomic analysis.

Sogancioglu, M., et al. (2019). "Behaviour of waste polypropylene pyrolysis char-based epoxy composite materials." Environmental science and pollution research international. **10**.

In this study, polypropylene (PP) plastic wastes were pyrolysed. Solid pyrolysis product (char) was used as filler material for the preparation of epoxy composite. 300, 400, 500, 600 and 700 degreeC were selected as final pyrolysis temperatures. Solid pyrolysis product (char) was analysed by elemental, FTIR, SEM, BET and TGA analysis. The epoxy composite samples were prepared with char obtained from pyrolysis. Mechanical properties of composites were analysed by hardness, tensile strength, elongation at break, electrical conductivity tests to explain the effects of pyrolysis temperature and char doses over composite properties. Thermogravimetric properties of composites were determined by TGA analyses. The water absorption behaviour of composite samples was determined by water adsorption test. Epoxy composite produced from PP char obtained under 300 degreeC showed the most ideal behaviour.

Soh, N., et al. (2004). "Chemiluminescence sequential injection immunoassay for vitellogenin using magnetic microbeads." Talanta **64**(5): 1160-1168.

A rapid and sensitive immunoassay for the determination of carp vitellogenin (Vg) is described. The method involves a sequential injection analysis (SIA) system equipped with a chemiluminescence detector and a samarium-cobalt magnet. An anti-Vg monoclonal antibody, immobilized on magnetic beads, was used as a solid support for the immunoassay. The introduction, trapping and release of the magnetic beads in the flow cell were controlled by a samarium-cobalt magnet and the flow of the carrier solution. The immunoassay was based on a sandwich immunoreaction of anti-Vg monoclonal antibody (primary antibody) on the magnetic beads, Vg, and the anti-Vg antibody labeled with horseradish peroxidase (HRP) (secondary antibody), and was based on a subsequent chemiluminescence reaction of HRP with hydrogen peroxide and p-iodophenol, in a luminol solution. The magnetic beads to which the primary antibody was immobilized were prepared by coupling the primary antibody with the magnetic beads after an agarose-layer on the surface of the magnetic beads was epoxidized. The primary antibody-immobilized magnetic beads were introduced, and trapped in the flow cell equipped with the samarium-cobalt magnet, a Vg sample solution, an HRP-labeled secondary antibody solution and the luminol solution were sequentially introduced into the flow cell based on an SIA programmed sequence. Chemiluminescence emission was monitored by means of a photomultiplier located at the upper side of the flow cell. The optimal incubation times both for the first and second immunoreactions were determined to be 20min. A concave calibration curve was obtained between Vg concentration and chemiluminescence intensity when various concentrations of standard Vg samples (2-100ngmL(-1)) were applied to the SIA system under optimal conditions. In spite of a narrow working range, the lower detection limit of the immunoassay was about 2ngmL(-1).

Soh, N., et al. (2002). "Spectrophotometric determination of carp vitellogenin using a sequential injection analysis technique equipped with a jet ring cell." Talanta **58**(6): 1123-1130.

A sequential injection analysis (SIA) technique, in which antibody-immobilized microbeads were transferred to a jet ring (JR) cell, was used in determination of carp vitellogenin (Vg). The determination is based on a sandwich immunoassay in which two types of reactions between anti carp Vg antibodies and carp Vg are used. Namely, the antibody for the first reaction step was immobilized on microbeads (Sephadex beads), and an antibody labeled with a horseradish peroxidase (HRP) was used in the second step of the reaction. A mixed solution of hydrogen peroxide and o-phenylenediamine (OPD) was used as the source of the chromophore in the reaction. The microbeads-immobilized antibody, Vg analyte, HRP-labeled anitbody and the color developing solution were introduced automatically into the JR cell of the SIA system in a programmed sequence, and the absorbance of the oxidized OPD product was used to determine the amount of Vg present. The optimal incubation times for the immuno-raction for the first and the second steps were determined at 120 and 60 min, respectively, taking into account the sensitivity to the Vg determination. Under these conditions, a good linear correlation was obtained between Vg concentration and the absorbance of the oxidized OPD. The lower detection limit for the determination of Vg was about 5 ng ml(-1) in this system. The method developed here represents a simple, accurate method for the determination method of Vg.

Sohail, A., et al. (2012). "Evaluation of Lactobacillus rhamnosus GG and Lactobacillus acidophilus NCFM encapsulated using a novel impinging aerosol method in fruit food products." International Journal of Food Microbiology **157**(2): 162-166.

This study investigated the effect of microencapsulation on the survival of Lactobacillus rhamnosus GG and Lactobacillus acidophilus NCFM and their acidification in orange juice at 25degreeC for nine days and at 4degreeC over thirty five days of storage. Alginate micro beads (10-40 mum) containing the probiotics were produced by a novel dual aerosol method of alginate and CaCl(2) cross linking solution. Unencapsulated L. rhamnosus GG was found to have excellent survivability in orange juice at both temperatures. However unencapsulated L. acidophilus NCFM showed significant reduction in viability. Encapsulation of these two bacteria did not significantly enhance survivability but did reduce acidification at 25degreeC and 4degreeC. In agreement with this, encapsulation of L. rhamnosus GG also reduced acidification in pear and peach fruit-based foods at 25degreeC, however at 4degreeC difference in pH was insignificant between free and encapsulated cells. In conclusion, L. rhamnosus GG showed excellent survival in orange juice and microencapsulation has potential in reducing acidification and possible negative sensory effects of probiotics in orange juice and other fruit-based products.

Sokka, L., et al. (2007). "Municipal solid waste production and composition in Finland—Changes in the period 1960–2002 and prospects until 2020." Resources, Conservation & Recycling **50**(4): 475-488.

Waste reduction was recognised as the main goal of waste management policy in the EU in the 1990s. Although knowledge of past waste generation is essential for effective waste reduction policy there are no comprehensive statistics on the past development of municipal solid waste (MSW) production. MSW management is currently under turmoil in many EU countries as the requirements of the EC landfill directive (1999/31/EC) are set into force. In this study, the production and composition of MSW in Finland between 1960 and 2002 is presented using historical data. The impact of population, affluence and technology on MSW production are analysed using the IPAT equation and three scenarios are constructed until year 2020. The results are compared with national future targets on MSW production. Production of MSW increased in Finland until 1990, declined to year 1997, increased to 2000 and then declined again. The share of organic and plastic waste increased over the study period while the share of paper and cardboard declined. The results suggest that so far national targets on MSW reduction have been set fairly low. Moreover, our scenarios depict a wide range of future MSW production, even though the time horizon is not longer than 15 years into the future. In order to narrow this range, continuous improvement of the statistics of MSW is essential. [Copyright &y& Elsevier]

Sokmen, T. O., et al. (2019). "Polystyrene nanoplastics (20 nm) are able to bioaccumulate and cause oxidative DNA damages in the brain tissue of zebrafish embryo (Danio rerio)." Neurotoxicology **77**: 51-59.

Nano-sized plastic particles formed from both daily use plastics and its debris have become a potential health and environmental problem due to features such as transportation through food webs and maternal transfer. Although many studies on the toxicity of plastics exist more detailed and molecular studies are needed to evaluate and review the effects of plastics especially in nano-size range. For this purpose, we have microinjected polystyrene nanoplastics (PNP) (20 nm) to the zebrafish embryo, which is one of the best model organisms for developmental toxicity studies, to simulate intake with food or maternal. Survival, hatching and malformations evaluated during the experimental period (120 h). Moreover, we have aimed to put forth the presence of reactive oxygen species (ROS) and apoptosis signalling accumulation in the body in addition to bioaccumulation of PNP and immunochemical toxicity (8-OHdG) on the brain of zebrafish larvae at the 120th hour. According to results, it has been demonstrated that 20 nm diameter PNP can reach the brain and bioaccumulate there, moreover lead to oxidative DNA damage in the brain regions where it bioaccumulates. Here we have also imaged the PNP from a vertebrate brain via transmission electron microscopy (TEM) for the first time. As a result of these, it has been detected increasing mortality and prevailing abnormalities in addition to excessive ROS and apoptosis in especially the brain. As a conclusion, obtained data have suggested that precautions, on the use and contamination of the plastic product, to be taken during both pregnancy and baby care/feeding are important for the health of the baby in future.

Sola, C., et al. (2015). "High-Throughput CRISPR Typing of Mycobacterium tuberculosis Complex and Salmonella enterica Serotype Typhimurium." Methods in Molecular Biology **1311**: 91-109.

Spoligotyping was developed almost 18 years ago and still remains a popular first-lane genotyping technique to identify and subtype Mycobacterium tuberculosis complex (MTC) clinical isolates at a phylogeographic level. For other pathogens, such as Salmonella enterica, recent studies suggest that specifically designed spoligotyping techniques could be interesting for public health purposes. Spoligotyping was in its original format a reverse line-blot hybridization method using capture probes designed on "spacers" and attached to a membrane's surface and a PCR product obtained from clustered regularly interspaced short

palindromic repeats (CRISPRs). Cowan et al. and Fabre et al. were the first to propose a high-throughput Spoligotyping method based on microbeads for MTC and S. enterica serotype Typhimurium, respectively. The main advantages of the high-throughput Spoligotyping techniques we describe here are their low cost, their robustness, and the existence (at least for MTC) of very large databases that allow comparisons between spoligotypes from anywhere.

Soltner, E., et al. (2009). "Adenosine inhibits RANKL-induced osteoclastogenesis in vitro." Arthritis and Rheumatism **10)**: 1296.

Purpose: Adenosine is an endogenous purine nucleoside that modulates many physiological processes. Cellular signaling occurs through four known adenosine receptor subtypes (A1, A2a, A2b, and A3). Adenosine is believed to be an anti-inflammatory agent, implicated in many pathologies such as asthma or inflammatory joint disease. However, there is very few information in the literature on the role and expression of adenosine receptors in bone cells. We investigated therefore whether osteoclasts express adenosine receptors and how adenosine could regulate osteoclastogenesis. Method(s): Human peripheral blood mononuclear cells (PBMCs) were isolated by centrifugation over Ficoll gradient. CD14+ cells were magnetically labelled with CD14+ microbeads and positively selected by MACS technology. CD14+ cells were cultured with human M-CSF (25 ng/ml) and, after 3 days of culture, with or without hRANK-L (100 ng/ml). The formation of TRAP positive cells occurred around the 12th day of culture and was observed by TRAP staining. Expression of adenosine receptors was determined by RT-PCR and micro-array analysis of CD14+ cells and osteoclasts. Activity of the PI3K pathway, a key signaling protein downstream of adenosine receptors, was analysed by western blotting. TRAP staining was used to evaluate the effects of adenosine and 4 specific agonists of the adenosine receptors [CCPA (A1), CGS21680 (A2a), NECA (A2b), IB-MECA (A3)] on osteoclast differentiation. Result(s): The mRNA for all four adenosine receptors (A1, A2a, A2b, and A3), was detectable by RT-PCR in both CD14+ cells and osteoclasts. Microarray analysis showed a 2-fold increase in expression of the A3 receptor subtype in osteoclasts compared to CD14+ cells, whereas expression of the 3 other subtypes remained stable during differentiation. Western blot analysis showed a decreased phosphorylation of PI3K in CD14+ cells and osteoclasts stimulated with adenosine. TRAP staining demonstrated that adenosine inhibited RANKL-induced osteoclastogenesis. All four specific agonists of individual receptor subtypes inhibited osteoclastogenesis with comparable efficacies. Conclusion(s): Our work shows that osteoclasts and CD14+ cells express all four subtypes of adenosine receptor. Furthermore, phosphorylation of PI3K was decreased following stimulation with adenosine, confirming that these receptors are functional. We also demonstrated that adenosine has a potent inhibitory effect on RANKL-induced osteoclastogenesis in vitro, through its 4 receptor subtypes. We hypothesise that adenosine may be a regulator of osteoclastogenesis and contribute to the balance between bone formation and resorption in inflammatory conditions.

Some, Y. S. C., et al. (2016). "The determiners of the choice of the plastic containers in the production of plants in Ouagadougou (Burkina Faso): a contribution to the management of plastic waste." International Journal of Biological and Chemical Sciences **10**(6): 2637-2645.

Plastic waste contributes to the degradation of the environment and affects human and animal health. However, plastics are widely used as containers by Nursery men of the city of Ouagadougou, for the production plants intended for the reforestation. This work is interested in the explanatory factors of the choice of the types of containers. Its objective is to contribute to a better waste management of plastic containers stemming from the production of plants by a better knowledge of the criteria of choice of the containers of the nursery gardeners of

Ouagadougou to Burkina Faso. The methodology is based on geographic and social surveys and data analysis (analysis of variance and correlation test). This work allowed identifying two groups of plastic containers: that resulting from salvaged materials and that stemming from a specific industrial production. These plastic containers are polyethylene (high and low density) and polypropylenes (single and laminated). The main factors of choice of containers are: the price and the availability. The most used containers are the ones which are the most available and having the lowest costs. This work could be extended to other cities, to the ways of elimination of used containers and to the use of alternative containers.

Somleva, M. N., et al. (2008). "Production of polyhydroxybutyrate in switchgrass, a value-added co-product in an important lignocellulosic biomass crop." Plant Biotechnology Journal **6**(7): 663-678.

SUMMARY: Polyhydroxyalkanoate bio-based plastics made from renewable resources can reduce petroleum consumption and decrease plastic waste disposal issues as they are inherently biodegradable in soil, compost and marine environments. In this paper, the successful engineering of the biomass crop switchgrass (Panicum virgatum L.) for the synthesis of polyhydroxybutyrate (PHB) is reported. Polymer production was monitored in more than 400 primary transformants grown under in vitro and glasshouse conditions. Plants containing up to 3.72% dry weight of PHB in leaf tissues and 1.23% dry weight of PHB in whole tillers were obtained. Results from the analysis of the polymer distribution at the cellular and whole plant levels are presented, and target areas for the improvement of PHB production are highlighted. Polymer accumulation was also analysed in the T(1) generation obtained from controlled crosses of transgenic plants. This study presents the first successful expression of a functional multigene pathway in switchgrass, and demonstrates that this high-yielding biomass crop is amenable to the complex metabolic engineering strategies necessary to produce high-value biomaterials with lignocellulose-derived biofuels.

Somner, J. E., et al. (2010). "The precautionary principle: what is the risk of reusing disposable drops in routine ophthalmology consultations and what are the costs of reducing this risk to zero?" Eye **24**(2): 361-363.

BACKGROUND: Instilling eye drops is a ubiquitous procedure in eye clinics. This audit aimed to assess the risk of contamination of disposable droppers and to quantify the financial and waste implications of reducing this risk to zero by using disposable droppers only once.

METHODS: A total of 100 disposable Minims were used to place one drop in each eye of 70 patients. The dropper tip was then cultured for aerobic and anaerobic microbes.

RESULTS: Coagulase-negative staphylococcus was cultured from five samples. The contamination rate per drop application was 2.5%. The risk of cross-contamination with coagulase-negative staphylococcus would be between 1 : 400 and 1 : 80 if the bottle was reused once or six times. Reducing this risk to zero costs between pound2.75 and pound4.6 million per annum and generates between 6.85 and 11.42 more tonnes of paper waste and between 12.69 and 21.15 more tonnes of plastic waste than a strategy that reuses the disposable dropper.

CONCLUSION: Reducing the risk of dropper contamination and subsequent cross infection has financial and environmental costs. As exposure to coagulase-negative staphylococcus is not necessarily associated with infection, it would be useful to decide acceptable risk levels for a given cost to maximise both cost-effectiveness and patient safety.

Somo, S. I., et al. (2018). "Synthesis and evaluation of dual crosslinked alginate microbeads." Acta Biomaterialia **65**: 53.

Alginate hydrogels have been investigated for a broad variety of medical applications. The ability assemble hydrogels at neutral pH and mild temperatures makes alginate a popular choice for the encapsulation and delivery of cells and proteins. Alginate has been studied extensively for the delivery of islets as a treatment for type 1 diabetes. However, poor stability of the encapsulation systems after implantation remains a challenge. In this paper, alginate was modified with 2-aminoethyl methacrylat hydrochloride (AEMA) to introduce groups that can be photoactivated to generate covalent bonds. This enabled formation of dual crosslinked structure upon exposure to ultraviolet light following initial ionic crosslinking into bead structures. The degree of methacrylation was varied and in vitro stability, Ion term swelling, and cell viability examined. At low levels of the methaciylation, the beads could be forme by first ionic crosslinks followed by exposure to ultraviolet light to generate covalent bonds. The methacrylated alginate resulted in more stable beads and cells were viable following encapsulatior Alginate microbeads, ionic (unmodified) and dual crosslinked. were implanted into a rat omentum pouch model. Implantation was performed with a local injection of 100 µl of 50 pg/µl of Lipopolysaccharid (LPS) to stimulate a robust inflammatory challenge in viva. Implants were retrieved at 1 and 3 week for analysis. The unmodified alginate microbeads had all failed by week I, whereas the dual crosslinked alginate microbeads remained stable up through 3 weeks. The modified alginate microbead may provide a more stable alternative to current alginate-based systems for cell encapsulation.

Sompuram, S. R., et al. (2018). "Quantitative Assessment of Immunohistochemistry Laboratory Performance by Measuring Analytic Response Curves and Limits of Detection." Archives of Pathology & Laboratory Medicine **142**(7): 851-862.

Context.--Numerous studies highlight interlaboratory performance variability in diagnostic immunohistochemistry (IHC) testing. Despite substantial improvements over the years, the inability to quantitatively and objectively assess immunostain sensitivity complicates interlaboratory standardization. Objective.--To quantitatively and objectively assess the sensitivity of the immunohistochemical stains for human epidermal growth factor receptor type 2 (HER2), estrogen receptor (ER), and progesterone receptor (PR) across IHC laboratories in a proficiency testing format. We measure sensitivity with parameters that are new to the field of diagnostic IHC: analytic response curves and limits of detection. Design.--Thirty-nine diagnostic IHC laboratories stained a set of 3 slides, one each for HER2, ER, and PR. Each slide incorporated a positive tissue section and IHControls at 5 different concentrations. The IHControls comprise cell-sized clear microbeads coated with defined concentrations of analyte (HER2, ER, and/or PR). The laboratories identified the limits of detection and then mailed the slides for quantitative assessment. Results.--Each commercial immunostain demonstrated a characteristic analytic response curve, reflecting strong reproducibility among IHC laboratories using the same automation and reagents prepared per current Good Manufacturing Practices. However, when comparing different commercial vendors (using different reagents), the data reveal up to 100-fold differences in analytic sensitivity. For proficiency testing purposes, quantitative assessment using analytic response curves was superior to subjective interpretation of limits of detection. Conclusions.--Assessment of IHC laboratory performance by quantitative measurement of analytic response curves is a powerful, objective tool for identifying outlier IHC laboratories. It uniquely evaluates immunostain performance across a range of defined analyte concentrations.

Somwanshi, N. R., et al. (2019). "Biodegradation of synthetic polymer waste using bacteria isolated from soil." Biochemical and Cellular Archives **19**(1): 1737-1740.

Synthetic polymer wastes accumulating in the environment are posing an ever increasing

ecological threat. Plastics that are biodegradable can be considered environment friendly, they have an increasing range of potential application and are driven by the growing use of plastics in packaging. Present study envisages biodegradation of synthetic polyethylene using different strains of bacteria isolated from industrial plastic waste disposal site. Polyethylene strips of 50 micro m thickness were treated with three bacterial isolates for 42 days resulting in on an average 20.47% reduction of dry weight. This value is much higher than observed in other studies.

Sonawane, S. L. and S. K. Asha (2016). "Fluorescent Polystyrene Microbeads as Invisible Security Ink and Optical Vapor Sensor for 4-Nitrotoluene." Acs Applied Materials & Interfaces **8**(16): 10590-10599.

Color-tunable solid-state emitting polystyrene (PS) microbeads were developed by dispersion polymerization, which showed excellent fluorescent security ink characteristics along with sensitive detection of vapors of nitro aromatics like 4-nitro toluene (4-NT). The fluorophores pyrene and perylenebisimide were incorporated into the PS backbone as acrylate monomer and acrylate cross-linker, respectively. Solid state quantum yields of 94 and 20% were observed for the pyrene and perylenebisimide, respectively, in the PS/Py and PS/PBI polymers. The morphology and solid state fluorescence was measured by SEM, fluorescence microscopy, and absorbance and fluorescence spectroscopy techniques. The ethanol dispersion of the polymer could be used directly as a fluorescent security "invisible" ink, which became visible only under ultraviolet light. The color of the ink could be tuned depending on the amounts of the pyrene and perylenebisimide incorporated with blue and orange-green for pyrene alone or perylenebisimide alone beads respectively and various shades in between including pure white for beads incorporating both the fluorophores. More than 80% quenching of pyrene emission was observed upon exposure of the polymer in the form of powder or as spin-coated films to the vapors of 4-NT while the emission of perylenebisimide was unaffected. The limit of detection was estimated at 10(-5) moles (2.7 ppm) of 4-NT vapors. The ease of synthesis of the material along with its invisible ink characteristics and nitro aromatic vapor detection opens up new opportunities for exploring the application of these PS-based materials as optical sensors and fluorescent ink for security purposes.

Sonawane, Y. B., et al. (2017). "High Calorific Value Fuel from Household Plastic Waste by Catalytic Pyrolysis." Nature Environment and Pollution Technology **16**(3): 879-882.

Plastic waste pollution causes several impacts on the environment, so its proper disposal is very essential. On the other hand, petroleum resources are vanishing due to high demand of fuel for growing population and limited resources in India. So, there is a need to save existing resources and find an alternative source for fossil fuels. We can convert household plastic waste into petroleum products by pyrolysis method. In the present study, lab scale borosilicate pyrolysis reactor set up was designed for plastic waste treatment. Major components of household plastic waste are HDPE, LDPE and PP material, so were used in pyrolysis. Shredding, washing and drying of plastic waste was done manually. Pyrolysis experiments were carried out for 100g of HDPE, LDPE and PP waste with and without catalyst. Temperature and reaction time were optimized for each type of waste. Different catalysts like alumina, scolecite, dolomite, ceramic powder, white cement, sand and red brick powder were tried in the pyrolysis process. As dolomite yielded maximum liquid fuel and is cost effective, it has been used in pyrolysis experiments with different catalysts to feed ratios. Liquid fuel obtained for HDPE, LDPE and PP enhanced from 72%, 73% and 84% to 82%, 83% and 85% respectively, by using 10% dolomite. For mixed plastic waste, liquid fuel obtained was about 72.96% without catalyst and 82% with 10 % dolomite. Liquid fuel was characterized for GC-MS, FTIR and calorific values. Results

showed the presence of alkanes and alkenes in major quantity and increase in concentration of low molecular weight hydrocarbon fractions (C10-C25) in the liquid fuel. Liquid fuel obtained from HDPE, LDPE and PP by using 10% dolomite showed higher calorific values (43000-46000 kJ/kg) as compared to that of without catalyst (40000-42000 kJ/kg). This liquid fuel can be used as a fuel in different industrial sectors.

Sondergaard, C. S., et al. (2009). "Minimal engraftment of human CD34+ cells mobilized from healthy donors in the infarcted heart of athymic nude rats." Stem Cells & Development **18**(6): 845-856.

Cell-based regenerative therapy may be useful for treatment of acute myocardial infarction (AMI). Animal xenograft models are ideally suited for preclinical studies evaluating prospective treatment regimes, identifying candidate human cell populations, and gaining mechanistic insight. Here we address whether the athymic nude rat is suitable as a xenograft model for the study of human CD34+ mobilized peripheral blood stem cells (M-PBSCs) in the repair of AMI. We injected human donor cells into the infarct border of athymic nude rats with surgically induced AMI and evaluated engraftment and functional improvement. We found no human engraftment by immunofluorescence staining at 14 days after transplantation or functional improvement at days 2 and 14 compared to controls. The lack of long-term human engraftment was furthermore confirmed in a time series study analyzing animals at 0, 24, 48, 72, and 96 h after transplantation. Although we found fluorescent microbeads coinjected with human CD34+ M-PBSCs at all time points, the number of donor cells rapidly declined and became undetectable at 96 h. CD34+ M-PBSCs from the same donor used to treat athymic nude rat hearts engrafted the bone marrow of nonobese diabetic/severe combined immunodeficient mice 8-10 weeks after transplantation. In conclusion, human CD34+ M-PBSCs with confirmed hematopoietic engraftment potential rapidly disappeared from the site of injury following intramyocardial transplantation in the athymic nude rat AMI model.

Song, K., et al. (2014). "Preparation, Mass Diffusion, and Biocompatibility Analysis of Porous-Channel Controlled Calcium-Alginate-Gelatin Hybrid Microbeads for In Vitro Culture of NSCs." Applied Biochemistry and Biotechnology **173**(3): 838-850.

The Ca-alginate/gelatin (CAG) microbeads were prepared and evaluated through assays for their mechanical strength, permeability, and the feasibility as a cell carrier for in vitro culture of neural stem cells. The effects of different concentrations of sodium alginate, gelatin, and calcium chloride on the mechanical strength of CAG microbeads were determined using a self-made puncture force tester. Following this, the microbeads were immersed in DMEM media for a specified period to test its decay resistance. A diffusion model including a calculation formula of diffusion coefficient was built to investigate the diffusion of glucose and bovine serum albumin (BSA) through the wall of the microbeads. Furthermore, the feasibility of the microbeads for in vitro culture was identified using neural stem cells from Kunming mouse. Through a systematic approach and comprehensive analysis, the optimal gelatin conditions for microbead preparation were determined; the final combination of parameters of 1.5 % (wt%) sodium alginate (SA), 0.5 % (wt%) gelatin, and 4 % (wt%) CaCl sub(2) were the best conditions for NSC cultures. This experiment demonstrated that CAG microbeads had good cytocompatibility that made it suitable for the culture and successfully maintained stemness of neural stem cells.

Song, K., et al. (2015). "Preparation and detection of calcium alginate/bone powder hybrid microbeads for in vitro culture of ADSCs." Journal of Microencapsulation **32**(8): 811-819.

Calcium alginate microbeads have been widely used in tissue engineering application, due to their excellent biocompatibility, biodegradability, enhanced mechanical strength and toughness. Bone powder containing abundant hydroxylapatite, type I collagen and growth factors such as BMP2 and BMP4, possesses good osteoinductive activity. Herein, a hybrid calcium alginate/bone powder microbead was therefore prepared. Afterwards, different seeding density of adipose-derived stem cells (ADSCs) in these hybrid microbeads was discussed systematically for further in vitro expansion. Optimised microbeads suitable for in vitro expansion and differentiation of ADSCs were prepared using the droplet method under overall considering suitable concentrations of calcium alginate and calcium chloride as well as the density of bone powder through an orthogonal experiment. The results showed that the concentration of sodium alginate had the most influence on inside mass transfer and mechanical strength of the hybrid microbeads, secondly the calcium chloride, then the density of bone powder. The hybrid microbeads could be optimally performed while the concentrations of sodium alginate and calcium chloride were 2.5% and 4.5%, as well as 5.0 mg/mL bone powder, respectively. Live/Dead assay showed that the expanded ADSCs differentiated well with an initial embedding density of 5 x 10(6) cells/mL.

Song, K. D., et al. (2010). "Microencapsulated Osteoblasts Support Hematopoietic Stem/Progenitor Cell Expansion in Hypoxic Environment." Progress in Biochemistry and Biophysics **37**(7): 754-761.

Microencapsulated osteoblasts were cocultured with hematopoietic stem/progenitor cells (HSPCs) under hematopoietic niche oxygen concentration to investigate the promoting effort of hematopoietic microenvironment on the expansion of umbilical cord blood HSPCs. The osteobalsts were isolated from human iliac bone and cultured, the third passage of osteoblasts at a density of 8 x 10 super(5) cells/ml were encapsulated in gelatin-alginiate-chitosan (GAC) beads with a diameter of 0.5 mm by the polyelectrolyte-complexation method. Three groups of cells were cultured in 5% oxygen incubator, A' group with microencapsulated osteoblasts and hematopoietic cells, B' with only hematopoietic cells and C' with only microencapsulated osteoblasts. Meanwhile, the similarly grouped cells were cultured under 20% oxygen condition, named as A, B and C groups, respectively. The expansion of HSPCs was evaluated by flow cytometry analysis and colony-forming assays. And the concentrations of two kinds of cytokines, LIF and IL-6, were tested to investigate the mechanism of osteoblast's action. The results showed that human osteoblasts dispersed uniformly and grew well in microbeads. There were amount of micro holes in the beads for nutrients transmission. Lots of hematopoietic cells adhered weakly on the surface of microbeads. After 7 days of culture, the hematopoietic cell expansion folds were (49.0 plus or minus 4.6), (3.3 plus or minus 0.5), (17.7 plus or minus 1.2) and (1.9 plus or minus 0.2) respectively for group A', B', A and B. And CD34 super(+) cells in groups A', B' and A were expanded (87.6 plus or minus 8.3)-fold, (2.2 plus or minus 0.3)-fold and (14.9 plus or minus 1.0)-fold, but CD34 super(+) cells in group B descended. CFU-Cs expansion folds in group A', B', A and B were (9.8 plus or minus 0.8), (3.5 plus or minus 0.4), (6.9 plus or minus 0.7) and (2.6 plus or minus 0.2) respectively. It was indicated that Hypoxic co-culture system could promote HSPCs expansion much more than normoxic co-culture system and somatic cell-free culture system. IL-6 and LIF concentrations in A', B' and C' were significantly higher than those in groups A, B and C, which were consistent with their expansion results. Moreover, microencapsulated osteoblasts could support the expansion of umbilical cord blood HSPCs, especially in 5% oxygen condition. Osteoblasts lived in low oxygen condition could secrete more cytokines and thus regulate HSPCs expansion.

Song, N. S. and S. K. Kim (2016). "A pilot study to measure microplastics in wastewater treatment plant (WWTPs)." Toxicology and Environmental Health Sciences **8 (4)**: S36.

Plastic pollution in the marine/ocean is a global concern because their micro-sized plastics (MPs) can be transferred into marine foodweb through ingestion by organisms in various trophic levels and hazardous additives can be released into surrounding environment. So far, most of MP studies has focused on marine system and freshwater system has been rarely studies. Considering that most of plastic debris found in marine environment originate from the land and MP amount found in marine environment was too small than estimate for discharge from land to ocean, significant amounts of plastic debris is inferred to stay in the freshwater system. Particularly, wastewater treatment plant (WWTPs) in urban area can be a significant source and sinker because wastes produced from human activities are treated through drainage system. This study aimed to develop the analytical method for MPs in wastewaters and to screen the distribution characteristics of MPs in WWTP system. In this pilot study, two WWTPs with different treatment process (A2O/MBR vs. MLE) were investigated. Various shapes and polymers were observed with average total abundance of ~0.2 particles/L in effluents. Major polymer was different for two WWTPs: polyurethane vs. polyethylene. We are going to measure MPs in influent to calculate mass balance of MPs.

Song, S. Y., et al. (2011). "A fluoro-microbead guiding chip for simple and quantifiable immunoassay of cardiac troponin I (cTnI)." Biosensors & Bioelectronics **26**(9): 3818-3824.

We have developed a fluoro-microbead guiding chip (FMGC) to perform an optical immunoassay of cardiac troponin I (cTnI). The plasma marker protein cTnI is the currently preferred marker to use for a definitive diagnosis and prognosis of myocardial infarction. The FMGC has four immunoreaction regions on a silicon oxide substrate, with five gold patterns imprinted on each region for multiple simultaneous assays. The FMGC assay clearly distinguished immunospecific binding from nonspecific binding by comparing optical signals from inside and outside of the patterns. To detect cTnI, a sandwich immunoassay was performed using antibody-tagged fluoro-microbeads. The cTnI-specific capture antibody was conjugated to the FMGC surface by reaction with 3-3'-dithiobis-propionic acid N-hydroxysuccinimide ester to create a self-assembling antigen-sensing monolayer (DTSP SAM) on the chip. A sample containing cTnI was applied to the antigen-sensing monolayer and allowed to react. To generate a binding signal, a cTnI detection antibody-linked fluoro-microbead preparation was added. The cTnI concentration in a sample was determined by counting the number of biospecifically bound fluoro-microbeads on the corresponding five patterns on the FMGC. The optical signal showed a linear correlation with cTnI concentrations in plasma samples containing from 3.4 pM to 3.4 nM (0.1-100 ng/ml) cTnI. The sensitivity of cTnI detection could be increased by reducing the non-specific binding of the beads to the antigen-sensing surfaces of the chip. Optical detection and quantification of binding by fluorescence microscopy gave results that correlated well with results from a commercial ELISA for cTnI in human plasma. Based on these findings, we propose that the FMGC-based immunoassay system may be adapted to detect and quantify a variety of clinically important targets in human samples.

Song, Y., et al. (2019). "Uptake and adverse effects of polyethylene terephthalate microplastics fibers on terrestrial snails (Achatina fulica) after soil exposure." Environmental Pollution **250**: 447-455.

Recent studies have demonstrated the occurrence of microplastic fibers (MFs) in soil environments. To determine whether MFs are harmful for soil biota, we evaluated toxic effects on terrestrial snails (Achatina fulica) after 28 d exposure to polyethylene terephthalate MFs at concentrations of 0.01-0.71 g kg⁻¹ (dry soil weight). Digestion kinetics experiments on 24 snails showed that MFs can be ingested and excreted within 48 h. We found the appearance of cracks and deterioration on the surface of MFs after depuration by the digestive

system. Prolonged exposure to 40 snails showed that 0.14-0.71 g kg⁻¹ MFs caused an average reduction of 24.7-34.9% food intake and 46.6-69.7% excretion. 0.71 g kg⁻¹ MFs induced significant villi damage in the gastrointestinal walls of 40% snails, but did not influence the histology of the liver and kidney. Moreover, 0.71 g kg⁻¹ MFs exposure reduced glutathione peroxidase (59.3+or-13.8%) and total antioxidant capacity (36.7+or-8.5%), but elevated malondialdehyde level (58.0+or-6.4%) in the liver, which indicates oxidative stress is involved in the toxic mechanism. Our results suggest that MFs have adverse impacts on the fitness of soil organisms, and highlight the ecological risks of microplastic pollution in terrestrial ecosystems.

Song, Y. K., et al. (2017). "Combined Effects of UV Exposure Duration and Mechanical Abrasion on Microplastic Fragmentation by Polymer Type." Environmental Science & Technology **51**(8): 4368-4376.
It is important to understand the fragmentation processes and mechanisms of plastic litter to predict microplastic production in the marine environment. In this study, accelerated weathering experiments were performed in the laboratory, with ultraviolet (UV) exposure for up to 12 months followed by mechanical abrasion (MA) with sand for 2 months. Fragmentation of low-density polyethylene (PE), polypropylene (PP), and expanded polystyrene (EPS) was evaluated under conditions that simulated a beach environment. PE and PP were minimally fragmented by MA without photooxidation by UV (8.7 +/- 2.5 and 10.7 +/- 0.7 particles/pellet, respectively). The rate of fragmentation by UV exposure duration increased more for PP than PE. A 12-month UV exposure and 2-month MA of PP and PE produced 6084 +/- 1061 and 20 +/- 8.3 particles/pellet, respectively. EPS pellets were susceptible to MA alone (4220 +/- 33 particles/pellet), while the combination of 6 months of UV exposure followed by 2 months of MA produced 12,152 +/- 3276 particles/pellet. The number of fragmented polymer particles produced by UV exposure and mechanical abrasion increased with decreasing size in all polymer types. The size-normalized abundance of the fragmented PE, PP, and EPS particles according to particle size after UV exposure and MA was predictable. Up to 76.5% of the initial EPS volume was unaccounted for in the final volume of pellet produced particle fragments, indicating that a large proportion of the particles had fragmented into undetectable submicron particles.

Song, Y. K., et al. (2015). "Occurrence and Distribution of Microplastics in the Sea Surface Microlayer in Jinhae Bay, South Korea." Archives of Environmental Contamination & Toxicology **69**(3): 279-287.
Microplastic contamination of the marine environment is a worldwide concern. The abundance of microplastics was evaluated in the sea surface microlayer in Jinhae Bay, on the southern coast of Korea. The microplastics in this study are divided into paint resin particles and plastics by polymer type. The mean abundance of paint resin particles (94 +/- 68 particles/L) was comparable to that of plastics (88 +/- 68 particles/L). Fragmented microplastics, including paint resin particles, accounted for 75 % of total particles, followed by spherules (14 %), fibers (5.8 %), expanded polystyrene (4.6 %), and sheets (1.6 %). Alkyd (35 %) and poly(acrylate/styrene) (16 %) derived from ship paint resin were dominant, and the other microplastic samples consisted of polypropylene, polyethylene, phenoxy resin, polystyrene, polyester, synthetic rubber, and other polymers. The abundance of plastics was significantly (p < 0.05) higher in Jinhae Bay, which is surrounded by a coastal city, than along the east coast of Geoje, which is relatively open sea. The floating microplastic abundance in surface water was the highest reported worldwide.

Song, Z., et al. (2016). "Preparation of alumina nanoshell coated porous silica spheres for inorganic anions separation." Journal of Chromatography A **1433**: 85-89.

It had been reported that alumina nanoshell coating could be obtained on the external surface of various substrates in one-nanometer precision in aqueous solution. In this work, alumina nanoshell coated mesoporous silica microbeads (nanoAl<inf>2</inf>O<inf>3</inf>/mesoSiO<inf>2</inf>) were prepared with the similar method, and were successfully applied to inorganic anions separation. As the mass transfer speed is largely constrained in the mesopore compared with that on the open surface, it was found that a complete alumina nanoshell coating could be obtained within the mesopore until the five-time coating was carried out. After characterization by BET, SEM and FTIR, it was found that the obtained nanoAl<inf>2</inf>O<inf>3</inf>/mesoSiO<inf>2</inf> particles are smooth and well dispersed, and the mesopores are well reserved. In addition, the full coverage of nanoAl<inf>2</inf>O<inf>3</inf> shell in mesopores was also confirmed by the binding capacity experiments with berberine. Finally, the nanoAl<inf>2</inf>O<inf>3</inf>/mesoSiO<inf>2</inf> particles were packed in silica capillary for the separation of inorganic anions I⁻, SCN⁻, Br⁻, NO<inf>2</inf> ⁻ and NO<inf>3</inf> ⁻ with ion chromatography (IC), and a column efficiency of 3.8 x 10⁴ plates per meter was obtained for I⁻. Song, Z., et al. (2019). "Fate and transport of nanoplastics in complex natural aquifer media: Effect of particle size and surface functionalization." Science of the Total Environment **669**: 120-128.

Environmental processes of nanoplastics in heterogeneous natural groundwater systems remain unclear. In this study, the control of particle size and surface functional groups on the fate and transport of nanoplastics in an organic matter (OM) rich aquifer was explored using batch and column tests. The carboxyl-modified 200nm (200CNP), carboxyl-modified 50nm (50CNP), and amino-modified 50nm (50ANP) polystyrene latex beads were used as surrogates for nanoplastics of contrasting sizes and surface functional groups. Aquifer sand and natural groundwater sampled from an agriculture-impacted shallow sandy aquifer were processed to obtain granule beds with/out surface minerals and groundwater containing different-sized fractions of OM.

Sonkkila, C. (2019). "Biodegradable versus compostable - knowing your eco-plastics." Ecos(255): 1-4.

The article focuses on analysis by IHS Markit, which reveals rise in demand of for biodegradable plastics. It presents views of CSIRO environmental chemist Mike Williams on rise in demand due to consumer awareness of plastic waste. It states that biodegradable plastics encompass a broad range of plastics made from different materials but are defined by their ability to break down completely into natural substances.

Sonoda, K. H. (2008). "[Association of ocular inflammation and innate immune response]." Nippon Ganka Gakkai Zasshi - Acta Societatis Ophthalmologicae Japonicae **112**(3): 279-297; discussion 298.

Immune response has been divided into innate immunity and acquired immunity. We focused on the role of innate immunity during the formation of uveitis and choroidal neovascularization (CNV)-related diseases. To carry out a comprehensive analysis of ocular inflammatory responses in patients with uveitis, vitreous fluid was analyzed using a microbead-based multiplex ELIZA system. We found that cytokines which were related with innate immunity were elevated, but cytokines which were related with acquired immunity were not. We also found that the role of IL-17 was to produce Th17 cells in the chronic phase of experimental uveitis. Next, we investigated the role of the natural killer (NK) T cells which restrict CD1 and participate in the innate immune response in laser-induced experimental CNV. We studied the CNV formation in two independent NK T cell-deficient strains of mice, CD1 knockout (KO) mice and Jalpha18 KO mice, and found that both KO mice showed significant reduction of the effects of experimental CNV. After laser treatment, both CD1 KO mice and Jalpha18 KO mice showed a decrease in the expression of vascular endothelial growth factor (VEGF) expression in retina and choroid. Interestingly, intravitreous inoculation of a galactosylceramide (alphaGalCer), which is the ligand of NK Tcells, inhibited CNV in C57BL6 mice. Collectively, we conclude that NK T cells play an important role in forming CNV as one of the inducers of VEGS. Because NK T cells bear the potential to regulate immune response, alphaGalCer might activate NK T cells differently to produce angiostatic factors and have a therapeutic potential in vivo. During the clinical process of CNV-related diseases, not only CNV formation, but also subretinal scarring is thought to be another important step. We thus established the experimental model of subretinal scaring by injecting peritoneal exudating macrophases into the subretinal space. This scaring was inhibited by inoculation of anti-IL-6 antibody and micro bubbles into the vitreous cavity following low power ultrasound treatment through the cornea. [References: 47]

Sorensen, L., et al. (2019). "Sorption of PAHs to microplastic and their bioavailability and toxicity to marine copepods under co-exposure conditions." Environmental Pollution **258**: 113844.

Organic chemical pollutants associated with microplastic (MP) may represent an alternative exposure route for these chemicals to marine biota. However, the bioavailability of MP-sorbed organic pollutants under conditions where co-exposure occurs from the same compounds dissolved in the water phase has rarely been studied experimentally, especially where pollutant concentrations in the two phases are well characterized. Importantly, higher concentrations of organic pollutants on ingested MP may be less bioavailable to aquatic organisms than the same chemicals present in dissolved form in the surrounding water. In the current study, the sorption kinetics of two model polycyclic aromatic hydrocarbons (PAHs; fluoranthene and phenanthrene) to MP particles in natural seawater at 10 and 20 degreeC were studied and the bioavailability of MP-sorbed PAHs to marine copepods investigated. Polyethylene (PE) and polystyrene (PS) microbeads with mean diameters ranging from 10 to 200 mum were used to identify the role of MP polymer type and size on sorption mechanisms. Additionally, temperature dependence of sorption was investigated.

Sorokin, N. V., et al. (2006). "Kinetics of hybridization on surface oligonucleotide microchips: Theory, experiment, and comparison with hybridization on gel-based microchips." Journal of Biomolecular Structure and Dynamics **24**(1): 57-66.

The optimal design of oligonucleotide microchips and efficient discrimination between perfect and mismatch duplexes strongly depend on the external transport of target DNA to the cells with immobilized probes as well as on respective association and dissociation rates at the duplex formation. In this paper we present the relevant theory for hybridization of DNA fragments with oligonucleotide probes immobilized in the cells on flat substrate. With minor modifications, our theory also is applicable to reaction-diffusion hybridization kinetics for the probes immobilized on the surface of microbeads immersed in hybridization solution. The main theoretical predictions are verified with control experiments. Besides that, we compared the characteristics of the surface and gel-based oligonucleotide microchips. The comparison was performed for the chips printed with the same pin robot, for the signals measured with the same devices and processed by the same technique, and for the same hybridization conditions. The sets of probe oligonucleotides and the concentrations of probes in respective solutions used for immobilization on each platform were identical as well. We found that, despite the slower hybridization kinetics, the fluorescence signals and mutation discrimination efficiency appeared to be higher for the gel-based microchips with respect to their surface counterparts even for the relatively short hybridization time about 0.5-1 hour. Both the divergence between signals for perfects and the difference in mutation discrimination efficiency for the counterpart platforms rapidly grow with incubation time. In particular, for hybridization during 3 h the signals for gel-based microchips surpassed their surface counterparts in 5-20 times, while the ratios of signals for perfect-mismatch pairs for gel microchips exceeded the corresponding ratios for surface microchips in 2-4 times. These effects may be attributed to the better immobilization efficiency and to the higher thermodynamic association constants for duplex formation within gel pads. ©Adenine Press (2006).

Sosne, G., et al. (2002). "Thymosin beta 4 promotes corneal wound healing and decreases inflammation in vivo following alkali injury." Experimental Eye Research **74**(2): 293-299.

Previously, thymosin beta 4 (Tbeta(4)) was found to promote wound healing in full thickness skin wounds and heptanol debrided corneas. Here, the effect of Tbeta(4) was examined treatment on corneal wound healing and inflammation in vivo after alkali injury, a more severe wound of the eye. Corneas from 129 Sv mice were chemically burned with a 2 mm disc soaked in 1 N NaOH for 30 sec. Eyes were irrigated copiously with phosphate buffered saline (PBS) and then treated topically with either Tbeta(4) (5 microg/5 microl PBS) or 5 microl PBS twice daily. Animals were killed, the eyes were enucleated, fixed and embedded in plastic resin or prepared for mRNA analysis. Mouse corneas topically treated with 5 microg of Tbeta(4) twice daily after alkali injury demonstrated accelerated re-epithelialization at all time points and decreased polymorphonuclear leukocyte (PMN) infiltration at 7 days post injury (p.i.) when compared to PBS-treated controls. mRNA transcript levels were decreased several fold for interleukin (IL)-lbeta, and the chemokines macrophage inflammatory protein (MIP)-1alpha, MIP-1beta, MIP-2 and monocyte chemoattractant protein (MCP)-1 from 1 to 7 days after injury in the Tbeta(4)- vs. PBS-treated corneas. Thus, Tbeta(4) may provide a new clinical treatment for severe traumatic corneal wound disorders by promoting rapid corneal wound healing and decreasing both PMN infiltration and inflammatory cytokine and chemokine mRNA levels.

Soud, S. A. (2019). "Biodegradation of polyethylene LDPE plastic waste using locally isolated Streptomyces sp." Journal of Pharmaceutical Sciences and Research **11**(4): 1333-1339.

Plastics become widely spread in would wild, plastic are strong and flexible, light material that make be widely used in different field and different application in medical, agricultural and industrial and in food packaging, that resolve many of problems related with transport, and other things,as a result, plasticaccumulated in environment andcaused serial of environmental pollution, this pollution include all area in environment soil water and air, and the traditional way for pollution treatment are very difficultand highly cost and effect of human and animal health,there for, in this paper, we focused on pollution treatment by used microorganism's and Streptomycessp. as the bestmicroorganism s for their biodegradable ability for plastic waste and other pollution .in this paper different isolates of Streptomycessp. were screened for polyrthelene low densitypolyethylene(LDPE) biodegradation, the result showed that Streptomyces isolate (SSP2, SSP4, SSP 14) have best degradationefficiency for LDPEin different tests ; Measurement the dry weight loss of plastic stripes [polyethylene bags (g) and plastic cup(p)] after cultivation in ATCC medium and incubation at 25-30degreeC in shaker incubator at 120 rpm, Spectrophotometric assay and determination of Bioemulsifer production yield after one months of incubation, the result showed that the loss in dry weight in LDPE stripes by

Streptomyces isolate (SSP2, SSP4, SSP 14) are (6%, 9%, 15%) for (p) stripes and (8%, 11%, 19%) for (g) stripes respectively, and spectrophotometric assay recorded best results for LDPEdegradation, SSP2, recorded (0.08, 0.55),SSP4 (0.09, 0.65) and SSP 14 recorded (0.13, 0.70) for p and g respectively. Finally, the bioemulsifer production determination also recorded highest results that play important role in biodegradation process, the results recorded thatbioemulsifer production yield by (SSP2, SSP4, SSP 14) isolates are (5.74%, 7.24%, 11.84%) for (p) stripes, and (8.44%, 9.84%, 12.94%) for (g)stripes. from these result, the SSP14 isolates shed best result for LDPE degradation that prove that the Streptomyceshave best biodegradable efficiency for many pollutant, that agreed with manyresearch in microbiological environmental science. Southwell, A. L., et al. (2015). "Ultrasensitive measurement of huntingtin protein in cerebrospinal fluid demonstrates increase with Huntington disease stage and decrease following brain huntingtin suppression." Scientific Reports **5**: 12166.

Quantitation of huntingtin protein in the brain is needed, both as a marker of Huntington disease (HD) progression and for use in clinical gene silencing trials. Measurement of huntingtin in cerebrospinal fluid could be a biomarker of brain huntingtin, but traditional protein quantitation methods have failed to detect huntingtin in cerebrospinal fluid. Using micro-bead based immunoprecipitation and flow cytometry (IP-FCM), we have developed a highly sensitive mutant huntingtin detection assay. The sensitivity of huntingtin IP-FCM enables accurate detection of mutant huntingtin protein in the cerebrospinal fluid of HD patients and model mice, demonstrating that mutant huntingtin levels in cerebrospinal fluid reflect brain levels, increasing with disease stage and decreasing following brain huntingtin suppression. This technique has potential applications as a research tool and as a clinical biomarker.

Souza e Silva Pegado, T. d., et al. (2018). "First evidence of microplastic ingestion by fishes from the Amazon River estuary." Marine Pollution Bulletin **133**: 814-821.

This study investigated occurrence of microplastic particles in digestive tracts of fishes from the Amazon River estuary. A total of 189 fish specimens representing 46 species from 22 families was sampled from bycatch of the shrimp fishery. Microplastic particles removed from fish gastrointestinal tracts were identified using Attenuated Total Reflectance - Fourier Transform Infrared (ATR-FTIR). In total, 228 microplastic particles were removed from gastrointestinal tracts of 26 specimens representing 14 species (30% of those examined). Microplastic particles were categorized as pellets (97.4%), sheets (1.3%), fragments (0.4%) and threads (0.9%), with size ranging from 0.38 to 4.16 mm. There was a positive correlation between fish standard length and number of particles found in gastrointestinal tracts. The main polymers identified by ATR-FTIR were polyamide, rayon and polyethylene. These findings provide the first evidence of microplastic contamination of biota from the Amazon estuary and northern coast of Brazil.

Sowa, M., et al. (2014). "Simultaneous automated screening and confirmatory testing for vasculitis-specific ANCA." PLoS ONE [Electronic Resource] **9**(9): e107743.

Anti-neutrophil cytoplasmic antibodies (ANCA) are the serological hallmark of small vessel vasculitis, so called ANCA-associated vasculitis. The international consensus requires testing by indirect immunofluorescence (IIF) on human ethanol-fixed neutrophils (ethN) as screening followed by confirmation with enzyme-linked immunosorbent assays (ELISAs). This study evaluates the combination of cell- and microbead-based digital IIF analysis of ANCA in one reaction environment by the novel multiplexing CytoBead technology for simultaneous screening and confirmatory ANCA testing. Sera of 592 individuals including 118 patients with

ANCA-associated vasculitis, 133 with rheumatoid arthritis, 49 with infectious diseases, 77 with inflammatory bowel syndrome, 20 with autoimmune liver diseases, 70 with primary sclerosing cholangitis and 125 blood donors were tested for cytoplasmic ANCA (C-ANCA) and perinuclear ANCA (P-ANCA) by classical IIF and ANCA to proteinase 3 (PR3) and myeloperoxidase (MPO) by ELISA. These findings were compared to respective ANCA results determined by automated multiplex CytoBead technology using ethN and antigen-coated microbeads for microbead immunoassays. There was a good agreement for PR3- and MPO-ANCA and a very good one for P-ANCA and C-ANCA by classical and multiplex analysis (Cohen's kappa [kappa] = 0.775, 0.720, 0.876, 0.820, respectively). The differences between classical testing and CytoBead analysis were not significant for PR3-ANCA, P-ANCA, and C-ANCA ($p<0.05$, respectively). The prevalence of confirmed positive ANCA findings by classical testing (IIF and ELISA) compared with multiplex CytoBead analysis (IIF and microbead immunoassay positive) resulted in a very good agreement (kappa = 0.831) with no significant difference of both methods ($p = 0.735$). Automated endpoint-ANCA titer detection in one dilution demonstrated a very good agreement with classical analysis requiring dilution of samples (kappa = 0.985). Multiplexing by CytoBead technology can be employed for simultaneous screening and quantitative confirmation of ANCA. This novel technique provides fast and cost-effective ANCA analysis by automated digital IIF for the first time.

Sowa, M., et al. (2014). "Simultaneous screening and confirmation of ANCAs and detection of anti-GBM antibodies in case of emergency." Clinical Chemistry and Laboratory Medicine **52 (11)**: eA139-eA140.

The novel CytoBead technology combines autoantibody analysis by cell-based screening with corresponding confirmation by multiplex microbead technology using immunofluorescence technique in one well. CytoBead ANCA allows the simultaneous screening and confirmation of anti-neutrophil cytoplasmic antibodies (ANCA) on neutrophils, proteinase 3 (PR3) and myeloperoxidase (MPO) coated microbeads. Furthermore, the detection of anti-GBM antibodies for emergency diagnostic of rapid progressive glomerulonephritis is integrated. This assay is interpretable with a standard fluorescence microscope (FITC channel) for semi-quantitative and with Aklides system for quantitative analysis. Performance of the CytoBead ANCA assay was investigated using 666 human sera including 118 patients with ANCA-associated vasculitis, 162 healthy controls, 352 disease controls and 34 anti-GBM positive sera. Receiver operating characteristics and inter-rater agreements were used to compare the results of novel CytoBead ANCA assay with routine autoantibody investigation. The comparison of ANCA screening showed very good agreement for pANCA and cANCA patterns (kappa = 0.862, 0.868; respectively) and the results of anti-PR3, anti-MPO, and anti-GBM detection revealed good to very good agreement (0.78,0.72,0.87; respectively). Consequently, CytoBead ANCA assay is an alternative to classical time-consuming single parameter diagnostic and is therefore a clinical diagnostic tool for emergency situations.

Sowa, M., et al. (2014). "Simultaneous screening and confirmation of ancas and detection of Anti-GBM antibodies with cytobead ANCA assay." Clinical Chemistry and Laboratory Medicine **1)**: S305.

BACKGROUND: The novel CytoBead technology combines autoantibody analysis by cell-based screening with the confirmation of corresponding autoantigen reactivities by multiplex microbead technology using immunofluorescence technique (IFT) in one reaction environment. METHOD(S): CytoBead ANCA allows the simultaneous detection of anti-neutrophil cytoplasmic antibodies (ANCA) on ethanol-fixed neutrophils for screening and confirmation thereof using proteinase 3 (PR3) and myeloperoxidase (MPO) coated microbeads. Furthermore, the detection of anti-GBM antibodies is integrated by adding glomerular basement membrane (GBM) coated

microbeads. Anti-GBM autoantibodies occur in 10% of rapid progressive glomerulonephritis patients together with ANCA and are required for the differential serological diagnosis in routine diagnostics. This assay format can be interpreted with a standard fluorescence microscope (FITC channel) for semi-quantitative and with the automated interpretation system Aklides for quantitative analysis. The performance of the CytoBead ANCA assay was investigated using sera of 666 individuals including 118 patients with ANCA-associated vasculitis, 162 healthy controls, 352 disease controls and 34 anti-GBM positive sera. Receiver operating characteristics and inter-rater agreements (kappa) were used to compare the results of novel CytoBead ANCA assay with routine autoantibody investigation. RESULT(S): The comparison of classical ANCA screening with ANCA screening by the novel CytoBead ANCA assay showed very good agreement for pANCA and cANCA patterns (kappa= 0.862, 0.868; respectively). The results of anti-PR3, anti-MPO, and anti-GBM detection by this novel method compared to anti-PR3-, anti-MPO as well as anti-GBM by ELISA revealed good to very good agreement (0.78,0.72,0.87; respectively). CONCLUSION(S): Consequently, CytoBead ANCA assay is an attractive alternative to classical time-consuming single parameter ANCA and anti-GBM antibody detection and is therefore applicable as a clinical diagnostic tool for emergency situations.

Sowa, M., et al. (2017). "Next-Generation Autoantibody Testing by Combination of Screening and Confirmation-the CytoBead Technology." Clinical Reviews in Allergy & Immunology **53**(1): 87-104.

Occurrence of autoantibodies (autoAbs) is a hallmark of autoimmune diseases, and the analysis thereof is an essential part in the diagnosis of organ-specific autoimmune and systemic autoimmune rheumatic diseases (SARD), especially connective tissue diseases (CTDs). Due to the appearance of autoAb profiles in SARD patients and the complexity of the corresponding serological diagnosis, different diagnostic strategies have been suggested for appropriate autoAb testing. Thus, evolving assay techniques and the continuous discovery of novel autoantigens have greatly influenced the development of these strategies. Antinuclear antibody (ANA) analysis by indirect immunofluorescence (IIF) on tissue and later cellular substrates was one of the first tests introduced into clinical routine and is still an indispensable tool for CTD serology. Thus, screening for ANA by IIF is recommended to be followed by confirmatory testing of positive findings employing different assay techniques. Given the continuous growth in the demand for autoAb testing, IIF has been challenged as the standard method for ANA and other autoAb analyses due to lacking automation, standardization, modern data management, and human bias in IIF pattern interpretation. To address these limitations of autoAb testing, the CytoBead technique has been introduced recently which enables automated interpretation of cell-based IIF and quantitative autoAb multiplexing by addressable microbead immunoassays in one reaction environment. Thus, autoAb screening and confirmatory testing can be combined for the first time. The present review discusses the history of autoAb assay techniques in this context and gives an overview and outlook of the recent progress in emerging technologies.

Sowa, M., et al. (2016). "Simultaneous comprehensive multiplex autoantibody analysis for rapidly progressive glomerulonephritis." Medicine **95**(44): e5225.

Rapidly progressive glomerulonephritis (RPGN) is mainly caused by anti-glomerular basement membrane (GBM) antibody-mediated glomerulonephritis, immune-complex or anti-neutrophil cytoplasmic antibody (ANCA)-associated vasculitides and leads to rapid loss of renal function. Detection of ANCA and autoantibodies (autoAbs) to GBM and dsDNA enables early diagnosis and appropriate treatment of RPGN aiding in preventing end-stage renal disease.Determination of ANCA on neutrophils (ANCA) as well as autoAbs to myeloperoxidase (MPO-ANCA), proteinase 3 (PR3-ANCA), GBM, and dsDNA was performed by the novel multiplex CytoBead technology

combining cell- and microbead-based autoAb analyses by automated indirect immunofluorescence (IIF). Forty patients with granulomatosis with polyangiitis (GPA), 48 with microscopic polyangiitis (MPA), 2 with eosinophilic GPA, 42 with systemic lupus erythematosus (SLE), 43 with Goodpasture syndrome (GPS), 57 with infectious diseases (INF), and 55 healthy subjects (HS) were analyzed and findings compared with classical single testing.The CytoBead assay revealed for GPA, MPA, GPS, and SLE the following diagnostic sensitivities and for HS and INF the corresponding specificities: PR3-ANCA, 85.0% and 100.0%; MPO-ANCA, 77.1% and 99.1%; anti-GBM autoAb, 88.4% and 96.4%; anti-dsDNA autoAb, 83.3% and 97.3%; ANCA, 91.1% and 99.1%, respectively. Agreement with classical enzyme-linked immunosorbent assay and IIF was very good for anti-GBM autoAb, MPO-ANCA, PR3-ANCA, and ANCA, respectively. Anti-dsDNA autoAb comparative analysis demonstrated fair agreement only and a significant difference (P = 0.0001).The CytoBead technology provides a unique multiplex reaction environment for simultaneous RPGN-specific autoAb testing. CytoBead RPGN assay is a promising alternative to time-consuming single parameter analysis and, thus, is well suited for emergency situations.

Sowa, M., et al. (2015). "Unique technology for the simultaneous screening and confirmation of autoantibodies in emergency situations of rapidly progressive glomerulonephritis." Nephron **129 (Supplement 2)**: 118-119.

Background: Rapidly progressive glomerulonephritis (RPGN) is clinically characterized by a rapid loss of renal function. RPGN is mainly caused by anti-glomerular basement membrane (GBM) antibody-mediated, immune-complex or anti-neutrophil cytoplasmic antibody (ANCA)-associated diseases. Detection of the specifically associated autoantibodies (anti-GBM, anti-dsDNA, ANCA) allows early diagnosis and appropriate treatment starting, in order to avoid progression to end stage renal disease. Objective(s): The novel CytoBead technology combines autoantibody analysis by cell-based screening with corresponding confirmation by multiplex microbead technology using indirect immunofluorescence (IIF) in one reaction environment. The CytoBead RPGN assay employs as autoantigenic substrates for autoantibody detection GBM as well as dsDNA, coated on microbeads, for the diagnosis of Goodpastures'syndrome/antiGBM disease (GPS) and systemic lupus erythematodes (SLE) nephritis, respectively. Additionally, ethanol fixed granulocytes as well as proteinase 3 (PR3) and myeloperoxidase (MPO) coated microbeads are provided as targets by the assay for the simultaneous determination of vasculitis specific autoantibodies (i.e. ANCA), detectable in RPGN patients. Method(s): This IIF assay can be analyzed with a standard fluorescence microscope for semi-quantitative and with the Aklides system for quantitative interpretation with lot specific standard curves. The specially designed microscopic glass slide consists of triple parted reaction compartments with ethanol fixed granulocytes in the middle compartment, PR3 and MPO coated microbeads in the right compartment and GBM and dsDNA coated microbeads in the left one. Result(s): Results of 293 tested human sera (40 Granulomatosis with Polyangiitis [GPA], 38 Microscopic Polyangiitis [MPA], 10 ANCA associated vasculitis [AAV], 2 Eosinophilic granulomatosis with polyangiitis [EGPA], 48 SLE, 43 GPS, 55 negative human sera [NHS], 57 infectious diseases [INF]) were generated by automated read-out processed tests with Aklides system in 60 seconds per sample and showed good agreement with manually obtained cell and microbead based data. The automated read-out provides quantitative results in international units (IU/ml) for antibodies to PR3, MPO and in units (U/ml) for dsDNA and GBM. Diagnostic sensitivity and specificity were carried out by receiver operating characteristic (ROC) and revealed 85.4% and 97.6% for PR3 microbeads, 73.5% and 95.5% for MPO micro beads, 88.4% and 96.8% for GBM microbeads and 83.3% and 94.7% for dsDNA microbeads, respectively. Conclusion(s): The CytoBead technology provides a unique combination of screening and confirmatory RPGN-specific autoantibody testing. CytoBead RPGN assay is a very promising alternative to classical time-consuming single parameter testing and, therefore, can be used for emergency situations.

Soydan, L. C., et al. (2015). "Accuracy of Doppler echocardiographic estimates of pulmonary artery pressures in a canine model of pulmonary hypertension." Journal of Veterinary Cardiology **17**(1): 13-24.

Objectives: To compare noninvasive estimates of pulmonary artery pressure (PAP) obtained via echocardiography (ECHO) to invasive measurements of PAP obtained during right heart catheterization (RHC) across a range of PAP. To examine the accuracy of estimating right atrial pressure via ECHO (RAP_{ECHO}) compared to RAP measured by RHC (RAP_{RHC}), and determine if adding RAP_{ECHO} improves the accuracy of noninvasive PAP estimations. Animals: 14 healthy female beagle dogs.

Spear, L. B., et al. (1995). "Incidence of plastic in seabirds from the tropical Pacific, 1984-91: Relation with distribution of species, sex, age, season, year and body weight." Marine environmental research. London **40**(2): 123-146.

The incidence of plastic in seabirds was studied (number of individuals of a species containing plastic per number inspected, and number of particles per individual), in 1574 individuals representing 36 species of seabirds collected in the tropical Pacific, mostly between 110 and 150 degree W longitude, from 1984 to 1991. Incidence of plastic was lower in resident species compared to those which bred to the south or north but wintered in the region, and especially when compared to species that crossed the tropics in migration between the South and North Pacific. Seasonal and age-related patterns in incidence of plastic, number of particles, and particle type (pellets versus user-plastic) among a group of five Procellariiform species (each with > 5% of the individuals containing plastic and for which samples were > 20 birds) indicated that degradation for an individual particle in the gizzard required less than one year, and that little plastic was regurgitated by parents to chicks. Two patterns emerged from this data regarding body weight: (i) heavier birds (for a given species, age-class, season and year) were more likely to contain at least some plastic, from which we hypothesize that birds in better physical condition fed more often in areas where higher densities of plastic and food are found, such as fronts and convergences; and (ii) among individuals who contained plastic (grouped by species), there was a significant negative correlation between number of plastic particles and body weight. This is the first solid evidence for a negative relationship between plastic ingestion and physical condition in seabirds. The likelihood that higher quality individuals are more prone to ingest plastic has serious implications regarding health of some seabird populations.

Spear, S. (2012). "Globetrotter." Local Authority Waste & Recycling **20**(7): 46-46.

The article reports that Japan's 77% plastic recycling rate is one of the highest in the world and is due to technology and the cooperation of consumers and businesses in segregating plastic waste at the source since 1997.

Spears, M., et al. (2012). "Discriminant analysis of sputum supernatant cytokine profiles can differentiate smokers from former smokers with asthma." American Journal of Respiratory and Critical Care Medicine. Conference: American Thoracic Society International Conference, ATS **185**(MeetingAbstracts).

Rationale Smokers with asthma display a distinct clinical phenotype compared to never smokers with asthma but little is known about how smoking causes this altered behaviour and even less is known about the impact of prior smoking on asthma. Simultaneous measurement of multiple

cytokines has the potential to improve our understanding of the airway inflammatory response in both groups. Therefore we undertook discriminant function analysis of sputum cytokine data to detect the impact of current and former smoking on asthma. Methods 22 smokers, 10 ex-smokers and 21 never smokers with asthma performed spirometry, sputum induction and completed asthma control questionnaires (ACQ). All smokers were regular smokers (at least five cigarettes a day). Ex-smokers had a prior history of habitual smoking and had stopped at least two years before participation. Smoking history was confirmed by exhaled carbon monoxide and urinary cotinine. Sputum supernatant was assessed for 25 cytokines by a multiplex microbead system (Invitrogen, UK) using a Luminex platform. Discriminant function analysis was performed using MINITAB 16. Results The subjects were well matched except for higher ACQ scores and inhaled corticosteroid dose in smokers and ex-smokers with asthma (Table 1). Ex-smokers with asthma had stopped smoking for a median of 6.5 years (IQR 3.8, 12). A number of cytokines were significantly higher in smokers and ex-smokers with asthma when compared to non-smokers with asthma. Discriminant function analysis demonstrated that the majority of patients could be correctly allocated to their clinical group by sputum cytokine profiling (Table 2). Conclusions Current and former smokers with asthma are readily distinguishable by their sputum supernatant cytokine profiles and therefore each group may possess distinct airway inflammatory phenotypes. Further study of airway cytokine profiles in both groups may increase understanding of the role of cytokines in the development of corticosteroid resistant inflammation. (Table Presented).

Spears, M., et al. (2013). "Smoking in asthma is associated with elevated levels of corticosteroid resistant sputum cytokines-an exploratory study." PLoS ONE [Electronic Resource] **8**(8): e71460.

BACKGROUND: Current cigarette smoking is associated with reduced acute responses to corticosteroids and worse clinical outcomes in stable chronic asthma. The mechanism by which current smoking promotes this altered behavior is currently unclear. Whilst cytokines can induce corticosteroid insensitivity in-vitro, how current and former smoking affects airway cytokine concentrations and their responses to oral corticosteroids in stable chronic asthma is unclear.

OBJECTIVES: To examine blood and sputum cytokine concentrations in never, ex and current smokers with asthma before and after oral corticosteroids.

METHODS: Exploratory study utilizing two weeks of oral dexamethasone (equivalent to 40 mg/day prednisolone) in 22 current, 21 never and 10 ex-smokers with asthma. Induced sputum supernatant and plasma was obtained before and after oral dexamethasone. 25 cytokines were measured by multiplex microbead system (Invitrogen, UK) on a Luminex platform.

RESULTS: Smokers with asthma had elevated sputum cytokine interleukin (IL) -6, -7, and -12 concentrations compared to never smokers with asthma. Few sputum cytokine concentrations changed in response to dexamethasone IL-17 and IFNalpha increased in smokers, CCL4 increased in never smokers and CCL5 and CXCL10 reduced in ex-smokers with asthma. Ex-smokers with asthma appeared to have evidence of an ongoing corticosteroid resistant elevation of cytokines despite smoking cessation. Several plasma cytokines were lower in smokers with asthma compared to never smokers with asthma.

CONCLUSION: Cigarette smoking in asthma is associated with a corticosteroid insensitive increase in multiple airway cytokines. Distinct airway cytokine profiles are present in current smokers and never smokers with asthma and could provide an explanatory mechanism for the altered clinical behavior observed in smokers with asthma.

Spencer, S. J., et al. (2019). "High-fat diet worsens the impact of aging on microglial function and morphology in a region-specific manner." Neurobiology of Aging **74**: 121-134.

Hippocampal microglia are vulnerable to the effects of aging, displaying a primed phenotype and hyper-responsiveness to various stimuli. We have previously shown that short-term high-fat diet (HFD) significantly impairs hippocampal- and amygdala-based cognitive function in the aged without affecting it in the young. Here, we assessed if morphological and functional changes in microglia might be responsible for this. We analyzed hippocampus and amygdala from young and aging rats that had been given three days HFD, a treatment sufficient to cause both hippocampal- and amygdala-dependent cognitive and neuroinflammatory differences in the aged. Aging led to the expected priming of hippocampal microglia in that it increased microglial numbers and reduced branching in this region. Aging also increased microglial phagocytosis of microbeads in the hippocampus, but the only effect of HFD in this region was to increase the presence of enlarged synaptophysin boutons in the aged, indicative of neurodegeneration. In the amygdala, HFD exacerbated the effects of aging on microglial priming (morphology) and markedly suppressed phagocytosis without notably affecting synaptophysin. These data reveal that, like the hippocampus, the amygdala displays aging-related microglial priming. However, the microglia in this region are also uniquely vulnerable to the detrimental effects of short-term HFD in aging.

Sreekanth Reddy, O., et al. (2019). "Sodium alginate/gelatin microbeads-intercalated with kaolin nanoclay for emerging drug delivery in wilson's disease." International Journal of Applied Pharmaceutics **11**(5): 71-80.

Objective: The aim of the present study was to fabricate and evaluate the drug release studies using Sodium Alginate (SA) and Gelatin (GE) microbeads intercalated with Kaolin (KA) nanoclay for sustained release of D-Penicillamine (D-PA). Method(s): Sodium alginate/gelatin/Kaolin blend microbeads were prepared by an extrusion method by using glutaraldehyde (GA) as a crosslinker. The obtained microbeads were characterized by Fourier transform infrared (FTIR) spectroscopy, scanning electron microscopy (SEM) and X-ray diffraction (XRD). Drug release kinetics of the microbeads was investigated in simulated intestinal fluid (pH 7.4) at 37 degreeC. Result(s): Microbeads formation was confirmed by FTIR spectroscopy. X-RD reveals that the KA should be intercalated with the drug and also it confirms the molecular level dispersion of D-Penicillamine into microbeads. Scanning Electron Microscopy (SEM) studies reveal that the beads were in spherical shape with some wrinkled depressions on the surface. The in vitro release study indicates the D-Penicillamine released in a controlled manner. The in vitro release kinetics was assessed by Korsmeyer-Peppas equation and the 'n' value lies in between 0.557-0.693 indicates Non-Fickian diffusion process. Conclusion(s): The results suggest that the developed KA intercalated microbeads are good potential drug carrier for the controlled release of D-PA. Copyright © 2019 The Authors.

Sreelakshmi, K., et al. (2019). Capsule Neural Networks and Visualization for Segregation of Plastic and Non-Plastic Wastes. 2019 5th International Conference on Advanced Computing and Communication Systems, ICACCS 2019.

Building an image processing model for prediction or classification application has to overcome quite a lot of challenges. Convolutional neural network (CNN) is the pillar of image processing in deep learning perspective. In order to bring down the disadvantages and for improving the performance compared to the CNN, a new architecture of CNN had been devised which is known as Capsule neural network (Capsule-Net). By this paper we analyze Capsule-Net for solid waste management which is separation of plastic and non-plastic. This task is viewed as of at most significance in today's world due to volumes of waste generated and nonavailability of human labor for this work. The capsule-Net is evaluated using 2 different datasets. Dataset 1

represents materials collected from public places and Dataset 2 represents materials collected from private environment. The proposed architecture with capsule-Net gives an accuracy of 96.3% for Dataset 1 and 95.7% for Dataset 2. The necessary hardware setup has been developed and tested. This will be a grace to the society which faces unexplainable difficulty in disposing wastes. It is inexpensive labor free and harmless to health. © 2019 IEEE.

Srivastava, A., et al. (2010). "Assessment of Plastic Waste Generation and Inventorization of Plastic Manufacturing Units in Madhya Pradesh." Journal of Solid Waste Technology & Management **36**(1): 620-630.

Plastics have become an integral part of our daily life. The day begins with use of plastic and ends with plastic. Today the plastic industry is rapidly growing and has changed our life style. The usage of plastic in India has also increased and its average annual consumption is 3.8Kg per capita per annum. The consumption of plastic per capita in our country is far lower than the developed countries. After its use, plastic waste remains in the environment, for a long time because of its non degradable characteristics and on account posing several of environmental problems. Thus the quality of plastics being durable and non degradable is a big problem. In some cases, on burning it could release toxic fumes. Furthermore, it can be claimed that the use of plastics helps the environment by saving water, oil and forest. For instance, plastics make cars and other automobiles lighter, thus saving oil and reducing CO2 emissions. On the other hand, as waste, plastic created serious problem to the Environment. It is becoming major cause of the air, water and soil pollution. On burning at low temperature, harmful gases are released. Plastic recycling programs are common in the developed nations and elsewhere. Thermoplastics can be re-melted and reused, and thermoset plastics can be ground up and are used as fillers, though the purity of the material tends to degrad with each recycle. The disadvantage of the degradation of biodegradable plastics is that the carbon that is locked up in them is released into the atmosphere as carbon dioxide, a greenhouse gas. In India, plastic waste is can be seen all around as roadside litter. When such plastic waste material is dumped into landfills, they can become "mummified" and persist for decades even if they are to be biodegradable. In this regard, plastics are just like food or paper which also fails to degrade in landfills. Scientists are seeking cheaper alternatives to plastic. The most promising alternatives are graphene, carbon nanotube, and carbon nanofoam. All three of these are made of nanocarbons, products of the new nanotechnology. Nanocarbons are very cheap, 100 times stronger than steel, slicker than Teflon, lightweight, and can be made very thin, made to stretch, and built into any shape - all the things plastic can do. In addition, nanocarbon manufacturing is non-polluting in comparison to the production of plastic. Already bowling balls, golf balls, sports equipment, and water-proof cotton balls are being made of nanocarbons. Plastic waste is a part of municipal solid waste [MSW]. A study on quantification of plastic waste generation in Madhya Pradesh has been undertaken and it is observed that 4.5% of MSW can be classified into plastic waste. The total quantity of MSW generated from all the 10 regions of M.P. viz., Rewa, Ujjain, Gwalior, Sagar, Satna, Dhar, Indore, Jabalpur, Bhopal & Guna is about 4377.44 MT/day. Out of which about 195.5 MT/day is plastic waste. About 147.55 and 48.45 MT/day classified into recyclable and non recyclable plastic waste respectively. It is thus evident that 75% of the total plastic waste is recyclable and 25% is non recyclable. About 190 plastic manufacturing and recycling units are established in various locations with in the State. These units engaged in manufacturing toys, pipes, molded articles and carry bags. The M.P. Pollution Control Board [MPPCB] is a regulatory authority for enforcing plastic rules in regards to the manufacture of plastic, in the State. MPPCB put efforts in utilizing the non recyclable plastic waste as co- fuel in the cement kilns. The emissions from the kilns were also monitored which was observed with in the norms laid down for the Hazardous Waste Incinerators. Thus the generated information on the plastic waste can be very well utilized by concerning authorities for framing strategies, techniques and methodology for waste management in the State. [ABSTRACT FROM AUTHOR]

Sruthy, S. and E. V. Ramasamy (2017). "Microplastic pollution in Vembanad Lake, Kerala, India: the first report of microplastics in lake and estuarine sediments in India." Environmental Pollution **222**: 315-322.

We present the first study of microplastics in the sediments of Vembanad Lake, a Ramsar site in India. Microplastics are emerging pollutants of increasing environmental concern with a particle size of <5 mm, which originate from successive degradation of larger plastic debris or are manufactured as small granules and used in many applications. The impact of microplastics pollution on the environment and biota is not well known. Vast data exist in the literature on marine microplastics while reports on freshwater ecosystems are scarce. In this context, to examine the occurrence of microplastic particles (MPs) in the Vembanad Lake, samples were collected from ten sites and processed for microplastic extraction through density separation. Identification of the polymer components of MPs was done using micro Raman spectroscopy. MPs were recovered from all sediment samples, indicating their extensive distribution in the lake. The abundance of MPs recorded from the sediment samples is in the range of 96-496 particles m⁻² with a mean abundance of 252.80+or-25.76 particles m⁻². Low density polyethylene has been identified as the dominant type of polymer component of the MPs. As clams and fishes are the major source of protein to the local population, the presence of MPs in the lake becomes critically important, posing a severe threat of contaminating the food web of this lake. This study, being the first report from India on MPs in lake sediments, provide impetus for further research on the distribution and impact of this emerging pollutant on the biota of many aquatic systems spread across India.

Stadler, B. M., et al. (2019). "Hydrogenation of Polyesters to Polyether Polyols." ChemSusChem **12**(17): 4082-4087.

The amount of plastic waste is continuously increasing. Besides conventional recycling, one solution to deal with this problem could be to use this waste as a resource for novel materials. In this study, polyesters are hydrogenated to give polyether polyols by using in situ-generated Ru-Triphos catalysts in combination with Lewis acids. The choice of Lewis acid and its concentration relative to the ruthenium catalyst are found to determine the selectivity of the reaction. Monitoring of the molecular weight during the reaction confirms a sequential mechanism in which the diols that are formed by hydrogenation are etherified to the polyethers. To probe the applicability of this tandem hydrogenation etherification approach, a range of polyester substrates is investigated. The oligoether products that form in these reactions have the chain lengths that are appropriate for application in the adhesives and coatings industries. This strategy makes polyether polyols accessible that are otherwise difficult to obtain from conventional fossil-based feedstocks.

Stadtmauer, E., et al. (2013). "Adoptive immunotherapy with engineered t cells expressing a TCR targeting NY-ESO-1 and lage-1 antigens after ASCT for mm." Clinical Lymphoma, Myeloma and Leukemia

1): S155.

This clinical trial investigates T cells engineered with an HLA-A0201 restricted, affinity-enhanced TCR that recognizes an epitope expressed by the NY-ESO-1 and LAGE-1 cancer testis antigens; cells are infused two days following high-dose chemotherapy given prior to autologous stem cell transplant (ASCT) in patients with high risk or relapsed multiple myeloma (MM). Inclusion criteria are 1) eligibility for auto-SCT, 2) PS of 0-2, 3) high risk MM or relapse after prior therapy, 4) HLA-A0201 positivity, and 5) NY-ESO-1 and/or LAGE- 1 positive tumor by RT-PCR. T cells are activated and expanded using anti-CD3/28 antibody conjugated microbeads, and gene modified with a lentiviral vector. Disease response is evaluated in accordance with the IMWG criteria at 6 weeks, and 3 and 6 months post infusion. Patients are monitored for persistence of gene modified cells and marrow is monitored for NY-ESO-1 and LAGE-1 antigen. 21 pts have enrolled, 17 patients have been infused (50% HR cytogenetics, 20% prior ASCT) with an average of 2.7 x 109 gene modified cells. 3 mos post ASCT, 77% experienced a VGPR or better. Infusions were well tolerated. GI toxicity resulting from autologous GVHD occurred in a subset of patients, possibly at a higher frequency than previously reported with non-gene modified T cell infusion after ASCT. Gene modified cells persisted at 6-12 months at approximately 10-100 gene modified cells per uL of blood. Disease progression has occurred in 4 pts and has been accompanied by very low levels or loss of engineered T cells or absence of target antigen on tumor.

Staff, W. (2018). "Bacardi Limited Teams with Lonely Whale to Remove One Billion Single-use Plastic Straws by 2020." Waste360: N.PAG-N.PAG.

The article offers information on the partnership between spirits company Bacardi Ltd. and nonprofit organization Lonely Whale to develop ideas to protect health of the ocean. Topics discussed include Bacardi's plans to review its global supply chain; its aim to remove the usage of non-recyclable single-use plastic waste; and the views of Rick Wilson, senior vice president of corporate responsibility for Bacardi, on it.

Staff, W. (2018). "Corona Campaign Addresses Issue of Marine Plastic Pollution." Waste360: N.PAG-N.PAG.

The article reports that Corona, a brand of AB InBev, has taken up the issue of marine plastic pollution to the global stage by hijacking iconic symbols of paradise for World Oceans Day. It notes that around eight million metric tons of plastic waste are released into the ocean each year. It notes that the partnership is working with local communities in the Maldives, Dominican Republic and Chile, which will increase its efforts in several regions within the next year.

Staff, W. (2018). "European Commission Proposes Ban on Some Plastic Products." Waste360: N.PAG-N.PAG.

The article offers information on a proposed ban on single-use plastic products such as cutlery, plates, and straws by European Commission prevent plastic pollution and reduce carbon emissions. It discusses forcing members to reduce the use of plastic food containers and drink cups by preventing free-of-charge distribution. It mentions views of Jyrki Katainen, vice-president of European Commission, on the helping move towards sustainable alternatives.

Staff, W. (2018). "Hospitality Industry Works to Combat Plastic Waste." Waste360: N.PAG-N.PAG.

The article informs that hospitality industry has taken various initiatives to curb the crisis of plastic waste worldwide. It is noted that hotels, airlines, cruise lines and restaurants are minimizing the use of single-use plastic like straws, cups, bottles and laundry bags. It is noted that Hilton has committed to eliminate plastic straws from its hotels by removing plastic bottles from its conference and event spaces.

Staff, W. (2018). "OECD Urges Government to Encourage Better Recycling of Plastics." Waste360: N.PAG-N.PAG.

The article reports that the Organisation for Economic Co-operation and Development (OECD) urges government to encourage improved recycling of plastics. It mentions that low recovery rates of plastic waste, poor quality of recycled plastic and an absence of price incentives lead to the slow growth of secondary plastic markets. It focuses on rising public concern on plastic pollution.

Staff, W. (2018). "A Sea of Plastic: 65 Years in the Making." Waste360: N.PAG-N.PAG.

The article presents information on the impact of ban on plastics, highlighting the non-biodegradable nature of plastics, and the prevention of plastic disposal in the oceans. Topics include the durability of the products, use of polypropylene in plastic products, and the impact of plastic waste on the ocean ecology.

Staff, W. (2018). "Thailand Announces Ban on E-waste, Plastic Imports." Waste360: N.PAG-N.PAG.

The article reports that in an effort to stop amassing garbage in Thailand, the government has announced it plans to ban imports of plastic and electronic waste. Topics include the initiative comes after massive amounts of e-waste from the U.S., European Union, Hong Kong, China, Singapore and Japan had been shipped to Thailand and statement of environment minister Surasak Kanchanarat that Thailand will stop importing cheap electronic and plastic waste in order to alleviate ecological problems.

Staffieri, E., et al. (2019). "Pressure and impact of anthropogenic litter on marine and estuarine reptiles: an updated “blacklist” highlighting gaps of evidence." Environmental science and pollution research international **26**(2): 1238-1249.

We report an arrangement on the effect of anthropogenic litter on marine and estuarine reptiles, checking for evidence about different types of impact (ingestion vs. entanglement) and pressure (three size-based categories). From 1976 to 2018, we obtained a “blacklist” of 11 species impacted by marine litter (about 13% of 85 species of marine and estuarine reptiles), belonging to three orders (Testudines, Squamata, and Crocodilia). We obtained only occasional evidence of an impact for Squamata (Hidrophis elegans, Disteira major) and Crocodilia (Crocodylus porosus). Regarding the different types of pressure, the highest number of evidence has been obtained for macro-litter (10 species) and the lowest for micro-litter (4 species, all Chelonidae). Among Testudines, Lepidochelys kempii and Natator depressus evidenced a lack of data for micro-plastic. In Squamata, information is lacking for micro-plastic with only occasional references for meso-plastic (in Hydrophis elegans) and macro-plastic (Disteira major and Crocodylus porosus). We obtained a direct correlation between the research effort and the number of citations regarding different types of pressure and impact of marine litter: therefore, our blacklist of impacted species could be increased, carrying out further research focused on other poorly studied marine and estuarine reptiles. We suggest the use of a standardized nomenclature to reduce the amount of lost information.

Stalke, A., et al. (2013). "Metal responsive elements as a new point of view in the pathogenesis of

Wilson Disease." Medizinische Genetik **25 (1)**: 166.
Background: Wilson Disease (WD) is a monogenic autosomal recessive disorder leading to toxic copper accumulation mainly in liver tissue. It is caused by mutations in the ATP7B gene (OMIM#606882). Currently, more than 500 disease-related ATP7B mutations are known, providing a basis for molecular genetic diagnosis of WD. In patients who exhibit clinical WD symptoms but lack a detectable ATP7B mutation, differential diagnosis remains difficult. Our previous studies revealed a decrease in liver ATP7B mRNA expression in molecular genetically proven WD patients compared to controls. Decreased ATP7B mRNA expression was also observed in patients with typical WD symptoms but without an ATP7B mutation. Metal responsive elements (MREs) are likely to be linked to this downregulation. MREs (a, c, d and e) can be found in the ATP7B promoter region and modulate the promoter activity by binding transcription factors in a metal ion concentration-dependent mechanism. An interaction partner in the ATP7B gene is already known for MRE a. Ultimate aim of our study is to unveil and characterize further MRE-interacting proteins that might orchestrate the aberrant ATP7B mRNA expression in patients with or without genetically detectable WD. Method(s): Nuclear proteins were extracted from human hepatocellular carcinoma cell line cells (HLE). To screen for protein-DNA interactions, an electrophoretic mobility shift assay (EMSA) was performed by incubating the nuclear extract with biotin-labeled double-stranded 31 bp probe corresponding to ATP7B MRE c sequence. To confirm the specificity of protein-DNA binding and to narrow down the protein binding site, excessive amounts of wild-type and mutated unlabeled MRE c oligonucleotides were used as competitors. The protein-DNA complex was isolated by means of magnetic streptavidin microbeads. Eluted proteins were identified by MALDI-TOF/TOF mass spectrometry. Result(s): A highly specific protein binding on the MRE c probe was revealed by EMSA experiments. The use of mutated MRE c competitor oligonucleotides also indicated that not only nucleotides of the consensus MRE c sequence, but also up to six nucleotides downstream of the MRE c are involved in protein binding. Among the isolated proteins are proline- and glutamine-rich splicing factor (SFPQ) and poly(U)-binding-splicing factor (PUF60), which are not only involved in splicing, but also in regulation of transcription. Conclusion(s): Our findings demonstrate that the regulatory MRE c sequence of the ATP7B gene is specifically bound by at least one protein. Candidate binding partners are the two factors SFPQ and PUF60. Specific interactions with either of these proteins have to be confirmed by supershift assays and their effects on transcriptional activation will have to be elucidated by luciferase assays. In prospective studies, liver samples of WD patients and possible WD patients without an ATP7B mutation could then be analyzed regarding validated MRE c binding transcription factors. More precisely, expression and mutational analysis of the transcription factors as well as mutational analysis of the MRE c itself are of immediate interest. A downregulation of transcription factors or disturbed interaction between transcription factors and MRE c may explain the decreased ATP7B mRNA expression in WD. These findings could provide new insights into the pathogenesis of WD but most of all enhance WD diagnosis in patients with disease symptoms but without an ATP7B mutation.

Stanič, A. (2016). "THE MICROPLASTIC THREAT TO OUR OCEANS." Resurgence & Ecologist(296): 6-7.
The article reports on the women's eXXpedition mission to evaluate pollution from plastics, chemicals, endocrine disrupters in the tropical Atlantic. It highlights the threat of microplastics to the ocean that can cause disease in personal and global environment. The expedition also includes taking water from the ocean as sample to test the presence of micro-and nanoplastic and toxins.

Stanisavljevic, N. and P. H. Brunner (2019). "Quantity AND quality: New priorities for waste management." Waste Management and Research **37**(7): 665-666.

Staniszewska, M., et al. (2016). "The fate of bisphenol A, 4-tert-octylphenol and 4-nonylphenol leached from plastic debris into marine water – experimental studies on biodegradation and sorption on suspended particulate matter and nano-TiO2." Chemosphere **145**: 535-542.

Experiments were carried out, the aim of which was to determine the leaching rates for bisphenol A (4,4'-(propane-2,2-diyl)diphenol - BPA), 4- tert -octylphenol (OP), 4-nonylphenol (NP) from polycarbonate and recycled tyre granules into the seawater. Additionally biodegradation, sorption on marine suspended particulate matter and sorption on various types of nano-TiO 2 of BPA, OP, NP were studied. Experiments were carried out on plastics at various stages of degradation. The conducted experiment confirmed the flux of BPA, OP and NP from the studied plastics into seawater. The initial photodegradation of the plastic had a significant influence on the amount of the studied components released into water. During the first days of the experiment leaching was weaker from aged materials. After 60 days leaching of BPA and OP was higher for aged plastic compared to unaged. On average, suspension adsorbed OP, BPA and NP from seawater at respective levels of 37%, 75% and 100%. On the other hand, during biodegradation on average 25%, 9% and 2% of OP, BPA and NP respectively are removed from water. Nano-TiO 2 of 21 nm pore size diameter adsorbed all the compounds more strongly than nano-TiO 2 of 15 nm pores sized coated with Al and stearic acid. The strongest sorption (100%) on different types of nano-TiO 2 was that of the most hydrophobic and more linear structured NP with just one phenol group. The weakest sorption was observed in the case of BPA, which is the least hydrophobic, and characterized by higher compared to NP and OP steric hindrance and electrostatic repulsion. Stanton, T., et al. (2019). "Freshwater and airborne textile fibre populations are dominated by 'natural', not microplastic, fibres." Science of the Total Environment **666**: 377-389.

The potential role of natural textile fibres as environmental pollutants has been speculated upon by some environmental scientists, however, there is a general consensus that their biodegradability reduces their environmental threat. Whilst the risks that they pose remain poorly understood, their environmental prevalence has been noted in several recent microplastic pollution manuscripts. Here we highlight the extent to which natural textile fibres dominate fibre populations of upstream reaches of the River Trent, UK, as well as the atmospheric deposition within its catchment, over a twelve month microplastic sampling campaign. Across 223 samples, natural textile fibres represented 93.8% of the textile fibre population quantified. Moreover, though microplastic particles including synthetic fibres are known to be pervasive environmental pollutants, extruded textile fibres were absent from 82.8% of samples. Natural textile fibres were absent from just 9.7% of samples.

Stapleton, J. A. and J. R. Swartz (2010). "Development of an in vitro compartmentalization screen for high-throughput directed evolution of [FeFe] hydrogenases." PLoS ONE [Electronic Resource] **5**(12): e15275.

BACKGROUND: [FeFe] hydrogenase enzymes catalyze the formation and dissociation of molecular hydrogen with the help of a complex prosthetic group composed of common elements. The development of energy conversion technologies based on these renewable catalysts has been hindered by their extreme oxygen sensitivity. Attempts to improve the enzymes by directed evolution have failed for want of a screening platform capable of throughputs high enough to adequately sample heavily mutated DNA libraries. In vitro compartmentalization (IVC) is a powerful method capable of screening for multiple-turnover enzymatic activity at very high throughputs. Recent advances have allowed [FeFe] hydrogenases to be expressed and activated in the cell-free protein synthesis reactions on which IVC is based; however, IVC is a demanding technique with which many enzymes have proven incompatible.

METHODOLOGY/PRINCIPAL FINDINGS: Here we describe an extremely high-throughput IVC screen for oxygen-tolerant [FeFe] hydrogenases. We demonstrate that the [FeFe] hydrogenase CpI can be expressed and activated within emulsion droplets, and identify a fluorogenic substrate that links activity after oxygen exposure to the generation of a fluorescent signal. We present a screening protocol in which attachment of mutant genes and the proteins they encode to the surfaces of microbeads is followed by three separate emulsion steps for amplification, expression, and evaluation of hydrogenase mutants. We show that beads displaying active hydrogenase can be isolated by fluorescence-activated cell-sorting, and we use the method to enrich such beads from a mock library.

CONCLUSIONS/SIGNIFICANCE: [FeFe] hydrogenases are the most complex enzymes to be produced by cell-free protein synthesis, and the most challenging targets to which IVC has yet been applied. The technique described here is an enabling step towards the development of biocatalysts for a biological hydrogen economy.

Stapleton, P. A. (2019). "Toxicological considerations of nano-sized plastics." Aims Environmental Science **6**(5): 367-378.

Undoubtedly, plastics have changed human existence. These pervasive products are used in nearly every field to include technological, biomedical, and domestic applications. Post-consumer plastic waste disposal leading to plastic pollution in landfills, waterways, and oceans represents a worldwide environmental challenge. Accumulation and continued material fragmentation from micro- to nanoplastics has identified concerns pertaining to environmental and human exposures and toxicity. While many studies have focused on particle fate and identification, the toxicological considerations must focus on the biological relevance of particle deposition within a particular organism, compartment, organ, and tissue. Further, concerns exist regarding the physical and chemical properties of the plastic particles during their production and/or degradation. In this mini-review we will discuss (1) particle characterization and assessment, (2) environmental concerns, and (3) human toxicity.

Starr, D. (1990). "SHOPPERS, SHOPPERS, EVERYWHERE." Audubon **92**(2): 98-103.

Presents an overview of plastic use and disposal in Italy. Use of plastic shopping bags every year; Garbage disposal problems; Emphasis on how these plastics are deposited in rivers; Controversies surrounding the ban on the use of plastics in the country; Environmental effects of incineration.

Stasolla, G., et al. (2015). "On the diet of the invasive crab Charybdis longicollis Leene, 1938 (Brachyura: Portunidae) in the eastern Mediterranean Sea." Israel Journal of Ecology & Evolution **61**(3/4): 130-134.

We present the first results on the diet of the invasive portunid crab Charybdis longicollis in the eastern Mediterranean. No differences were found between sexes, seasons, class size or

infection by the rhizocephalan Heterosaccus dollfusi. Size differences were noted between crabs collected at different depths, with larger specimens at shallower sites, as well as significant interaction between sex and infection factors, with males more parasitized than females. Sex has had no bearing on food items. No significant impacts were observed of seasons, depth, class size, sex and infection on stomach fullness. Charybdis longicollis is benthophagic, with preference for infaunal and slow moving prey, as attested by the notable amount of sediment in their stomachs; the most frequent food items were molluscs, crustaceans and fish, similar to congeners. Microplastics were detected in a quarter of the specimens examined. Since the species is extremely abundant in the Levantine littoral and sublittoral, it is likely to impact the local biota.

Stastny, P., et al. (2007). "Antibodies against donor human leukocyte antigens and the outcome of cardiac allografts in adults and children." Transplantation **84**(6): 738-745.

BACKGROUND: Mismatched histocompatibility antigens between donor organ and host stimulate the immune response that causes allograft rejection. Antibodies against human leukocyte antigen (HLA) are known to appear in the serum of heart transplant recipients.

METHODS: We have tested stored sera with HLA bound to polystyrene microbeads in a retrospective analysis of heart recipients transplanted in our center to better understand the impact of antibodies against HLA on the posttransplant course. Our analysis included two groups of patients: 113 adults and 31 children who received consecutive heart transplants performed between 1996 and 2003.

RESULTS: Presence of HLA antibodies, especially when donor-specific, as determined with single HLA class I or class II beads, was associated with more frequent occurrence of acute rejection, development of transplant-related coronary artery disease and decreased graft survival. Recipients having antibodies only to HLA not in the transplant and those without any HLA antibodies had similar outcomes, suggesting that antibodies against antigens not present on the donor organ did not harm the graft.

CONCLUSION: The results showed that presence of antibodies against HLA of the donor correlated with graft loss and suggested that testing for these antibodies may help in the management of heart transplant patients.

Statache, G., et al. (2012). "Regulation of microrna 223 expression in a gouty arthritis." Arthritis and Rheumatism **10)**: S811.

Background/Purpose: Gout is an inflammatory chronic disease caused by deposition of uric acid crystals in the joint and connective tissues causing pain and disability. Current data suggest that gout is mediated by IL-1b that is produced due to the activation of the inflammasome pathway by uric acid crystals. In addition, neutrophil influx in the joint is the key initiator of a gout flare. miR-223 has been identified as a masterswitch molecule limiting neutrophil activation. In addition, we showed previously that this miR negatively regulates NLRP3 (an inflammasome component) and IL-1b production in human macrophages. To investigate miR-223 expression and regulation in monocytes and neutrophils of gout patients. Method(s): CD14+ cells and neutrophils were isolated from gout patients (n=10) and healthy donors (n=6) peripheral blood using CD14 microbeads and polylymphoprep gradient buffer, respectively. CD14+ from healthy donors were stimulated with LPS (10 ng/ml) IL-1beta (100-10ng/ml), IL-6 (100 ng/ml), TNF alpha (10-100ng/ml) or monosodium urate crystals MSU (1mg-1ug/ml) for different time points (24-72h). Cells were harvested and miRNA extracted. Expression of miR-223 and endogenous control snRNA U1 was assessed by qPCR. Result(s): miR-223 expression in peripheral blood monocytes of patients with chronic gout was lower compared to healthy controls. This suggest

that overproduction of IL-1b in chronic disease might be partially mediated by low levels of miR-223. In vitro studies revealed that MSU, IL-1b, TNFa and IL-6 significantly inhibited miR-223 expression in monocytes in all time points (24-72h). In contrast, IL-10 strongly increased miR-223 expression. Interestingly, the levels of miR-223 in peripheral blood neutrophils were higher in gout patients compared to healthy controls Conclusion(s): A decrease in miR-223 expression in monocytes of chronic gout patients may contribute to uric acid crystals induced inflammasome activation and chronicity of disease. Upregulation of miR-223 expression in gout neutrophils may reflect the activation of mechanisms that limits neutrophils activation and lead to the resolution of gout flares.

Staub, C. (2019). "Recycling leaders respond to plastic industry's $1B pledge." Resource Recycling **38**(2): 8-9.

The article reports on the response of recycling leaders on the pledge made by plastic industry in the U.S. The topics discussed include the plan of the organization the Alliance to End Plastic Waste to concentrate resources by creating waste collection infrastructure, cleaning of the plastics from the environment, and educating the consumers about the waste, and the remarks of the Association of Plastic Recyclers executive director Steve Alexander on their commitment to the effort.

Staudinger, M., et al. (2013). "Elimination of AML leukemic stem cells by CD96 antibody as a new strategy in stem cell transplantation." Onkologie **7)**: 208.

Introduction: Residual leukemic stem cells (LSC) may account for relapse frequently observed in AML patients despite being consolidated by stem cell transplantation. Therefore, clearance of LSC by targeted therapy represents a therapeutic goal. Here, strategies are described addressing CD96 - a marker antigen recently identified on LSC of AML patients - for engineering autologous stem cell grafts by magnetic cell sorting (MACS) as well as for in vivo killing of LSC by antibody dependent cellular cytotoxicity (ADCC). Method(s): The CD96 antibody TH111 raised in our laboratory was biotinylated and used for depletion of AML-LSC cells by MACS. Efficiency of the procedure and its influence on the viability and differentiation of healthy hematopoietic progenitor cells (HPC) were analyzed by flow cytometry and colony forming assays. Chimeric CD96 antibodies were generated by recombinant DNA technologies. Antibody-mediated effector functions were analyzed in 51Cr-release assays. Result(s): To evaluate purging of LSC, a stem cell containing graft was spiked with CD96 positive AML cells. Up to a 1000-fold depletion of targeted cells was achieved using biotinylated CD96 antibody and anti-Biotin- microbeads. Viability, cell count and the potential of HPC to proliferate and differentiate were not affected. To target CD96+ AML-LSC by ADCC, chimeric antibodies containing wild type or affinity maturated variable regions in combination with an optimized human IgG1 Fc were generated. Not only antigen binding affinity of the maturated antibody was enhanced (EC50 0.6mug/ml vs. 2mug/ml), but also NK cell mediated lytic properties against CD96-positive target cells were elevated (EC50: 0.02 mug/ml vs. 0.15 mug/ml). Conclusion(s): CD96 antibodies can be efficiently used to target and to deplete CD96 positive AML-LSC from mixed cell populations similar to autologous grafts, without affecting normal HPC viability, proliferation or differentiation properties. Moreover, a chimeric, affinity maturated and Fc engineered antibody targeting CD96 was able to recruit NK cells and displayed enhanced lytic activity against CD96 positive targets. In summary, these approaches may be beneficial for the development of graft-engineering strategies to avoid transplantation of AML-LSC and revitalize autologous stem cell transplantation in this indication. The in vivo application may possibly open additional therapeutic avenues in eliminating residual disease in autologous as well as allogeneic situations.

Staudinger, M., et al. (2014). "Depletion of leukemic AML stem cells from autografts by CD96 antibody TH111." Oncology Research and Treatment **5)**: 128.

Background: Residual leukemic stem cells (LSC) residing in patients or autologous hematopoietic stem cell transplants may lead to repopulation of the tumor cells after therapy. Therefore, addressing these LSC by targeted therapy should lead to better therapeutic results. Here, CD96-an antigen identified on acute myeloid leukemia (AML) LSC-was used to deplete AML LSC from autologous stem cell grafts by magnetic cell sorting (MACS). Moreover, elimination of these AML LSC in vivo by antibody-dependent killing (ADCC) may be of therapeutic use in other situations. Method(s): For MACS based separation of AML LSC from autologous grafts, the CD96 antibody TH111 raised in our laboratory was labeled with Biotin and used in combination with anti-Biotin-MicroBeads. Healthy hematopoietic progenitor cells (HPC) viability, their differentiation properties and the efficiency of depletion were analyzed by colony forming assays and by flow cytometry. Chimeric CD96 antibodies optimized for Fc-receptor interaction were analyzed for purity by SDS page and specific binding by flow cytometry. Antibody-mediated effector functions were measured in 51Cr-release assays. Result(s): Hematopoietic stem cell containing grafts were spiked with AML cells to evaluate the efficiency of antibody mediated LSC purging by MACS. The combination of anti-Biotin-MicroBeads and biotinylated CD96 antibody facilitated an up to 1000-fold depletion of targeted cells. Viable HPCs cell count as well as their potential to proliferate and differentiate were not affected by the purging procedure. Chimeric antibodies containing wild type or affinity maturated variable regions in combination with an ADCC optimized human IgG1 Fc were generated to recruit Fc-receptor bearing effector cells for lysis of CD96 positive AML LSC. The higher antigen binding affinity of the maturated antibody (EC50 of 0.6 vs. 2 mug/ml) should account for the enhanced NK cell mediated lytic properties against CD96-positive cells (EC50: 0.02 vs. 0.15 mug/ml; E:T ratio 2.5:1). Conclusion(s): The efficient elimination of AML-LSC by MACS may be beneficial for the development of graft-engineering strategies to avoid transplantation of AML-LSC and provide rationale for autologous stem cell transplantation in certain patients with AML. The in vivo application of optimized recombinant chimeric antibodies targeting AML LSC may possibly open additional therapeutic avenues in eliminating residual disease in autologous as well as allogeneic situations.

Staudinger, M., et al. (2015). "Graft engineering in acute myeloid leukemia : CD96 antibody TH-111 depletes leukemic stem cells from autografts." Transfusion Medicine and Hemotherapy **1)**: 3-4.

Introduction: Residual leukemic stem cells (LSC) may account for the high rate of relapse observed in patients suffering from acute myeloid leukemia (AML). Therefore, addressing these LSC residing in patients or autologous hematopoietic stem cell transplants by targeted therapy should lead to better therapeutic results. Here, CD96 - an antigen identified on AML-LSC - was used to deplete AML LSC from autologous stem cell grafts by magnetic cell sorting (MACS). Moreover, a chimeric Fc-optimized CD96 antibody was developed to eliminate these AML-LSC by antibody-dependent killing (ADCC) in vivo. Method(s): To evaluate the efficiency of LSC purging HPC containing grafts were spiked with AML cells (KG1a, n = 10 experiments). To deplete AML-LSC from autologous grafts by MACS, the Biotin-labeled CD96 antibody TH-111 raised in our laboratory was used in combination with anti-Biotin-MicroBeads. The efficiency of depletion was analyzed by flow cytometry. Colony assays were used to evaluate the differentiation and proliferation characteristics of hematopoietic progenitor cells (HPC). Chimeric CD96 antibodies optimized for Fc-receptor engagement were analyzed for purity by

SDS page and specific binding by flow cytometry. Antibody-mediated effector functions were measured in 51Cr-release assays or by flow cytometry. Result(s): Up to a 1000-fold depletion of target cells was achieved by MACS. The potential of HPC to proliferate and differentiate was not affected by the purging procedure. Chimeric CD96 antibodies combining a Fc optimized human IgG1Fc and wild type or affinity maturated variable regions were generated to recruit Fc-receptor bearing effector cells for lysis of CD96+ AML-LSC. The affinity maturated CD96 antibody efficiently recruited NK cell for lysis of CD96 positive target cells while HPCs' viability was not impaired. The higher antigen binding affinity of the maturated antibody (EC50 0.6 vs. 2 mug/ml) may account for the elevated target cell lysis (EC50 0.02 vs. 0.15 mug/ml; E:T ratio 2.5:1). Conclusion(s): The efficient elimination of AML-LSC by MACS may be beneficial for the development of graft-engineering strategies to avoid re-transplantation of AML-LSC and provide rationale for autologous stem cell transplantation in certain patients with AML. In autologous as well as allogeneic situations the in vivo application of an Fc-optimized chimeric CD96 antibody targeting AML-LSC may possibly open additional therapeutic avenues in eliminating residual disease.

Steen, R., et al. (2016). "Plastic mistaken for prey by a colony-breeding Eleonora's falcon (Falco eleonorae) in the Mediterranean Sea, revealed by camera-trap." Marine Pollution Bulletin **106**(1/2): 200-201.

Discarded plastic is known to be harmful for marine animals through ingestion and entanglement. Here we report the first documentation of Eleonora's falcons providing plastic waste to dependent nestlings. Eleonora's falcons breed colonially on sea cliffs and islets in areas of the Mediterranean Sea and the Canary Islands in which they normally feed their nestlings exclusively with small migratory birds.

Steensgaard, I. M., et al. (2017). "From macro- to microplastics - Analysis of EU regulation along the life cycle of plastic bags." Environmental Pollution **224**: 289-299.

Plastic pollution and its environmental effects has received global attention the recent years. However, limited attention has so far been directed towards how plastics are regulated in a life cycle perspective and how regulatory gaps can be addressed in order to limit and prevent environmental exposure and hazards of macro- and microplastics. In this paper, we map European regulation taking outset in the life cycle perspective of plastic carrier bags: from plastic bag production to when it enters the environment. Relevant regulatory frameworks, directives and authorities along the life cycle are identified and their role in regulation of plastics is discussed. Most important regulations were identified as: the EU chemical Regulation, the Packaging and Packaging Waste Directive including the amending Directive regarding regulation of the consumption of lightweight plastic carrier bags, the Waste Framework Directive and the Directive on the Landfill of Waste. The main gaps identified relate to lack of clear definitions of categories of polymers, unambitious recycling rates and lack of consideration of macro- and microplastics in key pieces of legislation. We recommend that polymers are categorized according to whether they are polymers with the same monomer constituents (homopolymers) or with different monomer constituents (copolymers) and that polymers are no longer exempt from registration and evaluation under REACH. Plastics should furthermore have the same high level of monitoring and reporting requirements as hazardous waste involving stricter requirements to labelling, recordkeeping, monitoring and control over the whole lifecycle. Finally, we recommend that more ambitious recycle and recovery targets are set across the EU. Regulation of the consumption of lightweight plastic carrier bags should also apply to heavyweight plastic carrier bags. Last, the Marine and Water Framework Directives should

specifically address plastic waste affecting water quality.

Steer, M., et al. (2017). "Microplastic ingestion in fish larvae in the western English Channel." Environmental Pollution **226**: 250-259.

Microplastics have been documented in marine environments worldwide, where they pose a potential risk to biota. Environmental interactions between microplastics and lower trophic organisms are poorly understood. Coastal shelf seas are rich in productivity but also experience high levels of microplastic pollution. In these habitats, fish have an important ecological and economic role. In their early life stages, planktonic fish larvae are vulnerable to pollution, environmental stress and predation. Here we assess the occurrence of microplastic ingestion in wild fish larvae. Fish larvae and water samples were taken across three sites (10, 19 and 35 km from shore) in the western English Channel from April to June 2016. We identified 2.9% of fish larvae (n=347) had ingested microplastics, of which 66% were blue fibres; ingested microfibers closely resembled those identified within water samples. With distance from the coast, larval fish density increased significantly (P<0.05), while waterborne microplastic concentrations (P<0.01) and incidence of ingestion decreased. This study provides baseline ecological data illustrating the correlation between waterborne microplastics and the incidence of ingestion in fish larvae.

Stegmann, R. (2017). "Global pollution....Time to act." Waste Management **66**: 1-2.

Steinberg, F., et al. (1992). "Activity testing of alveolar macrophages and changes in surfactant phospholipids after irradiation in bronchoalveolar lavage: Experimental and clinical data." Environmental Health Perspectives **97**: 171-175.

This study presents results of bronchoalvolar lavage (BAL) after irradiation to the lungs in mice as well as clinical data. The number of BAL cells, mainly macrophages, lymphocytes, and granulocytes, changed in a time- dependent manner. The phagocytic activity of the macrophages measured as the phagocytosis of microbeads and measured as the esterase activity also showed a strong time-dependent increase during the acute phase up to 21 days after irradiation. The contents of surfactant phospholipids (SF) and sphingomyelin (SPH; as a parameter for cell death) were quantified by HPLC. Both were significantly changed between day 2 and 21 after irradiation. Three BALs of a patient with idiopathic interstitial pneumonitis, who had received an allogenic bone marrow graft after total body irradiation with 10 Gy, showed similar effects in the cellular and surfactant parameters. These data indicate that there are positive interactions between the number of different BAL cells, macrophage activity, and SF and SPH content in the preclinical model of the mouse as well as in the clinical situation after lung irradiation.

Steinmetz, Z., et al. (2016). "Plastic mulching in agriculture. Trading short-term agronomic benefits for long-term soil degradation?" Science of the Total Environment **550**: 690-705.

Plastic mulching has become a globally applied agricultural practice for its instant economic benefits such as higher yields, earlier harvests, improved fruit quality and increased water-use efficiency. However, knowledge of the sustainability of plastic mulching remains vague in terms of both an environmental and agronomic perspective. This review critically discusses the current understanding of the environmental impact of plastic mulch use by linking knowledge of agricultural benefits and research on the life cycle of plastic mulches with direct and indirect implications for long-term soil quality and ecosystem services. Adverse effects may arise from plastic additives, enhanced pesticide runoff and plastic residues likely to fragment into

microplastics but remaining chemically intact and accumulating in soil where they can successively sorb agrochemicals. The quantification of microplastics in soil remains challenging due to the lack of appropriate analytical techniques. The cost and effort of recovering and recycling used mulching films may offset the aforementioned benefits in the long term. However, comparative and long-term agronomic assessments have not yet been conducted. Furthermore, plastic mulches have the potential to alter soil quality by shifting the edaphic biocoenosis (e.g. towards mycotoxigenic fungi), accelerate C/N metabolism eventually depleting soil organic matter stocks, increase soil water repellency and favour the release of greenhouse gases. A substantial process understanding of the interactions between the soil microclimate, water supply and biological activity under plastic mulches is still lacking but required to estimate potential risks for long-term soil quality. Currently, farmers mostly base their decision to apply plastic mulches rather on expected short-term benefits than on the consideration of long-term consequences. Future interdisciplinary research should therefore gain a deeper understanding of the incentives for farmers and public perception from both a psychological and economic perspective in order to develop new support strategies for the transition into a more environment-friendly food production.

Stelmaszczyk-Emmel, A., et al. (2012). "Identification, frequency, activation and function of CD4+ CD25 ^{high}FoxP3+ regulatory T cells in children with juvenile idiopathic arthritis." Rheumatology International **32**(5): 1147-1154.

The aim of the study was to test the frequency of CD4+ CD25 ^{high}FoxP3 regulatory T cells in JIA patients and to assess their activation status and functional activity. The study involved 12 children with JIA and 35 healthy control subjects. PBMC were stained with monoclonal antibodies (anti-CD25, anti-CD4, anti-CD127, anti-CD69, anti-CD71, and anti-FoxP3). The samples were evaluated using flow cytometer. CD4+ CD25-and CD4+ CD25+ cells were isolated by negative and positive selection with magnetic microbeads. CD4+ CD25+ and CD4+ CD25-cells were cultured separately and co-cultured (1:1) with or without PHA. The percentage of Tregs in JIA patients was significantly decreased in comparison with controls (median, 3.2 vs. 4.6; P = 0.042). Relative fluorescence intensities of FoxP3 were higher in JIA patients than in controls (median, 9.1 vs. 6.8). The percentage of activated Tregs (CD71+) was significantly higher in JIA patients in comparison with controls (median, 6.5 vs. 2.8; P = 0.00043). CD4+ CD25+ cells derived from JIA patients and controls were anergic upon PHA stimulation, while CD4+ CD25-cells showed intensive proliferative response. The proliferation rate of CD4+ CD25-cells stimulated by PHA was decreased in co-cultures. In JIA patients, the inhibition of proliferation of CD4+ CD25-cells by CD4+ CD25+ cells was 37.9%, whereas in controls it was significantly lower (55.7%, P = 0.046). JIA patients had statistically lower percentage of Tregs in peripheral blood compared to controls. CD4+ CD25+ cells sorted from peripheral blood of JIA patients had statistically lower ability to suppress CD4+ CD25-cell proliferation in comparison with cells obtained from controls. © 2011 Springer-Verlag.

Stemple, C. C., et al. (2014). "Smartphone-based optofluidic lab-on-a-chip for detecting pathogens from blood." Journal of Laboratory Automation **19**(1): 35-41.

A novel smartphone-based detection device was created to detect infectious pathogens directly from diluted (10%) human whole blood. The model pathogen was histidine-rich protein 2 (HRP-2), an antigen specific to Plasmodium falciparum (malaria). Anti-HRP-2-conjugated submicrobeads were mixed with HRP-2-infused 10% blood in a lab-on-a-chip device. The white LED flash and the digital camera of the smartphone were used as light source and detector, which delivered light to and from the bead and blood mixture via optofluidic channels in the

lab-on-a-chip. The optofluidic channels were angled at 45 degrees to capture the Mie scatter from the sample. Considering the absorption and scattering characteristics of blood (red/infrared preferred) and the Mie scatter simulations for microbead immunoagglutination (UV preferred), blue detection showed the best results. The detection limit was 1 pg/mL in 10% blood. The linear range was from 1 pg/mL to 10 ng/mL. A handheld device, easily attachable to a single smartphone, was finally designed and fabricated using optical mirrors and lenses and successfully detected the HRP-2 from 10% blood. The total assay time was approximately 10 min. The proposed device can potentially be used for detecting a wide range of blood infection with high sensitivity.

Stephen, M. (2013). "WHY you need to understand SOLIDS FLOW." Canadian Plastics **71**(5): 11.

Resins are usually handled with a pneumatic conveying system that typically consists of a system of pipes, manifolds, valves, and controls that are powered by a high velocity stream of air. All plastic materials have certain characteristics which govern the amount of power or velocity required to move them properly, and plastics processors who want to specify an optimal resin feeding and conveying system need to know what they are. Plastic resin, either in pellet or granular form, is susceptible to flow problems such as blocking, sticking, erratic flow, inconsistent discharge, poor mixing, and lack of first-in/first-out flow. Abrasive, glass-filled materials won't necessarily affect the handling system equipment design, the experts say, but they can determine what the system is built from. The key to efficient raw materials conveying is to design the system to the measured flow properties of the resins to be handled.

Stephens, A. (1987). "The Case for HDPE Recycling." Resource Recycling **6**(5): 18.

Plastics represent a growing proportion of the municipal solid waste stream. The solution to this growing problem is to face the challenge to recycle post-consumer plastics waste. At 2.2 billion lb/year, high density polyethylene (HDPE) is by far the largest plastic resin used within the blow molded container market. Nearly four times more HDPE is destined for landfills than is other plastic bottle resins. Eaglebrook Plastics Inc. of Chicago, IL, recycles over 1.5 million lb/month of industrial scrap polyethylene. It has developed a technology that enables the recycling of post-consumer polyethylene bottles that are contaminated with paper labels, dirt, and product residue. Efforts are underway to develop technology for the recycling of dairy bottles.

Sterenborg, J., et al. (2017). Model tests to assess wave and current loads on ocean cleanup's conceptual plastic capturing barrier. ASME 2017 36th International Conference on Ocean, Offshore and Arctic Engineering, OMAE 2017, June 25, 2017 - June 30, 2017, Trondheim, Norway, American Society of Mechanical Engineers (ASME).

Lot of plastics enters the ocean every day with negative effects on the environment, economy and health. A large portion of the floating plastics accumulate in so-called gyres, where currents converge. One of the aims of the Ocean Cleanup is to develop technologies to extract plastic pollution from the oceans. The idea is to install a flexible barrier in the ocean that is supposed to concentrate the plastic at the Great Pacific Garbage Patch. The design of the barrier is still in the conceptual phase and the model tests described in this report are conducted to assist in the development of the barrier. The model tests were carried out in MARIN's Offshore Basin and served two main goals: 1) provide loads and displacements for numerical model calibrations and 2) examine the 3D fluid-structure interactions and the barrier performance for three different design concepts. A 360m prototype length barrier was considered that consists of a floater with a diameter of 1.5m and a screen with a height of 2m. To model larger lengths of the barrier, various pretensions were applied at the ends of the barrier. For the secondary mooring concept the barrier was moored each 60m via the bottom of the screen to a submerged tension line. For the low mooring and high mooring concepts, the model was only moored at both ends of the bottom of the screen or bottom of the floater. In general mooring loads were found to be the largest for the low mooring configuration. For this same configuration the mooring loads increment with increasing current velocity was the largest. Mooring load fluctuations seemed to be not strongly influenced by the amount of applied pretension. Vertical screen orientations, which are expected to be beneficial for the plastic capturing efficiency, were mostly observed for the secondary mooring and high mooring configurations. For the low mooring concept the offsets along the flow direction were the largest and the screen was more tilted. Additional ballast for the high mooring concept promoted a more vertical orientation of the screen with as downside increasing mooring loads. Overtopping or bridging (air gap exists below the barrier) negatively impact the plastic capturing efficiency and are important to consider. Both events are most likely to happen for shorter wave conditions and higher current velocities. The number of occurrences of overtopping and bridging was the lowest for the secondary mooring and the high mooring setup with a low pretension. For increasing pretension the number of overtopping and bridging events increased. Copyright 2017 ASME.

Sterne, R. E. and T. H. McCarver (1980). "Formation of sporangia by Phytophthora cryptogea and P. parasitica in artificial and natural soils." Soil Biology & Biochemistry **12**(4): 441-442.

In artificial soils (glass microbeads; 1-500 mu m diameter) Phytophthora cryptogea formed sporangia only when soil extract or nutrient solution were added, while P. parasitica formed sporangia equally well in artificial soils amended with deionised water, soil extract or nutrient solution. In a coarse bead mixture or in a coarse sandy soil, sporangia formation by both species occurred at -5, -10 and -25 kPa matric potential, but not at OkPa. In a fine lead mixture or in a clay loam soil formation of sporangia did not occur at matric potentials above -25 kPa. Inhibition of sporangia formation is attributed to poor aeration.

Stiffel, C., et al. (1990). "Genetics of acute inflammation: Inflammatory reactions in inbred lines of mice and in their interline crosses." Experimental and Clinical Immunogenetics **7**(4): 221-233.

Acute inflammation is induced by the subcutaneous injection of swollen polyacrylamide microbeads, its intensity measured by the cell and protein concentration of the local exudates. A large and continuous range of responses is obtained in different inbred strains of mice, which suggests a polygenic control of the inflammatory response. The variable levels of the global dominance observed in F1 hybrids issued from several parental combinations indicated that the pattern of alleles controlling high or low response was different in each parental strain. Balanced intercrossing of the 8 inbred strains studied has provided a genetically heterogeneous F3 population, presenting a high variability of responses. The value of the genetic part of F3 phenotypic variance, the spread of the interstrain differences, as well as the polygenic nature of the regulation of inflammatory responses pointed out the possibility to perform a bidirectional genetic selection by using the F3 mice as the foundation population, and response to microbeads as the selective phenotypic character.

Stock, C., et al. (2005). "Migration of human melanoma cells depends on extracellular pH and Na+/H+ exchange." Journal of Physiology **567**(Pt 1): 225-238.

Their glycolytic metabolism imposes an increased acid load upon tumour cells. The surplus protons are extruded by the Na+/H+ exchanger (NHE) which causes an extracellular acidification. It is not yet known by what mechanism extracellular pH (pHe) and NHE activity affect tumour cell migration and thus metastasis. We studied the impact of pHe and NHE activity

on the motility of human melanoma (MV3) cells. Cells were seeded on/in collagen I matrices. Migration was monitored employing time lapse video microscopy and then quantified as the movement of the cell centre. Intracellular pH (pHi) was measured fluorometrically. Cell-matrix interactions were tested in cell adhesion assays and by the displacement of microbeads inside a collagen matrix. Migration depended on the integrin alpha2beta1. Cells reached their maximum motility at pHe approximately 7.0. They hardly migrated at pHe 6.6 or 7.5, when NHE was inhibited, or when NHE activity was stimulated by loading cells with propionic acid. These procedures also caused characteristic changes in cell morphology and pHi. The changes in pHi, however, did not account for the changes in morphology and migratory behaviour. Migration and morphology more likely correlate with the strength of cell-matrix interactions. Adhesion was the strongest at pHe 6.6. It weakened at basic pHe, upon NHE inhibition, or upon blockage of the integrin alpha2beta1. We propose that pHe and NHE activity affect migration of human melanoma cells by modulating cell-matrix interactions. Migration is hindered when the interaction is too strong (acidic pHe) or too weak (alkaline pHe or NHE inhibition).

Stock, V., et al. (2019). "Uptake and effects of orally ingested polystyrene microplastic particles in vitro and in vivo." Archives of Toxicology **93**(7): 1817-1833.

Evidence exists that humans are exposed to plastic microparticles via diet. Data on intestinal particle uptake and health-related effects resulting from microplastic exposure are scarce. Aim of the study was to analyze the uptake and effects of microplastic particles in human in vitro systems and in rodents in vivo. The gastrointestinal uptake of microplastics was studied in vitro using the human intestinal epithelial cell line Caco-2 and thereof-derived co-cultures mimicking intestinal M-cells and goblet cells. Different sizes of spherical fluorescent polystyrene (PS) particles (1, 4 and 10 micro m) were used to study particle uptake and transport. A 28-days in vivo feeding study was conducted to analyze transport at the intestinal epithelium and oxidative stress response as a potential consequence of microplastic exposure. Male reporter gene mice were treated three times per week by oral gavage with a mixture of 1 micro m (4.55 x 10⁷ particles), 4 micro m (4.55 x 10⁷ particles) and 10 micro m (1.49 x 10⁶ particles) microplastics at a volume of 10 mL/kg/bw. Effects of particles on macrophage polarization were investigated using the human cell line THP-1 to detect a possible impact on intestinal immune cells. Altogether, the results of the study demonstrate the cellular uptake of a minor fraction of particles. In vivo data show the absence of histologically detectable lesions and inflammatory responses. The particles did not interfere with the differentiation and activation of the human macrophage model. The present results suggest that oral exposure to PS microplastic particles under the chosen experimental conditions does not pose relevant acute health risks to mammals.

Stock, V., et al. (2020). "Impact of artificial digestion on the sizes and shapes of microplastic particles." Food & Chemical Toxicology **135**: 111010.

Current analyses show a widespread occurrence of microplastic particles in food products and raise the question of potential risks to human health. Plastic particles are widely considered to be inert due to their low chemical reactivity and therefore supposed to pose, if at all only minor hazards. However, variable physicochemical conditions during the passage of the gastrointestinal tract gain strong importance, as they may affect particle characteristics. This study aims to analyze the impact of the gastrointestinal passage on the physicochemical particle characteristics of the five most produced and thus environmentally relevant plastic materials polyethylene, polypropylene, polyvinyl chloride, polyethylene terephthalate and polystyrene. Scanning electron microscopy (SEM) and subsequent image analysis were employed to characterize microplastic particles. Our results demonstrate a high resistance of all plastic particles to the artificial digestive juices. The present results underline that the main stages of the human gastrointestinal tract do not decompose the particles. This allows a direct correlation between the physicochemical particle characteristics before and after digestion. Special attention must be paid to the adsorption of organic compounds like proteins, mucins and lipids on plastic particles since it could lead to misinterpretations of particle sizes and shapes.

Stojkovska, J., et al. (2010). "Evaluation of alginate hydrogels under in vivo-like bioreactor conditions for cartilage tissue engineering." Journal of Materials Science: Materials in Medicine **21**(10): 2869-2879.

Alginate hydrogels in forms of discs and packed beds of microbeads (~800 mum) were tested in a novel bioreactor at 10% strain using two regimes: at a loading rate of 337.5 mum/s and at sequential increments of 50 mum displacement every 30 min. Compressive strength increased with the increase in alginate concentration (1.5 vs. 2% w/w) and the content of guluronic residues (38.5 vs. 67%). Packed beds of microbeads exhibited significantly higher (~1.5-3.4 fold) compression moduli than the respective discs indicating the effects of gel form and entrapped water. Short-term cultivation of microbeads with immobilized bovine calf chondrocytes (1.5% w/w, 33 x 10⁶ cells/ml) under biomimetic conditions (dynamic compression: 1 h on/1 h off, 0.42 Hz, 10% strain) resulted in cell proliferation and bed compaction, so that the compression modulus slightly increased. Thus, the novel bioreactor demonstrated advantages in evaluation of biomaterial properties and cell-biomaterial interactions under in vivo-like settings. © 2010 Springer Science+Business Media, LLC.

Stojkovska, J., et al. (2014). "A comprehensive approach to in vitro functional evaluation of Ag/alginate nanocomposite hydrogels." Carbohydrate Polymers **111**: 305-314.

In this work, we present a comprehensive approach to evaluation of alginate microbeads with included silver nanoparticles (AgNPs) at the concentration range of 0.3-5mM for potential biomedical use by combining cytotoxicity, antibacterial activity, and silver release studies. The microbeads were investigated regarding drying and rehydration showing retention of ∼ 80-85% of the initial nanoparticles as determined by UV-vis and SEM analyses. Both wet and dry microbeads were shown to release AgNPs and/or ions inducing similar growth delays of Staphylococcus aureus and Escherichia coli at the total released silver concentrations of ∼ 10 μg/ml. On the other hand, these concentrations were highly toxic for bovine chondrocytes in conventional monolayer cultures while nontoxic when cultured in alginate microbeads under biomimetic conditions in 3D perfusion bioreactors. The applied approach outlined directions for further optimization studies demonstrating Ag/alginate microbeads as potentially attractive components of soft tissue implants as well as antimicrobial wound dressings.

Stojkovska, J., et al. (2019). "Novel nano-composite hydrogels with honey effective against multi-resistant clinical strains of Acinetobacter baumannii and Pseudomonas aeruginosa." Applied Microbiology & Biotechnology **103**(20): 8529-8543.

Novel alginate hydrogels with silver nanoparticles (AgNPs) and honey components were produced with the aim to target multidrug-resistant bacterial strains causing nosocomial wound infections. AgNP synthesis was optimized in highly concentrated honey solutions so that a 5-month stable, colloid solution with 50% of honey and ~ 8 nm AgNPs at neutral pH was obtained. The colloid solution was further used to produce nano-composite Ag/alginate hydrogels in different forms (microbeads, microfibers and discs) that retained all AgNPs and high fractions of honey components (40-60%) as determined by the phenol-sulfuric acid and Folin-Ciocalteu methods. The hydrogels were characterized by UV-Vis spectroscopy and

Fourier-transform infrared-attenuated total reflectance spectroscopy while the antibacterial activity was investigated against a broad spectrum of Gram-negative and Gram-positive bacteria, including 13 multi-resistant clinical strains of Acinetobacter baumannii, one clinical strain of Pseudomonas aeruginosa and one clinical strain of Staphylococcus aureus. At the total released silver concentration of ~ 9 mug/ml, the hydrogels exhibited strong bactericidal activity against standard and most of the investigated multi-resistant hospital strains with the exemption of 3 clinical strains of A. baumannii in which antibacterial effects were absent. These results reveal the need for further in-depth studies of bacterial resistance mechanisms and, in the same time, potentials of the novel Ag/alginate hydrogels with honey components to combat wound infections and enhance healing as non-sticky, antibacterial, and bioactive dressings.

Stokke, B. T. (2017). "Biomarker characterization and development of functional soft materials." Nano Biomedicine and Engineering **9**(4): 275.

Detection and quantification of biomarkers are essential in providing key information of potential hazardous entities or disease states. Analogously, there is increasing interest in miniaturization of technologies suitable for biological assays, environmental monitoring, model systems and other domains, due to need for more efficient analysis processes, sensitivity, possibilities to deploy in point of care settings and reduction of consumables. In the presentation we illustrate application of direct force unbinding for determination of interaction potential of a therapeutic molecule related to treatment of mucus hyperviscosity in patients suffering from Cystic fibrosis. The data show a dosedependent perturbation of the interaction profiles in the presence of oligoguluronates that are under development as an adjuvant. In the second main activity summarized in the presentation, we are using molecular design of hydrogels to transform generic responsive hydrogels to bioresponsive ones. Integrated at the end of an optical fiber interferometer supporting determination of changes in the optical lengths within the hydrogels at 2 nanometer resolution, these functional soft materials are attractive in biosensing. Examples of various implemented recognition schemes will be given. In addition, there is transformation from empirical correlations between molecular parameters of the various constituents and the net swelling response to scrutinize the fundamental, cascading processes and their interrelation. Lastly, an example of microfluidic assisted homogeneous gel bead synthesis will be presented. The microfluidic assisted structuring of soft materials yielded homogeneously sized populations of Ca-alginate gel beads in a biocompatible process supporting immobilization of living entities. The process is based on decoupling of the droplet generation of pregel solution in the microfluidic device and the Ca-induced crosslinking process. A novel strategy for controlling the kinetics of the gelation kinetics of internal Ca-source for the alginate gelation was developed. The micro devices thus support encapsulation of cells in alginate microbeads and fibers in a clog-free and cell friendly microfluidic operation. Copyright © Bjorn Torger Stokke.

Stoler, J. (2012). "Improved but unsustainable: accounting for sachet water in post-2015 goals for global safe water." Tropical Medicine & International Health **17**(12): 1506-1508.

The advent and rapid spread of sachet drinking water in West Africa presents a new challenge for providing sustainable access to global safe water. Sachet water has expanded drinking water access and is often of sufficient quality to serve as an improved water source for Millennium Development Goals (MDG) monitoring purposes, yet sachets are an unsustainable water delivery vehicle due to their overwhelming plastic waste burden. Monitoring of primary drinking water sources in West Africa generally ignores sachet water, despite its growing ubiquity. Sub-Saharan Africa as a region is unlikely to meet the MDG Target for drinking water provision, and post-2015 monitoring activities may depend upon rapid adaptability to local drinking water trends.

Stolte, A., et al. (2015). "Microplastic concentrations in beach sediments along the German Baltic coast." Marine Pollution Bulletin **99**(1-2): 216-229.
The contamination with microplastic particles and fibres was evaluated on beaches along the German Baltic coast. Sediments were sampled near the Warnow and Oder/Peene estuaries, on Rugen island and along the Rostock coast to derive possible entry pathways. Seasonal variations were monitored along the Rostock coast from March to July 2014. After density separation in saline solution, floating particles were found to be dominated by sand grains. Water surface tension is shown to be sufficient to explain floatation of grains with sizes less than 1.5mm. Selecting intensely coloured particles and fibres, we find lower limits of the microplastic concentrations of 0-7 particles/kg and 2-11 fibres/kg dry sediment. The largest microplastic contaminations are measured at the Peene outlet into the Baltic Sea and in the North Sea Jade Bay. City discharges, industrial production sites, fishing activity and tourism are the most likely sources for the highest microplastic concentrations.

Stoner, M. A., et al. (2014). "A robotic BG1Luc reporter assay to detect estrogen receptor agonists." Toxicology in Vitro **28**(5): 916-925.
Endocrine disrupting chemicals with estrogenic activity (EA) have been associated with various adverse health effects. US agencies (ICCVAM/NICEATM) tasked to assess in vitro transcription activation assays to detect estrogenic receptor (ER) agonists for EA have recently validated a BG1Luc assay in manual format, but prefer robotic formats. We have developed a robotic BG1Luc EA assay to detect EA that demonstrated 100% concordance with ICCVAM meta-analyses and ICCVAM BG1Luc results in manual format for 27 ICCVAM test substances, i.e. no false negatives or false positives. This robotic assay also consistently assessed other, more problematic ICCVAM test substances such as clomiphene citrate, L-thyroxin, and tamoxifen. Agonist responses using this robotic BG1Luc assay were consistently inhibited by the ER antagonist ICI 182,780, confirming that agonist responses were due to binding to ERs rather than to a non-specific agonist response. This robotic assay also detected EA in complex mixtures of substances such as extracts of personal care products, plastic resins or plastic consumer products. This robotic BG1Luc assay had at least as high accuracy and greater sensitivity and repeatability when compared to its manual version or to the other ICCVAM/OECD validated assays for EA (manual BG1Luc and CERI). © 2014 Elsevier Ltd.

Storz, I., et al. (2016). "Therapeutic potential of GPR64 specific CAR T cells in pediatric sarcomas." Cancer Immunology Research. Conference: AACR Special Conference on Tumor Immunology and Immunotherapy **5**(3 Supplement 1).
Ewing Sarcoma (ES) is the second most common bone malignancy in children and young adolescents with a high potential of dissemination into lung and bones. Patients with localized disease receiving current treatment, have an approximate long-term survival of >65%. Patients with disseminated disease into the bone have an approximate longterm survival rate of only 10%, compelling the search for new therapeutic treatment modalities like engineered T cell therapy. Here the therapeutic potential of chimeric antigen receptor (CAR) transgenic T cells directed against G-protein coupled receptor 64 (GPR64), an orphan receptor with normal expression restricted to human epididymis and significant overexpression in ES, was examined. Therefore, two different monoclonal antibodies (mAb) directed against the extracellular region of GPR64 were generated and characterized. Subsequently, retroviral constructs containing

second generation CARs together with the scFv fragments of the respective mAbs were designed. Primary lymphocytes were transduced and tested in vitro via flow cytometry, ELISpot and xCelligence assay. Antibodies specifically stained ES cells as determined by flow cytometry. The signal intensity was reduced after RNAi mediated down-regulation of GPR64 in ES cell lines confirming specificity of mAbs. Following sequence determination of those mAbs two different CAR constructs were designed. Retroviruses containing such CARs transduced primary lymphocytes with good efficiency. The CAR transgenic T cells could be enriched for CD8+CAR+ cells via microbead isolation and showed strong proliferative capacities in vitro. Furthermore, target structures were specifically recognized as determined by ELISpot and xCelligence assays. CAR transgenic T cells targeting GPR64 show a promising approach to transfer the success of CARs in hematological malignancies to solid tumors. The cells generated in this study show strong specificity towards GPR64 and are able to control tumor cell growth in vitro. Since GPR64 expression is not restricted to ES but also up-regulated in a number of carcinomas derived from prostate, kidney or lung, GPR64-specific CARs may also be a future treatment option for other tumor entities.

Storz, M. A. (2018). "A Practical Guide for Physicians and Health Care Workers to Reduce Their Carbon Footprint in Daily Clinical Work." Permanente Journal **22**(03): 12.

With Earth Overshoot Day having recently passed, there is no space for complacency regarding taking care of our planet. On August 2, 2017, humanity used nature's resource budget for the entire year. For decades, we have lived far beyond our means by overexploiting natural resources and spewing pollution, such as microplastics and industrial chemicals, into our environment. On the other hand, public awareness of human-induced climate change has also increased since the 1980s. The frequent media coverage about extreme weather conditions and natural disasters, such as Hurricane Irma in 2017, serves as an important reminder that anthropogenic climate change is happening now.Adverse health conditions associated with climate change include an increased prevalence of diseases and disorders. Although we all contribute to this development, as physicians we also have the privileged duty to protect global human health. Therefore, we should make every effort to cut down our own carbon footprint and adapt a more sustainable lifestyle.The aim of this commentary is to provide feasible tips and strategies to effectively reduce one's individual carbon footprint, with a special focus on daily clinical and hospital work. Not only are these strategies easy to implement in daily clinical routine, but most of them are associated with important health benefits.

Stoven, K., et al. (2015). "Microplastic: a selfmade environmental problem in the plastic age." Journal fur Kulturpflanzen **67**(7): 241-250.

Microplastic is weathered mainly mineral oil based synthetic polymer (<5 mm) called as plastic. The environmentalpollution with plastic starts with particles in micro m-size. The multitude of plastic products is toxic andinert, unable to microbial degradation they remaindecades and centuries in the environment. Plastic productsare solely defragmented by wind and sunlight. Microplasticsocialized usually with persistent organic pollutions (POPs) as Phenanthren and DDT are ingested by organisms mistakable as food in fresh and marine water.By this way pollution enters the foodweb. Effects ofmicroplastic are investigated superiorly in marine biosphere than for limbic and terrestrial habitats. Up to now standardized research methods to characterize miroplasticwaste are lacking. Also in legislature the keyword "microplastic" is not considered. Plastic products areresident in agri- and horticulture for a long time as agrofoil and styromull. The distribution and disposition of microplastic in soil is unexplored so far.

Strady, E., et al. (2020). "Temporal dynamic of anthropogenic fibers in a tropical river-estuarine system." Environmental Pollution **259 (no pagination)**(113897).

Anthropogenic fibers, gathering synthetic fibers, artificial fibers and natural fibers are ubiquitous in the natural environment. Tremendous concentrations of anthropogenic fibers were previously measured in the tropical Saigon River (Vietnam), i.e. a river impacted by textile and apparel industries. In the present study, we want to examine the role of contrasted seasonal variation (e.g., dry and rainy seasons), via the rainfall and monthly water discharges, and of water's physico-chemical conditions on the concentrations of anthropogenic fibers in the surface water. The one year and half monthly survey evidenced that concentrations of anthropogenic fibers varied from 22 to 251 items L⁻¹ and their variations were not related to rainfall, water discharge or abiotic factors. However, their color and length distribution varied monthly suggesting variations in sources and sinks. Based on the 2017 survey, we estimated an annual emission of anthropogenic fibers from the river to the downstream coastal zone of 115-164 x 10¹² items yr⁻¹. Anthropogenic fibers in the Saigon River varied from 22 to 251 items L⁻¹ over eighteen months and their variations were not related to rainfall, water discharge or abiotic factors. Strasdat, B. and H. Bunjes (2015). "Development of a new approach to investigating the drug transfer from colloidal carrier systems applying lipid nanosuspension-containing alginate microbeads as acceptor." International Journal of Pharmaceutics **489**(1-2): 203-209.

Abstract As a new approach to analyzing the release behavior of lipophilic drugs from colloidal carriers, solid trimyristin nanoparticles were incorporated into differently sized (34-1363 mum) calcium alginate hydrogel microbeads to serve as acceptor in release studies. The microbeads were prepared by electrostatic droplet generation or by a spraying method. Trimyristin nanoemulsion samples loaded with the fluorescent drug model Nile red were mixed with the nanoparticle-containing microbeads to perform transfer studies. As a result of a rather large diffusion barrier a slow transfer (24-57 min) was observed using large acceptor beads (~330-1360 mum). In contrast, Nile red transferred quickly (~1.4 min) into smaller microbeads (<50 mum). This new experimental approach applying nanoparticle-containing hydrogel particles with a size below 50 mum as acceptor systems is a promising technique to investigate the release of lipophilic substances from lipid nanoparticles under close to realistic conditions. However, there is still room for technical improvement, e.g., with regard to the water loss from microbeads that was observed during sampling by centrifugation and filtration (required to separate the small sized alginate particles) which is expected to have had some effect on the dye content determined during these experiments. Copyright © 2015 Elsevier B.V.

Straub, S., et al. (2017). "Biodegradable and petroleum-based microplastics do not differ in their ingestion and excretion but in their biological effects in a freshwater invertebrate Gammarus fossarum." International Journal of Environmental Research and Public Health **14**(7).

Research on the uptake and effects of bioplastics by aquatic organisms is still in its infancy. Here, we aim to advance the field by comparing uptake and effects of microplastic particles (MPP) of a biodegradable bioMPP (polyhydroxybutyrate (PHB)) and petroleum-based MPP (polymethylmethacrylate (PMMA)) in the freshwater amphipod Gammarus fossarum. Ingestion of both MPP in different particle sizes (32-250 micro m) occurred after 24 h, with highest ingestion of particles in the range 32-63 micro m and almost complete egestion after 64 h. A four-week effect-experiment showed a significant decrease of the assimilation efficiency in amphipods exposed to the petroleum-based MPP from week two onwards. The petroleum-based PMMA affected assimilation efficiency significantly in contrast to the biodegradable PHB, but overall differences in direct comparison of MPP types were small. Both MPP types led to a significantly lower wet weight gain relative to the control treatments. After four weeks, differences between both MPP types and silica, used as a natural particle control, were detected. In summary, these results suggest that both MPP types provoke digestive constraints on the amphipods, which go beyond those of natural non-palatable particles. This highlights the need for more detailed research comparing environmental effects of biodegradable and petroleum-based MPP and testing those against naturally occurring particle loads.

Strifling, D. A. (2016). "THE MICROBEAD-FREE WATERS ACT OF 2015: MODEL FOR FUTURE ENVIRONMENTAL LEGISLATION, OR BLACK SWAN?" Journal of Land Use & Environmental Law **32**(1): 151-166.

Environmental law scholars have long lamented that it has become unthinkable--or at least exceedingly unlikely--for Congress to pass significant new environmental legislation. This is not uniformly the case, as shown by the recent enactment of Public Law 114-114, the Microbead-Free Waters Act of 2015 ("the Act"). Yet, more nuanced questions must be answered before the Act can be hailed as an important break in the legislative logjam. Was the Act insignificant, simply not worth the time and political currency necessary for opponents of environmental regulation to stop? Was it the fortuitous product of a unique confluence of circumstances, a "black swan"? Or could the circumstances surrounding its passage be instructive for future proponents of environmental legislation? This article asserts that the Act addressed a significant environmental issue, and that the strategic building blocks underlying the Act -- including an emphasis on public health issues and broad stakeholder support driven by industry concerns about unfair competition and opposition to local legislation--may provide innovative and useful foundations for future efforts to pass environmental legislation. Strong, B. (2018). "Plastic pollution and dentistry." Dental Nursing **14**(9): 428-429.

Dental nurse Bethan Strong considers the case for raising awareness

Strungaru, S. A., et al. (2019). "Micro- (nano) plastics in freshwater ecosystems: Abundance, toxicological impact and quantification methodology." TrAC - Trends in Analytical Chemistry **110**: 116-128.

Plastics entering the environment will persist and continue to degrade and fragment to smaller particles under the action of various environmental factors. These microplastics (MP) and nanoplastics (NP) are likely to pose a higher environmental impact, as well as they are more prone to adsorb organic contaminants and pathogens from the surrounding media, due to their higher surface area to volume ratio. Little known on their characteristics, fragmentation, distribution and impact on freshwater ecosystems. In order to respond to these open questions concerning the plastic particles dynamics and their environmental effects, detailed sampling strategies as well as an automated, rapid, cheap and reliable analytical technique suitable for routine analysis need to be developed. The review outlines the recent advances made on examination of the potential toxicological effects of MP and NP on freshwater biota, as well as the available analytical methods employed to identify and quantify them in environmental samples. Su, F. Y., et al. (2007). "Simple and sensitive bacterial quantification by a flow-based kinetic exclusion fluorescence immunoassay." Biosensors & Bioelectronics **22**(11): 2500-2507.

A flow-based immunoassay system utilizing secondary-antibody coated microbeads and Cy5-secondary antibody for signal production was successfully developed to quantitate target bacteria with a kinetic exclusion assay (KinExA 3000 Instrument). It directly measured the concentration of unliganded antibody separated from the equilibrated mixture of antibody and bacteria through a 0.2 microm polyethersulfone membrane, enabling it to quantify the concentration of bacteria. The novel method demonstrated the qualities of rapidness, sensitivity, high accuracy and reproducibility, and ease to perform. Detection of Pseudomonas aeruginosa and Staphylococcus aureus was accomplished with low detection limits of 4.10 x 10(6) and 5.20 x l0(4)cells/mL, respectively, with an assay time of less than 15 min. The working ranges for quantification were 4.10 x l0(6) to 1.64 x l0(10)cells/mL for P. aeruginosa, and 5.20 x l0(4) to 1.04 x l0(9)cells/mL for S. aureus. It yielded an assay with at least 10-fold greater sensitivity than ELISA and could correctly assess the concentration of predominant bacterium spiked in the mixture of P. aeruginosa and S. aureus. With this reliable platform, the average amount of antibody bound by one cell in the maximum capability could be further provided: (1.6-2.5) x l0(5) antibodies for one P. aeruginosa cell and (2.2-2.7) x l0(8) antibodies for one S. aureus cell. The KinExA system is flexible to determine different kinds of bacteria conveniently by using anti-mouse IgG as the same immobilizing agent. However, a higher specificity of the antibodies to the target bacteria will be required for the use of this system with higher detection sensitivity.

Su, L., et al. (2018). "Using the Asian clam as an indicator of microplastic pollution in freshwater ecosystems." Environmental Pollution **234**: 347-355.

Bioindicators play an important role in understanding pollution levels, bioavailability and the ecological risks of contaminants. Several bioindicators have been suggested for understanding microplastic in the marine environment. A bioindicator for microplastics in the freshwater environment does not exist. In our previous studies, we found a high frequency of microplastic pollution in the Asian clam (Corbicula fluminea) in Taihu Lake, China. In the present study, we conducted a large-scale survey of microplastic pollution in Asian clams, water and sediment from 21 sites in the Middle-Lower Yangtze River Basin from August to October of 2016. The Asian clam was available in all sites, which included diverse freshwater systems such as lakes, rivers and estuaries. Microplastics were found at concentrations ranging from 0.3-4.9 items/g (or 0.4-5.0 items/individual) in clams, 0.5-3.1 items/L in water and 15-160 items/kg in sediment. Microfibers were the most dominant types of microplastics found, accounting for 60-100% in clams across all sampling sites. The size of microplastics ranged from 0.021-4.83 mm, and microplastics in the range of 0.25-1 mm were dominant. The abundance, size distribution and color patterns of microplastics in clams more closely resembled those in sediment than in water. Because microplastic pollution in the Asian clam reflected the variability of microplastic pollution in the freshwater environments, we demonstrated the Asian clam as an bioindicator of microplastic pollution in freshwater systems, particularly for sediments.

Su, L., et al. (2019). "The occurrence of microplastic in specific organs in commercially caught fishes from coast and estuary area of east China." Journal of Hazardous Materials **365**: 716-724.

It is important to understand where microplastics go in the body of organisms. They can readily affect target organs and transport microplastic-associated chemicals to humans via consumption. The plastics (>20 mum) in guts and gills of 13 species of fishes from coast estuary areas of China were examined for the presence of microplastics. Muscle and liver were analyzed from a commercial species, the Asian seabass (Lateolabrax maculatus), of which 73% of the suspected items were verified by micro-Fourier Transform Infrared Spectroscopy. We targeted the organ specific distribution of microplastics. Microplastics were detected in gut and gills in 22%-100% and 22%-89% of total individuals, respectively. Microplastics in gut varied from 0.3 to 5.3 items/ind. and varied from 0.3 to 2.6 items/ind in gill, respectively. The size of microplastics in gills were smaller than those found in the guts. No microplastics were detected in the liver or muscle tissue of L. maculatus, and several non-plastic items detected in muscles can be attributed to background contamination. Further research is required using a larger number of specimens and better quality control and quality assurance are required to assess the presence of small microplastics or nanoplastics in fishes internal organs and muscle.

Su, L., et al. (2019). "Microplastics biomonitoring in Australian urban wetlands using a common noxious fish (Gambusia holbrooki)." Chemosphere **228**: 65-74.

Biomonitoring microplastics in freshwater ecosystems has been insufficient in comparison with its practice in marine environments. It is an important first step to understand microplastic uptake in organisms when assessing risk in natural freshwater habitats. We conducted microplastic biomonitoring within the Greater Melbourne Area; where the microplastic baseline pollution in freshwater organisms was largely unknown. A common noxious fish species, Gambusia holbrooki, was targeted. Individuals (n=180) from nine wetlands were analyzed. Uptake pathway, size, weight and gender were examined in relation to microplastic uptake in the body (presumed uptake via gut) and head (presumed uptake via gills). On average, 19.4% of fish had microplastics present in their bodies with an abundance of 0.6 items per individual (items/ind) and 7.2% of fish had microplastics in their heads with an abundance of 0.1 items/ind. Polyester was the dominant plastic type and fibers were the most common shape. The amount of microplastics in Gambusia holbrooki in current study is relatively low in a global comparison. The bodies of fish contained more microplastics on average than heads, and the size of microplastics detected in heads were smaller than those found in bodies. Microplastic uptake was directly proportional to size and weight. Furthermore, female individuals showed a tendency to ingest more microplastics than males. Laboratory experiments under controlled conditions are suggested to further explore such relationships. Our findings are important to understanding the potential ecological risks posed by microplastics to organisms in freshwater environments and provide suitable methodologies to conduct biomonitoring in future investigations.

Su, L., et al. (2016). "Microplastics in Taihu Lake, China." Environmental Pollution **216**: 711-719.

In comparison with marine environments, the occurrence of microplastics in freshwater environments is less understood. In the present study, we investigated microplastic pollution levels during 2015 in Taihu Lake, the third largest Chinese lake located in one of the most developed areas of China. The abundance of microplastics reached 0.01x10⁶-6.8x10⁶ items/km² in plankton net samples, 3.4-25.8 items/L in surface water, 11.0-234.6 items/kg dw in sediments and 0.2-12.5 items/g ww in Asian clams (Corbicula fluminea). The average abundance of microplastics was the highest in plankton net samples from the southeast area of the lake and in the sediments from the northwest area of the lake. The northwest area of the lake was the most heavily contaminated

area of the lake, as indicated by chlorophyll- alpha and total phosphorus. The microplastics were dominated by fiber, 100-1000 micro m in size and cellophane in composition. To our best knowledge, the microplastic levels measured in plankton net samples collected from Taihu Lake were the highest found in freshwater lakes worldwide. The ratio of the microplastics in clams to each sediment sample ranged from 38 to 3810 and was negatively correlated to the microplastic level in sediments. In brief, our results strongly suggest that high levels of microplastics occurred not only in water but also in organisms in Taihu Lake.

Su, Y., et al. (2013). "Adenovirus conducted connective tissue growth factor on extracellular matrix in trabecular meshwork and its role on aqueous humor outflow facility." Molecular Biology Reports **40**(11): 6091-6096.

Deposition of extracellular matrix (ECM) in trabecular meshwork, such as fibronectin, collagen IV, elastin. leads to increased resistance of trabecular meshwork in primary open angle glaucoma (POAG). Connective tissue growth factor (CTGF) is known to regulate the ECM deposits. In this study, we detect the effect of adenovirus conducted CTGF (Adv-CTGF) transfection on either the expression of ECM components or aqueous humor outflow facility. Adv-CTGF was used to transfect rat trabecular meshwork cells in vivo and in vitro. Aqueous humor outflow facility was test by microbeads perfusion. Protein expression of CTGF, fibronectin, and collagen IV was determined using Western blot. In the Adv-CTGF group, the outflow facility displayed a significant decrease from baseline. It appears as though the transfection with Adv-CTGF significantly affects the aqueous humor outflow pattern. A negative correlation between IOP and PEFL indicated that a decrease in the area of bead deposition corresponded to an overall decrease of outflow, leading to an elevated IOP. Adv-CTGF can enhance the expression of CTGF, fibronectin and collagen IV. CTGF is the novel target for treatment of POAG. It is necessary to further study to test inhibition of CTGF expression for treatment of POAG.

Su, Y., et al. (2019). "Microplastic exposure represses the growth of endosymbiotic dinoflagellate Cladocopium goreaui in culture through affecting its apoptosis and metabolism." Chemosphere **244**: 125485.

Microplastics are widespread emerging marine pollutants that have been found in the coral reef ecosystem. In the present study, using Cladocopium goreaui as a symbiont representative, we investigated cytological, physiological, and molecular responses of a Symbiodiniaceae species to weeklong microplastic exposure (Polystyrene, diameter 1.0 mum, 9.0 x 10⁹ particles L⁻¹). The density and size of algal cells decreased significantly at 7 d and 6-7 d of microplastic exposure, respectively. Chlorophyll a content increased significantly at 7 d of exposure, whereas Fv/Fm did not change significantly during the entire exposure period. We observed significant increases in superoxide dismutase activity and caspase3 activation level, significant decrease in glutathione S-transferase activity, but no change in catalase activity during the whole exposure period. Transcriptomic analysis revealed 191 significantly upregulated and 71 significantly downregulated genes at 7 d after microplastic exposure. Fifteen GO terms were overrepresented for these significantly upregulated genes, which were grouped into four categories including transmembrane ion transport, substrate-specific transmembrane transporter activity, calcium ion binding, and calcium-dependent cysteine-type endopeptidase activity. Thirteen of the significantly upregulated genes encode metal ion transporter and ammonium transporter, and five light-harvesting protein genes were among the significantly downregulated genes. These results demonstrate that microplastics can act as an exogenous stressor, suppress detoxification activity, nutrient uptake, and photosynthesis, elevate oxidative

stress, and raise the apoptosis level through upregulating ion transport and apoptotic enzymes to repress the growth of C. goreaui. These effects have implications in negative impacts of microplastics on coral-Symbiodiniaceae symbiosis that involves C. goreaui.

Su, Y., et al. (2019). "Occurrence of microplastics in landfill systems and their fate with landfill age." Water Research **164**: 114968.

Microplastics (MPs) are emerging pollutants that have been extensively detected in marine and terrestrial environments. Landfills are receptacles for cumulative loading of plastic waste derived from industry and households, but data on MPs occurrences in landfill systems are lacking. In the current study, the occurrence, characteristics and distribution patterns of MPs in landfills (including leachate and refuse) of the megacity Shanghai were investigated in accordance with different landfill ages (3-20 years). The results revealed that the average abundances of MPs in leachate and refuse were 8 (±3) items/L and 62 (±23) items/g, respectively. The predominant shapes and polymer types of the detected MPs were fibers and cellophane in leachate, whereas they were fragments and polyethylene in refuse. The patterns of abundance and size distribution of MPs in refuse varied from different landfill age, and different polymer MPs exhibited various occurrence patterns with increasing landfill age. Further spectra analysis suggested the presence of oxidative degradation of polyethylene MPs in the landfill process, especially for the landfill time of more than 20 years, so the fates of MPs in landfills were determined by the increase consumptions of plastics products and the degradation process of MPs in landfills. This study firstly provided a systematic overview of MPs pollution characteristics in landfill systems, and the results will foster the understanding of MPs fates over a long time scale in the environments.

Su, Y., et al. (2020). "Microplastic exposure represses the growth of endosymbiotic dinoflagellate Cladocopium goreaui in culture through affecting its apoptosis and metabolism." Chemosphere **244**.

Microplastics are widespread emerging marine pollutants that have been found in the coral reef ecosystem. In the present study, using Cladocopium goreaui as a symbiont representative, we investigated cytological, physiological, and molecular responses of a Symbiodiniaceae species to weeklong microplastic exposure (Polystyrene, diameter 1.0 μm, 9.0 × 109 particles L−1). The density and size of algal cells decreased significantly at 7 d and 6–7 d of microplastic exposure, respectively. Chlorophyll a content increased significantly at 7 d of exposure, whereas Fv/Fm did not change significantly during the entire exposure period. We observed significant increases in superoxide dismutase activity and caspase3 activation level, significant decrease in glutathione S-transferase activity, but no change in catalase activity during the whole exposure period. Transcriptomic analysis revealed 191 significantly upregulated and 71 significantly downregulated genes at 7 d after microplastic exposure. Fifteen GO terms were overrepresented for these significantly upregulated genes, which were grouped into four categories including transmembrane ion transport, substrate-specific transmembrane transporter activity, calcium ion binding, and calcium-dependent cysteine-type endopeptidase activity. Thirteen of the significantly upregulated genes encode metal ion transporter and ammonium transporter, and five light-harvesting protein genes were among the significantly downregulated genes. These results demonstrate that microplastics can act as an exogenous stressor, suppress detoxification activity, nutrient uptake, and photosynthesis, elevate oxidative stress, and raise the apoptosis level through upregulating ion transport and apoptotic enzymes to repress the growth of C. goreaui. These effects have implications in negative impacts of microplastics on coral-Symbiodiniaceae symbiosis that involves C. goreaui.

Subash, R., et al. (2018). "Transport and fate of microplastics in wastewater treatment plants: implications to environmental health." Reviews in Environmental Science and Bio/Technology **17**(4): 637-653.

Global studies of microplastic (MP) pollution confirm wastewater treatment plants serve as pathways for microplastics entering terrestrial and aquatic ecosystems. The behaviour, transport and fate of microplastics in wastewater effluents remain mostly unknown, rendering wastewater-derived microplastics as a contaminant of significant concern. We critically examine the literature to understand the sources and fate of microplastics in wastewater treatment plants (WWTPs) and the implications of treated effluents admitted to soil and aquatic systems. The transport of chemical and biological contaminants is also discussed in detail, using fundamental principles of vector relationships. For the removal and reduction of microplastics, profound knowledge is required from source to solution. This review presents a comprehensive overview of the significance of microplastics as a vector of water-borne contaminants in WWTPs.

Subba-Rao, R. V. and M. Alexander (1982). "Effect of Sorption on Mineralization of Low Concentrations of Aromatic Compounds in Lake Water Samples." Applied and Environmental Microbiology Vol 44, No 3, p 659-668, September, 1982. 5 Fig, 4 Tab, 22 Ref.

The influence of montmorillonite, kaolinite, and glass microbeads on the mineralization of low concentrations of organic compounds in samples from a eutrophic lake was examined. Montmorillonite/benzylamine complexes were formed immediately on addition of amine to suspensions containing the clay. The extent of amine sorbed was a linear function of equilibrium amine concentration in lake water. A larger percentage of the chemical was released from the complex during mineralization in the presence of high clay concentrations than in the presence of low clay concentrations. Montmorillonite did not enhance mineralization rates at amine levels of 200 ng/ml or lower, but it was stimulatory at 20 micrograms/ml. Except at high amine and clay concentrations, mineralization was more rapid than desorption during the early periods of decomposition when the amine concentration in solution was relatively high. Relative to the microbial demand, desorption was more rapid during later periods of decompositon when the amine level in solution was very low. Mineralization of benzoate was not usually affected by montmorillonite, kaolinite, or glass beads. More than 90% of the carbon from benzylamine and benzoate was often mineralized when the substrate concentration was 250 ng/ml or less. The data suggest that clay may have a significant effect on the microbial decomposition of low concentrations of certain organic compounds. (Baker-FRC)

Sugana Rani, K. and P. V. V. Prasada Rao (2012). "Evaluation of biodegradation of plastics and polythene bags from various soils." Journal of Pure and Applied Microbiology **6**(1): 281-287.

Plastic pollution has emerged as one of the most challenging problems of the mankind, and can be satisfactorily addressed through Biodegradation. The present study is an attempt to explore the bio degradation of plastic cups and polythene bags (carry bags) using mangrove soils, petroleum soil, and molasses soil. Plastic cups and polythene bags were incubated for a period of 2,4,6,9, months in various soils using microbes like Pseudomonas species, Staphylococcus, Aspergillus niger and Aspergillus glaucus. Degradation of plastics was determined by the weight loss of the sample and bacterial activity in soil. The microbial counts were recorded as 45.68xlu³/g for total bacteria and 33.33x10²/g for fungi in mangrove soil, 26.70x10³/g for total bacteria and 20.22x10²/g for fungi in petroleum soil, and 23.49x10³/g for total bacteria and 22.33x10²/g for fungi in molasses soil, The present work reveals that the above soils have the potential to degrade plastic cups and polythene bags among which Mangrove soil has the high degradability rate.

Sugawara, K., et al. (2009). "Electrochemical monitoring of binding between wheat germ agglutinin and cellohexose-modified magnetic microbeads." Analytical & Bioanalytical Chemistry **395**(3): 767-772.

An electrochemical method that uses glucose labeled with an electroactive compound was developed to evaluate the binding of wheat germ agglutinin (WGA) to cellohexose-modified magnetic microbeads. Cellohexose was attached to amino groups on the magnetic bead surface via formation of a Schiff's base. The labeled glucose acts as an electrochemical probe to monitor binding events between WGA and the cellohexose-modified beads. For a known quantity of cellohexose-modified beads, binding of WGA with cellohexose-modified beads was evaluated based on changes in electrochemical response of the labeled glucose. In particular, the peak current decreased as the concentration of WGA increased. Furthermore, the binding affinities of WGA for beads modified with four different cello-oligosaccharides were systematically compared using a voltammetric method.

Sugaya, S., et al. (2013). "Microfluidic production of single micrometer-sized hydrogel beads utilizing droplet dissolution in a polar solvent." Biomicrofluidics **7**(5): 54120.

In this study, a microfluidic process is proposed for preparing monodisperse micrometer-sized hydrogel beads. This process utilizes non-equilibrium aqueous droplets formed in a polar organic solvent. The water-in-oil droplets of the hydrogel precursor rapidly shrunk owing to the dissolution of water molecules into the continuous phase. The shrunken and condensed droplets were then gelled, resulting in the formation of hydrogel microbeads with sizes significantly smaller than the initial droplet size. This study employed methyl acetate as the polar organic solvent, which can dissolve water at 8%. Two types of monodisperse hydrogel beads-Ca-alginate and chitosan-with sizes of 6-10 mum (coefficient of variation < 6%) were successfully produced. In addition, we obtained hydrogel beads with non-spherical morphologies by controlling the degree of droplet shrinkage at the time of gelation and by adjusting the concentration of the gelation agent. Furthermore, the encapsulation and concentration of DNA molecules within the hydrogel beads were demonstrated. The process presented in this study has great potential to produce small and highly concentrated hydrogel beads that are difficult to obtain by using conventional microfluidic processes.

Sugimoto, Y., et al. (2012). "A novel FOXP1-PDGFRA fusion gene in a case of chronic eosinophilic leukemia." Blood. Conference: 54th Annual Meeting of the American Society of Hematology, ASH **120**(21).

Introduction: Myeloid and lymphoid neoplasms with eosinophilia and abnormalities of PDGFRA, PDGFRB, or FGFR1 is a new major category in the 2008 WHO classification of myeloid malignancies. FIP1L1-PDGFRA fusion gene is currently the most common abnormality in this category, but there are some other fusion genes incorporating part of PDGFRA. In a case of myeloproliferative neoplasms (MPN) with eosinophilia and hepatosplenomegaly, karyotype by G-banding and fluorescence in situ hybridization (FISH) for 4q12 rearrangements indicated a PDGFRA rearrangement other than FIP1L1-PDGFRA, and a novel FOXP1-PDGFRA fusion gene was identified. Case presentation: A 44-year-old male visited a clinic because of wet cough for one year. His peripheral blood showed leukocytosis of 43.15 x 109 /L with eosinophilia up to 57.5%, mild erythrocytosis (Hb 17.3 g/dL), and thrombocytopenia of 86 x 109 /L. CT scan of the abdomen revealed hepatosplenomegaly. He was referred to our hospital and received oral PSL (1 mg/kg) first, because pulmonary eosinophilic infiltration was suspected by follow-up CT

findings. Pulmonary infiltration and his cough disappeared rapidly in a week, but his leukocytosis with eosinophilia was exacerbated again with PSL tapering. His bone marrow at the time of admission disclosed hypercellular marrow with myeloid hyperplasia and eosinophilia, of which karyotype was 46, XY, t(3:4)(p13;q12), inv(9)(p12q13) in all of 20 metaphases. FISH analysis with tricolor 4q12 rearrangement probe set indicated that PDGFRA was disrupted in 97.3% of his peripheral blood cells. These cytogenetic abnormalities of his bone marrow cells suggested involvement of PDGFRA fusion gene except for FIP1L1-PDGFRA and did not disappear after steroid administration for 2 weeks. After low-dose of imatinib (100 mg/day) was started, he achieved a hematological response within 5 days, and PSL could be gradually tapered off. 3 months after therapy, he obtained complete cytogenetic response (CCyR). He has been in CCyR and free of symptoms for more than 6 months with only low-dose imatinib. Methods and Results: Genomic DNA and total RNA were isolated from white blood cells in his peripheral blood at diagnosis. Complementary DNA was synthesized from total RNA. FIP1L1-PDGFRA fusion transcript was proved to be negative by RT-PCR. Molecular cloning with 5'-RACE-PCR revealed a novel mRNA in-frame fusion between exon 23 of FOXP1 and a truncated PDGFRA exon12. Reciprocal PDGFRA-FOXP1 transcripts were confirmed by RT-PCR analysis and FOXP1-PDGFRA genomic DNA sequence was determined with genomic PCR. As in the case with FIP1L1-PDGFRA, the breakpoint of PDGFRA in FOXP1-PDGFRA was located between the two tryptophan (W) residues of the putative WW-domain. Meanwhile, the other breakpoint was near inverted repeat in intron 23 of FOXP1, which is presumed to be very fragile site. By FISH analysis after magnetic cell sorting with MicroBeads, the 4q12 abnormality attributed to FOXP1-PDGFRA fusion gene was detected in granulocytes, but not in CD19-positive B or CD3-positive T cells. Discussion(s): In a case with chronic eosinophilia harboring 46, XY, t(3:4)(p13;q12), inv(9)(p12q13), novel FOXP1-PDGFRA fusion gene was identified. Similar karyotypic abnormality harboring t(3:4)(p13;q12) was reported in a case of MPN with chronic eosinophilia, but responsible fusion gene was not identified (Myint H, et al. Br J Haematol. 1995). FOXP1 is a transcription factor which is implicated in a variety of cellular processes and has a role in immune regulation and carcinogenesis (Wlodarska I, et al. Leukemia. 2005). As a fusion partner of FOXP1, PAX5 and ABL1 are reported in cases with acute lymphoblastic leukemia. Thus, this is a first report showing that FOXP1-PDGFRA fusion gene is involved in hematologic malignancy. It is likely that FOXP1-PDGFRA is constitutively activated tyrosine kinase, which does not depend on dimerization but on the disruption of an autoinhibitory juxtamembrane domain encoded by exon 12 of PDGFRA from its structure. Eosinophilia responded well to low dose of imatinib as observed in CEL with FIP1L1-PDGFRA. Conclusion(s): FOXP1-PDGFRA was identified in CEL for the first time. This is the eighth reported fusion gene associated with PDGFRA in CEL so far. Our patient with FOXP1-PDGFRA promptly responded to low-dose of imatinib as same as other cases with PDGFRA abnormalities. Further investigation is still in progress.

Suh, S. P., et al. (2013). "Whole blood cytokine profiles for improved diagnosis of tuberculosis and discrimination between active and latent tuberculosis." Clinical Chemistry **1)**: A72.

Background: Interferon gamma release assay (IGRA) cannot discriminate between active and latent tuberculosis (TB). In addition, IGRA show relatively low sensitivity in patients with active TB. To determine if cytokine profiles could discriminate between active and latent TB, and improve the detection of TB. Method(s): Twenty-nine cytokines were measured by multiplex microbead-based immunoassay in supernatant of QuantiFERON-TB Gold-In Tube (QFT) assay tubes (Cellestis, Australia) obtained from subjects with QFT-negative healthy household contacts (n=13), QFT-positive healthy household contacts (latent TB infection: LTBI, n=15), culture confirmed QFT-negative pulmonary TB (n=12), and culture confirmed QFT-positive pulmonary

TB (n=36). Cytokine<inf>[Nil]</inf> and cytokine<inf>[Ag-Nil]</inf> represent the cytokine concentration in a nil tube and the cytokine concentration in a TB antigen tube minus the cytokine concentration in a nil tube, respectively. Result(s): Among 29 cytokines, levels of IFN-gamma<inf>[Ag-Nil]</inf>, IL-2<inf>[Ag-Nil]</inf>, IL-1Ra<inf>[Ag-Nil]</inf>, IP-10<inf>[Ag-Nil]</inf>, GM-CSF<inf>[Ag-Nil]</inf>, IL-3<inf>[Ag-Nil]</inf>, IL-13<inf>[Ag-Nil]</inf>, and MIP-1beta<inf>[Ag-Nil]</inf> in Mycobacterium tuberculosis (Mtb)-infected subjects were significantly different from uninfected subjects. Combination of these cytokines detected 8 of 12 IGRA-negative TB subjects. Moreover, levels of EGF<inf>[Ag-Nil]</inf>, GM-CSF<inf>[Ag-Nil]</inf>, IL-5<inf>[Ag-Nil]</inf>, IL-10<inf>[Ag-Nil]</inf>, MIP- 1beta<inf>[Ag-Nil]</inf>, VEGF<inf>[Ag-Nil]</inf>, TNF-alpha<inf>[Nil]</inf>, and VEGF<inf>[Nil]</inf> showed significant differences between active and latent TB. Sensitvity, specificity, positive predictive value, and negative predictive value of hierachial cluster analysis using infection cytokine profiles between Mtb-infected and uninfected subjects are 93.7%, 100%, 100%, and 76.5%, respectively. Sensitvity, specificity, positive predictive value, and negative predictive value of hierachial cluster analysis using activity cytokine profiles between active TB and LTBI are 81.2%, 65.2%, 100%, and 65.2%, respectively. Conclusion(s): Whole blood cytokine profiles provide distinct signatures for differentiation of active TB from LTBI and increasing the detection of IGRA-negative active TB.

Sujathan, S., et al. (2017). "Heat and Bleach: A Cost-Efficient Method for Extracting Microplastics from Return Activated Sludge." Archives of Environmental Contamination & Toxicology **73**(4): 641-648.

The extraction of plastic microparticles, so-called microplastics, from sludge is a challenging task due to the complex, highly organic material often interspersed with other benign microparticles. The current procedures for microplastic extraction from sludge are time consuming and require expensive reagents for density separation as well as large volumes of oxidizing agents for organic removal, often resulting in tiny sample sizes and thus a disproportional risk of sample bias. In this work, we present an improved extraction method tested on return activated sludge (RAS). The treatment of 100 ml of RAS requires only 6% hydrogen peroxide (HO) for bleaching at 70 °C, followed by density separation with sodium nitrate/sodium thiosulfate (SNT) solution, and is completed within 24 h. Extracted particles of all sizes were chemically analyzed with confocal Raman microscopy. An extraction efficiency of 78 ± 8% for plastic particle sizes 20 µm and up was confirmed in a recovery experiment. However, glass shards with a diameter of less than 20 µm remained in the sample despite the density of glass exceeding the density of the separating SNT solution by 1.1 g/cm. This indicates that density separation may be unreliable for particle sizes in the lower micrometer range. [ABSTRACT FROM AUTHOR]

Sukhanova, A. and I. Nabiev (2008). "Fluorescent nanocrystal-encoded microbeads for multiplexed cancer imaging and diagnosis." Critical Reviews in Oncology/Hematology **68**(1): 39-59.

Bead-based assays on very large numbers of molecules in proteomics, genomics, drug screening and clinical diagnostics require encoding of each of the microbeads according to the particular ligand bound to its surface. The benefits of using optically encoded microbeads (instead of the solid-state two-dimensional arrays) are derived from the freedom of bead to move in three

dimensions. Polymeric beads optically encoded with organic dyes allow for a limited number of unique codes whereas the use of semiconductor nanocrystals as fluorescent tags improves the beads multiplexed imaging capabilities, photostability and sensitivity of the antigen detection. Additionally, an employment of the recently demonstrated Forster resonance energy transfer (FRET) from the microbeads nanocrystal codes to the nearby antibody dye label allows for the very specific detection of the interaction between the microbead and the antibody. This interaction turns the fluorescence signal from dye label off and on thus effectively discriminating between the occurrence and the non-occurrence of antibody binding. The absence of fluorescent background from non-interacting with the beads dye-labelled antibodies additionally increases the sensitivity of detection and further facilitates the multiplexing capabilities of nanocrystals-based detection and diagnostics. This paper reviews the state-of-the-art results of development of microbeads optically encoded with the fluorescent nanocrystals "quantum dots" and their applications to proteomics for cancer antigens and autoantibodies imaging and diagnosis. © 2008 Elsevier Ireland Ltd. Sukhanova, A., et al. (2007). "Nanocrystal-encoded fluorescent microbeads for proteomics: antibody profiling and diagnostics of autoimmune diseases." Nano Letters **7**(8): 2322-2327.

The first application of nanocrystal (NC)-encoded microbeads to clinical proteomics is demonstrated by multiplexed detection of circulating autoantibodies, markers of systemic sclerosis. Two-color complexes, consisting of NC-encoded, antigen-covered beads, anti-antigen antibody or clinical serum samples, and dye-tagged detecting antibodies, were observed using flow cytometry assays and on the surface of single beads. The results of flow cytometry assays correlated with the ELISA technique and provided clear discrimination between the sera samples of healthy donors and patients with autoimmune disease. Microbead fluorescence signals exhibited narrow distribution regardless of their surface antigen staining, without the need of any fluorescence compensation-a parameter determining the limit of sensitivity of flow cytometry assays. In single bead measurements, less than 30 dye-labeled antibodies interacting with the topoI-specific antibodies at the surface of a bead have been detected by the emission of dye excited through the FRET from NCs. In this format, the antibody-bead interaction reaction turns specifically the fluorescence signal from dye label off and on, additionally increasing autoantibody detection sensitivity.

Sul, J. A. I. d., et al. (2011). "Plastic pollution at a sea turtle conservation area in NE Brazil: contrasting developed and undeveloped beaches." Estuaries and Coasts **34**(4): 814-823.

Sea turtles are highly susceptible to plastic ingestion and entanglement. Beach debris were surveyed along the most important sea turtle nesting beaches in Brazil (Costa dos Coqueiros, Bahia State). No significant differences among developed and undeveloped beaches were observed in terms of total number of items. Local sources (tourism activities) represented 70% of debris on developed beaches, where cigarette butts, straws, paper fragments, soft plastic fragments, and food packaging were the most abundant items. Non-local sources (domestic and fishing activities) accounted for about 70% of debris on undeveloped beaches, where the most abundant items were rigid plastic fragments, ropes, soft plastic fragments, caps, and polystyrene. The projected surface area of beach debris did not vary among developed and undeveloped beaches. Overseas containers accounted for about 25% of regional plastic pollution, implying that international pollution prevention agreements are not being respected off the Brazilian coast.

Sulochanan, B., et al. (2019). "Temporal and spatial variability of beach litter in Mangaluru, India."

Marine Pollution Bulletin **149 (no pagination)**(110541).
Monthly litter samples were collected from three major beaches in Mangaluru from 2011-2016. Fishing litter persisted at the beaches, resulting in higher abundances by number (59%) and weight (33.4%) relative to all litter in 2016. In addition to plastics, foam comprised 7.14-11.0% of total litter. Significant positive correlations were observed between the amount of plastic on the beaches and rainy days, rainfall, and river discharge. The maximum river discharge coincided with an increase in plastic items on the beach. Yearly quantities of plastic items ($p < 0.01$), plastic bags ($p < 0.001$), and plastic footwear ($p < 0.05$), on the beaches were significantly different indicating clean-up activities reduced the litter quantity. Changes in total beach litter revealed that Panambur Beach, a fishing boat landing centre was the least changed, and thus appropriate incentive-based management options for the resident fishermen could result in collection and elimination of litter. Sumitran-Karuppan, S. (1999). "The clinical importance of choosing the right assay for detection of HLA-specific donor-reactive antibodies." Transplantation **68**(4): 502-509.
BACKGROUNDWe found earlier that there is a close clinical correlation between the presence of histocompatibility leukocyte antigens (HLA) class I-specific donor-reactive antibodies in cross-match serum and a significantly higher frequency of early acute rejection episodes and graft loss during the first year after the transplant.METHODSSpecificity determinations of donor-reactive antibodies present in the cross-match serum before allogeneic kidney transplants were performed. In the present study, we compared the suitability and efficiency of (a) platelet absorptions, (b) blocking with anti-HLA monoclonal antibodies in the microcytotoxicity assay, and (c) donor-specific HLA antigen-coated magnetic microbeads in flow cytometric assays for the definition of clinically relevant HLA antibodies and their correlation with early acute rejections and early graft loss.RESULTSWe found that the microlymphocytoxicity test using donor splenic B lymphocytes often gave positive reactions in the absence of class I or class II antibodies; in other words, a high frequency of false positive reactions was observed. Flow cytometric tests are more sensitive than microlymphocytotoxicity, not only because they are more sensitive, but also because noncomplement-binding antibodies are detected. Platelet absorptions, which detect only reactivity against HLA class I antigens, is insufficient for use in specificity determinations of donor-reactive antibodies. We found that a positive test for HLA antibodies using paramagnetic beads coated with solubilized donor-derived HLA antigens (class I or class II) correlates with early immunological complications after a transplant ($P<0.001$).CONCLUSIONAssays to determine the specificity of donor-reactive antibodies are now available for use during an acute transplant situation. The introduction of such methods is expected to enhance graft survival and to reduce significantly the frequencies of acute rejections episodes after a transplant.

Summers, S., et al. (2018). "Agglomeration of nano- and microplastic particles in seawater by autochthonous and de novo-produced sources of exopolymeric substances." Marine Pollution Bulletin **130**: 258-267.
Microplastics (<5mm) have often been studied under in-vitro conditions where plastics have been investigated in isolation. However, in the natural environment microplastics readily form agglomerates conferring the particles with properties different to their pristine counterparts. Here, we examined the interaction of exopolymers with polystyrene nanoplastics and microplastics. Formation of plastic agglomerates was examined using simulated sea surface conditions. Flow cytometry coupled with microscopy revealed that nano- and microplastic particle spheres form agglomerates in seawater with a mucilagenous material and an associated

microbial community. To characterise this material, differential staining methods revealed it to be glycoprotein in composition. Exposing increasing concentrations of a marine bacterial glycoprotein EPS to nano- or microplastics revealed that these types of polymers contribute to the formation and abundance of plastic agglomerates. This work highlights the importance of EPS on the fate of plastic and future research should take this into account when evaluating the impact of plastics.

Sun, B., et al. (2016). "Kinetics of Brominated Flame Retardant (BFR) Releases from Granules of Waste Plastics." Environmental Science & Technology **50**(24): 13419-13427.

Plastic components of e-waste contain high levels of brominated flame retardants (BFRs), whose releases cause environmental and human health concerns. This study characterized the release kinetics of polybrominated diphenyl ethers (PBDEs) from millimeter-sized granules processed from the plastic exteriors of two scrap computer displays at environmentally relevant temperatures. The release rate of a substitute of PBDEs, 1,2-bis(2,4,6-tribromophenoxy)ethane (BTBPE), from the waste plastics, was reported for the first time. Deca-BDE was the most abundant PBDE congeners in both materials (87-89%), while BTBPE was also present at relatively high contents. The release kinetics of BFRs could be modeled as one-dimensional diffusion, while the temperature dependence of diffusion coefficients was well described by the Arrhenius equation. The diffusion coefficients of BFRs (at 30 °C) in the plastic matrices were estimated to be in the range of 10-27.16 to 10-19.96 m2·s-1, with apparent activation energies between 88.4 and 154.2 kJ·mol-1. The half-lives of BFR releases (i.e., 50% depletion) from the plastic granules ranged from thousands to tens of billions of years at ambient temperatures. These findings suggest that BFRs are released very slowly from the matrices of waste plastics through molecular diffusion, while their emissions can be significantly enhanced with wear-and-tear and pulverization. [ABSTRACT FROM AUTHOR]

Sun, B., et al. (2019). "Releases of brominated flame retardants (BFRs) from microplastics in aqueous medium: Kinetics and molecular-size dependence of diffusion." Water Research **151**: 215-225.

Microplastics (<5mm) are increasingly detected in aquatic environment, and the high levels of brominated flame retardants (BFRs) contained in them can potentially impact water quality. This study characterized the release kinetics of polybrominated diphenyl ethers (PBDEs) and 1,2-bis(2,4,6-tribromophenoxy)ethane (BTBPE) from millimeter-sized microplastic pellets in water at environmentally relevant temperatures. Leaching rates of BFRs from the microplastic pellets made of acrylonitrile butadiene styrene (ABS) were found to be controlled by their diffusion within the plastic matrix, and their diffusion coefficients (D) in the plastic matrices ranged from 10^{-28.30} to 10^{-20.84}m²s⁻¹. The apparent activation energies of the BFRs' diffusion coefficients were estimated to be in the range of 64.1-131.8kJmol⁻¹ based on their temperature dependence and the Arrhenius equation. The diffusion coefficients of the BFRs decrease with their molecular diameters, while the activation energies for diffusion increase with the molecular diameters, which are indicative of significant steric hindrance for BFR diffusion within the plastic matrices. A semi-empirical linear relationship was observed between Log₁₀D and the glass

transition temperature (T_g) of plastics, which allows prediction of the diffusion coefficients of BFRs in other types of microplastics commonly found in marine environment. The half-lives of BFR leaching (i.e., 50% depletion) from the microplastic pellets would range from tens of thousands to hundreds of billions of years at ambient temperatures if their physical and chemical structures could remain intact. Although the release fluxes of BFRs from microplastics are extremely low under the model conditions, a range of physical and chemical processes in the natural environment and the digestive systems of organisms that ingested them could potentially accelerate their leaching by causing breakdown and swelling of the plastic matrices.

Sun, F., et al. (2017). "Isolation of Murine Alveolar Type II Epithelial Cells." Bio protocol **7**(10): 20.

We have optimized a protocol for isolation of alveolar type II epithelial cells from mouse lung. Lung cell suspensions are prepared by intratracheal instillation of dispase and agarose followed by mechanical disaggregation of the lungs. Alveolar type II epithelial cells are purified from these lung cell suspensions through magnetic-based negative selection using a Biotin-antibody, Streptavidin-MicroBeads system. The purified alveolar type II epithelial cells can be cultured and maintained on fibronectin-coated plates in DMEM with 10% FBS. This protocol enables specific investigation of alveolar type II epithelial cells at molecular and cellular levels and provides an important tool to investigate in vitro the mechanisms underlying lung pathogenesis.

Sun, H., et al. (2014). Bead-based microfluidic RT-QPCR analysis of single cancer cells. 18th International Conference on Miniaturized Systems for Chemistry and Life Sciences, MicroTAS 2014.

Single-cell microfluidic RT-qPCR can enable gene expression assays of small volumes, with efficient thermal cycling, and reduced costs. Such devices currently use solution-based methods, which, while well established, do not allow efficient manipulation of samples and reagents or retrieval of reaction products for real-time single-cell genetic analysis. Employing a novel microbead-based approach and for the first time, we present a microchip that integrates all steps for genetic analysis of an individual cell. The effects of the chemotherapy drug (MMS) on the induction of CDKN1A in single human cancer cells (MCF-7) were assayed, demonstrating the potential of the device for single-cell analysis. © 14CBMS.

Sun, H., et al. (2015). "A Bead-Based Microfluidic Approach to Integrated Single-Cell Gene Expression Analysis by Quantitative RT-PCR." RSC advances **5**(7): 4886-4893.

Gene expression analysis at the single-cell level is critical to understanding variations among cells in heterogeneous populations. Microfluidic reverse transcription quantitative real-time polymerase chain reaction (RT-qPCR) is well suited to gene expression assays of single cells. We present a microfluidic approach that integrates all functional steps for RT-qPCR of a single cell, including isolation and lysis of the cell, as well as purification, reverse transcription and quantitative real-time PCR of messenger RNA in the cell lysate. In this approach, all reactions in the multi-step assay of a single lysed cell can be completed on microbeads, thereby simplifying the design, fabrication and operation of the microfluidic device, as well as facilitating the minimization of sample loss or contamination. In the microfluidic device, a single cell is isolated and lysed; mRNA in the cell lysate is then analyzed by RT-qPCR using primers immobilized on microbeads in a single microchamber whose temperature is controlled in closed loop via an integrated heater and temperature sensor. The utility of the approach was demonstrated by the analysis of the effects of the drug (methyl methanesulfonate, MMS) on the induction of the cyclin-dependent kinase inhibitor 1a (CDKN1A) in single human cancer cells (MCF-7), demonstrating the potential of our approach for efficient, integrated single-cell RT-qPCR for gene expression analysis.

Sun, J., et al. (2019). "Microplastics in wastewater treatment plants: Detection, occurrence and removal." Water Research **152**: 21-37.

Microplastics have aroused increasing concern as they pose threats to aquatic species as well as human beings. They do not only contribute to accumulation of plastics in the environment, but due to absorption they can also contribute to spreading of micropollutants in the environment. Studies indicated that wastewater treatment plants (WWTPs) play an important role in releasing microplastics to the environment. Therefore, effective detection of the microplastics and understanding their occurrence and fate in WWTPs are of great importance towards microplastics control. In this review, the up-to-date status on the detection, occurrence and removal of microplastics in WWTPs are comprehensively reviewed. Specifically, the different techniques used for collecting microplastics from both wastewater and sewage sludge, and their pretreatment and characterization methods are reviewed and analyzed. The key aspects regarding microplastics occurrence in WWTPs, such as concentrations, total discharges, materials, shapes and sizes are summarized and compared. Microplastics removal in different treatment stages and their retention in sewage sludge are explored. The development of potential microplastics-targeted treatment technologies is also presented. Although previous researches in microplastics have undoubtedly improved our level of understanding, it is clear that much remains to be learned about microplastics in WWTPs, as many unanswered questions and thereby concerns still remain; some of these important future research areas are outlined. The key challenges appear to be to harmonize detection methods as well as microplastics mitigation from wastewater and sewage sludge.

Sun, L. D., et al. (2008). "Differences in peripheral blood CD34⁺ cell morphology between systemic lupus erythematosus patients and healthy controls. [Chinese]." Journal of Clinical Rehabilitative Tissue Engineering Research **12**(51): 10081-10084.

Background: There is a debate addressing the existence of CD34⁺ cells in systemic lupus erythematosus patients. Objective(s): To observe the morphology of CD34⁺ cells from peripheral blood of systemic lupus erythematosus patients versus health human by atomic force microscopes. Design(s): A case-controlled analysis. Participant(s): Six systemic lupus erythematosus patients (3 male and 3 female), averagely aged 26.3 years old were selected. The disease course was averagely 19.0 months. They were accorded with the diagnostic criteria made by America Rheumatology Association in 1982. Three healthy volunteers were used as controls. Baseline data had comparability in both groups. Method(s): Systemic lupus erythematosus patients were injected with 4 g/ m² cyclophosphamide via intravenous injection. When leukocytes reached <1.0x10⁹/L, granulocyte colony-stimulating factor (5 mu g/kg) was administered. When leukocytes reached > 5.58x10⁹/L and CD34⁺>2%, peripheral blood stem cells were collected. Three healthy volunteers were subjected to mobilization of granulocyte colony-stimulating factor alone. CD34 MicroBeads FcR and FcR Blocking Reagent were added into the peripheral blood stem cells, which was made into cell suspension. Supernatant was removed. After resuspension, samples were filtered. CD34⁺ cells were purified by immunomagnetic bead cell sorting. Main Outcome Measure(s): Atomic force microscopes was used to observe the surface of the CD34⁺ cells. Twenty cells were observed randomly in two groups. The average of some parameters such as diameter, mean square root roughness, mean height and roughness of five images (2 mum x 2 mu m) in each cell represented as the whole cell. Result(s): When the scope of images were 12 mu mx12 mu m, the whole cells could be imaged. When the scope of images were 2 mumx2 mu m, there were

introcession of different sizes, oval process, and rough structure on the surface of the CD34⁺ cells. Compared with the healthy patients, there were no significant differences in the diameter, mean roughness, mean square root roughness, and mean height in systemic lupus erythematosus patients (F=0.203-4.553, P > 0.05). Conclusion(s): Atomic force microscopes can map the surface of CD34⁺ cells at image range of 2 mu mx2 mu m. There are no significant differences in CD34⁺ cell morphology between systemic lupus erythematosus patients and health human.

Sun, M., et al. (2018). "Changes in tetracycline partitioning and bacteria/phage-comediated ARGs in microplastic-contaminated greenhouse soil facilitated by sophorolipid." Journal of Hazardous Materials **345**: 131-139.

The emerging mixed contamination of antibiotics and microplastics in greenhouse soil has made the control of antibiotic resistant gene (ARG) transmission a novel challenge. In this work, surfactant sophorolipid was applied to enhance the dissipation of tetracycline (TC) and tet genes in the presence of microplastics in greenhouse soil. During 49days of incubation, soil bacteria and phages were both found to be the crucial reservoirs of ARGs. Meanwhile, microplastic's presence significantly inhibited the dissipation of TC and ARGs in the soil. However, sophorolipid application was proved to outweigh the negative impact caused by microplastic existence, and lead to the highest dissipation of soil TC and ARGs. Significant positive correlation was detected between the dissipation rate of water-soluble and exchangeable TC content and bacteria/phage co-mediated ARG levels. This also held true between the two fractions of soil TC and the ratio of ARG level in the bacteria to that in the phages (B_{ARGs}/P_{ARGs}). The opposite impacts of microplastic presence and sophorolipid amendment on the TC/ARG dissipation found in this work provides new information for understanding ARG transmission between bacteria and phages in the mixed contaminated greenhouse soil.

Sun, N. Y. (2008). China's Lam talks up recycling & change. **20:** 8-8.

This article presents an interview with Toland Lam, president of the Beijing, China-based China Plastics Processing Industry Association. When asked how would he quantify the current state of China's plastics recycling industry, he replied that China is the final destination of 70 percent of the world's plastic waste. He also said that the ban of imported post-consumer plastic bag will increase prices. He added that plastic recycling started in China in the 1980s.

Sun, Q., et al. (2017). "Ex vivo construction of human primary 3D-networked osteocytes." Bone **105**: 245-252.

A human bone tissue model was developed by constructing ex vivo the 3D network of osteocytes via the biomimetic assembly of primary human osteoblastic cells with 20-25mum microbeads and subsequent microfluidic perfusion culture. The biomimetic assembly: (1) enabled 3D-constructed cells to form cellular network via processes with an average cell-to-cell distance of 20-25mum, and (2) inhibited cell proliferation within the interstitial confine between the microbeads while the confined cells produced extracellular matrix (ECM) to form a mechanically integrated structure. The mature osteocytic expressions of SOST and FGF23 genes became significantly higher, especially for SOST by 250 folds during 3D culture. The results validate that the bone tissue model: (1) consists of 3D cellular network of primary human osteocytes, (2) mitigates the osteoblastic differentiation and proliferation of primary osteoblast-like cells encountered in 2D culture, and (3) therefore reproduces ex vivo the phenotype of human 3D-networked osteocytes. The 3D tissue construction approach is expected to provide a clinically relevant and high-throughput means for evaluating drugs and treatments that target bone diseases with in vitro convenience.

Sun, Q., et al. (2018). "Ex vivo replication of phenotypic functions of osteocytes through biomimetic 3D bone tissue construction." Bone **106**: 148-155.

Osteocytes, residing as 3-dimensionally (3D) networked cells in bone, are well known to regulate bone and mineral homeostasis and have been recently implicated to interact with cancer cells to influence the progression of bone metastases. In this study, a bone tissue consisting of 3D-networked primary human osteocytes and MLO-A5 cells was constructed using: (1) the biomimetic close-packed assembly of 20-25mum microbeads with primary cells isolated from human bone samples and MLO-A5 cells and (2) subsequent perfusion culture in a microfluidic device. With this 3D tissue construction approach, we replicated ex vivo, for the first time, the mechanotransduction function of human primary osteocytes and MLO-A5 cells by correlating the effects of cyclic compression on down-regulated SOST and DKK1 expressions. Also, as an example of using our ex vivo model to evaluate therapeutic agents, we confirmed previously reported findings that parathyroid hormone (PTH) decreases SOST and increases the ratio of RANKL and OPG. In comparison to other in vitro models, our ex vivo model: (1) replicates the cell density, phenotype, and functions of primary human osteocytes and MLO-A5 cells and (2) thus provides a clinically relevant means of studying bone diseases and metastases.

Sun, Q., et al. (2015). "Ex vivo 3D osteocyte network construction with primary murine bone cells." Bone Research **3**: 15026.

Osteocytes reside as three-dimensionally (3D) networked cells in the lacunocanalicular structure of bones and regulate bone and mineral homeostasis. Despite of their important regulatory roles, in vitro studies of osteocytes have been challenging because: (1) current cell lines do not sufficiently represent the phenotypic features of mature osteocytes and (2) primary cells rapidly differentiate to osteoblasts upon isolation. In this study, we used a 3D perfusion culture approach to: (1) construct the 3D cellular network of primary murine osteocytes by biomimetic assembly with microbeads and (2) reproduce ex vivo the phenotype of primary murine osteocytes, for the first time to our best knowledge. In order to enable 3D construction with a sufficient number of viable cells, we used a proliferated osteoblastic population of healthy cells outgrown from digested bone chips. The diameter of microbeads was controlled to: (1) distribute and entrap cells within the interstitial spaces between the microbeads and (2) maintain average cell-to-cell distance to be about 19 micro m. The entrapped cells formed a 3D cellular network by extending and connecting their processes through openings between the microbeads. Also, with increasing culture time, the entrapped cells exhibited the characteristic gene expressions (SOST and FGF23) and nonproliferative behavior of mature osteocytes. In contrast, 2D-cultured cells continued their osteoblastic differentiation and proliferation. This 3D biomimetic approach is expected to provide a new means of: (1) studying flow-induced shear stress on the mechanotransduction function of primary osteocytes, (2) studying physiological functions of 3D-networked osteocytes with in vitro convenience, and (3) developing clinically relevant human bone disease models.

Sun, R. and H. Zhuang (2015). "Biotin-streptavidin-amplified real-time immune-PCR assay for detecting dimethyl phthalate in beverage and drinking water samples." Analytical and bioanalytical chemistry **407**(4): 1261-1265.

Issue Title: A different way of looking at vibrational hyperspectral data/Micellar extraction for the analysis of Alzheimer's disease brain proteome/Quantification of polyolefin microplastics in personal-care products/Removal of Triton X-100 by microdialysis Dimethyl phthalate (DMP), one

family of the phthalic acid diesters (PAEs), is an increasing widely used plasticizer. A sensitive and high-throughput direct competitive biotin-streptavidin-amplified system based on real-time immune-PCR (BA-rt-IPCR) techniques was developed for detecting DMP in beverage and drinking water samples. In our assay, we selected dimethyl 4-aminophthalate as the optimal DMP hapten to prepare high titer of rabbit polyclonal anti-DMP antibodies (pAb-DMP). Under the optimized conditions, the proposed method was used to detect DMP with a linearity range from 10 to 100 ng L^sup -1^, and the limit of detection (LOD) was 1.98 pg L^sup -1^. Finally, the results about DMP in beverage and drinking water samples were consistent with those using gas chromatography-mass spectrometry (GC-MS), which proved that the proposed immunoassay for detecting DMP in the environment was accurate, reliably rapid, and receptive.

Sun, S., et al. (2014). "A method to observe the structure of the interface between mesocarbon microbeads and pitch." Journal of Colloid & Interface Science **426**: 206-208.

It is known that mesocarbon microbeads (MCMBs) have ordered structure and grow after absorbing molecules from pitch. However, the structure of pitch used for preparing MCMBs is disordered. Thus question of whether there is a region where the molecules absorbed from pitch change their orientations is a very interesting problem. In this paper, an interface between MCMBs and their pitch matrix has been found and the structure of the interface was observed by scanning electron microcopy. There are some ordered regions in the interface but the number of ordered regions in the interface is much fewer than the number inside the MCMBs. This indicates that the interface between the MCMBs and the pitch is the region where the orientations of the molecules absorbed from pitch change.

Sun, T., et al. (2018). "Suitability of mulching with biodegradable film to moderate soil temperature and moisture and to increase photosynthesis and yield in peanut." Agricultural Water Management **208**: 214-223.

There is a growing interest in developing suitable biodegradable films for mulching crops to minimize the environmental impacts of polyethylene (PE) film. In order to verify whether biodegradable film can satisfy the changing needs of soil conditions in different seasons of crops, six treatments were conducted including four different ratios of starch/polybutyrate adipate terephthalate (PBAT) biodegradable films mulching, containing 0% (B1), 10% (B2), 15% (B3), and 20% (B4) starch, respectively, and PE film mulching and no mulching. A randomized complete block design with three replications was used to compare their effects on soil temperature and moisture, and peanut yield. The results indicated that soil temperature under the B3 treatment was higher than those under other three biodegradable films for the entire grow season. B3 mulching can warm the soil similar to PE film before 60 days after sowing (DAS), however, lowers soil temperature by about 0.4-1.4 degrees C after that. Soil moisture of B3 was similar to that under the PE film at 0-40 cm depth at 20 DAS, lower at 40-60 and 120 DAS, however, higher at 80-100 DAS with the infiltration of rains because of biodegradation. With less (B1 and B2) or more starch (B4), the soil temperature and soil water was lower in whole stage than B3. Compared with other treatments, peanuts mulched with B3 maintained higher LAI, chlorophyll content and net photosynthetic rate at late growth stages. The pod yield under B3 was similar, however, economic benefit was a bit lower than that of PE film because of the higher present cost of biodegradable film. Thus, the results revealed that suitable biodegradable film can satisfy the changing needs of soil conditions in different seasons. The findings suggest that creating more suitable biodegradable mulches to meet the changing needs will be a new direction for maximizing the use of biodegradable film and reducing the long-term plastic pollution (i.e., "white pollution").

Sun, X., et al. (2018). "Toxicities of polystyrene nano- and microplastics toward marine bacterium Halomonas alkaliphila." Science of the Total Environment **642**: 1378-1385.

Nano- and microplastics have been shown to cause negative effects on marine organisms. However, the toxicities of nano- and microplastics toward marine bacteria are poorly understood. In this study, we investigated the toxic effects of polystyrene nano- and microplastics on the marine bacterium Halomonas alkaliphila by determining growth inhibition, chemical composition, inorganic nitrogen conversion efficiencies and reactive oxygen species (ROS) generation. The results showed that both nano- and microplastics inhibited the growth of H. alkaliphila in high concentrations, while nanoplastics rather than microplastics influenced the growth inhibition, chemical composition and ammonia conversion efficiencies of H. alkaliphila at concentration of 80mg/L. The ROS generation indicated oxidative stress induced by nano- but not microplastics, and the oxidative stress induced by nanoplastics may provide a significant effect on bacteria. Furthermore, the positively charged nanoplastics (amine-modified 50nm) induced higher oxidative stress toward bacteria than that induced by negatively charged nanoplastics (non-modified 55nm). The increased extracellular polymeric substances as evidenced by transmission electron microscope (TEM) observation suggested the possible bacterial protective mechanisms. The present study illustrates for the first time the impact of plastics debris on the inorganic nitrogen conversion efficiencies of marine bacteria. Our findings highlight the effects of microplastics on the ecological function of marine organisms.

Sun, X., et al. (2019). "Characteristics and retention of microplastics in the digestive tracts of fish from the Yellow Sea." Environmental Pollution **249**: 878-885.

Microplastics (MPs) are a major global issue in the marine environment, and fish inhabiting coastal environments are susceptible to the ingestion of MPs. Knowledge regarding MPs in fish along the coast of China is very limited. In this study, the characteristics and retention of MPs in 19 fish species in the Yellow Sea were systematically studied. MPs were detected in all of the fish species sampled. Overall, 34% (444/1320) of fish retained plastic, and 552 pieces of plastic were removed from these fish, among which 546 pieces (99%) were microplastics (i.e., <5 mm). Three MP types were found: fibers, pellets, and fragments, which accounted for 67%, 22%, and 11% of the total, respectively. MP length ranged from 16 to 4740 micro m, with an average of 941+or-43 micro m. The average lengths of the fibers, pellets, and fragments were 1233+or-57 micro m, 263+or-24 micro m, and 503+or-91 micro m, respectively, and MP length was positively correlated with fish length. Fourteen polymers were detected, with organic oxidation polymers (40%) being most abundant, followed by polyethylene (22%) and polyamide (11%). The retention of MPs in fish was affected by sampling areas and fish weight. Fish collected from the area adjacent to the Bohai Sea and the Yangtze River Estuary were found to possess higher levels of MPs than those collected from the center of the Yellow Sea. The average MP/fish for fish with plastic was negatively correlated with fish body weight. The retention of MPs may affect the quality and quantity of fishery resources in the Yellow Sea, especially the commercial fish. It is suggested that future studies be conducted to determine the ingestion rate, retention time, and egestion rate of MPs by fish to enable a rational risk assessment by combining the field results.

Sun, X., et al. (2017). "Ingestion of microplastics by natural zooplankton groups in the northern South China Sea." Marine Pollution Bulletin **115**(1/2): 217-224.

The ingestion of microplastics by five natural zooplankton groups in the northern South China Sea was studied for the first time and two types of sampling nets (505 micro m and 160 micro m in mesh size) were compared. The microplastics were detected in zooplankton sampled from 16 stations, with the fibrous microplastics accounting for the largest proportion (70%). The main component of the found microplastics was polyester. The average length of the microplastics was 125 micro m and 167 micro m for Nets I and II, respectively. The encounter rates of microplastics/zooplankton increased with trophic levels. The average encounter rate of microplastics/zooplankton was 5%, 15%, 34%, 49%, and 120% for Net I, and 8%, 21%, 47%, 60%, and 143% for Net II for copepods, chaetognaths, jellyfish, shrimp, and fish larvae, respectively. The average abundance of microplastics that were ingested by zooplankton was 4.1 pieces/m³ for Net I and 131.5 pieces/m³ for Net II.

Sun, X., et al. (2018). "Microplastics in seawater and zooplankton from the Yellow Sea." Environmental Pollution **242**(Part A): 585-595.

Marine plastic pollution is a worldwide problem. Microplastics (MPs) are the predominant form of marine plastic debris, a form small enough to be ingested by and potentially harm marine organisms. It is urgent to develop ecologically relevant metrics for the risk assessment of MPs based on in situ data, especially for coastal areas. For the first time, we performed a comprehensive study of the characteristics of MPs in seawater and zooplankton in the Yellow Sea. For MPs in seawater, the average concentration is 0.13+or-0.20 pieces/m³, dominated by fragments (42%). The average size is 3.72+or-4.70 mm, with the most frequent size appearing at 1200 micro m. The major polymer types are polypropylene and polyethylene, accounting for 88.13% in total. The distribution of MPs in seawater is patchy, with high MP concentrations close to the coastal cities. The average concentration of MPs in 11 total zooplankton groups is 12.24+or-25.70 pieces/m³. The average size is 154.62+or-152.90 micro m, with 90% being <500 micro m. Fiber is the dominant shape of MPs found in zooplankton, accounting for 46%, but the composition of the polymer type is diverse. The retention of MPs in zooplankton depends on the taxa and their abundance in the Yellow Sea. Siphonophorea, Copepoda, Euphausiacea and Amphipoda are the main repositories compared to other groups, achieving 3.57, 2.44, 1.41 and 1.36 pieces/m³, respectively. The high concentration area of MPs in zooplankton appeared near the adjacent waters of the Yangtze estuary. These results prove that zooplankton act as a repository for MPs in coastal waters. The retention of MPs in zooplankton is recommended as a key index for further ecological risk assessment of MPs.

Sun, X., et al. (2019). "Dual-layered pH-sensitive alginate/chitosan/kappa-carrageenan microbeads for colon-targeted release of 5-fluorouracil." International Journal of Biological Macromolecules **132**: 487-494.

A new pH-sensitive drug carrier based on alginate (Alg), chitosan (Cs), and kappa-carrageenan (kC) marine biopolymers was developed, comprising a dual-layered polyelectrolyte complexes microbead structure. Fourier-transform infrared spectroscopy (FT-IR), thermogravimetric analysis (TGA), and scanning electron microscopy (SEM) were used to investigate the structures, thermal stability, and morphological changes, respectively, of the microcapsules we developed. In the intestinal environment (pH7.4), the stability and swelling of Alg microbeads were enhanced after generation of the dual-layered polyelectrolyte complexes. The in vitro release profiles of 5-fluorouracil under simulated GI conditions were also examined. At gastric pH (1.2), the cumulative 5-FU release percentage was decreased by introduction of the additional kC layer from 14% in Alg/Cs microbeads to 7% in the dual-layered Alg/Cs/kC microbeads. Additionally, the release profiles were greatly improved under simulated intestinal and colon conditions. Finally, the microbeads were all biodegradable and showed no cytotoxicity in Chang liver cells. Our results clearly indicate that the dual-layer pH-sensitive Alg/Cs/kC microbeads could be used effectively for the targeted delivery of anticancer drugs to the colon.

Sun, X., et al. (2018). "Retention and characteristics of microplastics in natural zooplankton taxa from the East China Sea." Science of the Total Environment **640-641**: 232-242.

The ubiquitous presence and persistence of microplastics (MPs) in aquatic environments have become of particular concern in recent years. Biological interactions are among the key processes that affect the impact and fate of MPs in the oceans. Zooplankton is one of the most sensitive taxa because their prey is approximately the same size as MPs. However, the status of MPs in zooplankton within natural marine environments remains largely unknown. By focusing on zooplankton in the East China Sea, the characteristics, bioaccumulated concentration, and retention of MPs for 10 zooplankton groups were systematically studied. Three types of MPs were found in zooplankton: fibres, pellets, and fragments. The fibres (54.6%) were more common than the other two types. The average lengths of the fibres, pellets, and fragments were 295.2 +/- 348.6 mum, 20.3 +/- 11.0 mum, and 82.4 +/- 80.5 mum, respectively. Nineteen polymers were detected in the zooplankton via the Thermo Scientific Nicolet iN10 Infrared Microscope. Polymerized oxidized organic material and polyester were dominant, accounting for 35.9% and 25.6% of the polymers, respectively. The bioaccumulated concentration of MPs in the 10 zooplankton taxa varied from 0.13 pieces/zooplankton for Copepoda to 0.35 pieces/zooplankton for Pteropoda. The bioaccumulated concentration was negatively correlated with the abundance of zooplankton, showing a significant biological dilution effect. The bioaccumulated concentration was also influenced by the feeding mode of zooplankton, showing a trend of omnivorous > carnivorous > herbivorous. High retention of MPs was found in the zooplankton community of the East China Sea, achieving 19.7 +/- 22.4 pieces/m³. This is much higher than the MP retention in zooplankton from other reported sea areas. By revealing the characteristics and retention of MPs in the natural zooplankton taxa from the East China Sea, this research identified the influence that MPs have on zooplankton in a typical coastal environment. This information can be utilized for subsequent controlled experiments and risk assessments. Copyright © 2018 Elsevier B.V.

Sun, X., et al. (2019). "Preparation of pH-sensitive Fe3O4@C/carboxymethyl cellulose/chitosan composite beads for diclofenac sodium delivery." International Journal of Biological Macromolecules **127**: 594-605.

In this study, we prepared pH- and magnetism-responsive Fe3O4@C/carboxymethyl cellulose (CMC)/chitosan composite microbeads for controlled release of diclofenac sodium (DS) to (i) prevent complete drug release in gastric area, (ii) maintain blood drug concentration in a specific part of the body, (iii) reduce drug administration time and systemic drug toxicity, and (iv) improve drug efficacy. Through one-step solvent thermal treatment, a polyethylene glycol layer was wrapped into Fe3O4 nanoparticles. Then, Fe3O4@C nanoparticles were incorporated into CMC matrix and coated with chitosan layer via a self-assembly technique to form core-shell polyelectrolyte complexes (PECs). The composite beads were characterized by SEM, TEM, FT-IR spectrometry, and TGA. In addition, the effect of different concentrations of Fe3O4@C, CMC, aluminum chloride (AlCl3), and chitosan on the swelling process of composite beads, DS loading, and controlled release behavior was systematically studied. DS encapsulation efficiency in Fe3O4@C/CMC/chitosan beads reached 70.8 ± 0.65% at concentrations of 0.1% Fe3O4@C, 3% CMC, 3% AlCl3, and 1% chitosan. The beads showed a higher swelling index in phosphate buffer at pH 7.4 and 6.8 than at pH 1.2. The composite beads revealed excellent pH-sensitive in vitro drug release profiles and prevented burst release in the gastrointestinal tract.

Sun, X., et al. (2019). "Preparation of pH-sensitive Fe₃O₄@C/carboxymethyl cellulose/chitosan composite beads for diclofenac sodium delivery." International Journal of Biological Macromolecules **127**: 594-605.

In this study, we prepared pH- and magnetism-responsive Fe₃O₄@C/carboxymethyl cellulose (CMC)/chitosan composite microbeads for controlled release of diclofenac sodium (DS) to (i) prevent complete drug release in gastric area, (ii) maintain blood drug concentration in a specific part of the body, (iii) reduce drug administration time and systemic drug toxicity, and (iv) improve drug efficacy. DS encapsulation efficiency in Fe₃O₄@C/CMC/chitosan beads reached 70.8+/-0.65% at concentrations of 0.1% Fe₃O₄@C, 3% CMC, 3% AlCl_{3,} and 1% chitosan. The beads showed a higher swelling index in phosphate buffer at pH7.4 and 6.8 than at pH1.2. The composite beads revealed excellent pH-sensitive in vitro drug release profiles and prevented burst release in the gastrointestinal tract.

Sun, Y., et al. (2007). "Design and performances of immunoassay based on SPR biosensor with magnetic microbeads." Biosensors and Bioelectronics **23**(4): 473-478.

A surface plasmon resonance (SPR) biosensor system was developed for immunoassay, based on the conjugates of magnetic microbeads coupling with antibody which could be trapped on the Au film firmly due to the magnetic force. The magnetic microbeads were used as the solid support for the heat shock protein 70 (Hsp 70) antibody and antibody immobilized magnetic microbeads were utilized instead of the single antibody for the determination of Hsp 70. Since the magnetic bead is coated with dextran, the antibodies and some specific biomolecular receptors can be immobilized using a variety of chemical reactions. Compared to traditional antibody immobilization on the sensing film, there is not a covalent link between the Au film and the antibody. There is a great advantage in that sensor can be stripped and reused, and the same chemistry used to derivative dextran-coated SPR sensors can be used for the magnetic bead-coated sensors. The sensing layer was formed well. Different dilution ratios (v/v) of the conjugates result in different detectable ranges. When the dilution ratios of the conjugate are 1:10 and 1:5, the lowest concentrations of Hsp 70 that can be detected are 1.50 and 0.30 mu gml super(-) super(1), respectively.

Sun, Y., et al. (2012). "Host cytokine storm is associated with disease severity of severe fever with thrombocytopenia syndrome." Journal of Infectious Diseases **206**(7): 1085-1094.

BACKGROUND: Severe fever with thrombocytopenia syndrome (SFTS) is an emerging viral disease in China, caused by SFTS virus (SFTSV). Severe SFTS patients can quickly proceed to multiorgan dysfunction and death; however, underlying pathogenic mechanisms remain unclear.

METHODS: Serum samples from 15 fatal and 44 nonfatal SFTS cases were subjected to multiplex-microbead immunoassays to detect a broad spectrum of cytokines. The viral load and

virus-specific IgG titers were also tested by real-time PCR and ELISA, respectively.
RESULTS: Cytokines IL-1RA, IL-6, IL-10, G-CSF, IP-10, and MCP-1 were elevated in SFTS patients and produced at robust levels in fatal cases. In contrast, cytokines PDGF-BB and RANTES decreased in SFTS patients. These cytokines reverted to normal ranges during the convalescent phase of SFTSV infection. Cytokines IL-1beta, IL-8, MIP-1alpha, and MIP-1beta showed a unique pattern of elevation in fatal cases but not in nonfatal cases. However, these cytokines increased in the convalescent phase of nonfatal SFTS cases. Our regression analysis revealed that the serum viral load correlated with these cytokines. Moreover, levels of these cytokines correlated with various clinical parameters and virus-specific IgG titers.
CONCLUSION: The study demonstrates that SFTSV infection induces a cytokine storm with abnormally expressed cytokine profiles, which are associated with the disease severity.

Sun, Y., et al. (2008). "Improvement of surface plasmon resonance biosensor with magnetic beads via assembled polyelectrolyte layers." Analytica Chimica Acta **624**(2): 294-300.

The conjugates of magnetic beads coupled with an antibody can be trapped on the Au film firmly due to the magnetic force for the immunoassay of a surface plasmon resonance (SPR) biosensor. However, this approach exhibits significant limitations in robustness and sensitivity due to incomplete dissociation of magnetic beads from the Au film. The incorporation of a polyelectrolyte film on the Au surface can prevent the magnetic beads from the direct contact with the Au film. The layer-by-layer assembly of polyelectrolyte was used as spacer between the gold surface and the magnetic bead. Different layers of polyelectrolyte can be assembled onto the Au film based on an electrostatic force between polycations and polyanions. After the polyelectrolyte film was fabricated on the Au film, the deposition of the magnetic beads was maintained effectively on the film, which favors the sensitivity of the biosensor and the regeneration of the sensing membrane. When the polyelectrolyte layers of (PAH/PSS)<inf>3</inf> were constructed on the Au film, the SPR biosensor with magnetic beads exhibited a satisfactory response to human IgG in the concentration range from 0.25 to 30.00 mug mL⁻¹, and the determination limit obtained is eight times lower than that obtained with (PAH/PSS)<inf>1</inf> layer. © 2008 Elsevier B.V. Sun, Y., et al. (2019). "Small-sized microplastics negatively affect rotifers: changes in the key life-history traits and rotifer- phaeocystis population dynamics." Environmental Science and Technology **53**(15): 9241-9251.

Most coastal waters are at risk from microplastics, which vary in concentration and size. Rotifers, as important primary consumers linking primary producers and higher trophic consumers, usually coexist with the harmful alga Phaeocystis and microplastics in coastal waters; this coexistence may interfere with rotifer life-history traits and ingestion of Phaeocystis. To evaluate the effects of microplastics on rotifers, we designed a series of experiments concerning rotifer Brachionus plicatilis life-history traits and rotifer-Phaeocystis (predator-prey) population dynamics under different concentrations and sizes of microplastics. The results showed that small-sized microplastics (0.07 mum) at high levels (>=5 mug mL⁻¹) decreased rotifer survival and reproduction, prolonged the time to maturation, and reduced the body size at maturation, whereas large-sized microplastics (0.7 and 7 mum) had no effect on rotifer life-history traits. For rotifer-Phaeocystis population levels, small-sized microplastics (0.07 mum) significantly delayed the elimination of Phaeocystis by rotifers; this is the first study to test the effects of microplastics on predator-prey dynamics. The results of rotifer-Phaeocystis population dynamics are consistent with the changes in the life-history traits of rotifers and further confirm the negative effects of small-sized microplastics

(0.07 mum) on rotifers. These findings help to reveal the effect of pollutants on predator-prey population dynamics. Copyright © 2019 American Chemical Society.

Sundaran, P. S., et al. (2017). "Drug loaded microbeads entrapped electrospun mat for wound dressing application." Journal of Materials Science: Materials in Medicine **28 (6) (no pagination)**(88).

Abstract: A new design of antibiotic loaded wound dressing and its initial in vitro evaluation is described. Chitosan microbeads loaded with ampicillin were sandwiched within polycaprolactone electrospun mat (MbAPPCL). The morphology was analyzed by scanning electron microscopy and surface chemistry was characterized by Fourier Transform Infrared Spectroscopy. In vitro cytotoxicity using L-929 fibroblast cells by direct contact test and elution assay revealed non-cytotoxic nature of MbAPPCL. The cell adhesion and viability analysis further confirmed the cytocompatibility of MbAPPCL as a wound dressing material. Percentage hemolysis and platelet adhesion on the mat exposed to blood substantiated the hemocompatibility. The antibiotic susceptibility test analyzed on Staphylococcus aureus by agar plate method confirmed the drug release and antimicrobial property. The proposed wound dressing model explained with ampicillin as a candidate drug has the potential to include microbeads with different antibiotics for multi drug treatment. Sundbaek, K. B., et al. (2018). "Sorption of fluorescent polystyrene microplastic particles to edible seaweed Fucus vesiculosus." Journal of Applied Phycology **30**(5): 2923-2927.

Increased global demands for food have raised interest for seaweed as a healthy and sustainable food source. At the same time, the large amounts of microplastic in the oceans have raised concern in relation to pollution of seafood including sea vegetables. The aim of this study was to examine sorption of fluorescent polystyrene (PS) microplastic particles to edible macroalga (seaweed) Fucus vesiculosus, and to investigate to what extent adsorbed PS particles could be washed off, using an industrial relevant method. PS microplastic particles (diameter of 20 micro m) were used in a concentration of 2.65 mg L⁻¹ (corresponding to 597 particles per mL) in filtrated seawater (50 mL) to treat F. vesiculosus distal tips in blue cap flasks (100 mL) placed in a rotary box for 2 h. Results showed sorption of PS microplastic particles to F. vesiculosus analysed by microscopy and a significant reduction of 94.5% by washing. These results were based on high microplastic concentrations, not comparable to natural conditions/concentrations. Nonetheless, this study provides methodological and mechanistic insights into procedures for investigating the sorption of microplastics to seaweed, for which there is currently no established standardised method.

Super, M. S., et al. (1993). "Density-based separation of thermoplastics found in the post-consumer waste stream." Resources, Conservation and Recycling **9**(1-2): 75-88.

Separation of thermoplastics from each other and from contaminants facilitates their recycling and improves the properties of the reprocessed material. Clean, dry, shredded thermoplastics obtained from post-consumer, plastic waste were separated using pure CO<inf>2</inf> and mixtures of CO<inf>2</inf> and SF<inf>6</inf> in a lab-scale, density-based separator. The separator was designed to operate at the pressures and temperatures required to attain the appropriate densities for the separations using these near-critical fluids. Separation efficiency, factors affecting separation purity, and favorable operating conditions and procedures were determined. Several thermoplastic mixtures were separated, including HDPE/LDPE/PP and PVC/PET. The purity of the separated homopolymers ranged from 100%-77% by weight, with

most runs yielding 96%-100% purity.

Sussarellu, R., et al. (2016). "Oyster reproduction is affected by exposure to polystyrene microplastics." Proceedings of the National Academy of Sciences of the United States of America **113**(9): 2430-2435.

Plastics are persistent synthetic polymers that accumulate as waste in the marine environment. Microplastic (MP) particles are derived from the breakdown of larger debris or can enter the environment as microscopic fragments. Because filter-feeder organisms ingest MP while feeding, they are likely to be impacted by MP pollution. To assess the impact of polystyrene microspheres (micro-PS) on the physiology of the Pacific oyster, adult oysters were experimentally exposed to virgin micro-PS (2 and 6 micro m in diameter; 0.023 mg.L⁻¹) for 2 mo during a reproductive cycle. Effects were investigated on ecophysiological parameters; cellular, transcriptomic, and proteomic responses; fecundity; and offspring development. Oysters preferentially ingested the 6- micro m micro-PS over the 2-micro m-diameter particles. Consumption of microalgae and absorption efficiency were significantly higher in exposed oysters, suggesting compensatory and physical effects on both digestive parameters. After 2 mo, exposed oysters had significant decreases in oocyte number (-38%), diameter (-5%), and sperm velocity (-23%). The D-larval yield and larval development of offspring derived from exposed parents decreased by 41% and 18%, respectively, compared with control offspring. Dynamic energy budget modeling, supported by transcriptomic profiles, suggested a significant shift of energy allocation from reproduction to structural growth, and elevated maintenance costs in exposed oysters, which is thought to be caused by interference with energy uptake. Molecular signatures of endocrine disruption were also revealed, but no endocrine disruptors were found in the biological samples. This study provides evidence that micro-PS cause feeding modifications and reproductive disruption in oysters, with significant impacts on offspring.

Sutherland, W. J., et al. (2012). "A horizon scanning assessment of current and potential future threats to migratory shorebirds." Ibis **154**(4): 663-679.

We review the conservation issues facing migratory shorebird populations that breed in temperate regions and use wetlands in the non-breeding season. Shorebirds are excellent model organisms for understanding ecological, behavioural and evolutionary processes and are often used as indicators of wetland health. A global team of experienced shorebird researchers identified 45 issues facing these shorebird populations, and divided them into three categories (natural, current anthropogenic and future issues). The natural issues included megatsunamis, volcanoes and regional climate changes, while current anthropogenic threats encompassed agricultural intensification, conversion of tidal flats and coastal wetlands by human infrastructure developments and eutrophication of coastal systems. Possible future threats to shorebirds include microplastics, new means of recreation and infectious diseases. We suggest that this review process be broadened to other taxa to aid the identification and ranking of current and future conservation actions.

Sutton, R., et al. (2016). "Microplastic contamination in the San Francisco Bay, California, USA." Marine Pollution Bulletin **109**(1): 230-235.

Despite widespread detection of microplastic pollution in marine environments, data describing microplastic abundance in urban estuaries and microplastic discharge via treated municipal wastewater are limited. This study presents information on abundance, distribution, and composition of microplastic at nine sites in San Francisco Bay, California, USA. Also presented are characterizations of microplastic in final effluent from eight wastewater treatment plants, employing varying treatment technologies, that discharge to the Bay. With an average microplastic abundance of 700,000particles/km(2), Bay surface water appears to have higher microplastic levels than other urban waterbodies sampled in North America. Moreover, treated wastewater from facilities that discharge into the Bay contains considerable microplastic contamination. Facilities employing tertiary filtration did not show lower levels of contamination than those using secondary treatment. As textile-derived fibers were more abundant in wastewater, higher levels of fragments in surface water suggest additional pathways of microplastic pollution, such as stormwater runoff.

Suwanmanee, U., et al. (2013). "Life cycle assessment of single use thermoform boxes made from polystyrene (PS), polylactic acid, (PLA), and PLA/starch: Cradle to consumer gate." International Journal of Life Cycle Assessment **18**(2): 401-417.

Purpose: Currently, the bio-based plastics have been drawing considerable attention from the packaging industry as a sustainable solution for replacing petroleum-based plastics in order to reduce the accumulation of plastic waste in the environment. This work has benchmarked the environmental impact of bio-based against petroleum-based plastics for single use boxes. In this paper, the cradle to consumer gate environmental impact data of these boxes was calculated and reported as part 1. End-of-life options of both bio- and petroleum-based boxes are an important subject which will be further studied for part 2. The energy sources in this work were taken from the Thailand energy database namely: Thai electricity grid mix (TEGM), Thai coal electricity (TCE), Thai natural gas combine cycle (TNGCC), and Thai coal integrated gasification combine cycle (TIGCC). Method(s): The materials studied were polystyrene (PS) derived from petroleum, polylactic acid (PLA) derived from corn, and PLA/cassava starch blend (PLA/starch). The tray with lid (herein after called box) was processed in a plastic manufacturing in Thailand using cast sheet extrusion and then thermoforming techniques. The functional unit is specified as 10,000 units of 8.0 x 10.0 x 2.5 cm of PS, PLA, and PLA/starch boxes which weigh 447.60, 597.60, and 549.56 kg, respectively. Three impact categories; namely global warming potential including direct greenhouse gas, and indirect land use change (LUC) emissions, acidification, and photochemical ozone formation are investigated. Finally, the normalization results including and excluding LUC consideration were compared and reported. Results and discussion: The results from this study have shown that the total environmental impact including LUC emission of bio-based boxes were different when the various energy sources were supplied throughout the life cycle production stage. It can be seen that the PS box has lower environmental impact than

PLA and PLA/starch boxes when TEGM, TCE, TNGCC, and TIGCC were used as energy supplied. LUC of renewable feedstocks, such as corn and cassava, were considered as the biggest impact of absolute scores of PLA and PLA/starch boxes. These results are consistent with Piemonte and Gironi (2010). Conclusion(s): PLA and PLA/starch boxes give a slightly higher environmental impact than the PS box by 1.59 and 1.09 times, respectively, when LUC was not accounted in the absolute scores and clean energy TIGCC was used throughout the life cycle. © 2012 Springer-Verlag.

Suzuki, R., et al. (2002). "Development of a Novel Cytomedical Treatment that can Protect Entrapped Cells from Host Humoral Immunity." Cell Transplantation **11**(8): 787-797.

Cell therapy is expected to relieve the shortage of donors needed for organ transplantation. When patients are treated with allogeneic or xenogeneic cells, it is necessary to develop a means by which to isolate administered cells from an immune attack by the host. We have developed "cytomedicine, " which consists of functional cells entrapped in semipermeable polymer, and previously reported that alginate-poly-l-lysine-alginate microcapsules and agarose microbeads could protect the entrapped cells from injury by cellular immunity. However, their ability to isolate from humoral immunity was insufficient. It is well known that the complement system plays an essential role in rejection of transplanted cells by host humoral immunity. Therefore, the goal of the present study was to develop a novel cytomedical device containing a polymer capable of inactivating complement. In the screening of various polymers, polyvinyl sulfate (PVS) exhibited high anticomplement activity and low cytotoxicity. Murine pancreatic beta-cell line (MIN6 cell) entrapped in agarose microbeads containing PVS maintained viability and physiological insulin secretion, replying in response to glucose concentration, and resisted rabbit antisera in vitro. PVS inhibited hemolysis of sensitized sheep erythrocytes (EAs) and rabbit erythrocytes by the complement system. This result suggests that PVS inhibits both the classical and alternative complement pathways of the complement system. Next, the manner in which PVS exerts its effects on complement components was examined. PVS was found to inhibit generation of C4a and Ba generation in activation of the classical and alternative pathways, respectively. Moreover, when the EAC1 cells, which were carrying C1 on the EAs, treated with PVS were exposed to C1-deficient serum, hemolysis decreased in a PVS dose-dependent manner. These results suggest that PVS inhibits C1 in the classical pathway and C3 convertase formation in the alternative pathway. Therefore, PVS may be a useful polymer for developing an anticomplement device for cytomedical therapy.

Suzuki, Y., et al. (1977). "A simulation model for regional environmental impact analysis: a case study for the Kinki Region." International Journal of Environmental Studies **10**(2): 91-99.

This paper is concerned with an environmental impact analysis model for decision making in regional planning and management. The model considered in this paper is composed of three environmental impact submodels; namely, air pollution model (APM), water pollution model (WPM) and the model for solid wastes disposal, especially for plastic waste (SWM). All the submodels are set up to be interconnected in a simple but effective way to analyze the essential features of environmental impacts due to our activities in the region. By using the model stated above, a case study has been made of impact analysis for the Kinki Region, one of the economically important regions in Japan. The results of the case study indicate feasibility and applicability of the model to assess the future environmental impacts due to population increase and changes in pattern of material consumptions and of industrial activities in the region.

Svetlicky, N., et al. (2017). "Optimization of donor." Hla **89 (6)**: 405.

The pre-transplant complement-dependent cytotoxicity (CDC) cross-match (Xm) assay is a gold standard method for organ rejection prediction. There are three possible tissue sources for lymphocyte separation: lymph nodes, spleen and peripheral blood. A long established procedure for cell purification is using nylon wool column T and B cells separation. This method is convenient and cost effective, but has been found to be impractical when the lymphocyte source is donor's peripheral blood. In most of cases, results of CDC with nylon wool separated lymphocytes from peripheral blood are un-interpretable for cadaver sources due to high background non-specific cell mortality. However, the logistics of obtaining lymph nodes is more complicated and hence final result is usually much later than that of peripheral blood. The aim of this study was to determine the most effective way to obtain T and B lymphocytes from donor's blood. Toward this end, we compared four methods of separation with regard to yield, purity and convenience: RosetteSep gradient negative selection (StemCell), MACS MicroBeads magnetic beads positive separation (Miltenyi Biotec), MagniSort magnetic beads negative selection (eBioscience) and MACSprep HLA magnetic beads negative separation (Miltenyi Biotec). We found a significant decrease in concentration of lymphocytes in blood of deceased organ donors compared to living donors (2.7 x10^6/mL vs. 0.57 x10^6/mL). Each separation method had its advantages and disadvantages. Overall in our hands, we found the MACSprep HLA kit advantageous especially in terms of yield, purity and convenience. In addition, we compared CDC Xm results with cells that were separated from blood versus cells that were derived from lymph node of the same donor. We found no difference in T cell Xm results; however the B cell CDC sensitivity was much higher with peripheral blood (50% positive vs. 15%). These results requisite additional consideration in the analysis of cross-matches.

Syakti, A. D., et al. (2017). "Beach macro-litter monitoring and floating microplastic in a coastal area of Indonesia." Marine Pollution Bulletin **122**(1-2): 217-225.

Qualitative analysis of the structures of the polymers composing floating plastic debris was performed using attenuated total reflectance-Fourier transform infrared spectroscopy (ATR-FTIR), and the aging of the debris was assessed by measuring carbonyl group formation on the particle surfaces. Plastic material made up >75% of the 2313 items collected during a three-year survey. The size, shape and color of the microplastic were correlated with the polymer structure. The most abundant plastic materials were polypropylene (68%) and low-density polyethylene (11%), and the predominant colors of the plastics were white, blue and green. Cilacap Bay, Indonesia, was contaminated with microplastic at a concentration of 2.5mg.m³. The carbonyl index demonstrated that most of the floating microplastic was only slightly degraded. This study highlights the need to raise environmental awareness through citizen science education and adopting good environmental practices.

Syakti, A. D., et al. (2018). "Simultaneous grading of microplastic size sampling in the Small Islands of Bintan water, Indonesia." Marine Pollution Bulletin **137**: 593-600.

Despite Indonesia being considered as second highest source of marine plastic debris in the world, few studies have been conducted on plastic debris in Indonesia, particularly microplastics. By using a simple device to simultaneously grade floating microplastics, we investigated microplastic contamination in the ecosystem of small islands in Bintan Regency, Riau Island Province, Indonesia. The average number of floating microplastics from 11 beach stations around Bintan Island was 122.8+/-67.8 pieces per station, which corresponds to 0.45 pieces per m³ and represents a low-medium microplastic pollution level compared to the levels of other marine environments worldwide. Polymer identification using Attenuated

Total Reflectance-Fourier Transform Infrared (ATR-FTIR) Spectroscopy successfully identified Polyethylene (PE) (17.3+/-8.3%), Low Density PE (17.6+/-5.5%), Oxidized LDPE (<0.1%), Polypropylene (PP) (54+/-13%), PP Atactic (<0.4%), PP isotactic (<0.2%) and Polystyrene (PS) (10.4+/-9.1%) from different forms and shapes of microplastics i.e., fragments (50.9+/-4.9%), fibers (26.2+/-3%), granule (13.1+/-3.8%) and films (9.8+/-5.1%). We suggest that the generation of these microplastics was likely due to physicochemical processes, including biological degradation in this tropical ecosystem. Environmental implication of microplastics in this area increases the problems associated with ingestion, bioaccumulation and biomagnification across trophic levels and co-pollutants absorbed onto microplastics.

Syakti, A. D., et al. (2019). "Daily apportionment of stranded plastic debris in the Bintan Coastal area, Indonesia." Marine Pollution Bulletin **149 (no pagination)**(110609).

This study aims to provide a baseline report of the apportionment of stranded plastic debris (macro) in Bintan Island beaches. Their quantity and composition were assessed during a 45-day survey demonstrating the occurrence of the 3378 plastic fragments, which were, in decreasing order, constituted by LDPE (22.9%), PS (19.5%), PP (16.6%), PET (10.4%), HDPE (9.2%), PVC (7.2%), PU (4.9%), polyester (4.7%), polyamide (4.3%), and styrene/butadiene (0.3%). The abundance ranged from 1.2 to 4.7 items/m². Additional apportionment ranged from 0.03 to 0.15 items/m² per day with an arithmetic mean of 0.09 +/- 0.05 items/m² per day, mainly related to domestic waste influenced by hydrodynamic action such as longshore current and wind dynamics. Furthermore, we suggested mitigation measures focused on local action to address the plastic debris problem in Bintan beaches, which are typical of the coasts of small islands in Indonesia. Syakti, A. D., et al. (2019). "Bleaching and necrosis of staghorn coral (Acropora formosa) in laboratory assays: Immediate impact of LDPE microplastics." Chemosphere **228**: 528-535.

The impact of low-density polyethylene (LDPE) microplastics (<100 mum; P100-A P100-B, P100-C, 100-200 mum; P200, 200-500 mum; P500) on Acropora formosa was investigated. This study investigated the bleaching and necrosis extent of A. formosa caused by LDPE contamination via laboratory assay. The staghorn coral ingested the microplastics, resulting in bleaching and necrosis that concomitantly occurred with the release of zooxanthellae. P100-A experimentation was the worst case, showing bleaching by day 2 (10.8 +/- 2.2%) and continued bleaching to 93.6% +/- 2.0 by day 14 followed by 5.9 +/- 2.5% necrosis. The overall results confirmed that the LDPE concentration impacts coral health. We highlighted that microplastics have been ingested and partially egested. Their presence showed either a direct or indirect impact on coral polyps via direct interaction or through photosynthesis perturbation due to microplastics that cover the coral surface. Syberg, K., et al. (2015). "Microplastics: Addressing ecological risk through lessons learned." Environmental Toxicology and Chemistry **34**(5): 945-953.

Plastic litter is an environmental problem of great concern. Despite the magnitude of the plastic pollution in our water bodies, only limited scientific understanding is available about the risk to the environment, particularly for microplastics. The apparent magnitude of the problem calls for quickly developing sound scientific guidance on the ecological risks of microplastics. The authors suggest that future research into microplastics risks should be guided by lessons learned from the more advanced and better understood areas of (eco) toxicology of engineered nanoparticles and mixture toxicity. Relevant examples of advances in these twofields are provided to help accelerate the scientific learning curve within the relatively unexplored area of microplastics risk

assessment. Finally, the authors advocate an expansion of the "vector effect" hypothesis with regard to microplastics risk to help focus research of microplastics environmental risk at different levels of biological and environmental organization. Syberg, K., et al. (2017). "Microplastic potentiates triclosan toxicity to the marine copepod Acartia tonsa (Dana)." Journal of Toxicology and Environmental Health. Part A **80**(23-24): 1369-1371.

Microplastics (MP) are contaminants of environmental concern partly due to plastics ability to sorb and transport hydrophobic organic contaminants (HOC). The importance of this "vector effect" is currently being debated in the scientific community. This debate largely ignores that the co-exposures of MP and HOC are mixtures of hazardous agents, which can be addressed from a mixture toxicity perspective. In this study, mixture effects of polyethylene microbeads (MP) and triclosan (TCS) (a commonly used antibacterial agent in cosmetics) were assessed on the marine copepod Acartia tonsa. Data indicated that MP potentiate the toxicity of TCS, illustrating the importance of understanding the mixture interaction between plastics and HOC when addressing the environmental importance of the vector effect.

Szal, A. (2015). "Is Your State Considering Changes in Chemical Regulations?" Food Manufacturing.

Six states are considering phasing out bisphenol A, or BPA, from consumer products, while four states are set to take up restrictions on cadmium. Other potential measures include restrictions on formaldehyde, triclosan and microbeads.

Szczepanski, M. (2019). "Carbios' Technology Aims to Bio-recycle Plastic on an Industrial Scale." Waste360: N.PAG-N.PAG.

Companies across the globe are developing new ways to reduce plastic waste, which has become a growing problem of concern. Carbios' technology leverages enzymes that fully break down polyethylene terephthalate (PET) plastic waste and polyester fibers feedstock to successfully produce consumer-grade, 100 percent recycled plastic. "Carbios is the first and only company to combine two sciences that are solutions for the end of life of plastics", says Martin Stephan, deputy CEO of Carbios. [Extracted from the article]

Szczepanski, M. (2019). "India Announces Plans to Ban Scrap Plastic Imports." Waste360: N.PAG-N.PAG.

The article highlights India's announcement for planning ban scrap plastic imports. Topic includes India's efforts to strengthen the implementation of environmentally sound management of hazardous waste; exemption of industries that do not require consent under the Water Prevention and Control of Pollution Act, 1974 and the Air Prevention and Control of Pollution Act, 1981; and encouragement in education especially as programs to reduce contamination.

Szczotka, M., et al. (2012). "Blood dendritic cells in cattle infected with bovine leukemia virus (BLV): isolation and phenotyping." Polish Journal of Veterinary Sciences **15**(4): 599-608.

Dendritic cells (DCs) are most potent antigen presenting cells (APCs) with unique ability to prime

effective immune responses. They express higher levels of MHC class II and accesory molecules on their surface, than other professional APCs. The investigations were performed on DCs generated from blood with the use of microbeads magnetically labeled with mouse anti human CD14. Flow cytometry was applied for determination of DCs immunophenotype in healthy and naturally infected with BLV cattle. For immunophenotyping mouse monoclonal antibodies anti bovine: CD11a, CD11b, CD11c, MHC-I and MHC-II were used. Our results demonstrated that dendritic cells infected with BLV expressed very high percentage of determinants: CD11a, CD11b, CD11c, MHC-I and MHC-II class. Leukaemic DCs exhibited DCs morphology and had a phenotype of mature DCs. The expression of gp51 glycoprotein of BLV on leukaemic DCs was detected in flow cytometry investigations.

T. R, Y. "Towards a Pollution-Free Planet".

The article discusses the highlights of the Third Session of the United Nations Environment Assembly (UNEA-3) held in Nairobi, Kenya in December 2017. Resolutions presented at the session focused on pollution issues, including air quality, marine plastic litter and microplastics and lead paint and lead-acid batteries. Delegates adopted a critical decision on the United Nations Environment Programme's management of trust funds and earmarked contributions.

Tabrizian, N., et al. (2017). "The Biology of beta-D-mannuronic acid (M2000) on Human Dendritic Cell Based on MicroRNA-155 and MicroRNA-221." Current Drug Discovery Technologies **14**(1): 53-58.

BACKGROUND: The aim of this study was to evaluate the effect of s-Dmannuronic acid (M2000) on related miRNAs to dendritic cells (DCs) differentiation. DC-based immunosuppressive drugs can suppress the progression of autoimmune diseases, however, their notable side effects in increasing the risk of infectious diseases and cancers should be considered. The beta-D-mannuronic acid, as a novel non-steroidal anti-inflammatory agent, has been tested in various experimental models.

METHOD: The effect of M2000 on expression of miRNA-155 and miRNA-221 was examined. To investigate how M2000 affects differentiation of human dendritic DCs in a defined inflammatory environment, human peripheral blood mononuclear cells were isolated from healthy blood and the monocytes were purified using anti-CD14 microbeads. The so isolated monocytes were subsequently incubated in the presence of M2000 in two different doses (3 and 6 mMol/well) adding granulocyte-macrophage colony-stimulating factor (GM-CSF) and interleukin-4 for inducing monocytes to immature DC and lipopolysaccharide for running DC differentiation. The expression of miRNA-155 and miRNA-221 were examined with Real Time PCR.

RESULTS: The results demonstrate that M2000 has no significant side effect on expression of miR-155 and miR-221 in both immature DC and mature DC process in vitro.

CONCLUSION: Our findings show that beta-D-mannuronic acid is a safe agent which has no adverse effect on regulatory miRNA-155 and miRNA-221 in dendritic cells.

Tabuenca, B., et al. (2019). "Massive Open Online Education for Environmental Activism: The Worldwide Problem of Marine Litter." Sustainability **11**(10).

Because of the increasing amounts of microplastics and plastics in the environment there are serious concerns about the effects on marine ecosystems, human health [10,11], and food safety [12]. Thinking globally and acting locally is a fundamental attitude to reduce this threat to the environment. [...]in this work, MOOCs are studied as a massive tool focused on action, to explore and disseminate ways of tackling the global problem of marine litter from an educational perspective. Providing in-depth knowledge is the key to identifying the origin of the problem and to providing reachable solutions. [...]this paper shows that students enrolled in the

course aimed at identifying people and specialized organizations to join skills, knowledge, and experiences towards joining forces to combat a worldwide problem (see Section 3.1.2). From a critical perspective, environmental activists might sometimes be isolated in the virtual world leading to inconclusive actions. [...]it is key to facilitate ways to enroll and to participate in active groups to keep the germ of environmental activism from the virtual world (see Section 3.2.1, perceived activism) and also alive in the physical world.

Tagg, A. S. and J. A. Ivar do Sul (2019). "Is this your glitter? An overlooked but potentially environmentally-valuable microplastic." Marine Pollution Bulletin **146**: 50-53.

As microplastic pollution evolved to a well-established research field, microplastic scientists started to explore new avenues in the field. Yet, while a multitude of different types of microplastics (microbeads, fibres, fragments) have been well-documented in microplastic literature, our analysis of this literature shows that glitter particles have been overlooked by the field. However, due to the presence of glitter-based research in forensic science, we explore the idea that glitter may have the potential to act as "flag items" - or markers - of a likely source, due to the often complex and individual composition of glitter particles compared to traditional microplastics, such as microbeads. As such, this article demonstrates glitter has insofar been overlooked as a microplastic particle, and demonstrates that glitter may have an important role in explaining microplastic pollution dynamics from source to sink.

Tagg, A. S. and M. Labrenz (2018). "Closing Microplastic Pathways before They Open: A Model Approach." Environmental Science and Technology **52**(6): 3340-3341.

Taguchi, K., et al. (2014). "Biobased carbon content of resin extracted from polyethylene composite by carbon-14 concentration measurements using accelerator mass spectrometry." Springerplus **3**: 6.

An estimation procedure for biobased carbon content of polyethylene composite was studied using carbon-14 ((14)C) concentration ratios as measured by accelerated mass spectrometry (AMS). Prior to the measurement, additives and fillers in composites should be removed because they often contain a large amount of biobased carbon and may shift the estimation. Samples of resin with purity suitable for measurement were isolated from composites with a Soxhlet extractor using heated cyclohexanone. After cooling of extraction solutions, the resin was recovered as a fine semi-crystalline precipitate, which was easily filtered. Recovery rates were almost identical (99%), even for low-density polyethylene and linear low-density polyethylene, which may have lower crystallinity. This procedure could provide a suitable approach for estimation of biobased carbon content by AMS on the basis of the standard ASTM D 6866. The biobased carbon content for resin extracted from polyethylene composites allow for the calculation of biosynthetic polymer content, which is an indicator of mass percentage of the biobased plastic resin in the composite.

Taguchi, T., et al. (2007). "Detection of Cryptosporidium parvum oocysts using a microfluidic device equipped with the SUS micromesh and FITC-labeled antibody." Biotechnology and Bioengineering **96**(2): 272-280.

Development of a microfluidic device equipped with micromesh for detection of Cryptosporidium parvum oocyst was reported. A micromesh consisting of 10 x 10 cavities was microfabricated on the stainless steel plate by laser ablation. Each cavity size, approximately 2.7 mum in diameter, was adopted to capture a single C. parvum oocyst. Under negative pressure operation, suspensions containing microbeads or C. parvum oocysts flowed into the microchannel. Due to strong non-specific adsorption of microbeads onto the PDMS microchannel surface during sample injection, the surface was treated with air plasma, followed by treatment with 1% sodium dodecyl sulfate (SDS) solution. This process reduced the non-specific adsorption of microbeads on the microchannel to 10% or less in comparison to a non-treated microchannel. This microfluidic device equipped with the SUS micromesh was further applied for the capture of C. parvum oocysts. Trapped C. parvum oocysts were visualized by staining with FITC-labeled anti-C. parvum oocyst antibody on a micromesh and counted under fluoroscopic observation. The result obtained by our method was consistent with that obtained by direct immunofluorescence assay coupled with immunomagnetic separation (DFA-IMS) method, indicating that the SUS micromesh is useful for counting of C. parvum oocysts. The newly designed microfluidic device exploits a geometry that allowed for the entrapment of oocysts on the micromesh while providing the rapid introduction of a series of reagents and washes through the microfluidic structure. Our data indicate that this microfluidic device is useful for high-throughput counting of C. parvum oocysts from tap water sample. © 2006 Wiley Periodicals, Inc.

Tahir, A., et al. (2019). Studies on microplastic contamination in seagrass beds at Spermonde Archipelago of Makassar Strait, Indonesia. Journal of Physics: Conference Series.

There is growing awareness and concern on microplastics pollution in marine environments. Seagrasses are among the most productive shallow water ecosystems, serving a diverse assemblage of fish and invertebrates. Sediment and benthic animal samples collected from small islands at Spermonde archipelago confirmed the presence of microplastics with different levels of contamination. The occurrence of microplastics for up to 28.29% and 25% of contamination level in sediments and benthic animals, respectively, clearly indicated an alarming state of the microplastics pollution in rich and productive shallow water seagrass ecosystem of tropical seas. Moreover, all positively contaminated microplastics of benthic animals are for human consumption and therefore pose threats for microplastics transfers which may facilitate pathways for a wide spectrum of organic pollutants entering the food web and affecting human health. © 2019 Published under licence by IOP Publishing Ltd.

Tahir, A., et al. (2019). "Microplastics in water, sediment and salts from traditional salt producing ponds." Global Journal of Environmental Science and Management **5**(4): 431-440.

Plastic pollution has universally known accumulated in all environment compartments and accelerating threat to the sustainability of earth. Field survey to examine the occurrence of microplastics in ancient sea water evaporation technology of ponds at Pallengu-Jeneponto, was conducted. From this sea salt producing ponds, samples of water, sediment and freshly harvested salts were collected. Sixteen samples each of water and sediments and 12 salts were collected. From 16 water and sediment samples there are 31 microplastics item discovered in 11 water samples (68.75% of total contamination) and 41 microplastics item observed in 10 sediment samples (62.5% total contamination), respectively. Interestingly, sampling points at sedimentation/heating pools were found to be the locations with highest occurrence of microplastics in both water and sediment. There are 7 salt samples positively contaminated with 29 microplastics or 58.3% of total contamination, which predominated by line and fragment forms. Fourier transform infra-red spectroscopy analysis has revealed polymers of polyvinyl acetate (41.7%), polyethylene (33.3%) and polystyrene (25%). There was no significant difference found on microplastics occurrence from 3 kinds of samples collected, although there was a decreasing trend of total microplastics found from water, sediment and salt. Microplastics abundance were ranged 7-55 items/L water, 14.6-50 items/kg sediments and 6.7-53.3 items/kg salt. With microplastics abundance reached over 53 microplastics items/kg salt, it is believed

that continuous consumption by people will end up with possible accumulation of potentially absorbed of various toxic chemical pollutants which present in sea water as salt raw materials. The need for robust and practical strategy in water quality management for reduction of microplastics contamination in consumed salts is a must.

Takacova, M., et al. (2016). "Encapsulation of anti-carbonic anhydrase IX antibody in hydrogel microspheres for tumor targeting." Journal of Enzyme Inhibition & Medicinal Chemistry **31**(sup1): 110-118.

Encapsulation is a well-established method of biomaterial protection, controlled release, and efficient delivery. Here we evaluated encapsulation of monoclonal antibody M75 directed to tumor biomarker carbonic anhydrase IX (CA IX) into alginate microbeads (SA-beads) or microcapsules made of sodium alginate, cellulose sulfate, and poly(methylene-co-guanidine) (PMCG). M75 antibody release was quantified using ELISA and its binding properties were assessed by immunodetection methods. SA-beads showed rapid M75 antibody release in the first hour, followed by steady release during the whole experiment of 7 days. In contrast, the M75 release from PMCG capsules was gradual, reaching the maximum concentration on the 7th day. The release was more efficient at pH 6.8 compared to pH 7.4. The released antibody could recognize CA IX, and target the CA IX-positive cells in 3D spheroids. In conclusion, SA-beads and PMCG microcapsules can be considered as promising antibody reservoirs for targeting of cancer cells.

Takamatsu, H., et al. (2016). "Development of novel human anti-HLA-monoclonal antibodies for clinical applications using peripheral blood B cells derived from anti-HLA antibody-positive donors." Blood. Conference: 58th Annual Meeting of the American Society of Hematology, ASH **128**(22).

Introduction: The development of monoclonal antibodies (mAbs) such as anti-CD20 mAb (rituximab) and anti-CD38 mAb (daratumumab) has revolutionized the treatment of lymphoid malignancies. Potential efficacy of HLA allele-specific mAbs in treating malignant lymphoma has been shown by several studies. However, treatment of B-cell malignancies with humanized mAbs against HLA-DR alleles is associated with infusion-related toxicities (Lin et al., Leuk Lymphoma, 2009). In addition, previous attempts to develop mAbs specific to some HLA alleles (e.g., HLA-B61) by immunizing mice with recombinant HLA proteins have failed, likely because of a wide Variety of polymorphisms of HLA molecules. To overcome these problems, we recently created a novel method to develop mAbs using microarray technology and human peripheral blood (PB) B lymphocytes derived from donors who are positive for anti-HLA antibodies. The process took approximately 1 month to produce human anti-HLA mAbs. Method(s): Approximately 20 ml of PB was collected from anti-HLA antibody-positive donors, and mononuclear cells (MNCs) isolated using the Ficoll-Hypaque method were cultured in RPMI-1640 + 10% FCS containing 5 mug/ml R-848, 1000 IU/ml hIL2, 2.5 mug/ml CpG2006, 2.5 mug/ml anti-CD40 antibody, 100 ng/ml hIL21, 2 ng/ml hIL17, 10 ng/ml hIL4, and 100 ng/ml hBAFF for 6 days. CD138⁺ cells were then isolated using anti-CD138-antibody-conjugated microbeads. A microwell array chip was manufactured using micromachining techniques, as previously described (Jin et al., Nature Medicine, 2009). Microwells (diameter, 10 mum; depth, 15 mum) were formed on a silicon surface. The chip was coated with a PBS-containing purified HLA antigen (10 mug/ml) and incubated overnight at 4degreeC. After removing the antigen solution, 50 mul of the CD138⁺ cell suspension was added to the chip, and the mixture was incubated for 4 h at 37degreeC. After gentle washing with PBS, 2 mug/ml of anti-human IgG Fc-Cy3 solution was added to the microwells, and the plate was left at room temperature for 15 min. Finally, the cells were

stained with 1 muM Oregon Green for 2 min. The microwells were screened for the antigen-specific antibodies released from single cells under a fluorescence microscope. Antigen-specific antibody-secreting cells (ASCs) from individual wells were isolated using a micromanipulator fitted with capillaries under the fluorescence microscope and were then expelled to microtubes for reverse transcription. The antibody cDNA fragments for VH and VL fragments were amplified using the single-cell 5'-RACE method and inserted into expression vectors containing the complete constant region of cDNA for heavy or light chains. Thereafter, CHO cells were transfected with both the heavy and light chain expression vectors to obtain a supernatant containing complete antibody molecules. The antigen specificity of the recombinant antibodies was examined using ELISA and flow cytometry (FCM). The frequency of ASCs in the PB-MNCs of donors was quantified using allele-specific oligonucleotide PCR. Complement-dependent cytotoxicity (CDC) and antibody-dependent cellular cytotoxicity (ADCC) of the mAbs were assessed using conventional methods. Results and Discussion: Two novel human mAbs specific to HLA-A24 and HLA-B61 were successfully generated. The antigen specificity of the mAbs was confirmed using ELISA and FCM. The mAbs bound to normal and malignant blood cells that expressed corresponding HLA alleles and showed CDC/ADCC activities against five B lymphoblastoid cell lines but not against lymphocytes/monocytes/granulocytes derived from five healthy donors, probably because of low expression levels of the target HLA alleles. The frequency of ASCs in PB-MNCs of donors was less than 0.001%. Conclusion(s): The present method enabled the generation of mAbs specific to HLA alleles, which can be used for detecting minimal residual diseases of hematological malignancies as well as for treating B-cell lymphoma, within 1 month.

Takano, K., et al. (2015). "Increase of transglutaminase 2 expression and endocytosis activity by amphotericin B in mouse microglial cell line BV-2." Journal of Pharmacological Sciences **1)**: S221.

Amphotericin B (AmB), a polyene antibiotic, is reported to have therapeutic effects on prion diseases, in which the activation of glial cells has been suggested to play important roles by proliferating and producing various factors such as nitric oxide (NO), proinflammatory cytokines, and so on. In the previous study, we presented that AmB induced NO production and proinflammatory cytokines expression, and changed neurotrophic factors expression in cultured microglia. On the other hand, transglutaminase 2 (TG2), a crosslinking enzyme, is reported to be involved in inflammation and neurodegenerative diseases. In the present study, we investigated the effects of AmB on TG2 expression and endocytosis activity in mouse microglial cell line BV-2. We found that AmB could increase TG2 expression and TG activity in a concentration-dependent manner. AmB also increased endocytosis activity assessed by incorporation of fluorescent microbeads or dead-cells. AmB-increased TG2 expression and endocytosis activity were suppressed by a TG inhibitor, cystamine. These results suggest that AmB could activate microglia to increase phagocytosis accompanied with TG2 expression.

Takao, M., et al. (2018). "Flow cytometric quantitation of EpCAM-positive extracellular vesicles by immunomagnetic separation and phospholipid staining method." Genes to Cells **23**(11): 963-973.

Extracellular vesicles (EV) have attracted attention as circulating biomarkers for many diseases, particularly cancer. Conventional immunofluorescence staining has been used for the detection of target antigens on EV by flow cytometry. However, the staining intensity depends on the amount of antigen expressed on the vesicles and is often only around the noise level. Instead of immunofluorescence, we combined immunomagnetic separation using nanosize MACS MicroBeads with phospholipid staining of EV (IMS-PS method). EpCAM-positive EV were prepared from the culture supernatants of OVCAR3 (EpCAM-high), A431 (EpCAM-low) or

Colon-26 (non-human control) cells as cancer models and were examined by the IMS-PS method using EpCAM mAb-coated MicroBeads. By employing Polaric-500c6F as the dye for staining EV phospholipids and using appropriate flow cytometry settings, autofluorescence was excluded, whereas pretreatment of the MicroBeads with conventional blocking agents reduced nonspecific binding to non-target vesicles. These modifications resulted in a linear relation between the number of EV detected and the sample volume, regardless of the level of EpCAM expression on the vesicles. A431 EV spiked into healthy volunteer plasma were enumerated with good accuracy. The IMS-PS method may be useful for clinical evaluation of EV with low levels of antigen expression that are difficult to detect by conventional immunofluorescence.

Takao, M. and K. Takeda (2011). "Enumeration, characterization, and collection of intact circulating tumor cells by cross contamination-free flow cytometry." Cytometry Part A: The Journal of the International Society for Analytical Cytology **79**(2): 107-117.

Circulating tumor cells (CTC) are an important biomarker for several solid cancers. Most of the commercially available systems for enumeration of CTC are based on immunomagnetic enrichment of epithelial cell adhesion molecule (EpCAM/CD326)-expressing CTC before microscopic cell imaging or reverse-transcription PCR (RT-PCR). The aim of this study was to establish a practical method for enumeration of CTC using a novel flow cytometer that has a disposable microfluidic chip, which is designed to realize absolute cross contamination-free measurements and to collect the analyzed cell sample. Although the process of enumeration and labeling of CTC was optimized for this device, the simplified protocol described here could be applied to other flow cytometers. Cultured cancer cells spiked into normal blood were enriched using MACS EpCAM-MicroBeads following cell labeling with an allophycocyanin (APC)-conjugated EpCAM mAb, instead of by intracellular staining of cytokeratins (CK). The EpCAM double-positive selection/labeling method allows enumeration of intact CTC, maintenance of cellular integrity, and the concomitant performance of a CTC viability test. The combination of the fine-tuned CTC enrichment process and the cytometric multicolor analysis resulted in a linear relationship between the output cell count and the input cell number from zero to hundreds of cells. In particular, a satisfactory signal/noise ratio was obtained by gate-exclusion of leukocyte signals using an anti-CD45 mAb. The entire process had little influence on the viability of the spiked lung cancer cell PC-9. Measured PC-9 and breast cancer MCF-7 cells bearing EpCAM-MicroBeads, APC-conjugated EpCAM mAb, and the DNA staining dye SYTO9 grew normally, demonstrating the potential usefulness of the collected samples for further studies. This intact CTC enumeration and analysis procedure (iCeap) would be of great benefit to clinicians by providing them with rapid stratification of antitumor therapy, and to basic researchers by permitting further molecular and cellular characterization of CTC.

Takayama, H., et al. (1985). "[A case of ossifying fibroma of the skull]." No Shinkei Geka - Neurological Surgery **13**(6): 669-673.

A 23-year-old woman was admitted to our hospital because of a soft, painful mass in the right parietal region for a month. Neurological examination revealed no abnormality. Laboratory data including serum Ca, P and alkaline phosphatase were normal. Skull x-ray film showed a partially osteolytic, not well circumscribed lesion in the right frontal, parietal and occipital bone. No remarkable sclerotic area was seen in the lesion. CT scan showed that the lesion was located in the diploe, destroying both inner and outer tables of the bone. Right external carotid angiogram revealed that the lesion is supplied by the branches of superficial temporal artery and middle meningeal artery. 99mTc bone scan showed increased uptake in the lesion. The patient underwent a right parietal craniectomy. The skull bone was invaded by the tumor, which was yellow-brown in color, thickened and fragile. We could easily perforate it through. The tumor didn't invade the dura mater or periosteum. It was extensively removed with an airtome and rongeurs. A cranioplasty was carried out using a plastic resin. The pathological specimen showed that the tumor was mainly composed of mature, regularly-aligned bone and intermingled fibrous tissue. Neither mitosis nor atypical cellular features was seen. These findings were compatible with the diagnosis of ossifying fibroma. The postoperative course was uneventful and the patient was discharged in a good condition. There was no evidence of local recurrence 10 months later. Ossifying fibroma is a rare, benign bone tumor that mainly involves the craniofacial bone. The differential diagnosis of ossifying fibroma versus fibrous dysplasia is difficult. These diseases can be differentiated on combined clinical, radiological and morphological grounds.

Takenouchi, T., et al. (2017). "Immortalization and Characterization of Porcine Macrophages That Had Been Transduced with Lentiviral Vectors Encoding the SV40 Large T Antigen and Porcine Telomerase Reverse Transcriptase." Frontiers in Veterinary Science **4**: 132.

The domestic pig is an important agricultural animal, and thus, infectious diseases that affect pigs can cause severe economic losses in the global swine industry. Various porcine pathogens target macrophages, which are classical innate immune cells. Although macrophages basically protect the host from pathogens, they also seem to contribute to infectious processes. Therefore, cultured macrophages can be used to develop in vitro models for studying not only genes associated with porcine innate immunity but also the infectious processes of porcine pathogens. However, the availability of porcine macrophage cell lines is limited. In this study, we describe a novel immortalized porcine kidney-derived macrophage (IPKM) cell line, which was generated by transferring the SV40 large T antigen (SV40LT) and porcine telomerase reverse transcriptase (pTERT) genes into primary porcine kidney-derived macrophages using lentiviral vectors. The IPKM displayed a typical macrophage morphology and was routinely passaged (doubling time: about 4 days). These cells were immunostained for macrophage markers. In addition, they exhibited substantial phagocytosis of polystyrene microbeads and released inflammatory cytokines upon lipopolysaccharide (LPS) stimulation. Furthermore, the maturation and secretion of interleukin-1beta were observed after nigericin-induced inflammasome activation in LPS-primed IPKM. These findings suggest that IPKM exhibit the typical inflammatory characteristics of macrophages. By transferring the SV40LT and pTERT genes using lentiviral vectors, we also successfully immortalized macrophages derived from the peripheral blood of a low-density lipoprotein receptor-deficient pig. These results suggest that the co-expression of SV40LT and pTERT is an effective way of immortalizing porcine macrophages.

Takeuchi, M., et al. (2009). "Chemistry of fly ash and cyclone ash leachate from waste materials and effects of ash leachates on bacterial growth, nitrogen-transformation activity, and metal accumulation." Journal of Hazardous Materials **165**(1-3): 967-973.

The effects of waste ash leachates on soil microorganism were evaluated along with a chemical characterization of ash leachates. Thirty fly ash samples and cyclone ash samples obtained from the incineration of municipal solid waste, plastic waste, and construction waste were used. Twenty-one and 22 samples inhibited N transformation activity of soil microorganism and growth of Bacillus subtilis, respectively. On the other hand, 11 and 18 samples stimulated bacterial activity and growth, respectively, at low concentrations. Generally, cyclone ash contained a smaller amount of toxic metals than fly ash. Our results suggest that cyclone ash can be further studied for reuse, perhaps as a soil amendment. Pb was found to be highly accumulated in B. subtilis cells, and should be carefully monitored when waste ash is reused in

the environment.

Taki, H., et al. (2019). "Fundamental evaluation and optimization of porous spherical silica for developing functional fine particles via fluidized bed coating." International Journal of Pharmaceutics **571**: 118685.

Particle coating, a taste-masking technique for drugs, is limited by its long manufacturing time, which is caused by the decrease in the spray rate required to prevent particle agglomeration. Mesoporous silica particles, which have a high surface area and pore sizes in the range of 2-50nm, possess high surface free energy; they have attracted significant interest for numerous applications in adsorption, separation, and catalysis and drug delivery. A form of mesoporous silica, microbead silicate, can prevent particle aggregation because of its good water absorbency and drying properties. Hence, it has been suggested to be applicable for particle coating. This study evaluated the physical properties and drug release capability of microbead silicate with different pore sizes. Although microbead silicate with small pores displayed a rapid drug release profile, drug release was incomplete. Contrastingly, microbead silicate with large pores achieved complete drug release even with high drug loading. Furthermore, in the case of 100% layering, the porosity of microbead silicate was maintained, thus sufficiently preventing aggregation due to the prevention of formation of liquid bridging of the coating solution. These results suggest that using microbead silicate with large pores for particle coating enables complete drug release while improving manufacturability.

Tallec, K., et al. (2019). "Surface functionalization determines behavior of nanoplastic solutions in model aquatic environments." Chemosphere **225**: 639-646.

Plastic debris are classified as a function of their size and recently a new class was proposed, the nanoplastics. Nano-sized plastics have a much greater surface area to volume ratio than larger particles, which increases their reactivity in aquatic environment, making them potentially more toxic. Only little information is available about their behavior whereas it crucially influences their toxicity. Here, we used dynamic light scattering (DLS) to explore the influence of environmental factors (fresh- and saltwater, dissolved organic matter) on the behavior (surface charge and aggregation state) of three different nano-polystyrene beads (50nm), with (i) no surface functionalization (plain), (ii) a carboxylic or (iii) an amine functionalization. Overall, the positive amine particles were very mildly affected by changes in environmental factors with no effect of the salinity gradient (from 0 to 653mM) and of a range 1-30mug.L⁻¹ and 1-10mug.L⁻¹ of organic matter in artificial seawater and ultrapure water, respectively. These observations are supposedly linked to a coating specificity leading to repulsive mechanisms. In contrast, the stability of the negatively charged carboxylic and plain nanobeads was lost under an increasing ionic strength, resulting in homo-aggregation (up to 10mum). The increase in organic matter content had negligible effect on these two nanobeads. Analysis performed over several days demonstrated that nanoplastics formed evolving dynamic structures detected mainly with an increase of the homo-aggregation level. Thus, surface properties of given polymers/particles are expected to influence their fate in complex and dynamic aquatic environments.

Tallec, K., et al. (2018). "Nanoplastics impaired oyster free living stages, gametes and embryos." Environmental Pollution **242**(Part B): 1226-1235.

In the marine environment, most bivalve species base their reproduction on external fertilization. Hence, gametes and young stages face many threats, including exposure to plastic wastes which represent more than 80% of the debris in the oceans. Recently, evidence has been produced on the presence of nanoplastics in oceans, thus motivating new studies of their impacts on marine life. Because no information is available about their environmental concentrations, we performed dose-response exposure experiments with polystyrene particles to assess the extent of micro/nanoplastic toxicity. Effects of polystyrene with different sizes and functionalizations (plain 2- micro m, 500-nm and 50-nm; COOH-50 nm and NH₂-50 nm) were assessed on three key reproductive steps (fertilization, embryogenesis and metamorphosis) of Pacific oysters (Crassostrea gigas). Nanoplastics induced a significant decrease in fertilization success and in embryo-larval development with numerous malformations up to total developmental arrest. The NH₂-50 beads had the strongest toxicity to both gametes (EC₅₀=4.9 micro g/mL) and embryos (EC₅₀=0.15 micro g/mL), showing functionalization-dependent toxicity. No effects of plain microplastics were recorded. These results highlight that exposures to nanoplastics may have deleterious effects on planktonic stages of oysters, presumably interacting with biological membranes and causing cyto/genotoxicity with potentially drastic consequences for their reproductive success.

Talvitie, J., et al. (2015). "Do wastewater treatment plants act as a potential point source of microplastics? Preliminary study in the coastal Gulf of Finland, Baltic Sea." Water Science & Technology **72**(9): 1495-1504.

This study on the removal of microplastics during different wastewater treatment unit processes was carried out at Viikinmaki wastewater treatment plant (WWTP). The amount of microplastics in the influent was high, but it decreased significantly during the treatment process. The major part of the fibres were removed already in primary sedimentation whereas synthetic particles settled mostly in secondary sedimentation. Biological filtration further improved the removal. A proportion of the microplastic load also passed the treatment and was found in the effluent, entering the receiving water body. After the treatment process, an average of 4.9 (+/-1.4) fibres and 8.6 (+/-2.5) particles were found per litre of wastewater. The total textile fibre concentration in the samples collected from the surface waters in the Helsinki archipelago varied between 0.01 and 0.65 fibres per litre, while the synthetic particle concentration varied between 0.5 and 9.4 particles per litre. The average fibre concentration was 25 times higher and the particle concentration was three times higher in the effluent compared to the receiving body of water. This indicates that WWTPs may operate as a route for microplastics entering the sea.

Talvitie, J., et al. (2017). "Solutions to microplastic pollution - Removal of microplastics from wastewater effluent with advanced wastewater treatment technologies." Water Research **123**: 401-407.

Conventional wastewater treatment with primary and secondary treatment processes efficiently remove microplastics (MPs) from the wastewater. Despite the efficient removal, final effluents can act as entrance route of MPs, given the large volumes constantly discharged into the aquatic environments. This study investigated the removal of MPs from effluent in four different municipal wastewater treatment plants utilizing different advanced final-stage treatment technologies. The study included membrane bioreactor treating primary effluent and different tertiary treatment technologies (discfilter, rapid sand filtration and dissolved air flotation) treating secondary effluent. The MBR removed 99.9% of MPs during the treatment (from 6.9 to 0.005 MP L⁻¹), rapid sand filter 97% (from 0.7 to 0.02 MP L⁻¹), dissolved air flotation 95% (from 2.0 to 0.1 MP L⁻¹) and discfilter 40-98.5% (from 0.5 - 2.0 to 0.03-0.3 MP L⁻¹) of the MPs during the treatment. Our study shows that with advanced final-stage wastewater treatment technologies WWTPs can substantially reduce the MP pollution discharged from wastewater treatment plants into the aquatic environments.

Talvitie, J., et al. (2017). "How well is microlitter purified from wastewater? - A detailed study on the stepwise removal of microlitter in a tertiary level wastewater treatment plant." Water Research **109**: 164-172.

Wastewater treatment plants (WWTPs) can offer a solution to reduce the point source input of microlitter and microplastics into the environment. To evaluate the contributing processes for microlitter removal, the removal of microlitter from wastewater during different treatment steps of mechanical, chemical and biological treatment (activated sludge) and biologically active filter (BAF) in a large (population equivalent 800 000) advanced WWTP was examined. Most of the microlitter was removed already during the pre-treatment and activated sludge treatment further decreased the microlitter concentration. The overall retention capacity of studied WWTP was over 99% and was achieved after secondary treatment. However, despite of the high removal performance, even an advanced WWTP may constitute a considerable source of microlitter and microplastics into the aquatic environment given the large volumes of effluent discharged constantly. The microlitter content of excess sludge, dried sludge and reject water were also examined. According to the balance analyses, approximately 20% of the microlitter removed from the process is recycled back with the reject water, whereas 80% of the microlitter is contained in the dried sludge. The study also looked at easy microlitter sampling protocol with automated composite samplers for possible future monitoring purposes.

Tamaddon, F. and W. Hogland (1993). "Review of cadmium in plastic waste in Sweden." Waste Management and Research **11**(4): 287-295.

Cadmium containing stabilizers are used only in certain polyvinylchloride (PVC) products for special weather, light or temperature resistance. The total consumption of cadmium used as a chemical stabilizer in Sweden is expected to be about 1.5 tonnes/year in 1991-1992, while the amount in pigments is approximated to be 6 tonnes/year. It is determined that most of the cadmium that enters into the combustible fraction of municipal solid waste (MSW) comes from plastics and pigments in various products. Acrylonitrile Butadiene Styrene copolymers (ABS) products are the main source of plastics contained cadmium pigments. These products are usually consumer electronics such as television and telephone sets, computer, radios, etc. In practice, it is very difficult for a country like Sweden to act alone and implement regulations for cadmium due to international trade and heavy import/export of products. There is no doubt that the transition period to adopt other alternatives, as requested by the Swedish Cadmium Ordinance, takes time and a flow of cadmium from plastic wastes into landfills and incinerators is expected during the coming years. This is also due to the long lifetime of some plastic products which contain cadmium. Continuous and consistent monitoring of cadmium in landfills and incineration plants is required in order to be able to evaluate the effect of the Ordinance on cadmium.

Tamminga, M., et al. (2018). "Microplastic analysis in the South Funen Archipelago, Baltic Sea, implementing manta trawling and bulk sampling." Marine Pollution Bulletin **128**: 601-608.

Microplastic contamination in surface waters of the South Funen Archipelago in Denmark was assessed. Therefore, ten manta trawls were conducted in June 2015. Moreover, 31 low-volume bulk samples were taken to evaluate, whether consistent results in comparison to the net-based approach can be obtained. Microplastic contamination in the South Funen Archipelago (0.07+/-0.02particles/m3) is slightly below values reported before. The sheltered position of the study area, low population pressure on adjacent islands and the absence of any major potential point sources were identified as major factors explaining the low concentration of microplastics. Within the Archipelago, harbors or marinas and the associated vessel traffic are the most probable sources of microplastics. The concentration of microplastics in low-volume bulk samples is not comparable to manta trawl results. This is mainly due to insufficient representativeness of the bulk sample volumes.

Tamminga, M., et al. (2019). "On the representativeness of pump water samples versus manta sampling in microplastic analysis." Environmental Pollution **254**: N.PAG-N.PAG.

To broaden the understanding of sources, pathways and sinks for microplastic pollution in the environment, the exact and representative determination of pollution levels is crucial. Still, sampling techniques differ greatly between studies and the influence of these differences is not fully understood. Thus, we evaluate the representativeness of manta trawling and pump sampling for microplastics in a freshwater lake. While large microplastics are not captured by most pump sampling approaches due to their low abundance, small and fibrous microplastics pass the relatively coarse nets of volume-reduced techniques. Testing different water volumes for pump samples, we show that sample volumes should be large enough to minimize overestimation induced by scaling up results. Moreover, we discuss the influence of sample numbers for microplastic analysis. Finally, we argue that manta trawling and pump sampling are complementary techniques, as they cover different parts of the overall microplastic pollution. Image 1 • Manta trawling and pump sampling are complementary techniques. • Sample volumes have a strong influence on obtained results. • Sampling replicates of more than five are needed to prevent extensive variation. • Nile Red staining showed a high validation rate (98.6%) by µ-Raman-spectroscopy. • Microplastic pollution followed spatial gradients driven by human activities. We assess the representative collection of microplastics in freshwater bodies by comparing manta trawling and bulk water sampling and demonstrate these to be complementary techniques. Tamura, M., et al. (2014). "Optical cell separation from three-dimensional environment in photodegradable hydrogels for pure culture techniques." Scientific Reports **4**: 4793.

Cell sorting is an essential and efficient experimental tool for the isolation and characterization of target cells. A three-dimensional environment is crucial in determining cell behavior and cell fate in biological analysis. Herein, we have applied photodegradable hydrogels to optical cell separation from a 3D environment using a computer-controlled light irradiation system. The hydrogel is composed of photocleavable tetra-arm polyethylene glycol and gelatin, which optimized cytocompatibility to adjust a composition of crosslinker and gelatin. Local light irradiation could degrade the hydrogel corresponding to the micropattern image designed on a laptop; minimum resolution of photodegradation was estimated at 20 micro m. Light irradiation separated an encapsulated fluorescent microbead without any contamination of neighbor beads, even at multiple targets. Upon selective separation of target cells in the hydrogels, the separated cells have grown on another dish, resulting in pure culture. Cell encapsulation, light irradiation and degradation products exhibited negligible cytotoxicity in overall process.

Tan, X., et al. (2019). "Microplastics and associated PAHs in surface water from the Feilaixia Reservoir in the Beijiang River, China." Chemosphere **221**: 834-840.

Microplastics have been a prevalent and persistent contamination problem in the global aquatic environment. In particular, microplastics that can adsorb persistent organic pollutants (POPs) and therefore transfer these POPs to organisms in the aquatic environment have received much attention. In this study, an investigation of microplastics in the surface water of the Feilaixia Reservoir (Guangdong Province, China), which is an important part of people's daily lives in Guangdong Province was carried out, mainly focusing on the characteristics and spatial distribution of microplastics, as well as microplastics and their adsorded PAHs in the surface water of the Feilaixia Reservoir were investigated. The average abundance of microplastics in the surface water of the Feilaixia Reservoir was 0.56+/-0.45 items/m³. Six kinds of polymers, including polyethylene (PE), polypropylene (PP), polystyrene (PS), expanded polystyrene (EPS), polyvinyl chloride (PVC) and polyethylene terephthalate (PET), were identified, among which PP (52.31%) and PE (27.39%) were the major compositions. Four shapes of microplastics, i.e., foams, films, fragments and fibers were found, and films (37.78%) being the main shape. The most common typical size of the plastic particles ranged from 0.6 to 2mm (41.36%). The total concentration of the sixteen PAHs carried on the EPS, PE and PP microplastics ranged from 282.4 to 427.3ng/g; chrysene, benzo [ghi] perylene, and phenanthrene were abundant in the samples, at concentrations of 39.5-89.6ng/g, 34.6-56.8ng/g and 25.6-45.6ng/g, respectively. Based on the ratios of the PAH isomers (Flut/Py<1 and Phe/Ant >10), it was speculated that the source of the PAHs may be derived from the imperfect combustion of fossil fuels.

Tan, Y., et al. (2010). "Mechanical characterization of human red blood cells under different osmotic conditions by robotic manipulation with optical tweezers." IEEE Transactions on Biomedical Engineering **57**(7): 1816-1825.

The physiological functions of human red blood cells (RBCs) play a crucial role to human health and are greatly influenced by their mechanical properties. Any alteration of the cell mechanics may cause human diseases. The osmotic condition is an important factor to the physiological environment, but its effect on RBCs has been little studied. To investigate this effect, robotic manipulation technology with optical tweezers is utilized in this paper to characterize the mechanical properties of RBCs in different osmotic conditions. The effectiveness of this technology is demonstrated first in the manipulation of microbeads. Then the optical tweezers are used to stretch RBCs to acquire the force-deformation relationships. To extract cell properties from the experimental data, a mechanical model is developed for RBCs in hypotonic conditions by extending our previous work , and the finite element model is utilized for RBCs in isotonic and hypertonic conditions. Through comparing the modeling results to the experimental data, the shear moduli of RBCs in different osmotic solutions are characterized, which shows that the cell stiffness increases with elevated osmolality. Furthermore, the property variation and potential biomedical significance of this study are discussed. In conclusion, this study indicates that the osmotic stress has a significant effect on the cell properties of human RBCs, which may provide insight into the pathology analysis and therapy of some human diseases.

Tanabe, S., et al. (2004). "PCDDs, PCDFs, and Coplanar PCBs in Albatross from the North Pacific and Southern Oceans: Levels, Patterns, and Toxicological Implications." Environmental Science & Technology **38**(2): 403-413.

Concentrations of polychlorinated dibenzo-p-dioxins (PCDDs), polychlorinated dibenzofurans

(PCDFs), and coplanar polychlorinated biphenyls (coplanar PCBs) were determined in five albatross species collected from the North Pacific and Southern Oceans to assess the north-south differences in residue levels, accumulation patterns, and toxic potential. Black-footed and Laysan albatrosses from the North Pacific Ocean contained higher levels of PCDD/ Fs and coplanar PCBs than albatrosses from the Southern Ocean, indicating that emission sources of these contaminants were predominant in the northern hemisphere. Residue levels in albatrosses from the remote North Pacific Ocean far from the point source of pollution were comparable to or higher than those in terrestrial and coastal birds from contaminated areas in developed nations, suggesting the specific exposure and accumulation of PCDD/ Fs and coplanar PCBs in albatross. The long life span and ingestion of plastic resin pellets by albatrosses could be the plausible explanations for the elevated accumulation of persistent and lipophilic contaminants including PCDD/ Fs and coplanar PCBs in these birds. Relative proportions of PCOFs and coplanar PCBs in albatross were higher than those observed in birds inhabiting terrestrial and coastal areas, suggesting that these toxic chemicals may have higher transportability by air and water than PCDDs. [ABSTRACT FROM AUTHOR]

Tanaka, K. and H. Takada (2016). "Microplastic fragments and microbeads in digestive tracts of planktivorous fish from urban coastal waters." Scientific Reports **6**: 34351.

We investigated microplastics in the digestive tracts of 64 Japanese anchovy (Engraulis japonicus) sampled in Tokyo Bay. Plastic was detected in 49 out of 64 fish (77%), with 2.3 pieces on average and up to 15 pieces per individual. All of the plastics were identified by Fourier transform infrared spectroscopy. Most were polyethylene (52.0%) or polypropylene (43.3%). Most of the plastics were fragments (86.0%), but 7.3% were beads, some of which were microbeads, similar to those found in facial cleansers. Eighty percent of the plastics ranged in size from 150 mum to 1000 mum, smaller than the reported size range of floating microplastics on the sea surface, possibly because the subsurface foraging behavior of the anchovy reflected the different size distribution of plastics between surface waters and subsurface waters. Engraulis spp. are important food for many humans and other organisms around the world. Our observations further confirm that microplastics have infiltrated the marine ecosystem, and that humans may be exposed to them. Because microplastics retain hazardous chemicals, increase in fish chemical exposure by the ingested plastics is of concern. Such exposure should be studied and compared with that in the natural diet.

Tanaka, Y., et al. (2003). "Nasal reconstruction with an auricular helix free flap. [Japanese]." Japanese Journal of Plastic and Reconstructive Surgery **46**(9): 901-908.

Free flaps derived from the ascending helix of the ear have been used to reconstruct defects of the nose. However, the pedicle of an auricular helix free flap is short and the recipient vessels in the naso-labial groove are often too small for microsurgical anastomosis. Therefore, long vein grafts are necessary in most cases for arterial and venous repair. Long vein grafts are believed to carry a greater risk of failure and this is the reason why many surgeons are reluctance to use an auricular helix free flap even though it could provide an excellent match of color and contour. Our methods of nasal reconstruction with an auricular free flap are described here. To allow greater reliability in an auricular free flap transfer, we used the descending branch of the lateral circumflex femoral artery and its venae comitantes instead of vein grafts. In addition, cranio-plastic resin and a nasal-retainer were used to fashion a complicated three-dimensional defect of the nose, and the resin model was transferred to the ascending helix to determine the amount of skin and cartilage required. These strategies will be of use in obtaining good results for nasal reconstruction using an auricular helix free flap.

Tanase, E. E., et al. (2017). "Sustainable packaging solutions for organic fresh berries." Food and Environment Safety **16**(4): 269-275.

Climate changes and particularly global warming are topics carefully treated by specialists already since decades. The most pregnant factor that influences climate change is pollution, namely the high level carbon dioxide emissions. Besides other substances used by the most of the industries (oil, charcoal, fertilizers, etc.), plastics are not to be ignored when talking about pollution. Plastic waste affects animals and humans, as well as their habitat. In this respect, food industry engages in preserving the good functioning of the environment by developing and using biodegradable and bio-based resources for food packaging. The aim of this literature review was to identify the optimal sustainable packaging solution used for berries. The results of the study pointed out that the most used environmentally friendly packaging technique is the one that involves modified atmosphere. In terms of packaging materials, the literature is limited when it comes to biodegradable/bio-based solutions. However, active packaging gains popularity among researchers, considering the endless possibilities to include sustainable compounds in a biopolymer based matrix, in order to prolong the shelf-life of berries or fruits in general.

Tang, B. L. (2017). "Commentary: Tissue accumulation of microplastics in mice and biomarker responses suggest widespread health risks of exposure." Frontiers in Environmental Science.

In recent years, a good number of studies have indeed demonstrated that microplastics (either pristine or dye-conjugated) exert detectable acute and toxic effects on marine invertebrate and fishes under controlled laboratory settings (see Table 1 for a non-exhaustive summary). Again, the authors reported that focused analysis on liver tissues revealed signs of inflammation, accumulation of lipid droplets, elevation of oxidative stress markers, defects in energy metabolism, and altered metabolomics. [...]although the changes reported were moderate, they were statistically significant. [...]the findings of Deng et al.

Tang, D., et al. (2015). "Modeling and Simulation of Mass Transfer Process of Tubular Cathode in a Direct Ethanol Fuel Cell." Electrochemistry **83**(11): 962.

The tubular cathode bodies of a direct ethanol fuel cell (DEFC) are shaped by the gelcasting technology and the tubular cathode is prepared by spraying the diffusion layer and the Pt/C catalyst layer after the sintering process based on raw material of mesocarbon microbead (MCMB) and graphite. The process of mass transfer in DEFC is simulated using CFD software including the concentration of oxygen, liquid water saturation inside the tubular cathode and the cell performance under different operating temperature, inlet pressure and porosity. The results show that proper increase in operating temperature and porosity have obvious improvements on mass transfer process and the cell performance, while inlet pressure has little impact on cell performance.

Tang, G., et al. (2018). "Microplastics and polycyclic aromatic hydrocarbons (PAHs) in Xiamen coastal areas: Implications for anthropogenic impacts." Science of the Total Environment **634**: 811-820.

Microplastics and polycyclic aromatic hydrocarbons (PAHs) were investigated to study the influence of human activities and to find their possible relationship on the coastal environments, where the coastal areas around Xiamen are undergoing intensive processes of industrialization and urbanization in the southeast China. The abundance of microplastics in Xiamen coastal areas was 103 to 2017 particles/m³ in surface seawater and 76 to 333 particles/kg in sediments. Concentrations of dissolved PAHs varied from 18.1 to 248 ng/L in surface seawater. The abundances of microplastics from the Western Harbor in surface seawater and sediments were higher than those from other areas. Foams were dominated in surface seawater samples, however, no foams were found in sediments samples. The microscope selection and FTIR analysis suggested that polyethylene (PE) and polypropylene (PP) were dominant microplastics. The cluster analysis results demonstrated that fibers and granules had the similar sources, and films had considerably correlation with all types of PAHs (3 or 4-ring PAHs and alkylated PAHs). Plastic film mulch from agriculture practice might be a potential source of microplastics in study areas. Results of our study support that river runoff, watershed area, population and urbanization rate influence the distribution of microplastics in estuarine surface water, and the prevalence of microplastic pollution calls for monitoring microplastics at a national scale. Copyright © 2018 Elsevier B.V.

Tang, J., et al. (2018). "Acute microplastic exposure raises stress response and suppresses detoxification and immune capacities in the scleractinian coral Pocillopora damicornis." Environmental Pollution **243**(Part A): 66-74.

Microplastics are widespread emerging contaminants that have been found globally in the marine and freshwater ecosystem, but there is limited knowledge regarding its impact on coral reef ecosystem and underpinning mechanism. In the present study, using Pocillopora damicornis as a model, we investigated cytological, physiological, and molecular responses of a scleractinian coral to acute microplastic exposure. No significant changes were observed in the density of symbiotic zooxanthellae during the entire period of microplastic exposure, while its chlorophyll content increased significantly at 12 h of microplastic exposure. We observed significant increases in the activities of antioxidant enzymes such as superoxide dismutase and catalase, significant decrease in the detoxifying enzyme glutathione S-transferase and the immune enzyme alkaline phosphatase, but no change in the other immune enzyme phenoloxidase during the whole experiment period. Transcriptomic analysis revealed 134 significantly up-regulated coral genes at 12 h after the exposure, enriched in 11 GO terms mostly related to stress response, zymogen granule, and JNK signal pathway. Meanwhile, 215 coral genes were significantly down-regulated at 12 h after exposure, enriched in 25 GO terms involved in sterol transport and EGF-ERK1/2 signal pathway. In contrast, only 12 zooxanthella genes exhibited significant up-regulation and 95 genes down-regulation at 12 h after the microplastic exposure; genes regulating synthesis and export of glucose and amino acids were not impacted. These results suggest that acute exposure of microplastics can activate the stress response of the scleractinian coral P. damicornis, and repress its detoxification and immune system through the JNK and ERK signal pathways. These demonstrate that microplastic exposure can compromise the anti-stress capacity and immune system of the scleractinian coral P. damicornis, despite the minimal impact on the abundance and major photosynthate translocation transporters of the symbiont in the short term.

Tang, J., et al. (2019). "Molecular characterization of thioredoxin reductase in waterflea Daphnia magna and its expression regulation by polystyrene microplastics." Aquatic Toxicology **208**: 90-97.

Global scale concerns regarding rise in microplastics pollution in the environment have recently aroused. Ingestion of microplastics by biota, including freshwater zooplankton has been well studied, however, despite keystone species in freshwater food webs, the molecular response (e.g. oxidative defense) of zooplankton in response to microplastics is still in its infancy. The thioredoxin (TRx) system has a vital function in cellular antioxidative defense via eliminating the excessive generation of reactive oxygen species (ROS). Therefore, it is necessary to investigate the effects of thioredoxin reductase (TRxR), due to its triggering the TRx catalysis cascade. The present study identified TRxR in Daphnia magna (Dm-TRxR) for the first time, and found that the full-length cDNA was 1862 bp long, containing an 1821-bp open reading frame. Homologous alignments showed the presence of conserved catalytic domain CVNVGC and the seleocysteine (SeCys) residue (U) located in the N- and C-terminal portions. Subsequently, the expression of Dm-TRxR, together with permease, arginine kinase (AK), was investigated by approach of quantitative real-time PCR after exposure to four (1.25- micro m) polystyrene (PS) microbeads concentrations: 0 (control), 2, 4 and 8 mg L⁻¹ for 10 days. Dm-TRxR, permease and AK mRNA were significantly upregulated after exposure to 2, 4 mg L⁻¹ of PS, but then declined in the presence of 8 mg L⁻¹ PS. The gene expression results suggested that oxidative defense, energy production and substance extra cellular transportation were significantly regulated by microplastic exposure. Collectively, the present study will advance our knowledge regarding the biological effects of microplastic pollution on zooplankton, and builds a foundation for freshwater environmental studies on mechanistic and biochemical responses to microplastics.

Tang, L., et al. (2012). "Colorimetric and ultrasensitive bioassay based on a dual-amplification system using aptamer and DNAzyme." Analytical Chemistry **84**(11): 4711-4717.

Rapid detection of ultralow amount of biomarkers in a biologically complex mixture remains a major challenge. Herein, we report a novel aptamer-based protein detection assay that integrates two signal amplification processes, namely, polymerase-mediated rolling-circle amplification (RCA) and DNA enzyme-catalyzed colorimetric reaction. The target biomarker is captured in a sandwich assay by primary aptamer-functionalized microbeads (MBs) and a secondary aptamer that is connected to a RCA primer/circular template complex. RCA reaction, which amplifies the single biomarker binding events by a factor of hundreds to thousands (the first amplification) produces a long DNA molecule containing multiple DNAzyme units. The peroxidase-like DNAzyme catalyzes the oxidation of 2,2'-azino-bis(3-ethylbenzothiazoline-6-sulfonic acid) (the second amplification), which generates a blue-green colorimetric signal. This new biosensing platform permits the ultrasensitive, label-free, colorimetric detection of biomarker in real time. Using platelet-derived growth factor B-chain (PDGF-BB) as a model system, we demonstrated that our assay can detect a protein marker specifically in a serum-containing medium, at a concentration as low as 0.2 pg/mL in ~2 h, which rivals traditional assays such as ELISA. We anticipate this simple methodology for biomarker detection can find utility in point-of-care applications.

Tang, M., et al. (2012). "Human embryonic stem cell encapsulation in alginate microbeads in macroporous calcium phosphate cement for bone tissue engineering." Acta Biomaterialia **8**(9): 3436-3445.

Human embryonic stem cells (hESC) are promising for use in regenerative medicine applications because of their strong proliferative ability and multilineage differentiation capability. To date there have been no reports on hESC seeding with calcium phosphate cement (CPC). The objective of this study was to investigate hESC-derived mesenchymal stem cell (hESCd-MSC) encapsulation in hydrogel microbeads in macroporous CPC for bone tissue engineering. hESC were cultured to form embryoid bodies (EB), and the MSC were then migrated out of the EB.

hESCd-MSC had surface markers characteristic of MSC, with positive alkaline phosphatase (ALP) staining when cultured in osteogenic medium. hESCd-MSC were encapsulated in alginate at a density of 1millioncellsml(-1), with an average microbead size of 207mum. CPC contained mannitol porogen to create a porosity of 64% and 218-mum macropores, with 20% absorbable fibers for additional porosity when the fibers degrade. hESCd-MSC encapsulated in microbeads in CPC had good viability from 1 to 21days. ALP gene expression at 21days was 25-fold that at 1day. Osteocalcin (OC) at 21days was two orders of magnitude of that at 1day. ALP activity in colorimetric p-nitrophenyl phosphate assay at 21days was fivefold that at 1day. Mineral synthesis by the encapsulated hESCd-MSC at 21days was sevenfold that at 1day. Potential benefits of the CPC-stem cell paste include injectability, intimate adaptation to complex-shaped bone defects, ease in contouring to achieve esthetics in maxillofacial repairs, and in situ setting ability. In conclusion, hESCd-MSC were encapsulated in alginate microbeads in macroporous CPC, showing good cell viability, osteogenic differentiation and mineral synthesis for the first time. The hESCd-MSC-encapsulating macroporous CPC construct is promising for bone regeneration in a wide range of orthopedic and maxillofacial applications.

Tang, P. L., et al. (2019). "Handheld FT-IR Spectroscopy for the Triage of Micro- and Meso-Sized Plastics in the Marine Environment Incorporating an Accelerated Weathering Study and an Aging Estimation." Spectroscopy **34**(2): 54-60.

Debris in the marine environment can be either natural, such as floating vegetation or volcanic ash deposits, or man-made. The man-made sources cover the whole gamut of material types, such as sewage, glass, mineral, fabric, and, of increasing concern, plastic or polymeric materi-als. Virtually all plastics absorb infrared (IR) light in a highly selective manner, making their infrared spectra a useful qualitative diagnostic. The triage of the visible micro- (~1 mm to 5 mm), meso-, macro- or mega-sized plastic particles with handheld Fourier Transform IR (FT-IR) enables rapid determination of the material on-site, and reduces time wasted on non-polymers on-site or at site. Four of the most prevalent neustonic plastic types, and their FT-IR spectral changes correlated with accelerated weathering, were successfully examined chronologically, detailing significant differences in aging profiles and chemical changes. Subsequently, a small spectroscopically identifiable degraded piece of plastic found in Greenland was correlated to the appropriate aging profile. Finally, a targeted methodology for quantification of submilli-meter microplastic in dried estuarine sediment was evaluated to ascertain the potential limit of detection.

Tang, R., et al. (2012). "X-ray Phase Contrast Imaging of Cell Isolation with Super-Paramagnetic Microbeads." PLoS ONE **7**(9).

Super-paramagnetic microbeads are widely used for cell isolation. Evaluation of the binding affinity of microbeads to cells using optical microscopy has been limited by its small scope. Here, magnetic property of microbeads was first investigated by using synchrotron radiation (SR) in-line x-ray phase contrast imaging (PCI). The cell line mouse LLC (Lewis lung carcinoma) was selected for cell adhesion studies. Targeted microbeads were prepared by attaching anti-VEGFR2 (vascular endothelial growth factor receptor-2) antibody to the shell of the microbeads. The bound microbeads were found to better adhere to LLC cells than unbound ones. PCI dynamically and clearly showed the magnetization and demagnetization of microbeads in PE-50 tube. The cells incubated with different types of microbeads were imaged by PCI, which provided clear and real-time visualization of the cell isolation. Therefore, PCI might be considered as a novel and efficient tool for further cell isolation studies.

Tang, S., et al. (2019). "Pb(II) uptake onto nylon microplastics: Interaction mechanism and adsorption performance." Journal of Hazardous Materials **386**: 121960.

Both heavy metals and microplastic pollutants are ubiquitous in the aquatic environment. The uptake of lead(II) ions from aqueous solutions onto aged nylon microplastics was investigated as a function of pH, contact time, temperature, supporting electrolyte concentration and fulvic acid concentration in batch studies. The effect of surface properties on the adsorption behavior of lead(II) was investigated with scanning electron microscope equipped with the energy dispersive X-ray spectroscope (SEM-EDAX), Fourier transform-infrared (FTIR) spectroscopy, thermal gravimetric analysis (TGA), X-ray diffraction (XRD) and differential scanning calorimetric (DSC). The adsorption kinetics conformed to the pseudo-second order equation, Elovich equation and intraparticle diffusion model well. The experimental data of the adsorption process was fitted to the Langmuir and Freundlich adsorption isotherms and the parameters were estimated. The lead(II) uptake on aged nylon microplastics was spontaneous and endothermic in nature. The lead(II) adsorption was significantly dependent on the sodium chloride concentrations, initial solution pH and fulvic acid concentrations.

Tang, Y., et al. (2019). "Immunotoxicity of microplastics and two persistent organic pollutants alone or in combination to a bivalve species." Environmental Pollution **258**: 113845.

Both microplastics and persistent organic pollutants (POPs) are ubiquitously present in natural water environment, posing a potential threat to aquatic organisms. While it has been suggested that the immune responses of aquatic organisms could be hampered by exposure to microplastics and POPs, the synergistic immunotoxic impact of these two types of pollutants remain poorly understood. In addition, little is known about the mechanism behind the immunotoxic effect of microplastics. Therefore, in the present study, the immunotoxicity of microplastics and two POPs, benzo[a]pyrene (B[a]P) and 17beta-estradiol (E2), were investigated alone or in combination in a bivalve species, Tegillarca granosa. Evident immunotoxicity, as indicated by alterations of haemocyte count, blood cell composition, phagocytic activity, intracellular content of ROS, concentration of Ca²⁺ and lysozyme, and lysozyme activity, was revealed for both microplastics and the two POPs examined. In addition, the expression of six immune-, Ca²⁺ signalling-, and apoptosis-related genes was significantly altered by exposure of clams to the contaminants studied. Furthermore, the toxicity of POPs was generally aggravated by smaller microplastics (500 nm) and mitigated by larger ones (30 mum). This size dependent effect on POP toxicity may result from size dependent interactions between microplastics and POPs. Data obtained in this study also indicate that similar to exposure to B[a]P and E2, exposure to microplastics may hamper the immune responses of clams through a series of interdependent physiological and molecular processes.

Tang, Z., et al. (2014). "Polybrominated diphenyl ethers in soils, sediments, and human hair in a plastic waste recycling area: a neglected heavily polluted area." Environmental Science & Technology **48**(3): 1508-1516.

The release of pollutants during the recycling of contaminated plastics is a problem which has drawn worldwide attention; however, little information on the transfer of polybrominated diphenyl ethers (PBDEs) in these processes is available. We conducted a survey of PBDEs in soils, sediments, and human hair in a typical plastic waste recycling area in northern China. The total concentrations (ng/g) of 21 PBDEs were 1.25-5504 (average 600), 18.2-9889 (average 1619), and 1.50-861 (average 112) in soils, sediments, and hair, respectively. The PBDE concentrations were comparable to concentrations observed in e-waste recycling areas; however, the concentrations

in soils and sediments were 1-3 orders of magnitude higher than in other areas, and the concentrations in hair were much higher than in other areas. This indicates that this area is highly polluted with PBDEs. BDE-209 was the dominant congener (representing 91.23%, 92.3%, and 91.5% of the total PBDEs observed in soils, sediments, and hair, respectively), indicating that the commercial deca-BDE product was dominant. The commercial penta- and octa-BDE products made small contributions to the total PBDE concentrations, unlike what has been found in some e-waste recycling areas. Our results show that crude plastic waste processing is a major contributor of PBDEs to the environment and humans, which should be of great concern.

Tang, Z., et al. (2016). "Polybrominated diphenyl ethers (PBDEs) and heavy metals in road dusts from a plastic waste recycling area in north China: implications for human health." Environmental Science & Pollution Research **23**(1): 625-637.

Road dusts were collected from an area where intense mechanical recycling of plastic wastes occurs in Wen'an, north China. These dusts were investigated for polybrominated diphenyl ethers (PBDEs) and heavy metals contamination to assess the health risk related to these components. Decabromodiphenyl ether (BDE-209) and SIGMA21PBDE concentrations in these dusts ranged from 2.67 to 10,424 ng g(-1) and from 3.23 to 10,640 ng g(-1), respectively. These PBDE concentrations were comparable to those observed in road dust from e-waste recycling areas but were 1-2 orders of magnitude higher than concentrations in outdoor or road dusts from other areas. This indicates that road dusts in the study area have high levels of PBDE pollution. BDE-209 was the predominant congener, accounting for 86.3% of the total PBDE content in dusts. Thus, commercial deca-BDE products were the dominant source. The average concentrations of As, Cd, Cr, Cu, Hg, Pb, Sb, and Zn in these same dust samples were 10.1, 0.495, 112, 54.7, 0.150, 71.8, 10.6, and 186 mg kg(-1), respectively. The geoaccumulation index suggests that road dusts in this area are moderately to heavily polluted with Cd, Hg, and Sb. This study shows that plastic waste processing is a major source of toxic pollutants in road dusts in this area. Although the health risk from exposure to dust PBDEs was low, levels of some heavy metals in this dust exceeded acceptable risk levels for children and are of great concern.

Tang, Z., et al. (2015). "Contamination and risk of heavy metals in soils and sediments from a typical plastic waste recycling area in North China." Ecotoxicology & Environmental Safety **122**: 343-351.

Plastic wastes are increasingly being recycled in many countries. However, available information on the metals released into the environment during recycling processes is rare. In this study, the contamination features and risks of eight heavy metals in soils and sediments were investigated in Wen'an, a typical plastic recycling area in North China. The surface soils and sediments have suffered from moderate to high metal pollution and in particular, high Cd and Hg pollution. The mean concentrations of Cd and Hg were 0.355 and 0.408 mg kg(-1), respectively, in the soils and 1.53 and 2.10 mg kg(-1), respectively, in the sediments. The findings suggested that there is considerable to high potential ecological risks in more than half of the soils and high potential ecological risk in almost all sediments. Although the health risk levels from exposure to soil metals were acceptable for adults, the non-carcinogenic risks to local children exceeded the acceptable level. Source assessment indicated that heavy metals in soils and sediments were mainly derived from inputs from poorly controlled plastic waste recycling operations in this area. The results suggested that the risks associated with heavy metal pollution from plastic waste recycling should be of great concern.

Tanikawa-Takahashi, Y., et al. (1997). Fabrication of dynamic optical head phantoms from an MRI head model. Proceedings of SPIE - The International Society for Optical Engineering.

Optical tomography is a new modality of noninvasive diagnosis for imaging the distribution of optical properties in human bodies. In the process of developing optical tomography systems which can be applicable to human heads for diagnosis of disease and study of brain functions, we need realistic optical phantoms which anatomically and optically simulate human heads with complicated and multi-layered structures. Previously we have reported design and fabrication methods of optical head phantoms based on an MRI human head image. The phantoms have simulated the multi-layered structure with different optical properties specified to each layer. They had five layers; i.e., skin, skull, cerebrospinal fluid layer, gray matter and white matter. Also some inclusions simulating hematoma were embedded in some part of the head phantoms. However, the phantoms were made all of solid plastic resin and the temporal variation of physiological functions in brain could not be simulated by the static phantoms. We have improved the fabrication method and succeeded in making dynamic optical phantoms which are able to include some parts simulating the temporal variation of blood flow rate and oxygenation status.

Taoka, M., et al. (2017). "A Sensitive Microbead-Based Organic Media-Assisted Method for Proteomics Sample Preparation from Dilute and Denaturing Solutions." Acs Applied Materials & Interfaces **9**(49): 42661-42667.

We developed a robust and sensitive sample preparation method for proteomics termed microbead-based and organic-media-assisted proteolysis strategy (BOPs). BOPs combines two advantages of current techniques, (1) unbiased binding of reversed-phase polymeric microbeads to any type of protein and (2) enhanced trypsin digestion efficiency in CH₃CN-aqueous solvent systems, into a single-tube workflow. Compared with conventional techniques, this method effectively concentrates proteins and improves proteolytic digestion, and can be used with submicromolar protein samples in dilute or denaturing solutions, such as 70% formic acid, 8 M urea, or 7 M guanidine hydrochloride without any sample pretreatment. Proteome analysis of single Caenorhabditis elegans organisms demonstrates that BOPs has the sensitivity, reproducibility, and unbiasedness required to characterize worm proteins at a single organism level. We also show that, by simply incorporating an acetone washing step for detergent removal, BOPs is applicable to low concentration samples contaminated with a variety of detergents, including sodium dodecyl sulfate, with negligible protein loss. Moreover, the utility of this modification has also been demonstrated through proteomic characterization of 2000 human (HEK293T) cells lysed using 1% Triton X-100. The simplicity and availability of the present BOPs make it especially attractive for next-stage proteomics of rare and sample-limited systems.

Taoka, M., et al. (2019). "An Ionic Liquid-Based Sample Preparation Method for Next-Stage Aggregate Proteomic Analysis." Analytical Chemistry **91**(21): 13494-13500.

A wide variety of proteomic methods have been applied for protein profiling of insoluble aggregates or inclusion bodies deposited in various cells or tissues. However, these are essentially optimized or modified classical protein chemistry techniques using conventional denaturing agents such as formic acid, urea, and sodium dodecyl sulfate (SDS). The use of these denaturants has several shortcomings, including limited solubilization, contamination, and restrictions on absolute sample quantity and throughput. Here, we describe an alternative proteomic sample preparation platform for widespread aggregation analysis. This approach combines two techniques, (1) the use of ionic liquid for protein solubilization and (2) the recently published microbead-based and organic-media-assisted proteolysis strategy (BOPs), into a single-tube workflow. We demonstrate that the combined approach (iBOPs) enabled the successful solubilization of heat-aggregated hen egg whites within 10 min and supported sensitive mass spectrometry (MS) analysis. The performance of the iBOPs system surpassed those of conventional detergents and chaotropes. Moreover, this technology enabled ultrasensitive proteomic characterization of protein aggregates deposited in individual Caenorhabditis elegans nematodes. We identified ubiquitin and other molecules as candidate stochastic factors whose accumulation levels varied among aging nematode individuals. The sensitivity and applicability of the present iBOPs make it especially attractive for next-stage aggregate proteomic analysis of various biological processes.

Tappin, A. D. and G. E. Millward (2015). "The English Channel: contamination status of its transitional and coastal waters. (Special Issue: The English Channel and it's catchments: status and responses to contaminants.)." Marine Pollution Bulletin **95**(2): 529-550.

The chemical contamination (organic compounds, metals, radionuclides, microplastics, nutrients) of English Channel waters has been reviewed, focussing on the sources, concentrations and impacts. River loads were only reliable for Pb, whereas atmospheric loads appeared robust for Cd, Pb, Hg, PCB-153 and gamma -HCH. Temporal trends in atmospheric inputs were decreasing. Contaminant concentrations in biota were relatively constant or decreasing, but not for Cd, Hg and HBCDD, and deleterious impacts on fish and copepods were reported. However, data on ecotoxicological effects were generally sparse for legacy and emerging contaminants. Intercomparison of activity concentrations of artificial radionuclides in sediments and biota on both Channel coasts was hindered by differences in methodological approaches. Riverine phosphate loads decreased with time, while nitrate loads remained uniform. Increased biomass of algae, attributable to terrestrial inputs of nutrients, has affected benthic production and shellfisheries. A strategic approach to the identification of contaminant impacts on marine biota is recommended.

Taqvi, S. Z. (2007). Notch ligand functionalized microbeads for T cell differentiation of stem cells.

In recent years, great advances have been made in the field of stem cell differentiation. Seminal insights in the area of developmental biology and tissue regeneration have made ex vivo differentiated cells a realistic alternative for transplantation applications. The recent application of these murine-based insights to human systems has paved new paths in autoimmune disease, chemotherapy, and immuno-deficiency research. Such strides would eliminate the hurdles associated with adoptive transfer including limited availability of transplantable cells, site morbidity, difficulties in cell isolation and expansion lag time. Current approaches in ex vivo hematopoiesis and T cell differentiation have begun to explore the effects of biomaterials on differentiation efficiency. These approaches, however, have not fully studied the quantitative effects of biomaterials and their properties on hematopoietic and T cell differentiation generation. Our goal was to design biomaterials whose properties could be tailored to improve differentiation efficiencies in T cell differentiation. Our work is dedicated to fabricating and characterizing Notch ligand functionalized microbeads for T cell differentiation applications. Our work has shown stable functionalization of Notch ligands on microbeads that can be quantitatively varied to achieve optimal Notch signaling. We have also demonstrated limited cellular toxicity and effective Notch signaling upon exposure to Notch ligand functionalized beads. Finally, we have successfully differentiated T cell progenitors from hematopoietic stem cells using the functionalized microbeads. As a side study, we have fabricated and characterized polymeric PLA scaffolds that were systematically varied and studied for their effects on hematopoietic differentiation efficiency. Insights gained from these studies should provide a better understanding of the microenvironmental signals in hematopoiesis and aid in the development of efficient technologies for the production of hematopoietic progenitors and T cells for therapeutic applications.

Tarnok, A., et al. (2001). "Preoperative prediction of postoperative edema and effusion in pediatric cardiac surgery by altered antigen expression patterns on granulocytes and monocytes." Cytometry **44**(4): 247-253.

Postoperative edema and effusion (POEE) following cardiopulmonary bypass (CPB) surgery in children retards recovery and may aggravate postpericardiotomy (PPS), capillary leak syndrome (CLS), or multiorgan failure (MOF). Compared with complication-free children, POEE affected children have different preoperative serum levels of circulating cytokines and adhesion molecules. These levels may be used preoperatively to assess POEE, but their determination is time consuming, costly, and a substantial blood volume is required. Altered serum levels of cytokines and adhesion molecules also may be reflected in altered antigen expression on circulating blood leukocytes. The predictive potential of flow cytometric (FCM) leukocyte immunophenotyping was explored as a sensitive and fast method that required small blood samples. Blood samples taken 24 h preoperatively from 49 patients (3-18 years old) were stained with monoclonal antibodies for adhesion molecules (ICAM-1, LFA-1, Mac-1) or constitutive/activation markers (CD4, CD14, CD16, CD25, CD54, CD69, HLA-DR) and measured on a microbead calibrated FCM. Neutrophils, monocytes, and eosinophils from POEE patients express higher preoperative levels of LFA-1, monocytes, HLA-DR, and other activation markers (all $P < 0.03$). Over 89% of the patients were classified correctly by using two discriminant analysis methods (sensitivity, >76%; specificity, >86%; positive prediction, >80%; negative prediction, >83%). Granulocytes and monocytes of postoperative POEE patients exhibit significant preoperative immune activation, suggesting an increased risk for patients with atopic/allergic predisposition. Surgical trauma and CPB cause additional immune activation, leading to POEE by a summative response. Most patients at risk for POEE can be identified preoperatively by using data pattern analysis on FCM-derived parameters. © 2001 Wiley-Liss, Inc.

Tatsuno, K., et al. (2016). "TSLPR expressing CD4+ T cells produce enhanced IL-4 by directly responding to TSLP in AD." Journal of Dermatological Science **84 (1)**: e63.

Recent studies have suggested that thymic stromal lymphopoi-etin (TSLP) activates LCs to induce the differentiation of naive T cells into Th2 cells, and previous documentations underscore the contributory role of TSLP in the pathogenesis of AD via this type of DCs. Meanwhile, TSLP receptor (TSLPR) is expressed on various immunocompetent cells, including mast cells, basophils, monocytes, and T cells, indicating the possibility of direct TSLP interaction with these cells. We therefore investigated the expression of TSLPR, focusing on T cells. In freshly isolated PBMCs from normal individuals, TSLPR expression was minimal (0.045% of PBMCs) whilePBMCsfromADpatientsdemonstratedincreasedfre-quencies of TSLPR⁺CD4⁺T cells (0.40% of PBMCs) ($p<0.05$). TSLPR+ T cells were CCR4+, CXCR3-, CLA+, CCR7-, CCR10+, and CD45RO+, indicative of skin-homing effector CD4+ T cells. Furthermore, CD4+ T cells isolated from PBMCs of AD patients (n=23) and normal individuals (n=7) were stimulated with anti-CD3/28 Ab-coated microbeads with or without rhTSLP, and cultured for 48h. Subsequently, supernatants were collected and cytokine concentration was measured by CBA assay. Production of IL-4 was enhanced by 30% in CD4+ T cells from AD patients in response to TSLP, and secretion of IL-17A also increased moderately (10%). In comparison, CD4+ T cells from normal individuals responded to TSLP with augmented production of IFN-g, but not with IL-4 or IL-17A. In conclusion, TSLP seems to possess the ability

to directly modify the cytokine producing ability of effector T cells, and the effect was favored toward Th2 in AD. Interestingly, TSLP acted differently on T cells of normal individuals, and this discrepancy in the T cell response to TSLP may be associated with the development of AD.

Ta-Tung, W. and L. Yueh-Hui (2015). "A WASTE CATALYST FOR A HAZARDOUS CHLORINE -- CONTAINING PLASTIC WASTE." Environmental Engineering & Management Journal (EEMJ) **14**(9): 2127-2138.

The recycling of plastic waste is important both in the conservation of resources and the environmental protection. A plastic waste (PE/PP/PS/PVC) was pyrolyzed over a series of post-use FCC catalysts using a fluidizing reaction system similar to the FCC process operating isothermally at ambient pressure. Experiments carried out with these catalysts gave good yields of valuable hydrocarbons with differing selectivity in the final products dependent on reaction conditions. A model based on kinetic considerations associated with chemical reactions and catalyst deactivation in the catalytic degradation of plastics has been developed. Greater product selectivity was observed with a hybrid catalyst of MCM-41/Cat-R1 with more than 70.5 wt% olefins products. It is demonstrated that the catalytic degradation of post-consumer chloro-commingled plastics over these recycled catalysts coped with the utility of fluidizing cracking system was shown to be a useful method for the production of potentially valuable hydrocarbons. [ABSTRACT FROM AUTHOR]

Tavakoli, S., et al. (2016). "Mechanobiophysics of the alveolus-reconstruction of strain and forces at the gas-blood barrier." Pneumologie. Conference **70**(5).

Congress Abstract Introduction: In the last years, the importance of mechano-chemical cellular responses for biology and pathobiology has been recognized. As cells sense their mechanical environment, they respond to extracellular forces. This is particularly important for lung epithelial and endothelial cells forming the air-blood barrier where they constantly get stretched during breathing. Mechanical stretch in the alveolus plays a key role in triggering the secretion of pulmonary surfactant which reduces surface tension at the alveolar air-liquid interface. However, an integrated research of the alveolar environment has been precluded due to the complex biophysical environment of the alveoli that has to be reconstructed. This includes a multiphase system with an air-liquid-interface, a co-culture model combining cell types with different mechanical properties, as well as the occurrence of cyclic mechanical stretch. Method(s): Biomimetic microfluidic devices have appeared to be a promising solution in this matter. These devices are mostly made of a transparent biocompatible polymer known as Polydimethylsiloxane (PDMS), and are fabricated using soft lithography. Cell growth and differentiation of primary lung epithelial cells on PDMS is currently under testing. Result(s): At the moment, we are engineering a lung-on-a-chip prototype based on the publication by Huh (Huh, D. et al., 2010). The chip contains a porous PDMS membrane with a thickness of 10 mum, which separates the two central channels. On the apical side of the membrane, primary epithelial cells obtained from rat lung are cultured at the air-liquid-interface, while on the bottom side endothelial cells are perfused with media. The smaller side channels of the chip can be air-evacuated to stretch the membrane, and thereby approximately 10% cyclic strain can be applied to cells attached on the membrane. Discussion(s): This lab-on-a-chip device will enable to explore distinct biomechanical response of different lung cells, under cyclic strain conditions combined with pathophysiological conditions. For that purpose, we will incorporate fluorescent microbeads into the porous membrane as subcellular force/strain sensor, which allows the evaluation of cell stiffness and viscosity by tracking and analyzing bead displacements (Das, T. et al., 2008). Alongside the sensory application, the lab-on-a-chip device can also be used for live cell imaging of surfactant release and adsorption at the air-liquid interface and it has the potential for drug delivery studies.

Tavares, R., et al. (2018). "Microplastics thermal treatment by polyethylene terephthalate-biomass gasification." Energy Conversion and Management **162**: 118.

In this paper, a previously developed Aspen Plus model for gasification of biomass was adapted to the gasification of microplastics in a temperature range of 400–1200 °C. The effect of parameters such as equivalence ratio (ER), steam-to-biomass ratio (SBR) and gasification temperature in hydrogen production was evaluated, as well as three different gasifying agents namely air, O2 and steam were tested. The relationship between all these variables was assessed in order to better characterize the final syngas. Results showed that for higher hydrogen yields, microplastics composition should be majorly polyethylene terephthalate (PET), assuring H2 molar fraction contents in the order of 63–66%. The achieved lower heating value (LHV) was 9.2 MJ/Nm3 which endorsed high-quality syngas.

Tayebi, M., et al. (2011). "PrP(Sc)-specific antibodies with the ability to immunodetect prion oligomers." PLoS ONE [Electronic Resource] **6**(5): e19998.

The development of antibodies with binding capacity towards soluble oligomeric forms of PrPSc recognised in the aggregation process in early stage of the disease would be of paramount importance in diagnosing prion diseases before extensive neuropathology has ensued. As blood transfusion appears to be efficient in the transmission of the infectious prion agent, there is an urgent need to develop reagents that would specifically recognize oligomeric forms of the abnormally folded prion protein, PrPSc.To that end, we show that anti-PrP monoclonal antibodies (called PRIOC mAbs) derived from mice immunised with native PrP-coated microbeads are able to immunodetect oligomers/multimers of PrPSc. Oligomer-specific immunoreactivity displayed by these PRIOC mAbs was demonstrated as large aggregates of immunoreactive deposits in prion-permissive neuroblastoma cell lines but not in equivalent non-infected or prn-p(0/0) cell lines. In contrast, an anti-monomer PrP antibody displayed diffuse immunoreactivity restricted to the cell membrane. Furthermore, our PRIOC mAbs did not display any binding with monomeric recombinant and cellular prion proteins but strongly detected PrPSc oligomers as shown by a newly developed sensitive and specific ELISA. Finally, PrioC antibodies were also able to bind soluble oligomers formed of Abeta and alpha-synuclein. These findings demonstrate the potential use of anti-prion antibodies that bind PrPSc oligomers, recognised in early stage of the disease, for the diagnosis of prion diseases in blood and other body fluids.

Taylor, B. (2009). "Scarcely Different." Recycling Today **47**(9): 8-8.

The article looks at the condition of the global economy and its impact on the scrap recycling industry as of 2009. It says that during the decade, more oil, steel, copper and other materials have been consumed by the developing economies of Asia. According to the article, the demand of Asia for materials has impacted pricing in North America, Europe and other areas where basic materials are produced and consumed.

Taylor, M. L., et al. (2016). "Plastic microfibre ingestion by deep-sea organisms." Scientific Reports **6**: 33997.

Plastic waste is a distinctive indicator of the world-wide impact of anthropogenic activities. Both macro- and micro-plastics are found in the ocean, but as yet little is known about their ultimate fate and their impact on marine ecosystems. In this study we present the first evidence that microplastics are already becoming integrated into deep-water organisms. By examining organisms that live on the deep-sea floor we show that plastic microfibres are ingested and internalised by members of at least three major phyla with different feeding mechanisms. These results demonstrate that, despite its remote location, the deep sea and its fragile habitats are already being exposed to human waste to the extent that diverse organisms are ingesting microplastics.

Taylor, V. F., et al. (2019). "Preliminary investigation of polymer-based in situ passive samplers for mercury and methylmercury." Chemosphere **234**: 806-814.

Development of an in situ passive sampler for mercury (Hg), and its toxic form, methylmercury (MeHg), using simple polymer films, was explored for the potential to make an efficient and environmentally relevant monitoring tool for this widespread aquatic pollutant. The sulfur-containing polymers polysulfone (PS), and polyphenylene sulfide (PPS), were found to accumulate both MeHg and inorganic Hg (iHg), whereas polyethylene (PE) sorbed iHg but not MeHg, and polyoxymethylene (POM) and polyethersulfone (PES) films had low affinity for both Hg species. Uptake rates of Hg species into polymers were linear over two weeks, and dissolved organic matter at natural levels had no effect on partitioning of MeHg or iHg to the polymers. Sorption of MeHg to PS and PPS from three estuarine sediments correlated with uptake into diffusive gel-type samplers over time, and in PPS, with accumulation by the estuarine amphipod, Leptocheirus plumulosus. These polymers had lower MeHg adsorption rates, but are simpler to assemble, than diffusive gel-type samplers. Higher contaminant concentrations in polymer and gel-type samplers corresponded with porewater concentrations across sediments, suggesting they sample the dissolved MeHg pool, whereas MeHg levels in amphipods were more elevated with higher bulk sediment MeHg, which may reflect feeding strategy. While polymers with higher affinity for MeHg and iHg are needed for some environmental applications, this work suggests a simple sampling approach has potential for time-integrated, environmentally-meaningful MeHg monitoring in contaminated sediments. Image 1 • Plastics adsorb mercury and methylmercury at a constant rate. • Sulfur containing polymers have a high affinity for mercury species. • Methylmercury levels in passive samplers correspond with porewater concentrations. Tayot, J. L., et al. (1987). "Large scale use of Spherosil ion exchangers in plasma fractionation." Developments in Biological Standardization **67**: 15-24.

Spherosil microbeads are spherical and made of porous silica. Their surface is coated with hydrophilic and/or hydrophobic polymers. They are specially designed for the separation of proteins on an industrial scale either by ion exchange or by bioaffinity chromatography. Since 1980, large columns have been used in Institut Merieux for the purification of placental albumin and several vaccines. Here we describe a chromatographic process for the purification of human albumin and immunoglobulins (IgG) from 25 1 of plasma per cycle. First the plasma was freed of the coagulation factors and then clarified at pH 5.25. The corresponding supernatant was filtered and processed in sterile conditions. Albumin was then purified by ion exchange on 3 successive columns, respectively containing: 6.25 kg of DEAE SPHEROSIL W-1000; 3.5 kg of QMA SPHEROSIL PH-1000; 8 kg of COOH-SPHEROSIL W-1000. The concentration and pH of the buffers were selected to reduce, as much as possible, the total quantity of ion exchangers required per cycle. IgG were then purified from the filtrate of the first of the previous columns. 1 column of 6.25 kg of DEAE SPHEROSIL W-1000 was used at pH 6.8. The selected chromatographic parameters allowed us to demonstrate a total elimination of HBs Ag and HB Virus when voluntarily added to an initial sample (RIA determination and HBV-DNA analysis by molecular hybridization). A second column of a large pore anion exchanger: DEAE SPHEROSIL LP-3000 was added at the end of the IgG purification, as a final security to avoid any risk of transmitting the Hepatitis B virus. The yield and quality of the final products will be presented.

Tekman, M. B., et al. (2017). "Marine litter on deep Arctic seafloor continues to increase and spreads to the North at the HAUSGARTEN observatory." Deep-Sea Research Part I: Oceanographic Research Papers **120**: 88-99.

The increased global production of plastics has been mirrored by greater accumulations of plastic litter in marine environments worldwide. Global plastic litter estimates based on field observations account only for 1% of the total volumes of plastic assumed to enter the marine ecosystem from land, raising again the question 'Where is all the plastic? '. Scant information exists on temporal trends on litter transport and litter accumulation on the deep seafloor. Here, we present the results of photographic time-series surveys indicating a strong increase in marine litter over the period of 2002–2014 at two stations of the HAUSGARTEN observatory in the Arctic (2500 m depth). Plastic accounted for the highest proportion (47%) of litter recorded at HAUSGARTEN for the whole study period. When the most southern station was considered separately, the proportion of plastic items was even higher (65%). Increasing quantities of small plastics raise concerns about fragmentation and future microplastic contamination. Analysis of litter types and sizes indicate temporal and spatial differences in the transport pathways to the deep sea for different categories of litter. Litter densities were positively correlated with the counts of ship entering harbour at Longyearbyen, the number of active fishing vessels and extent of summer sea ice. Sea ice may act as a transport vehicle for entrained litter, being released during periods of melting. The receding sea ice coverage associated with global change has opened hitherto largely inaccessible environments to humans and the impacts of tourism, industrial activities including shipping and fisheries, all of which are potential sources of marine litter. © 2016 The Authors

Telang, S., et al. (2012). "Small molecule inhibition of 6-phosphofructo-2-kinase suppresses t cell activation." Journal of Translational Medicine **10 (1) (no pagination)**(95).

Background: T cell activation is associated with a rapid increase in intracellular fructose-2,6-bisphosphate (F2,6BP), an allosteric activator of the glycolytic enzyme, 6-phosphofructo-1-kinase. The steady state concentration of F2,6BP in T cells is dependent on the expression of the bifunctional 6-phosphofructo-2-kinase/fructose-2,6-bisphosphatases (PFKFB1-4) and the fructose-2,6-bisphosphatase, TIGAR. Of the PFKFB family of enzymes,

PFKFB3 has the highest kinase:bisphosphatase ratio and has been demonstrated to be required for T cell proliferation. A small molecule antagonist of PFKFB3, 3-(3-pyridinyl)-1-(4-pyridinyl)-2-propen-1-one (3PO), recently has been shown to reduce F2,6BP synthesis, glucose uptake and proliferation in transformed cells. We hypothesized that the induction of PFKFB3 expression may be required for the stimulation of glycolysis in T cells and that exposure to the PFKFB3 antagonist, 3PO, would suppress T cell activation. Method(s): We examined PFKFB1-4 and TIGAR expression and F2,6BP concentration in purified CD3⁺ T cells stimulated with microbead-conjugated agonist antibodies specific for CD3 and the co-stimulatory receptor, CD28. We then determined the effect of 3PO on anti-CD3/anti-CD28-induced T cell activation, F2,6BP synthesis, 2-[1-¹⁴C]-deoxy-d-glucose uptake, lactate secretion, TNF-alpha secretion and proliferation. Finally, we examined the effect of 3PO administration on the development of delayed type hypersensitivity to methylated BSA and on imiquimod-induced psoriasis in mice. Result(s): We found that purified human CD3⁺ T cells express PFKFB2, PFKFB3, PFKFB4 and TIGAR, and that anti-CD3/anti-CD28 conjugated microbeads stimulated a >20-fold increase in F2,6BP with a coincident increase in protein expression of the PFKFB3 family member and a decrease in TIGAR protein expression. We then found that exposure to the PFKFB3 small molecule antagonist, 3PO (1-10 muM), markedly attenuated the stimulation of F2,6BP synthesis, 2-[1-¹⁴C]-deoxy-D-glucose uptake, lactate secretion, TNF-alpha secretion and T cell aggregation and proliferation. We examined the in vivo effect of 3PO on the development of delayed type hypersensitivity to methylated BSA and on imiquimod-induced psoriasis in mice and found that 3PO suppressed the development of both T cell-dependent models of immunity in vivo. Conclusion(s): Our data demonstrate that inhibition of the PFKFB3 kinase activity attenuates the activation of T cells in vitro and suppresses T cell dependent immunity in vivo and indicate that small molecule antagonists of PFKFB3 may prove effective as T cell immunosuppressive agents. © 2012 Telang et al.; licensee BioMed Central Ltd.

Tellini, M. G. and P. Céntola (2007). "Automobile Shredder Residue (ASR) destruction in a plasma gasification reactor." International Journal of Environmental Technology & Management **7**(1/2): 21-38.

Test results on Automobile Shredder Residue (ASR), or car fluff, demonstrated destruction efficiency and safe conversion to synthesis gas and a glass residue, in a plasma gasification system. The synthesis gas consists primarily of hydrogen and carbon monoxide in the range between 20 and 22 vol-% respectively, or 45 and 55 vol-% dry basis, when corrected for nitrogen. In dry reforming operation, carbon dioxide conversion approached 90%. The system is designed to work with oxygen in autothermal conditions, reducing thus the electric power requirement for the plasma reactor. The vitrified residue leach rate makes the product suitable for construction works. [ABSTRACT FROM AUTHOR]

Teltschik, H. M., et al. (2010). "Haploidentical stem cell transplantation in paediatric patients with myelodysplastic syndrome." Bone Marrow Transplantation **2)**: S266-S267.

We investigated a cohort of 11 pediatric patients with myelodysplatic syndrome transplanted with T-cell depleted grafts from haploidentical donors. 2 patients had refractory cytopenia, 5 patients had refractory cytopenia with excess blasts in transformation (REAB-T). 4 patients had relapsed MDS (RAEBT) after a previous transplantation from a matched unrelated donor and received a 2nd allogeneic stem cell transplantation (SCT) from a haploidentical donor. Median age was 7.7 years (1.7-18). 6 patients received Busilvex/Cyclophosphamid/Melphalaned, 5 patients underwent a reduced intensity conditioning with Melphalane/Thiotepa and Fludarabine or Clofarabine. All patients received peripheral stem cells. In 7 patients Graft manipulation was carried out by direct depletion using antiCD3/ antiCD19 coated magnetic microbeads. 4 patients received CD34 positive selected stem cells. Median CD34 + progenitor cell content of the grafts was 13.6 x 10⁶/kg BW (4.6 - 41 x 10⁶), the median T-cell content of the grafts was 63.9 x 10³/kg BW (1.8-162.4 x 10³). Primary engraftment occured in 10 of 11 patients. 1 patient failed to engraft but could be rescued with a second stem cell donation from the same donor. 2 patients rejected the graft after primary engraftment. Both patients could be successfully retransplanted from a second parental donor. Thus, Final engraftment could be obtained in all patients. Median time to reach > 500 neutrophiles/microliter was 11 days (9-15). Independence from platelet substitution was reached after a median time of 10 days (7-18). No severe (>degree2) acute graft versus host disease (GvHD) was observed, 36% (4 out of 11) developed acute GvHD degree1-2 and 64% of the patients (7 out of 11) developed no acute GvHD at all. 2 out of 11 patients relapsed (19%), median time to relapse was 106 days. There was no transplant related mortality (TRM) within the first 100 days after SCT. Over all TRM was 2 out of 11 patients (20%). Event free survival (EFS) was 64%. Conclusion(s): Fast recoveries of neutrophiles and platelets were achieved without occurrence of severe acute GvHD. TRM was low although more than 1/3 of the patients underwent intensive pretreatment according to previous allogeneic SCT. Low relapse rate let to a favourable event free survival. Thus, haploidentical SCT with T-cell depleted grafts is a save and effective treatment for MDS if no matched donor is available.

Teltschik, H. M., et al. (2016). "Haploidentical stem cell transplantation (SCT) with T cell depleted grafts in advanced pediatric sarcomas." Bone Marrow Transplantation **1)**: S265-S266.

Introduction: The rationale for transplanting pediatric sarcoma patients with haploidentical grafts is a hypothesised graft-vs-tumour effect. We investigated a cohort of 21 pediatric patients with advanced sarcomas transplanted with T- and B-cell depleted peripheral stem cell grafts from haploidentical donors between 2005 and 2013. Material (or patients) and methods: 11 patients had advanced Ewings sarcoma, only 2 of them achieved complete remission (CR) before SCT. 10 patients had advanced Rhabdomyosarcomas or Rhabdo-like tumours (RMS), 6 of them achieved CR prior to SCT. Median follow up was 8.4 month. Median age at SCT was 14.3 years. Standard conditioning regimen consisted of Melphalan (2x70mg/m²), Fludarabin (4x40mg/m²), Thiotepa (1x10mg/kg), and OKT3 or ATG. Graft manipulation was carried out by direct depletion using anti CD3/CD19 or TCRalphabeta/CD19 coated magnetic microbeads. A median number of 10.4x10⁶ CD34+ Progenitor cells and 38.8x10³ T cells/kg body weight (BW) were transfused. Pharmacological Graft vs. Host Disease (GvHD) prophylaxis was carried out with Mycofenolate until day 60, if residual T-cells in the graft exceeded 25000/kg BW. 4/21 patients rejected the haplo graft and needed reconditioning with Fludarabine (3x40mg/m²), Thiotepa (1x5mg/kg), ATG and/or OKT3, 7 Gy TLI and a second stem cell donation from a different donor. Result(s): Final engraftment was achieved in 21/21 patients. Median time to reach 500/mul neutrophiles was 10 days (8-15). Independence from platelet substitution was reached after 9 days (7-21). 17/21 patients (81%) had no signs of GvHD or GvHD grade I, 1 patient (5%) had GvHD grade II, 3 patients developed grade III (15%). TRM at day+100 and after 3 years was 0% and 15%, respectively. Event free survival (EFS) of the total cohort after 3 years was 18% (4 out of 21). EFS of RMS was 29% after 3 years, whereas patients with Ewings sarcoma showed a poorer outcome with only 1 out of 11 patient surviving at 2 years, which was presumably due to the higher portion of Ewing patients being transplanted in non remission (NR) (9 out of 11). According to remission status at SCT none of the patients with progressive disease or NR survived, whereas patients with complete remission (CR) had a more favorable outcome of 47% (4 out of 8 patients) surviving at 3 years. Conclusion(s): Fast recoveries of neutrophiles and platelets as well as low incidence of high grade GvHD resulted in a low TRM even if retransplantation was necessary. Hence haploidentical SCT with T-cell depleted grafts presents a feasible therapy option for patients with advanced sarcomas achieving remission prior to transplant.

Teltschik, H. M., et al. (2012). "Flow cytometry based chimerism analysis can predict graft rejection in pediatric patients receiving hla mismatched stem cell transplantation." Blood. Conference: 54th Annual Meeting of the American Society of Hematology, ASH **120**(21).

Graft failure is a life-threatening complication after allogeneic stem cell transplantation and its probability increases with the degree of HLA disparity between donor and recipient. In HLA-mismatched transplantation, specific T cells against mismatched HLA class I alleles were shown to be associated with rejection. Moreover, HLA mismatches allow to monitor the chimerism status of several cell populations by flow cytometry with specific monoclonal antibodies against HLA alleles with high sensitivity even in very low cell numbers. We report our experience with this method in a cohort of 90 pediatric patients who received T and B cell depleted haploidentical stem cells after myeloablative conditioning regimens. Diagnoses were: leukemias n=43, solid tumors n=28, non malignant diseases n=19. Graft manipulation was carried out by magnetic microbeads and the clinimacsO device with 4 to 5 log depletion efficacy. Conditioning regimens were TBI, Bu or Mel based and comprised ATG or OKT3. Immunosuppression with mycophenolate mofetil (MMF) was given in most patients (if donor T cells in the graft exceeded 25.000/kg body weight) Flow cytometry with HLA antibodies for detection of chimerism status of T and NK cell subsets in peripheral blood was started at day 0 and was repeated at least weekly. 14 out of 90 patients (15%) rejected the graft between day 19 and 86 (median day 33). Two different rejection patterns were observed: early rejections (diagnosis of rejection, day 19-40, median day 28) with cytokine release syndrome including high fever, massive elevation of CRP, ferritin, LDH and D-Dimers or late rejections without signs of inflammation (diagnosis of rejection, day 53-86). In all patients, residual T cells of recipient origin were still detectable after the conditioning procedure. The portion of residual recipient T cells within the first week (day 0-7) was predictive: Non-rejectors had a median percentage of 46+-5% recipient T cells detectable (n=42 analyses) whereas rejectors showed a significant higher percentage (85+-7%, n=13 analyses, p<0.001). In more than 90% of the rejectors, the portion of detectable autologous recipient T cells exceeded 60%. Thus, the risk of rejection for patients with >60% detectable recipient T cells was 41% (12 out of 29 rejected), whereas patients with <60% recipient T cells had a risk of 4% (only 1 out of 27 rejected; p=0.001). In non-rejectors, recipient T cells where detectable at a very low level (median 0,7/mul) up to day 60 without proliferation tendency, whereas strongly increasing and significantly higher numbers were observed in rejectors (from 3/mul at day 0-3 up to 617/mul at day 15-18; p< 0,05 for all data pairs). Based on these data, donor lymphocyte infusions (DLI) and cessation of MMF were performed in 12 patients with increasing residual recipient T cells to prevent imminent rejection (1-4 infusions, median number: 1; starting dose: 25.000 CD3+cells/kg bw). Recipient T cells were reduced/eradicated in 7/12 patients (60%) after DLIs and no rejection occurred. In 5 patients, DLIs had no impact on increasing recipient T cells, resulting in graft rejection in 4 out of these 5

patients. Conclusion(s): Flow cytometry with specific monoclonal antibodies against HLA alleles allows to analyze the origin of lymphocyte subsets and their kinetics after HLA mismatched transplantation with high sensitivity even in very low cell numbers. The percentage of residual recipient T cells in the first week posttransplant was predictive, since patients with >60% detectable recipient T cells had a significantly higher risk to experience graft rejection. In all cases, rejection was associated with increasing recipient T cells. Intervention with DLI and cessation of immune suppression may contribute to prevent rejection.

Tendulkar, S., et al. (2012). "A three-dimensional microfluidic approach to scaling up microencapsulation of cells." Biomedical Microdevices **14**(3): 461-469.

Current applications of the microencapsulation technique include the use of encapsulated islet cells to treat Type 1 diabetes, and encapsulated hepatocytes for providing temporary but adequate metabolic support to allow spontaneous liver regeneration, or as a bridge to liver transplantation for patients with chronic liver disease. Also, microcapsules can be used for controlled delivery of therapeutic drugs. The two most widely used devices for microencapsulation are the air-syringe pump droplet generator and the electrostatic bead generator, each of which is fitted with a single needle through which droplets of cells suspended in alginate solution are produced and cross-linked into microbeads. A major drawback in the design of these instruments is that they are incapable of producing sufficient numbers of microcapsules in a short-time period to permit mass production of encapsulated and viable cells for transplantation in large animals and humans. We present in this paper a microfluidic approach to scaling up cell and protein encapsulations. The microfluidic chip consists of a 3D air supply and multi-nozzle outlet for microcapsule generation. It has one alginate inlet and one compressed air intlet. The outlet has 8 nozzles, each having 380 micrometers inner diameter, which produce hydrogel microspheres ranging from 500 to 700 mu m in diameter. These nozzles are concentrically surrounded by air nozzles with 2 mm inner diameter. There are two tubes connected at the top to allow the air to escape as the alginate solution fills up the chamber. A variable flow pump 115 V is used to pump alginate solution and Tygon registered tubing is used to connect in-house air supply to the air channel and peristaltic/syringe pump to the alginate chamber. A pressure regulator is used to control the flow rate of air. We have encapsulated islets and proteins with this high throughput device, which is expected to improve product quality control in microencapsulation of cells, and hence the outcome of their transplantation.

Teng, J., et al. (2019). "Microplastic in cultured oysters from different coastal areas of China." Science of the Total Environment **653**: 1282-1292.

Microplastics are an emerging concern in the marine environment due to their small size; they can be ingested by aquatic organisms, especially filter-feeding organisms, such as oysters. The presence of microplastics in seafood may pose a threat to food safety, and there is an urgent need to evaluate the potential risks of microplastics to human health. This study quantified the microplastics in oysters from 17 sites along the coastline of China. Qualitative attributes, such as shape and size, were also determined under a microscope. Additionally, the polymer types were identified using Fourier-Transform Infrared Micro-Spectroscopy (μ-FT-IR). The results showed that the average abundance of microplastics in oyster was 0.62 items/g (wet weight) or 2.93 items/individual. Additionally, 84% of the sampled oysters had inhaled microplastics, indicating the high prevalence of microplastic pollution in different coastal areas of China. Fibers were the most common shape (60.67%), and the most common size was <1500 μm, accounting for 81.89% of the total microplastics. The μ-FT-IR analysis identified eight different polymers, and the main polymeric types of microplastics were cellophane (CP), polyethylene (PE) and

polyethylene terephthalate (PET). Our results suggest the widespread prevalence of microplastics in cultured oysters from different coastal areas of China with similar or lower abundances than other countries. In addition, our results exhibited regional characteristics of high microplastics abundance in southern coastal area of China and low microplastics abundance in northern China. Further investigations are warranted to examine microplastics contamination in other seafood species from different geographical sites in coastal area of China. Graphical abstract Unlabelled Image Highlights • Microplastic uptake was identified in cultured oysters from 17 cites of China. • Eighty-four percent of sampled oysters had inhaled microplastics. • The average microplastics abundance was 0.62 items/g (ww) or 2.93 items/individual. • The most common polymeric types of microplastics in oysters were CP, PE and PET. [ABSTRACT FROM AUTHOR]

Teo, Y., et al. (2016). "Relationship between virus replication and apoptosis events in IgM+ cells from chicken spleen and bursa of Fabricius infected with Malaysia strain of very virulent infectious bursal disease virus." Acta Scientiae Veterinariae **44**(1419).

Infection of IBDV was reported to be endemic worldwide, including Malaysia, and can be spread orally through polluted fodder and water sources, thus causing economic losses especially in the commercial poultry industry. The infection results in the depletion of B lymphocytes and subsequently destruction of the bursa, which leads to immunosuppression of the bird and it was postulated that the depletion of cells in the bursa was due to induction of apoptosis. In the current study, the infection of a Malaysian isolate of very virulent IBDV UPM0081 on IgM bearing B lymphocytes (IgM+ cells) from chicken spleen and bursa was compared. A total of sixty eggs were obtained and raised until the age of 3 weeks old. The birds were divided into two groups (n=30), which one of them served as control while IBDV strain UPM0081 was used to infect another group of birds at the concentration of 103 ELD50. The birds were observed and sacrificed at days 2, 4 and 5 post infections. Spleen and bursa of Fabricius were harvested and subjected to IgM+ cell enrichment using microbeads. The cell viability of enriched cells was assayed using MTT and cell cycle was analysed using propidium iodide. Annexin V FITC and acridine orange/propidium iodide double stain assays were used to determine the event of apoptosis in the enriched IgM+ cells. Also, the IBDV viral load was also quantified by using real time polymerase chain reaction (PCR) to evaluate the relationship between virus replication and apoptosis events in the infected chickens. Current results showed that the apoptotic events were observed to be significantly higher in IgM+ cells isolated from chicken bursa as compared to the cells isolated from spleen. The bursal B lymphocytes cell viability decreased following the infection of very virulent IBDV. The cells were then investigated of their apoptotic rate and data showed that increasing apoptotic cells (early and late apoptosis) were observed in AO/PI double stain as well as increment of SubG0/G1 population in the cell cycle analysis and also increment of Annexin V FITC bound cells in the apoptosis study. As for B lymphocytes from chicken spleen, the magnitude of damage caused by very virulent IBDV was not as severe as that in the chicken bursa, with the cell viability drastically decreased on day 4 following IBDV infection. IBDV caused severe destruction in bursa of Fabricius compared to spleen, in which cell death events in the former was reported to be directly caused by the virus. Apoptotic event in chicken spleen

following IBDV infection was observed to be caused by oxidative stress. Thus, viral replication played a role in inducing bursal IgM+ cells death while such phenomenon was not observed in spleen isolated IgM+ cells. In summary, the cell death events of IgM+ cells in chicken spleen and bursa of Fabricius may be accounted for by different factors upon infection with the Malaysian strain of IBDV UPM0081. It is obvious that IgM+ cells from chicken bursa suffered from apoptotic cell death in an increasing manner considerably with time of infection and RNA load detected in the cells, which supported by previous literature that IBDV induces host cells apoptosis, with both VP2 and VP5 playing a role in binding and apoptosis. Meanwhile, the cell death events of B lymphocytes in chicken spleen was observed to be more relevant to other factors such as the oxidative stress or proinflammatory cytokines that caused by the virus infection rather than the viral RNA load.

Ter Halle, A., et al. (2016). "Understanding the Fragmentation Pattern of Marine Plastic Debris." Environmental Science & Technology **50**(11): 5668-5675.

The global estimation of microplastic afloat in the ocean is only approximately 1% of annual global plastic inputs. This reflects fundamental knowledge gaps in the transformation, fragmentation, and fates of microplastics in the ocean. In order to better understand microplastic fragmentation we proceeded to a thorough physicochemical characterization of samples collected from the North Artlantic subtropical gyre during the sea campaign Expedition seventh Continent in May 2014. The results were confronted with a mathematical approach. The introduction of mass distribution in opposition to the size distribution commonly proposed in this area clarify the fragmentation pattern. The mathematical analysis of the mass distribution points out a lack of debris with mass lighter than 1 mg. Characterization by means of microscopy, microtomography, and infrared microscopy gives a better understanding of the behavior of microplastic at sea. Flat pieces of debris (2 to 5 mm in length) typically have one face that is more photodegraded (due to exposure to the sun) and the other with more biofilm, suggesting that they float in a preferred orientation. Smaller debris, with a cubic shape (below 2 mm), seems to roll at sea. All faces are evenly photodegraded and they are less colonized. The breakpoint in the mathematical model and the experimental observation around 2 mm leads to the conclusion that there is a discontinuity in the rate of fragmentation: we hypothesized that the smaller microplastics, the cubic ones mostly, are fragmented much faster than the parallelepipeds.

Teramo, A., et al. (2014). "Analysis of STAT3 mutations in patients affected by lymphoproliferative disorders of large granular lymphocyte." Haematologica **2)**: S53.

Introduction. T large granular lymphocytes leukemia (T-LGLL) and NKtype chronic lymphoproliferative disorder (CLPD-NK) are rare diseases characterized by the abnormal expansion of large granular lymphocytes (LGL). The majority of patients are asymptomatic, although neutropenia or autoimmune rheumatic diseases can be reported in a significant percentage of cases. Actually, the pathogenesis of these disorders is still unknown. Several data indicate that LGL proliferation is maintained through the activation of many signaling pathways, among them JAK/STAT pathway has a relevant role in LGL survival and proliferation. Recently, both in T-LGLL and CLPD-NK, somatic STAT3 mutations have been reported in the SH2 domain, mostly represented by Y640F and D661Y. The aims of this study include: i) the analysis of STAT3 point mutations in T-LGLL and CLPD-NK patients DNA samples; ii) the evaluation of these mutations over time (mean follow-up 6 + 3 y); iii) the correlation between the presence of STAT3 mutations and clinical (in particular neutropenia) and biological (namely immunophenotypic) features of patients' LGL. Methods. One hundred one patients were

included in the study: 60 affected by T-LGLL and 41 by CLPD-NK. Peripheral blood mononuclear cell (PBMC) immunophenotype was analyzed by flow cytometry for CD3, CD16, CD57, CD56, CD4, CD8, CD5, CD19, gammadelta, Vbeta and Killer Immunoglobulin like Receptor (KIR) markers. For molecular analysis, LGLs were purified by microbeads or FACSAria cell sorting and DNA samples were sequenced by Sanger method. In addition, DNA samples were analyzed by Amplification Refractory Mutations System (ARMS-PCR) for Y640F and D661Y STAT3 mutations. Results. By the combination of Sanger sequencing and ARMS-PCR, 14/101 patients were found mutated in STAT3: 11 with T-LGLL (18% of all T-LGLL patients analyzed), and 3 with CLPDNK (7% of all CLPD-NK patients analyzed). By flow cytometry we defined a discrete immunophenotype of LGLs in mutated T-LGLL patients characterized by CD8+, CD57+, CD16+ expression, a restricted TCR BV repertoire or KIR expression and more than 55% of total lymphocytes represented by LGLs. In all mutated patients mutations have been detected also during the follow-up. Furthermore, we found that 9/11 (82%) of T-LGLL mutated patients were characterized by neutropenia (ANC<1,000/mul), in particular 5/11 (45%) presenting with severe neutropenia (ANC<500/mul). Conclusions. Although the clinical relevance of STAT3 mutations is not yet completely clarified in these disorders, our results indicate that patients carrying STAT3 mutations might represent a subset with clinical and biological features suggestive for a more symptomatic disease.

Terao, C., et al. (2012). "The human leukocyte antigen DRB1*13:02-DQB1*06:04-DPB1*04:01 haplotype isclosely associated with dermatomyositis patients with Anti-CADM-140 (melanoma differentiation-associated protein 5: MDA5) antibody. Yuji hosono1." Arthritis and Rheumatism **10)**: S821-S822.

Background/Purpose: Recent studies have revealed that anti-CADM- 140 (MDA5/IFIH1)-antibody positive dermatomyositis (DM) patients frequently develop acute or subacute progressive interstitial pneumonia (A/SIP) with poor prognosis. However, genetic background of anti-CADM-140- antibody positive DM is currently unclear. Here, we intended to analyze the relationship between specific human leukocyte antigen (HLA) alleles in anti-CADM-140-positive DM patients. Method(s): Anti-CADM-140-antibody positive DM patients (CADMs, N=20) and healthy controls (HCs, N=2972) were enrolled in this study. Autoantibodies were screened using immunoprecipitation with [35S]methionine-labelled HeLa cells. HLA class I (A, B, and C) and class II (DRB1, DQA1, DQB1, and DPB1) genotyping was carried out with a highthroughput, high-resolution genotyping method (WAKFlow WAKUNAGA) by combining PCR and sequence-specific oligonucleotide probe protocols with the Luminex 100 xMAP flow cytometry dual-laser system to quantify fluorescently labelled oligonucleotides attached to colour-coded microbeads. Allele frequency was compared between CADMs and HCs by chi-square test or Fisher's exact test. Haplotypes with frequency more than 10% in CADMs were analyzed for comparison between CADMs and HCs with chi-square test. Result(s): No specific HLA class I alleles show significant associations with CADMs.CADMs demonstrated higher allele frequencies of DRB1*1302 (15% vs 5.5%; with OR=2.73,0.0854), DQB1*0604 (12.5% vs 5.5%; with OR=2.5,P= 0.0114), and DPB1*0401 (12.5% vs 5G with OR=2.5,P= 0.03469) than HCs. However, no specific HLA alleles reached significant difference between CADMs and NCs due to lack of power. The observed distribution of HLA class II alleles among patients and controls suggested the notion that specific combinations of alleles at the DRB1, DQB1, and DPB1 loci are associated with the risk for CADMs. Haplotype analysis showed the frequency of the haplotype DRB1*13:02-DQB1*06:04- DPB1*04:01 was higher in CADMs than NCs (12.5% vs 3.6%;OR 3.79, 95%CI 1.47-9.76, P = 0.0030). Conclusion(s): HLA-DRB1*13:02-DQB1*06:04-DPB1*04:01 haplotype is closely associated with CADMs, suggesting that the production of anti- CADM-140

may be associated with a certain immunogenetive background.

Terry, V. H., et al. (2009). "CD44 MicroBeads accelerate HIV-1 infection in T cells." Virology **388**(2): 294-304.

Super-paramagnetic CD44 MicroBeads (Miltenyi) designed for the isolation of infectious HIV-1 from dilute or difficult biological samples dramatically enhance the infectivity of bound HIV virions, even if the original viral suspension is merely incubated with beads. Infection of the CEM T cell line with the NL4-3 virus clone or primary human CD4 T cells with X4- and R5-tropic clones and a clade C primary virus isolate all showed accelerated p24 production and larger fractions of infected target cells. Effects could be detected very early; incubation of virus with the CD44 MicroBeads promoted higher levels of viral integration within the first infection cycle. In summary, CD44 MicroBeads provide the means not only to concentrate dilute viral samples, but also to directly facilitate within days rather than weeks the in vitro expansion of patient isolates independent of coreceptor usage and the performance of HIV replication assays that require a large fraction of infected primary T cells.

Teschner, D., et al. (2012). "Clinical grade depletion of naive T cells using CD45RA MicroBeads." Onkologie **6)**: 156-157.

Introduction: We and others have previously demonstrated that naive T cells contain a much higher frequency of alloreactive precursors compared to memory T cells. This study aims at the development of a good manufacturing practice (GMP) procedure for depleting naive CD45RA+ T cells from donor lymphocyte infusion (DLI) products, as a new approach to primary graft-versus-host disease (GvHD) prophylaxis. Method(s): Leukapheresis products from healthy donors (n = 6) were depleted from CD45RA+ cells under clean room conditions, using CliniMACS CD45RA MicroBeads. Two fractions (i.e. unseparated, CD45RA-) were analyzed by phenotypic and functional assays. Result(s): CD45RA depletion eliminated >99.9% of CD45RA+ cells (median 4.4 log depletion). The CD45RA- subset contained a higher proportion of CD4+ T cells than the untouched leukapheresis (median 17.5 vs. 11.6 %). In contrast, CD8+ T cells and CD4+CD25+FOXP3+ regulatory T cells were reduced in the CD45RA- fraction (6.8 vs. 13.9% and 1.3 vs. 1.8%). CD16+CD56+ NK cells and CD19+ B cells were almost completely eliminated (0.1 vs. 7.7% and 0 vs. 13.9%), whereas CD14+ monocytes and CD15+ granulocytes were enriched in the CD45RA- fraction (40.9 vs. 23.1% and 7.9 vs. 1.6%). CD4+ and CD8+ T cells in the CD45RA- subset showed a memory phenotype (entirely CD45ROpositive, low expression of CD62L and CCR7, intermediate expression of CD27 and CD28). In IFN-gamma ELISpot assays, persistent reactivity to cytomegalovirus, Epstein-Barr virus, candida, and aspergillus antigens could be demonstrated in the CD45RA- subset. In allogeneic mixed lymphocyte reaction (MLR) assays, alloreactive CD8+ T cells were strongly reduced (around 1-log) upon CD45RA depletion, even in clinically inapplicable (10 out of 10) HLA mismatch settings. In contrast to our previous in vitro work (single HLA mismatch), alloreactive CD4+ precursors appeared in similar quantities in both fractions when applying 10 out of 10 HLA mismatch MLR. Conclusion(s): Clinical grade depletion of CD45RA+ cells from entire leukapheresis products is feasible and highly efficient using GMP CD45RA MicroBeads. The CD45RA- target fraction contains memory T cells that show preserved reactivity to common viral and fungal pathogens. T cell mediated alloreactivity appears to be reduced in the CD45RA- fraction, with apparently stronger efficacy in the CD8 compared to the CD4 subset. Our data pave the way for clinical trials that investigate if CD45RA-depletion of DLI can reduce GvHD.

Teschner, D., et al. (2011). "Depletion of alloreactive naive T cells using GMP-conform CD45RA

MicroBeads." Onkologie **6)**: 284.

Introduction: Alloreactive T cells are major inducers of graft-versus-host disease (GvHD) and originate mainly from naive precursors. We have previously shown that naive CD45RA+ CD4 and CD8 T cells contain an overall 1-log higher frequency of allo-HLA mismatch reactive T cells compared to memory CD45RA-counterpart fractions in vitro. Therefore, the aim of the current study is to establish a good manufacturing practice (GMP) procedure for depleting naive CD45RA+ T cells from donor allografts as a new approach of primary GvHD prophylaxis. Method(s): Leukapheresis products from healthy donors were separated under clean room conditions using novel GMP-conform CliniMACS CD45RA MicroBeads into CD45RA+ and CD45RA-cells. Flow cytometric phenotyping of unseparated cells and CD45RA fractions was performed for T cell subsets including natural killer (NK) cells and B cells. Compatible with the intended clinical setting, three fractions (i.e. unseparated, CD45RA+, CD45RA-) were frozen under GMP guidelines. Ongoing work analyzes all fractions for numbers of regulatory T cells, monocytes and neutrophils, and for T cell responses to alloantigens and to common pathogens such as cytomegalovirus, Epstein-Barr virus, candida, and aspergillus. Result(s): Untouched leukapheresis products showed a typical distribution of cell types with a proportion of 38.1% +/- 5.8 CD3+CD45RA+ T cells and a CD4/ CD8 ratio of 2.9-3.1/1. Depletion by CD45RA MicroBeads eliminated >99.9% of CD45RA+ cells (>7-log depletion) during a 4-hour CliniMACS procedure. The CD45RA-subset contained a higher proportion of CD4⁺ T cells than the CD45RA+ counterpart subset (73.3 vs. 39.0 % in separated viable cells). In contrast, CD8+ T cells were increased in the CD45RA+ fraction (19.8 vs. 10.9%). CD16+CD56+ NK cells and CD19+ B cells were almost completely depleted by CD45RA beads (0.1% vs. 19.0% and 0% vs. 8.6%, respectively). Conclusion(s): In vitro depletion of CD45RA+ cells from entire leukapheresis products is highly efficient using GMP-conform CD45RA MicroBeads. The CD45RA-target fraction is enriched for memory T cells, and contains more CD4⁺ T cells compared to the CD45RA+ counterpart subset. In contrast, CD45RA depletion decreases the numbers of CD8+ T cells as well as NK and B cells to different extent. Further experiments concerning phenotype, alloreactivity and anti-pathogen reactivity of both subsets are ongoing and will be presented at the meeting.

Tetik, S., et al. (2010). "Oxidative modification of fibrinogen affects its binding activity to glycoprotein (GP) IIb/IIIa." Clinical & Applied Thrombosis/Hemostasis **16**(1): 51-59.

AIM: Proteins are sensitive biomarkers of human disease condition associated with oxidative stress. Alteration of protein structures by oxidants may result in partial or complete loss of protein functions. We have investigated the effect of structural modifications induced by metal ion catalyzed oxidation of fibrinogen on its binding capacity to glycoprotein IIb/IIIa (GpIIb/IIIa) and human platelets.

METHODS: We identified and quantified of binding capacity of native and oxidized fibrinogen to its receptor in vitro by flow cytometer. Dityrosine formation on oxidized fibrinogen were detected spectrophotometrically. Elevated degradation products of fibrinogen after oxidation were revealed in the HPLC analysis. The native and oxidized fibrinogen were analyzed on mass spectrum upon digestion with trypsin.

RESULTS: Oxidatively modified fibrinogen showed less binding activity than native fibrinogen to GpIIb/IIIa coated micro beads and human platelets whereas slightly higher binding capacity to ADP induced stimulated platelets. Formation of di-tyrosines in the amino acid side chains of fibrinogen were observed upon oxidation. Decreased binding capacity of oxidized fibrinogen correlated with intensities of dityrosine formation. Oxidized fibrinogen had more ion-mass intensities at higher than native fibrinogen.

CLINICAL IMPLICATIONS: Important point is decreased of binding capacity of the oxidized fibrinogen to own receptor. The decreased rate of binding, leading to effect in the diseases of clot formation may account for the association between oxidation of fibrinogen and the incidence of effect in human diseases.

Tetik, S., et al. (2008). "Low-density lipoprotein specifically binds glycoprotein IIb/IIIa: a flow cytometric method for ligand-receptor interaction." Clinical & Applied Thrombosis/Hemostasis **14**(2): 210-219.

Primary platelet aggregation requires agonist-mediated activation of membrane receptor glycoprotein (GP) IIb/IIIa, binding of fibrinogen to GpIIb/IIIa, and cellular events after fibrinogen binding. This study investigated whether fibrinogen receptor GpIIb/IIIa is also the binding site for low-density lipoprotein (LDL) in platelets by using GpIIb/IIIa-coated polystyrene microbeads incubated with various concentrations of fluorescein isothiocyanate (FITC)-labeled ligands. Binding was assayed by flow cytometry. Binding of fibrinogen (Fg)-FITC and LDL-FITC to GpIIb/IIIa coated microbeads was concentration dependent, reaching saturation. Binding of LDL-FITC to GpIIb/IIIa coated microbeads was inhibited by fibrinogen. Binding of LDL-FITC or Fg-FITC to freshly isolated platelets gave similar results as those of GpIIb/IIIa coated microbeads. Glycoprotein IIb/IIIa, the fibrinogen receptor on platelets is also one of the binding sites of LDL on platelets. This rapid and reliable flow cytometric technique using coated microbeads may be used as a first step for the study of all ligand receptor interactions.

Tetu, S. G., et al. (2019). "Plastic leachates impair growth and oxygen production in Prochlorococcus, the ocean's most abundant photosynthetic bacteria." Communications Biology **2**(1): 184.

Plastic pollution is a global threat to marine ecosystems. Plastic litter can leach a variety of substances into marine environments; however, virtually nothing is known regarding how this affects photosynthetic bacteria at the base of the marine food web. To address this, we investigated the effect of plastic leachate exposure on marine Prochlorococcus, widely considered the most abundant photosynthetic organism on Earth and vital contributors to global primary production and carbon cycling. Two strains of Prochlorococcus representing distinct ecotypes were exposed to leachate from common plastic items: high-density polyethylene bags and polyvinyl chloride matting. We show leachate exposure strongly impairs Prochlorococcus in vitro growth and photosynthetic capacity and results in genome-wide transcriptional changes. The strains showed distinct differences in the extent and timing of their response to each leachate. Consequently, plastic leachate exposure could influence marine Prochlorococcus community composition and potentially the broader composition and productivity of ocean phytoplankton communities.

Teunou, E. and D. Poncelet (2005). "Rotary disc atomisation for microencapsulation applications - prediction of the particle trajectories." Journal of Food Engineering **71**(4): 345-353.

Disintegration of a liquid by a rotating disc is a technique that has been widely used in spray drying, cooling or freezing for atomisation of the liquid into fine droplets before drying or freezing. This technique is applied today for microencapsulation, which is a promising method to protect the core material, improve the product characteristics and functionalities. It is actually one of the few methods that can be economically applied for microencapsulation in food industries. For this purpose, the structure and the quality of the capsules are determining factors in guaranteeing the properties of the capsules. The capsules, in this case, must be collected in a gentle way, and the trajectory of the capsules, which is the objective of this paper, must be determined. So, paraffin microbeads (1-1000 micro m in diameter) were produced by disintegration of hot liquid paraffin with a rotating disc. The trajectory of the particle was measured. A theoretical model of a capsule travelling in static air was derived to predict the trajectory. It estimates closely the distance of projection of particles. Since it has been developed on a real basis such as the mechanism of disintegration for beads formation, slippage of liquid on the surface, radial velocity of the formed droplet at the edge of the disc and has taken into account interactions between the surrounding air, the atomised liquid and rotating disc characteristics, it can be used to predict the trajectory of beads produced by any type of rotating disc and atomised liquid. This model can also help to determine a surface productivity parameter of such system on an industrial scale.

Thai, K., et al. (2013). "Chronic inflammation-induced hematuria involves molecular modulation of the urothelial barrier and bladder vasculature." Journal of Urology **1)**: e468.

INTRODUCTION AND OBJECTIVES: Bladder surgery-, chemotherapy-, and infection-induced inflammation can breach the urothelial barrier and cause hematuria. Defining the mechanisms of urothelial compromise and hematuria in inflammation models may reveal shared pathways suitable as therapeutic targets. METHOD(S): We expanded on our mouse model of urogenital schistosomiasis (Fu et al., PLOS Pathogens 2012) to study how chronic inflammation breaches the urothelial barrier and causes hematuria. In this model, Schistosoma haematobium eggs are injected into the bladder walls of mice, which recapitulates key features of human infection, i.e. urothelial hyperplasia and hematuria. RESULT(S): Microarray analysis demonstrated that despite the onset of urothelial hyperplasia, transcription of junctional adhesion molecule, claudin and uroplakin genes, key components of the urothelial barrier, were all decreased compared to controls after bladder exposure to eggs (>=2-fold, p<0.05). Luminex liquid microbead immunoassays demonstrated higher levels of bladder vascular endothelial growth factor (VEGF) compared to controls after egg injection (p>0.05). Correspondingly, microarray and DAVID pathways analysis revealed more transcription of VEGF pathway-related genes in egg- vs. control-injected bladders. Perfusion of egg-injected mice with FITClectin and Red Fluoromax microspheres revealed widespread bladder neovascularization and more microvascular permeability relative to controls (Figure). Finally, mass spectrometry of urine from egg-injected mice demonstrated the presence of multiple blood proteins not observed in control-injected mice. CONCLUSION(S): These unexpected findings suggest that chronic inflammation-induced hematuria is associated with intricate modulation of the bladder vasculature and urothelial barrier on the cellular and molecular level. Future work will define how VEGF and other factors mediate these processes, which may lead to new management approaches for hematuria. (Figure Presented).

Thanh, N. P., et al. (2010). "Household solid waste generation and characteristic in a Mekong Delta city, Vietnam." Journal of Environmental Management **91**(11): 2307-2321.

This study was undertaken to evaluate the quantity and composition of household solid waste to identify opportunities for waste recycling in Can Tho city, the capital city of the Mekong Delta region in southern Vietnam. Two-stage survey of 100 households was conducted for dry season and rainy season in 2009. Household solid waste was collected from each household and classified into 10 physical categories and 83 subcategories. The average household solid waste generation rate was 285.28 g per capita per day. The compostable and recyclable shares respectively accounted for 80.02% and 11.73%. The authors also analyzed the relations between some socioeconomic factors and household solid waste generation rates by physical categories

and subcategories. The household solid waste generation rate per capita per day was positively correlated with the population density and urbanization level, although it was negatively correlated with the household size. The authors also developed mathematical models of correlations between the waste generation rates of main physical categories and relevant factors, such as household size and household income. The models were proposed by linear models with three variables to predict household solid waste generation of total waste, food waste, and plastic waste. It was shown that these correlations were weak and a relationship among variables existed. Comparisons of waste generation by physical compositions associated with different factors, such as seasonal and daily variation were conducted.

Thanh, N. P., et al. (2011). "Assessment of plastic waste generation and its potential recycling of household solid waste in Can Tho City, Vietnam." Environmental Monitoring & Assessment **175**(1-4): 23-35.

Plastic solid waste has become a serious problem when considering the disposal alternatives following the sequential hierarchy of sound solid waste management. This study was undertaken to assess the quantity and composition of household solid waste, especially plastic waste to identify opportunities for waste recycling. A 1-month survey of 130 households was carried out in Can Tho City, the capital city of the Mekong Delta region in southern Vietnam. Household solid waste was collected from each household and classified into ten physical categories; especially plastic waste was sorted into 22 subcategories. The average household solid waste generation rate was 281.27 g/cap/day. The compostable and recyclable shares respectively accounted for high percentage as 80.74% and 11%. Regarding plastic waste, the average plastic waste generation rate was 17.24 g/cap/day; plastic packaging and plastic containers dominated with the high percentage, 95.64% of plastic waste. Plastic shopping bags were especially identified as the major component, accounting for 45.72% of total plastic waste. Relevant factors such as household income and household size were found to have an existing correlation to plastic waste generation in detailed composition. The household habits and behaviors of plastic waste discharge and the aspects of environmental impacts and resource consumption for plastic waste disposal alternatives were also evaluated.

Thanh Truc, N. T. and B. K. Lee (2019). "Sustainable hydrophilization to separate hazardous chlorine PVC from plastic wastes using H₂O₂/ultrasonic irrigation." Waste Management **88**: 28-38.

Polyvinyl chloride (PVC) products comprise a large portion of plastic wastes and cause severe environmental burdens in thermal recycling such as toxic release and disposal difficulties. Selective separation methods for PVC containing hazardous chlorine are required for the development of suitable disposal or material recycling processes. However, separating PVC selectively from municipal plastic waste mixtures is difficult due to their similar hydrophobic surface and appearance densities. This study presents a one-step, selective separation technique for PVC using H₂O₂ solution under ultrasonic irrigation to promote the selective development of hydrophilicity only on the PVC surface. The combined treatment helped to decrease air bubbles attached on the PVC surface because of increased wettability, which allowed the treated PVC to settle on the bottom of the flotation reactor. However, the remaining plastic wastes were easily floated off because they maintained their hydrophobicity. The combined treatment with a low concentration of 3% H₂O₂ and ultrasonic irrigation for 30min afforded 100% purity and recovery of the PVC separated from the municipal plastic waste mixture. This proposed treatment is therefore a promising and inexpensive way to improve plastic recycling quality

through selective PVC separation by the selective development of hydrophilicity on its surface.

Thanh Truc, N. T., et al. (2017). "Surface hydrophilization of acrylonitrile butadiene styrene by the mild heat treatment for its selective separation to recycling." Separation and Purification Technology **173**: 226-232.

Acrylonitrile-butadiene-styrene (ABS) is one of hazardous halogenic plastics which containing brominated flame-retardants (BFRs) is considered as toxic wastes due to releasing hydrogen bromide and brominated dioxins through incineration or disposal activities. In present, recycling is aimed as a sustainable plastic waste management of ABS containing BFRs in ways that minimize the potential impact on human health and environment. This study was conducted to facilitate the separation of ABS plastics from heavy plastic mixture by froth flotation after surface rearrangement of ABS with mild heat treatment for its recycling. Hydrophilic moieties would be more likely to develop on the mild heat-treated ABS surfaces than on other plastics perhaps due to the difference of molecular mobility. This provides an excellent base for selective separation of ABS by froth flotation technique. As a result of froth flotation after mild heat treatment, about 97% of ABS with 100% purity was selectively separated from heavy plastics. The detailed mechanism for the selective separation of the ABS in the treatment (froth flotation after mild heat treatment) was discussed. Finally, this study facilities selective separation application effective and inexpensive method for of ABS from waste plastics.

Thavakumar, A., et al. (2016). "Eosinophil apoptosis is negatively associated with body mass index in asthma." Thorax **71 (Supplement 3)**: A218.

Background Obese asthmatics are known to have reduced eosinophils in sputum, as well as poor control of asthma symptoms.1 We have shown that, compared to non-obese patients, there is an elevated number of eosinophils in the airway submucosa of obese asthmatic patients.2 This study aims to determine whether a differential susceptibility to apoptosis, between obese and non-obese patients, could contribute to these clinical observations. Method Patients with a clinical diagnosis of asthma were recruited (n = 28) and consented at Glenfield Hospital for blood donation to study eosinophil apoptosis; the patients recruited had varying severities of asthma and BMI. Eosinophils were isolated from whole blood by negative immunomagnetic selection using CD16 microbeads to a purity of mean +/- SD 95.7% (+/- 4). Purified eosinophils (Time 0) were placed into culture in RPMI (1640 + GlutaMAX-1 supplemented with 10% FBS and 1% penicillin and streptomycin) and harvested at 17 and 21 hours later to measure apoptosis by flow cytometry using Annexin V and Propidium Iodide (Becton Dickinson). Cells were considered apoptotic if they were Annexin V positive/PI negative and reported as a percentage of total eosinophils. Results At 0 hours, the mean% of annexin V positive cells was 0.47% and there was no significant association with BMI (r = -0247, p value = 0.245). At 17 and 21 hours there were 12.68% and 21.0% annexin V positive cells, respectively, and we noted a significant negative Pearson's correlation between eosinophil apoptosis and BMI at time 17 (r = -0.449; p = 0.028) and time 21 (r = -0.448; p = 0.028). These correlations were independent of lung function, steroid medication and percentage eosinophil purity. Conclusion Eosinophils from obese asthmatic patients are less susceptible to apoptosis compared to those from non-obese patients. This may contribute to the differential presence of eosinophils in the lamina propria and airway of obese patients compared to non-obese individuals.

Theaker, S. M., et al. (2016). "T-cell libraries allow simple parallel generation of multiple peptide-specific human T-cell clones." Journal of Immunological Methods **430**: 43-50.

Isolation of peptide-specific T-cell clones is highly desirable for determining the role of T-cells in human disease, as well as for the development of therapies and diagnostics. However, generation of monoclonal T-cells with the required specificity is challenging and time-consuming. Here we describe a library-based strategy for the simple parallel detection and isolation of multiple peptide-specific human T-cell clones from CD8(+) or CD4(+) polyclonal T-cell populations. T-cells were first amplified by CD3/CD28 microbeads in a 96U-well library format, prior to screening for desired peptide recognition. T-cells from peptide-reactive wells were then subjected to cytokine-mediated enrichment followed by single-cell cloning, with the entire process from sample to validated clone taking as little as 6 weeks. Overall, T-cell libraries represent an efficient and relatively rapid tool for the generation of peptide-specific T-cell clones, with applications shown here in infectious disease (Epstein-Barr virus, influenza A, and Ebola virus), autoimmunity (type 1 diabetes) and cancer.

TheinHan, W., et al. (2013). "Non-rigid calcium phosphate cement containing hydrogel microbeads and absorbable fibres seeded with umbilical cord stem cells for bone engineering." Journal Of Tissue Engineering & Regenerative Medicine **7**(10): 777-787.

The need for bone repair has increased as the population ages. Non-rigid calcium phosphate scaffolds could provide compliance for micro-motions within the tissues and yet have load-supporting strength. The objectives of this study were to: (a) develop a non-rigid calcium phosphate cement (CPC) with microbeads and fibre reinforcement; and (b) investigate human umbilical cord mesenchymal stem cell (hUCMSC) proliferation, osteodifferentiation and mineralization on non-rigid CPC for the first time. Non-rigid CPC was fabricated by adding extra tetracalcium phosphate in the traditional CPC and by incorporating chitosan, absorbable fibres and hydrogel microbeads. The non-rigid CPC-microbead scaffold possessed a strain-at-failure of 10.7%, much higher than the traditional CPC's strain of 0.05% which is typical for brittle bioceramics. Flexural strength of non-rigid CPC-microbead was 4-fold that of rigid CPC-microbead scaffold, while work-of-fracture (toughness) was increased by 20-fold. The strength of non-rigid CPC-microbead-fibre scaffold matched that of cancellous bone. hUCMSCs on non-rigid CPC proliferated from 100 cells/mm(2) at 1 day to 600 cells/mm(2) at 8 days. Alkaline phosphatase, osteocalcin and collagen gene expressions of hUCMSCs were greatly increased, and the cells synthesized bone minerals. hUCMSCs on non-rigid CPC-microbead-fibre constructs had higher bone markers and more mineralization than those on rigid CPC controls. In conclusion, this study developed the first non-rigid, in situ-setting calcium phosphate-microbead-fibre scaffold with a strain-at-failure exceeding 10%. hUCMSCs showed excellent proliferation, osteodifferentiation and mineralization on non-rigid CPC scaffold. The novel non-rigid CPC-hUCMSC construct with good strength, high strain-at-failure and toughness, as well as superior stem cell proliferation, osteodifferentiation and mineralization, is promising for load-bearing bone regeneration applications.

Theodoropoulou, E., et al. (2019). "Different epigenetic clocks reflect distinct pathophysiological features of multiple sclerosis." Epigenomics **11**(12): 1429-1439.

Aim: Accumulating evidence links epigenetic age to diseases and age-related conditions, but little is known about its association with multiple sclerosis (MS). Material(s) and Method(s): We estimated epigenetic age acceleration measures using DNA methylation from blood or sorted cells of MS patients and controls. Result(s): In blood, sex (p = 4.39E-05) and MS (p = 2.99E-03) explained the variation in age acceleration, and isolated blood cell types showed different epigenetic age. Intrinsic epigenetic age acceleration and extrinsic epigenetic age acceleration were only associated with sex (p = 2.52E-03 and p = 1.58E-04, respectively), while PhenoAge Acceleration displayed positive association with MS (p = 3.40E-02). Conclusion(s): Different age acceleration measures are distinctly influenced by phenotypic factors, and they might measure separate pathophysiological aspects of MS. Data deposition: DNA methylation data can be accessed at Gene Expression Omnibus database under accession number GSE35069, GSE43976, GSE106648, GSE130029, GSE130030. Copyright © 2019 Maja Jagodic.

Thiagarajan, V., et al. (2019). "Influence of differently functionalized polystyrene microplastics on the toxic effects of P25 TiO₂ NPs towards marine algae Chlorella sp." Aquatic Toxicology **207**: 208-216.

Increased utilization of titanium dioxide nanoparticles (TiO₂ NPs) for commercial as well as industrial purposes resulted in the accumulation of nanoparticles in the marine system. Microplastics being an emerging secondary pollutant in the marine ecosystem have an impact on the toxic effects of TiO₂ NPs which has not been evaluated up to date. So it is important to assess the toxic effects of both these pollutants on the marine environment. The present study examines the impact of differently functionalized microplastics on the toxic effects of P25 TiO₂ NPs to marine algae Chlorella sp. The tendency of nanoparticles to undergo aggregation in artificial seawater was observed with increase in time. The median effective concentration for TiO₂ NPs was found to be 81 muM which indicates higher toxic effects of NPs toward algae. In contrast, microplastics irrespective of their difference in functionalization had minimal toxic effect of about 15% at their higher concentration tested, 1000 mg L⁻¹. Plain and aminated polystyrene microplastics enhanced the TiO₂ NPs toxicity which was further validated with oxidative stress determination studies like reactive oxygen species and lipid peroxidation assays. Negatively charged carboxylated polystyrene microplastics decreased the TiO₂ NPs toxicity with possible hetero-aggregation between TiO₂ NPs and microplastics in the system. The toxicity data obtained for the mixture was further corroborated with Abbott's mathematical model.

Thiele, C. J., et al. (2019). "Evaluation of existing methods to extract microplastics from bivalve tissue: Adapted KOH digestion protocol improves filtration at single-digit pore size." Marine Pollution Bulletin **142**: 384.

Methods standardisation in microplastics research is needed. Apart from reagent-dependent effects on microplastics, varying target particle sizes can hinder result comparison between studies. Human health concerns warrant recovery of small microplastics. We compared existing techniques using hydrogen peroxide, Proteinase-K, Trypsin and potassium hydroxide to digest bivalve tissue. Filterability, digestion efficacy, recoverability of microplastics and subsequent polymer identification using Raman spectroscopy and a matching software were assessed. Only KOH allowed filtration at ≤25 µm. When adding a neutralisation step prior to filtration, KOH digestates were filterable using 1.2-µm filters. Digestion efficacies were >95.0% for oysters, but lower for clams. KOH destroyed rayon at 60 °C but not at 40 °C. Acrylic fibre identification was affected due to changes in Raman spectra peaks. Despite those effects, we recommend KOH as the most viable extraction method for exposure risk studies, due to microplastics recovery from bivalve tissues of single-digit micrometre size.

Thomas, A. C., et al. (2019). "A self-preserving, partially biodegradable eDNA filter." Methods in Ecology and Evolution **10**(8): 1136-1141.

eDNA studies often rely on water filtration in the field and immediate sample preservation to prevent DNA degradation during sample transport. However, filter membrane transfer steps for preservation can increase risk of sample contamination and the reliance on typical single-use filter housings produces significant plastic waste.We created a new eDNA filter housing (compatible with any suction pump) partially comprised of a biodegradable, hydrophilic material that functions to automatically preserve captured eDNA via desiccation—no filter membrane transfer steps, no chemical or cold storage required.We tested the self-preservation capabilities of the desiccating filter housings by filtering replicate samples in an eDNA mesocosm study and compared with ethanol preservation. Self-preserving filters were placed back into original packaging for storage, and samples for both preservation methods were kept at room temperature until extraction at prescribed time points (11 days, 18 days, 25 days, 32 days, 60 days, 88 days, 172 days) post-filtration. Paired field samples were also collected from six pond locations targeting an additional species to demonstrate field performance.Quantitative PCR results from the mesocosm study indicated that both methods effectively preserved eDNA over a 6-month storage period, with the self-preserving filters yielding slightly more target DNA on average (SQ = 329 copies) than ethanol-preserved samples (SQ = 288 copies) (F1,38 = 4.050, p = 0.051). Neither method showed signs of degradation after 172 days. Results from field sampling indicated a larger difference between preservation methods, with the self-preserving filters containing approximately 2X the eDNA of ethanol-preserved samples on average (paired t test, p = 0.020).These data suggest that self-preserving eDNA filter housings are a viable alternative to standard ethanol preservation methods and may provide higher detection sensitivity in some circumstances. The new filter housings should also help in reducing the risk of sample contamination, minimize protocol steps and result in less plastic waste. Such innovations are important to assure eDNA data quality and to help in facilitating the inclusion of non-expert sample collectors (e.g. citizen scientists) in research programs.

Thomas, J. H., et al. (2004). "Microbead-based electrochemical immunoassay with interdigitated array electrodes." Analytical Biochemistry **328**(2): 113-122.

The objective of this study was to develop a sensitive and miniaturized immunoassay by coupling a microbead-based immunoassay with an interdigitated array (IDA) electrode. An IDA electrode amplifies the signal by recycling an electrochemically redox-reversible molecule. The microfabricated platinum electrodes had 25 pairs of electrodes with 1.6-mum gaps and 2.4-mum widths. An enzyme-labeled sandwich immunoassay on paramagnetic microbeads with mouse IgG as the analyte and beta-galactosidase as the enzyme label was used as the model system. beta-Galactosidase converted p-aminophenyl beta-D- galactopyranoside to p-aminophenol (PAP). This enzyme reaction was measured continuously by positioning the microbeads near the electrode surface with a magnet. Electrochemical recycling occurred with PAP oxidation to p-quinone imine (PQI) at +290mV followed by PQI reduction to PAP at -300mV vs Ag/AgCl. Dual-electrode detection amplified the signal fourfold compared to single-electrode detection, and the recycling efficiency reached 87%. A calibration curve of PAP concentration vs anodic current was linear between 10⁻⁴ and 10⁻⁶M. A signal from 1000 beads in a 20-muL drop was detectable and the immunoassay was complete within 10min with a detection limit of 3.5x10⁻¹⁵mol mouse IgG. © 2004 Elsevier Inc. All rights reserved.

Thomas, M., et al. (2020). "The world is your oyster: low-dose, long-term microplastic exposure of juvenile oysters." Heliyon **6**(1): e03103.

Bivalve filter feeders, such as oysters, filter large volumes of water and are particularly exposed to microplastics (MP). Consequently, these animals digest and assimilate high levels of MP in their bodies that may likely impact their physiology, and potentially affect shellfish stocks, benthic habitats and, indirectly, the health status of the marine ecosystem and human consumers. In this study we exposed juvenile oysters, Crassostrea gigas, to 3 different MP concentrations (10⁴, 10⁵ and 10⁶ particles L⁻¹), represented by 6mum Polystyrene (PS) microbeads, compared to a control treatment receiving no MP. The study ran for a period of 80 days to test for the impacts of MP on growth, Condition Index and Lysosomal Stability. From histological analysis, microbeads were detected in the intestines of exposed oysters and in the digestive tubules, but no cellular inflammatory features were observed over time. Weight and shell length remained comparable between the different treatments and control. We found that Condition Index in the highest concentration increased initially but significantly reduced over time. The oysters in the highest MP exposure also showed the lowest mean Lysosomal Stability score throughout the experiment. Lysosomes play a vital role in the cells defense mechanisms and breakdown of constituents, crucial for the oysters' wellbeing. Most importantly, we detected an increased mortality in those oysters who were chronically exposed to the highest loads of MP.

Thompson, J. A. and H. H. Bau (2011). "Pulsating Bead-Based Assay." Analytical Chemistry **83**(8): 2858.

In recent years, there has been a growing interest in using porous microbeads such as agarose beads as solid supports to bind target molecules from complex fluid samples. Porous beads have large surface area to volume ratios and high receptor concentrations, and they facilitate relatively high sensitivity detection and multiplexing. Unfortunately, to take full advantage of the porous beads' attributes, long incubation times are needed due to the relatively slow mass transfer of target molecules from the exterior solution into the beads' interior. To accelerate the mass transfer process, we propose a novel assay in which functionalized porous beads are periodically compressed and expanded. Preliminary experiments were carried out to compare the performance of the pulsating beads with that of conventional, nonpulsating beads. These experiments indicate that the pulsating beads significantly accelerate binding rates with minimal increase in nonspecific binding. Thus, pulsing has the potential of significantly reducing assay time. [PUBLICATION ABSTRACT]

Thompson, R. C., et al. (2004). "Lost at Sea: Where Is All the Plastic?" Science **304**(5672): 838.

Thompson et al seek to establish that microscopic plastic fragments and fibers are also widespread in the oceans and have accumulated in the pelagic zone and sedimentary habitats. To quantify the abundance of microplastics, they collected sediment from beaches and from estuarine and subtidal sediments around Plymouth, UK. To assess the extent of contamination, a further 17 beaches were examined, and similar fibers were found, demonstrating that microscopic plastics are common in sedimentary forms. Their findings demonstrate that the broad spatial extent and accumulation of this type of contamination. Given the rapid increase in plastic production, the longevity of plastic, and the disposable nature of plastic items, the contamination is likely to increase, aside from the potential for plastics to adsorb, release, and transport chemicals. However, it remains to be shown whether toxic substances can pass from plastics to the food chain.

Thorp, B. H., et al. (1986). "Embedding of skeletal tissue in plastic for vascular and histological study to demonstrate delayed endochondral ossification in Leghorn type fowl." Research in Veterinary Science **40**(2): 236-240.

A method is described which enables visualization of the blood supply in developing avian long bones, followed by the preparation of undecalcified histological sections from the same material. The circulatory system was perfused with a solution of fixative, dye and barium sulphate. The skeletal tissue was cleared in plastic resin before embedding and tissue blocks were cut into 1 mm slabs. The vascular canals were then examined with a dissecting microscope. Slabs were re-embedded in resin and 5 micro m sections cut for routine undecalcified histological staining. Focal areas of delayed endochondral ossification were demonstrated in slabs prepared from the proximal ends of femora of White Leghorns. These lesions are considered to be a less severe form of the dyschondroplastic condition occurring in broilers.

Thushari, G. G. N., et al. (2017). "Effects of microplastics on sessile invertebrates in the eastern coast of Thailand: An approach to coastal zone conservation." Marine Pollution Bulletin **124**(1): 349-355.

This study assessed the microplastic contamination of 3 most abundant sessile and intertidal invertebrates (Rock Oyster: Saccostrea forskalii, Striped Barnacle: Balanus amphitrite, Periwinkle: Littoraria sp.) in 3 beaches of the eastern coasts of Thailand. The results showed a significant accumulation of microplastics in the invertebrates at rates of 0.2-0.6 counts/g indicating higher pollution levels along the coastline. Filter feeding organisms showed comparatively higher accumulation rates of microplastics. Thus, contaminated bivalves pose potential health risks for seafood consumers. The plastic pollutant prevalence in sessile and intertidal communities was corresponded with pollution characteristics of contaminated beach habitats where they live. Thus, bivalves, gastropods and barnacles can be used as indicators for contamination of microplastics in the areas. This study also demonstrated the need for controlling plastic pollution in Thai coastal areas. Copyright © 2017 The Authors

Tian, F., et al. (2015). "B10 cells induced by Schistosoma japonicum soluble egg antigens modulated regulatory T cells and cytokine production of T cells." Parasitology Research **114**(10): 3827-3834.

A distinct subset of B cells, also known as regulatory B cells, can negatively regulate T cell immune responses, but the role of these cells in schistosomiasis has not been clarified. Soluble egg antigen (SEA) and soluble adult worm antigen preparation (SWAP), which are two important antigen sources during Schistosoma japonicum infection, both can induce Th1, Th2, Th17, and Treg cells and the corresponding cytokines. However, whether they can induce the production of regulatory B cells and the regulatory function of schistosome-induced regulatory B cells remains unclear. In our studies, we first analyzed the production of regulatory B cells stimulated by SEA or SWAP using flow cytometry and enzyme-linked immunosorbent assay, and observed these cells in mice immunized by SEA or SWAP. Then, B10 cells sorted by MicroBeads were co-cultured with CD4⁺ T cells, and the proportion of Treg cells were detected. At the same time, the IFN- gamma , IL-4, and IL-17 levels in the culture supernatant were measured. The results showed that B10 cells were preferentially induced by SEA in vitro, and B10 could also be induced in mice immunized by SEA. SEA-induced B10 cells promoted the expansion of regulatory T cells and induced IL-4 secretion, but inhibited IL-17 production. These findings reveal that the generation of B10 cells is determined by parasitic antigen, and suggest the function of B10 cell induced by SEA. This study significantly contributes to the understanding of the immune regulatory role in schistosomiasis and may help protect hosts from infection.

Tian, L., et al. (2009). "Influence of antigen dose and DC number on CD8⁺ T cell differentiation and proliferation of OT-I transgenic mice." Journal of Northwest A & F University Natural

Science Edition **37**(9): 7-12.

Objective: The study was to investigate the influence of peptide SIINFEKL concentration and Dendritic Cell (DC) number on primary CD8⁺ T cell differentiation and proliferation. Method: Bone marrow-derived DCs were generated from bone marrow cells in the presence of GM-CSF and IL-4. OT-I mice CD8⁺ T cells were isolated by anti-mCD8 conjugated magnetic microbeads, and stimulated by SIINFEKL peptides and mature dendritic cells (maDC). Serial diluted peptides SIINFEKL (100, 10, 1, 0.1, 0.01, 0.001 ng/mL) and different amounts of DCs (DC/T ratio of 1/20, 1/5) were co-cultured with CD8⁺ T cells to stimulate the activation of CD8⁺ T cells. Then the cell number, division rate and activated surface marker of co-cultured CD8⁺ T cells were analyzed by flow cytometry, and cell vitality was measured by propidium iodide (PI) stain. Result: Deficient peptides result in insufficient CD8⁺ T cell proliferation, while excess peptides impair live CD8⁺ T cell number. CD8⁺ T cell proliferation was more pronounced when more DCs were used to present peptides ranging from 0.001 ng/mL to 0.1 ng/mL and fewer DCs were used to present peptides ranging from 1 ng/mL to 100 ng/mL. High concentration of peptide antigen or large numbers of DCs lead to the fully activation and division of CD8⁺ T cells but followed a remarkable decrease in CD8⁺ T cell number, which may be caused by activation induced cell death (AICD).

Tian, L., et al. (2019). "A carbon-14 radiotracer-based study on the phototransformation of polystyrene nanoplastics in water <i>versus</i> in air (Electronic supplementary information (ESI) available. See DOI: 10.1039/c9en00662a)." Environmental Science: Nano **6**(9): 2907-2917.

Nanoplastic (<1 μm plastic debris) pollution, derived from degradation of larger plastic debris or direct release from cosmetic or cleaning products, is an emerging concern in the environment. In this study, we quantitatively investigated the degradation and mineralization of polystyrene (PS) nanoplastics under ultraviolet (UV) radiation at 254 nm using 14C radioisotope tracer technology. 14C-polystyrene (PS) nanoplastics were synthesized from 14C-styrene. Moreover, to study the role of water during the photodegradation of PS nanoplastics, 14C-PS nanoplastics were exposed to UV radiation in air or suspended in water. The X-ray photoelectron spectroscopy (XPS) results showed that after 48 h of UV irradiation, C–O groups formed on the surface while no significant change was observed from the Fourier-transform infrared spectroscopy (FTIR) analysis, indicating that short-term photo-oxidation only occurs on the thin surface layer of the PS nanoplastics. The molecular weight (Mw) of the PS nanoplastics increased in air after the irradiation, suggesting cross-linking of the PS chains, while it did not show significant changes in the presence of water. The mineralization of the PS nanoplastics was higher in water (17.1 ± 0.55%) than in air (6.17 ± 0.1%). A significant amount (11.0 ± 0.1%) of by-products with small Mw was detected in water during UV irradiation, much higher than that being washed out from the surface of nanoplastics exposed in air. The higher photoreactivity in water suggests that the mechanisms underlying the phototransformation of the PS nanoplastics in the two matrices could be different. The present study provided the first evidence of photodegradation of PS nanoplastics in aqueous environments.

Tian, L., et al. (2017). "Mineralisation of ¹⁴C-labelled polystyrene plastics by Penicillium variabile after ozonation pre-treatment." New Biotechnology **38**(Part B): 101-105.

Large amounts of polystyrene (PS), one of the most widely used plastics in the world, end up in the environment through industrial discharge and littering, becoming one of the major components of plastic debris. Such plastics, especially the small-sized microplastics and nanoplastics, have received increasing concerns in terms of their potential environmental risks.

Feasible approaches for the degradation of PS in waste materials and in the environment are highly desirable. Physicochemical pretreatments of PS may be applied to enhance biological degradation. In the present study, we synthesized ¹⁴C-labelled PS polymers, either uniformly labelled on the ring ([U-ring-¹⁴C]-PS) or labelled at the beta -carbon position of the alkyl chain ([beta -¹⁴C]-PS), and investigated the mineralisation of the ¹⁴C-PS polymers by the fungus Penicillium variabile CCF3219 as well as the effect of ozonation as a physico-chemical pre-treatment on the mineralisation by the fungi. Biodegradation of the ¹⁴C-PS polymers was studied in liquid medium (pH 7.5, without additional carbon substrate) with P. variabile for 16 weeks. During the incubation time, ¹⁴CO₂ was captured to calculate the mineralisation of ¹⁴C-PS and the remaining polymers were analysed by means of scanning electron microscopy (SEM), Fourier transform infrared (FT-IR) spectrometry and gel-permeation chromatography (GPC). The results showed that the fungi mineralised both labelled polymers, and that the [U-ring-¹⁴C]-PS with a lower molecular weight led to a higher mineralisation rate. Ozonation pre-treatment strongly enhanced mineralisation of [beta -¹⁴C]-PS. SEM analysis showed that the surface of the ozonated [beta -¹⁴C]-PS became uneven and rough after the incubation, indicating an attack on the polymer by P. variabile. FT-IR analysis showed that ozonation generated carbonyl groups on the [beta -¹⁴C]-PS and the amount of the carbonyl groups decreased after incubation of the [beta -¹⁴C]-PS with P. variabile. GPC analysis showed that the molecular weights of the ozonated [beta -¹⁴C]-PS decreased after incubation. The present data suggest that ozonation pretreatment could be a potential approach for degradation of PS waste and remediation of PS-contaminated sites.

Tian, X., et al. (2019). "A Magnetic Dynamic Microbiointerface with Biofeedback Mechanism for Cancer Cell Capture and Release." Acs Applied Materials & Interfaces **11**(44): 41019-41029.

Dynamic biointerfaces with reversible surface bioactivities enable dynamic modulation of cell-material interactions, thus attracting great attention in biomedical science. Herein, we demonstrated a paradigm shift of dynamic biointerfaces from macroscopical substrates to micron-sized particles by reversible engineering of a phenylboronic acid (PBA)-functionalized magnetic microbead with mussel-inspired cancer cell-targeting peptide. Due to reversible catechol-boronate interactions between the peptides and microbeads, the micron-sized dynamic biointerface exhibited sugar-responsive cancer-targeting activity, showing the potential as a microplatform for magnetic and noninvasive isolation of cancer cells through natural biofeedback mechanism (e.g., human glycemic volatility). Our results demonstrated that the dynamic magnetic platform was capable of selective cancer cell capture (~85%) and sugar-triggered release of them (>93%) in cell culture medium with high efficiency. More importantly, by using this platform, a decent number of target cells (~23 on average) could be magnetically isolated and identified from artificial CTC blood samples (1 mL) spiked with 100 cancer cells. In view of the biomimetic nature, high capture efficiency, excellent selectivity, and superiority in cell separation and purification processes, the dynamic magnetic microplatform reported here would be a promising and general tool for rare cell detection and separation and cell-based disease diagnosis.

Tian, X. L., et al. (2012). "Changes of Fcγ receptors on monocytes in children with acute Henoch-Schonlein purpura." Chinese Journal of Microbiology and Immunology (China) **32**(10): 885-889.

Objective: To investigate the changes and roles of Fc gamma receptors (FcγR) expressed on monocytes in the immune pathogenesis of Henoch-Schonlein purpura (HSP). Methods: Thirty children of HSP and 15 health controls were enrolled in this study. The expressions of FcγR I and FcγR III on monocytes were determined by flow cytometry, and real-time PCR was performed to detect the transcription levels of FcγR II a, FcγR II b, cytokines (IL-1β, IL-6, TNF-α, IFN-α), chemokine(IP-10, RANTES, iNOS), and BLyS/April in monocytes isolated by microbeads. The plasma concentrations of IL-4, IL-10 and TNF-a were analyzed by enzyme-linked immunosorbent assay (ELISA). Results: (1) The expressions of FcγR I and FcγR III on monocytes in patients with HSP were significantly up-regulated compared with healthy controls. Transcription level of FcγR II a on monocytes in patients with acute HSP was found to be higher than that in healthy controls while the inhibitory FcγR II b mRNA was significant down-regulated (P<0.05), which resulted in a higher ratio of FcR II a/II b in patients with acute HSP. (2) The expressions of cytokine/chemokines factor such as IL-1β, IL-6, TNF-α, IP-10, RANTES, and iNOS in patients with HSP was detected to be higher than those in healthy controls(P<0.05). In addition, expression levels of BLyS/April were up-regulated during acute HSP(P<0.05), the positive correlations were observed between the FcγR II a/FcγR II b and the cytokine/chemokines factor in monocytes (P<0.05). (3) Plasma concentrations of IL-4, IL-10 and TNF-α were significantly elevated during acute HSP(P<0.05), and a negative correlation was observed between concentrations of TNF-a and the mRNA level of FcγR II b in monocytes. Conclusion: The abnormal expression of the cytokines and the imbalance of stimulatory and inhibitory FcγR of monocyte in acute HSP. Copyright © 2012 by the Chinese Medical Association.

Tiani, K. A., et al. (2018). "Extending viability of Lactobacillus plantarum and Lactobacillus johnsonii by microencapsulation in alginate microgels." International Journal of Food Sciences & Nutrition **69**(2): 155-164.

AIM: To investigate whether microencapsulation of Lactobacillus in alginate microbeads will lead to increased longevity during refrigerated storage or simulated digestion.

MATERIALS AND METHODS: Microscopy was used to confirm that Lactobacillus plantarum ATCC BAA-793 and Lactobacillus johnsonii ATCC 33200 were immobilised within the microbeads and laser scattering analysis was used to determine the mean diameter of the microbeads. The number of viable cells were enumerated throughout refrigerated storage and simulated digestion experiments.

RESULTS: Microencapsulation was shown to have differing effects on viability depending on the species, but led to extended viability during refrigerated storage and simulated digestion in L. johnsonii and L. plantarum respectively.

CONCLUSION: Fermented functional foods contain microbes beneficial to human health. However, extended shelf storage and the harsh environment of the GI tract significantly reduces the number of viable microbes reaching the consumer. Microencapsulation allows beneficial microbes to reach the gut of the consumer in higher numbers, and thus confer greater health benefits.

Tibbetts, J., et al. (2018). "Abundance, distribution, and drivers of microplastic contamination in urban river environments." Water **10**(11).

Given the persistence of microplastics in the environment and their potential toxicity to ecosystems, understanding of likely microplastic accumulation 'hotspots' in rivers is urgently needed. To contribute to this challenge, this paper reports results of a microplastic survey from a heavily urbanised catchment, the River Tame and four of its tributaries, which flows through the city of Birmingham, UK. All sediment sampled was found to contain microplastics with an average abundance of 165 particles kg⁻¹. While urban areas generally have a greater abundance of microplastics as compared with rural, there is no simple relationship

between microplastic numbers and population density or proximity to wastewater treatment sites. The greatest change in microplastic abundance was due to the presence of a lake along the course of the River Tame - i.e., flow velocities are reduced on entering the lake, which promotes the deposition of fine sediment and potentially microplastics. This suggests that the greatest concentrations of microplastics will not be found in-channel but rather on the floodplain and other low velocity environments such as meander cutoffs. We also identified a new mechanism of microplastic fixation in freshwater environments through ecological engineers, specifically caddisflies, that incorporated microplastics into their casing. These results highlight the need to explore further hydrodynamic and ecological impacts on microplastics fate and transport in rivers.

Tibbetts, J. H. (2015). "Managing Marine Plastic Pollution." Environmental Health Perspectives **123**(4): A90-A93.

The article focuses on plastic waste management to reduce marine pollution. Topics discussed include causes of pollution such as lost fishing nets and containers, marine plastic pollution by coastal countries such as the U.S., the growth of megacities which contribute to marine pollution and extended producer responsibility (EPR) model adopted by European countries to manage their plastic wastes by recycling, reusing and diverting plastics to power plants to be used as fuels. INSET: Fate of Plastics in the Ocean.

Tibbetts, J. H. (2015). "Plastics on the Half Shell." BioScience **65**(8): 836-836.

The article focuses on the studies directing towards the evidence that small plastic fragments enter the human diet through wild and cultured seafood. Topics discussed include views of environmental toxicologist Lisbeth Van Cauwenberghe, on tiny plastic fragments drawn by bivalves and plankton; challenges faced by researchers in the extraction of microscopic plastic bits from fleshy bivalves; and efforts of scientists for the identification of microplastics lodged in marine animals.

Tickell, O. (2016). "BRITAIN COULD BAN PLASTIC MICROBEADS." Resurgence & Ecologist(298): 8-8.

The article reports on the potential ban of plastic microbeads from use in toothpaste, cosmetics and other products to protect fish and ocean wildlife under a new policy in Great Britain. Minister of State George Eustice at the Department of Environment, Food and Rural Affairs states that the manufacture of products with microbeads could be banned in the country. It mentions that the hazard presents by microplastics on human health and environment.

Tiercy, J. M., et al. (2010). "A shared HLA-DRB1 epitope in the DR beta first domain is associated with Vogt-Koyanagi-Harada syndrome in Indian patients." Molecular Vision **16**: 353-358.

PURPOSE: Vogt-Koyanagi-Harada (VKH) disease and sympathetic ophthalmia (SO) are two distinct entities that share common clinical and histopathological features; however, it remains unknown whether they have a common genetic susceptibility. Several studies have shown an association of human leukocyte antigen (HLA)-DR4 with VKH disease in patients of different ethnic backgrounds. We present in this paper the HLA-DRB1 genotyping analysis of a large cohort of VKH patients from southern India and compare these patients to patients with SO and to healthy individuals from the same geographic area.

METHODS: VKH patients were diagnosed according to the revised criteria of the International Committee on VKH disease. Patients with granulomatous uveitis after ocular trauma or multiple eye surgeries were diagnosed as having SO. Genomic DNA was extracted from all patients and controls. Samples were analyzed for HLA-DRB1 alleles by reverse polymerase chain reaction

(PCR) sequence-specific oligonucleotide (SSO) hybridization on microbeads, using the Luminex technology, and by PCR sequence-specific primers (SSP) typing for DRB1*04 allele determination. Strength of associations was estimated by odds ratios (OR) and 95% confidence intervals (CI) and frequencies were compared using the Fisher's exact test.
RESULTS: HLA-DRB1 alleles were determined in 94 VKH patients, 39 SO patients, and 112 healthy controls. HLA-DRB1*04 frequency was higher in VKH patients (20.2% versus 10.3% in controls; OR=2.2, p=0.005, pc=0.067). This association was lower than the association of HLA-DRB1*04 frequency in cohorts of patients from different origins. No significant DR4 association with SO was detected. HLA-DRB1*0405 and HLA-DRB1*0410 alleles were significantly increased in VKH patients (8.5% versus 0.9% in controls; OR=10.3, 95% CI=2.34-45.5, p<0.001). These two alleles share the epitope S57-LLEQRRAA (67-74) in the third hypervariable region of the HLA-DR molecule. None of the DRB1 alleles was significantly associated with SO.
CONCLUSIONS: Based on the association of HLA-DRB1*0405 and HLA-DRB1*0410 alleles with VKH disease, we propose that the epitope S57-LLEQRRAA (67-74) in the third hypervariable region of the HLA-DRbeta1 molecule is the relevant susceptibility epitope. This genetic component seems specific to VKH disease since no correlation could be identified in SO patients. The weaker association with HLA-DR4 in this VKH patient cohort compared to VKH patients from northern India is probably related to the lower frequency of HLA-DRB1*0405 in our study group. The HLA-DRB1 association with susceptibility to VKH syndrome seems weaker in Indian patients compared to Japanese or Hispanic patients, suggesting a different non-HLA immunogenetic background in Indian VKH patients.

Tijhuis, L., et al. (1994). "Solids retention time in spherical biofilms in a biofilm airlift suspension reactor." Biotechnology and Bioengineering **44**(8): 867-879.

Fluorescent microparticles were used as tracer beads to measure the dynamics of solids in spherical biofilms in a biofilm airlift suspension reactor. Attachment to, release from, and penetration into the biofilms of the tracer beads were measured. The coverage of the biofilm surface was low and the steady state particle concentration on the surface was dependent on the biofilm surface characteristics. The measured attachment rate constant was identical in both experiments and appeared to be determined by the hydrodynamic conditions in the turbulent lent reactor. The attachment rate was much faster than the release rate of the tracer beads and, therefore, the solids retention time in the biofilm particle is not due to a simple reversible adsorption-desorption process. The heterogeneity of the distribution of tracer beads on different sectors on the biofilm surface decreased during the attachment period. Due to random detachment processes the heterogeneity of the tracer bead distribution increased during the release period. The tracer beads quickly penetrated into the biofilm and became distributed throughout the active layer of the biofilm. The observed penetration into biofilms, the nonuniform distribution on the biofilm surface, and the fast uptake and slow release of tracer beads cannot be described by a simple model based on a reversible adsorption-desorption mechanism, nor with existing biofilm models. These biofilm models, which balance growth and advection assuming a uniform biofilm with a homogeneous surface, are inadequate for the description of the observed solids retention time in biofilms. Therefore, a new concept of biofilm dynamics is proposed, in which formation of cracks and fissures, which are rapidly filled with growing biomass, combined with nonuniform local detachment, explains the observed fast penetration into the biofilm of tracer beads, the long residence time, and the nonuniform distribution of fluorescent microparticles.

Till, P. (1976). "Solid tissue model for the standardization of the echo-ophthalmograph 7200 MA

(Kretztechnik)." Documenta Ophthalmologica **41**(2): 205-240.
After discussion of the biologic basis of echographic tissue differentiation and of the required standardization of the ultrasonic diagnostic device by means of tissue models (citrated blood), a technical standard is presented. This solid tissue model, which can be used an unlimited number of times, enables the investigator to determine or check the tissue sensitivity of his instrument at any time easily and quickly. The model consists of a synthetic resin (Wacker Silgel 504) to which a certain number of microbeads (glass beads S-100) are added before it hardens. The acoustic properties of this technical standard correspond to those of the biologic standard (citrated blood) including all important factors such as reflectivity, degree of scattering and sound attenuation.

Tillman, J., et al. (2015). "Rowcovers and strip tillage provide an alternative to plasticulture systems in summer squash production." HortScience **50**(12): 1777-1783.
Plastic mulch is often used in cucurbit production, but it has negative soil health and environmental implications due to use of tillage for installation and generation of plastic waste. This 2-year study aimed to find a viable alternative to plastic mulch through the use of strip tillage and rowcovers, as rowcovers could help minimize yield loss from strip tillage by providing warmer air and soil as well as providing insect protection. A split-plot design was used in both conventionally and organically managed summer squash (Cucurbita pepo), with production system as the whole-plot factor [conventional tillage with black plastic mulch also referred to as plasticulture (PL) and strip tillage into rolled cereal rye (Secale cereale) (ST)] and rowcover use as the subplot factor (rowcover until anthesis or no rowcover). Rowcovers reduced the incidence of squash vine borer (Melittia cucurbitae) and eliminated the need for insecticide sprays to control this insect pest, but did not reduce the incidence of yellow vine decline or the sprays needed to control squash bug (Anasa tristis). Rowcovers increased average air temperature by 1.6 to 4.0 degrees C and increased maximum air temperature by up to 10.3 degrees C. Rowcovers decreased average light intensity by 33% to 39%. Though soil temperature in PL tended to be higher than in ST, in 1-year rowcovers helped bridge the gap. Plant biomass was consistently higher in the PL than the ST system. Averaged across rowcover treatments, plants in PL had higher marketable yields than those in ST; however, the use of rowcovers often led to comparable yields between the production system treatments. Rowcover was a significant factor explaining marketable yield for the organically managed fields both years. There was no consistent effect of production system on soil microbial biomass carbon (MBC). Based on our results, strip tillage into rolled rye could be a viable alternative to plasticulture for summer squash production in Iowa, and rowcovers could help increase yields in ST especially in an organic management system.

Tilmatine, A. and L. Dascalescu (2010). "Set-point identification of a free-fall triboelectrostatic separation process for plastic particles." International Journal of Environmental Studies **67**(1): 27-40.
Identification of the optimal operating conditions and evaluation of their sensibility to changes in certain critical factors are critical issues for the industrial application of electrostatic separation techniques. The aim of this paper is to validate an experimental procedure for optimising the selective sorting of non-conductive constituents of granular industrial plastic wastes using a free-fall triboelectrostatic separator. Tione Buranda, T. B. J. H., et al. (2003). "Biomimetic Molecular Assemblies on Glass and Mesoporous Silica Microbeads for Biotechnology." Langmuir **19**(5): 1654-1663.

This paper describes the use of glass and mesoporous silica microspheres (typically 1-50 *mm) as supports for biomimetic lipid bilayer membrane architectures for use in biotechnological applications. We present methods and characterization of lipid bilayer membranes supported on commercially available glass beads and mesoporous silica beads formed by an aerosol process that takes advantage of self-assembly of surfactant template phases in sol-gel synthesis. Methods for controlling the concentration of fluorescent lipids, ligands, receptors, and transmembrane proteins in the bead-supported bilayer assemblies are discussed, along with methods for measuring the concentration of these species using flow cytometry. Diffusion of molecular species both within the lipid bilayer and within the mesoporous bead structure is probed using fluorescence recovery after photobleaching. Flow cytometry and confocal fluorescence microscopy are used to examine dye uptake of the porous beads and the stability of the encapsulating lipid bilayer membranes to proton and fluorophore leakage. The studies presented herein form the basis for the use of several new types of biomimetic bead-supported bilayer architectures in a variety of biotechnological applications including microimmunoassays and fluorescence-based high-throughput screening of biochemical recognition and protein function.

Tirapu-Azpiroz, J., et al. (2017). "Dielectrophoretic microbead sorting using modular electrode design and capillary-driven microfluidics." Biomedical Microdevices **19**(4): 95.

Multiplexing assays using microbeads in microfluidics offers high flexibility and throughput, but requires the ability to sort particles based on their physical properties. In this paper, we present a continuous method for separating microbeads that is compact, modular and adaptive, employing an optimized electrode layout that alternates sorting and concentration of microbeads using dielectrophoresis and a nested design. By simulating the combined effects of the hydrodynamic drag and dielectrophoresis forces on polystyrene beads, the parameters of

the electrode layout and voltage configuration are optimized for maximum separation based on particle size with a small number of slanted planar electrodes. Experimental verification confirms the efficient separation of 10 mum and 5 mum beads, with ~98% of all concentrated beads sorted in two separate streams and only ~2% of 5 mum beads leaking into the 10 mum bead stream. In addition, this method is implemented on capillary-driven microfluidic chips for maximum portability and ease of use.

Tirella, A., et al. (2014). "Sphyga: a multiparameter open source tool for fabricating smart and tunable hydrogel microbeads." Biofabrication **6**(2): 025009.

Hydrogel microbeads are used in many biological applications, particularly for cell, protein or drug encapsulation. Although there are several methods for fabricating microbeads with controlled shapes and dimensions, many are limited to a small range of materials or sizes. We describe a compact open source tool-the spherical hydrogel generator (Sphyga)-for the fabrication of highly reproducible hydrogel based microbeads with predictable shapes and diameters ranging from 100 to 2000 micro m. The unique feature of the system is the ability to modulate multiple parameters independently, so as to create a wide range of working conditions for fabricating tailored microbeads. Hence, by combining the different fabrication parameters, hydrogel beads with chosen shapes, sizes and materials can be generated with Sphyga. A multiparameter working-window was obtained by fixing the concentration of the base material, alginate, and varying the viscosity of the solution along with Sphyga's fabrication parameters (needle size, external air pressure, and material outflow). To validate the multiparameter working window, components such as proteins, cells, dyes and nanoparticles were also used to fabricate composite microbeads. The results show that the architecture of hydrogel microbeads can be engineered by considering the viscosity of the initial solution, which depends principally on the pH and composition of alginate solution. Coupled with Sphyga's multiple working parameters, material viscosity can then be used to tune hydrogel domains and thereby generate complex biologically relevant microenvironments for many biomedical applications.

Tirthankar, B. and R. K. Srivastava (2012). "Plastics waste management and resource recovery in India." International Journal of Environment and Waste Management **10**(1): 90-111.

Exponential growth in plastic production and consumption has evoked concerns for its effective management. Within a decade, India has witnessed a substantial growth of 890% and 340% in plastic production and per capita consumption, respectively. Plastic recycling industries have mushroomed autonomously and accounts for 47% of annual recycling. Further, unscientific collection, transportation, uncontrolled disposal of plastic waste has grave environmental implications. This paper reviews contemporary research done on the integrated management of plastic waste and also considers the potential options available for optimum resource recovery. Other innovative waste management technologies are also considered to find out their adaptability under Indian circumstances.

Tirupati, S., et al. (2016). "Production of Laccase by Cochliobolus sp. Isolated from Plastic Dumped Soils and Their Ability to Degrade Low Molecular Weight PVC." Biochemistry Research International **2016**.

One of the utmost man-made problems faced today has been the ever-increasing plastic waste filling the world. It accounts for an estimated 20-30% (by volume) of municipal solid waste in landfill sites worldwide. Research on plastic biodegradation has been steadily growing over the past four decades. Several fungi have been identified that produce enzymes capable of plastic degradation in various laboratory conditions. This paper presents a study that determined the

ability of fungi to degrade low molecular weight polyvinyl chloride (PVC) by the enzyme laccase. We have isolated a fungal species, Cochliobolus sp., from plastic dumped soils and they were cultured on Czapek Dox Agar slants at 30°C. The effectiveness of this fungal species on the degradation of commercial low molecular weight polyvinyl chloride (PVC) was studied under laboratory conditions. Significant differences were observed from the FTIR, GC-MS, and SEM results in between control and Cochliobolus sp. treated PVC.

Tittlbach, H., et al. (2017). "GMP-production of purified human B lymphocytes for the adoptive transfer in patients after allogeneic hematopoietic stem cell transplantation." Journal of Translational Medicine **15**(1): 228.

BACKGROUND: We have recently shown that memory B cells from murine CMV immune donor animals adoptively transferred into immunodeficient mice were highly effective in protecting from a viral infection indicating a therapeutic potential of virus specific memory B cells. These preclinical data provided evidence that a cell-based strategy supporting the humoral immune response might be effective in a clinical setting of immunodeficiency after allogeneic hematopoietic stem cell transplantation. As adoptive transfer of B cells has not been used before in a clinical setting it was necessary to establish a technology for the generation of good manufacturing practice (GMP)-grade B cell products.

METHODS: Starting from the leukapheresis product of healthy blood donors, B cells were purified by two different separation strategies using GMP-grade microbeads and the CliniMACS system. A one-step protocol was used for positive enrichment of B lymphocytes with anti-CD19 microbeads. In a two-step enrichment protocol, first T lymphocytes were depleted by anti-CD3 microbeads and the remaining fraction was positively selected by anti-CD19 microbeads.

RESULTS: The purity and recovery after enrichment of B lymphocytes from the leukapheresis material in both separations strategies was not statistically different. However, contamination of the B-cell product with T cells was significantly lower after the two-step protocol (0.16%, range 0.01-0.43% after two-step separation and 0.55%, range 0.28-0.85% after one-step separation, p < 0.05). Therefore, a combined CD3 depletion and CD19 enrichment was used for the production of GMP-conform B-cell products from the leukapheresis material of 17 healthy stem cell donors. The absolute B-cell numbers obtained in the final product was 4.70 +/- 3.64 x 10⁸ with a purity of 95.98 +/- 3.31% B lymphocytes and a recovery of 18.9 +/- 10.6%. Importantly, the contamination with CD3⁺ T cells was extremely low in the final B- cell products (0.10 +/- 0.20%). Purified B cells exhibited normal antibody production after in vitro stimulation and showed excellent viability after cryopreservation.

CONCLUSIONS: A GMP-grade B-cell product can be obtained with high purity and very low T-cell contamination using the two-step enrichment protocol based on CliniMACS technology.

Tiwari, M., et al. (2019). "Distribution and characterization of microplastics in beach sand from three different Indian coastal environments." Marine Pollution Bulletin **140**: 262.

The occurrence of microplastic particles were evaluated on beaches along the Indian coast from three different locations Girgaon Mumbai (Arabian sea coast), Tuticorin, and Dhanushkodi (Bay of Bengal coast). Density separation method was adopted for isolation of microplastics from sand. Isolated microplastics were characterized using three different analytical techniques e.g. fluorescence microscopy (after staining with Nile Red), FTIR and SEM-EDS techniques. Microplastic concentrations in beach sands were from 45 ± 12 # MP kg−1 to 220 ± 50 # MP kg−1 of dry sand. The order of abundance of plastic type was polyethylene (43%) > polyethylene terephthalate (17.3%) ≈ polystyrene (17%) > polypropylene (12.3%) > Others (11%) > polyvinylchloride (1.33%), and very similar profile was observed for all monitored locations. SEM

images show microplastics surfaces with characteristic cracks, suggests their polymer aging, mechanical and oxidative weathering, which was found highest for the microplastics collected from Mumbai.

Tlili, S. and C. Mouneyrac (2019). "The wedge clam Donax trunculus as sentinel organism for Mediterranean coastal monitoring in a global change context." Regional Environmental Change **19**(4): 995-1007.

The wedge clam Donax trunculus is commonly used in environmental monitoring studies as sentinel species for the biomonitoring of sandy beaches in Mediterranean areas. Taking in account the combined effects of chemical stressors and global changes in marine organisms, research efforts in ecotoxicology should be up-to-date for a more relevant and integrative monitoring studies. In the same context, it is an actual need to select bioindicators able to reflect both global change effects and conventional/emergent stressors in marine ecosystems. D. trunculus indeed appears as appropriate integrative sentinel specie. Apart from being an easy to collect species, D. trunculus presents many advantages justifying its use in (eco)toxicological studies such as large distribution, bioaccumulation capacity, responses (biomarkers) to contaminants and well studied biology, physiology and ecology. Herein, we propose a review based on a literature survey of (eco)toxicological aspects of D. trunculus with a special focus on the suitability of its use as a sentinel species in laboratory/ field studies and as potential indicator for regional and global changes. We recommend its further use in the environmental impact assessment of emerging contaminants (such as pharmaceuticals, micro and nanoplastics). Recommendations for an integrative environmental monitoring in a global change context are also highlighted. [ABSTRACT FROM AUTHOR]

Todd, W. W. (1996). "PFA-a Component in Building Materials Produced from the German Plastic Packaging Waste Stream." Waste Management **16**(1): 203.

Extensive plastics recycling is practiced in Germany, which has created surpluses of packaging waste. To deal with this surplus, a composite material has been produced for the construction industry, which consists of plastic-waste agglomerate combined with pulverized fuel ash (PFA). The structural properties of the composite material are described, including compressive, flexural, and tensile-splitting strength, punching shear resistance, water absorption and porosity, shrinkage and swelling, and creep stiffness. The material is shown to be viscoelastic and susceptible to time of loading and temperature, similar to that of bituminous mortars. The composite exhibits very low porosity and permeability, and is frost-resistant and moderately resistant to sulfate attack. The material is shown to be suitable for non-structural use, such as paving blocks, fence posts, and crash barriers.

Togashi, M., et al. (2014). "Practical fluorescence detection of acrolein in human plasma via a two-step tethering approach." Chemical Communications **50**(95): 14946-14948.

Acrolein, a cytotoxic alpha,beta-unsaturated aldehyde and disease biomarker, was determined in plasma by means of a novel tethering strategy using Michael addition of the compound to a fluorescent dye, followed by immobilization of the product on microbeads via the aldehyde

moiety. Elevation of blood acrolein was detected in mice treated with an anticancer agent cyclophosphamide, which releases acrolein upon activation. This method should be suitable for high-throughput diagnostic and clinical application.

Tohda, K. and M. Gratzl (2006). "Micro-miniature autonomous optical sensor array for monitoring ions and metabolites 1: design, fabrication, and data analysis." Analytical Sciences **22**(3): 383-388.

A micro-miniature array of sensing capsules for optical monitoring of pH, potassium and glucose is described. Optode technology translates the respective ionic levels into variable colors of ionophore/dye/polymeric liquid micro-beads stuffed into individual capsules. Glucose is monitored indirectly, by coupling through glucose oxidase (GOX) immobilized in cellulose acetate phthalate (CAP) based microscopic beads that are stuffed into another microcapsule together with pH sensitive optical microscopic beads. The electrolyte and glucose sensing capsules are embedded in a transparent cellulose acetate bar 300-500 microm wide and 2-2.5 mm long called the sliver sensor that includes also a white capsule made of micro-beads without dye for optical reference. By adding further capsules custom combinations of analytes can be monitored in biomedical and non-biological contexts. In this work, as an example, design, fabrication and testing of a sliver sensor that could be developed for in vivo use are described.

Tokes-Fuzesi, M., et al. (2018). "Microparticles as potential biomarkers in chronic obstructive pulmonary disease." Clinical Chemistry and Laboratory Medicine **56 (9)**: eA155.

Microparticles (MPs) are small shedding membrane vesicles released into the extracellular microenvironment from circulating blood and endothelial cells during cell activation or apoptosis mainly under inflammatory conditions. The role of endothelial microparticles (EMPs) in pathophysiology of chronic obstructive pulmonary disease (COPD) is relatively well-known. On the contrary, the release and function of MPs from other cellular origin (e.g. platelets, leukocytes, red blood cells) are not clearly evaluated in this patient group. We measured - in addition to the EMPs - MPs derived from other cells in the circulation of stable and exacerbated COPD patients. 19 healthy volunteers and 50 patients with COPD (34 with stable and 16 with exacerbated COPD) were enrolled in the study. Endothelial (CD31+, CD62E+), platelet derived (CD61+, CD41+, CD42a+, PAC1+), red blood cell derived (GlyA+), leukocyte derived (CD45+, CD13+, CD14+) and lymphocyte derived (CD56+) MPs were measured. MPs were separated from the cell free plasma after centrifugation of citrated blood. Flow cytometry was performed on Beckman Coulter FC500 analyzer. MP reference gate was set using 0.3-0.5-1mum microbeads with MP size gates of 0.5-1mum. Statistical analysis was done with SPSS 19 software. All the measured MPs were significantly ($p<0.001$) higher in COPD patients than in the controls. Furthermore, CD62E+, CD41+, CD42a+ and CD14+ MP values were significantly ($p<0.001$) elevated in exacerbated COPD compared to stable COPD. COPD is accompanied by increased numbers of various MPs in the systemic circulation, particularly platelet and monocyte derived MPs seem to be important in the process of exacerbation.

Tokes-Fuzesi, M., et al. (2018). "Role of microparticles derived from monocytes, endothelial cells and platelets in the exacerbation of COPD." International Journal of Copd **13**: 3749-3757.

Background: Microparticles (MPs) are shedding membrane vesicles released from activated blood and endothelial cells under inflammatory conditions. The role of endothelial MPs (EMPs) in pathophysiology of COPD is relatively well known. However, the release and function of MPs of other cellular origins, eg, platelets, red blood cells and leukocytes, are not clearly evaluated in COPD.

Purpose: The aim of this study was to measure EMPs and other cell-derived circulating MPs in stable and

exacerbated COPD patients.
Patients and methods: A total of 50 patients with COPD and 19 healthy volunteers were enrolled in the study. EMPs (CD31+, CD62E+) and platelet-derived (CD61+, CD41+, CD42a+, PAC1+), red blood cell-derived (GlyA+) and leukocyte-derived (CD45+, CD13+, CD14+, CD56+) MPs were measured. Flow cytometry (FC) was performed on Beckman Coulter FC500 analyzer. MP reference gate was set using 0.3-0.5-0.9 micro m microbeads with MP size gates of 0.5-1.0 micro m.
Results: All the measured MPs were significantly (P<0.001) higher in COPD patients than in the controls. Furthermore, CD62E+, CD41+, CD42a+ and CD14+ MP values were significantly (P<0.001) increased in exacerbated COPD compared to stable COPD. These MPs showed significant (P<0.001) inverse correlation with FEV₁/FVC, as well.
Conclusion: In this study, we describe a reliable flow cytometric assay for MP analysis that was successfully applied in COPD. Besides EMPs, COPD is accompanied by an increased concentration of various MPs in the systemic circulation; particularly, platelet- and monocyte-derived MPs seem to be important in exacerbation.

Tolic-Norrelykke, I. M. and N. Wang (2005). "Traction in smooth muscle cells varies with cell spreading." Journal of Biomechanics **38**(7): 1405-1412.

Changes in cell shape regulate cell growth, differentiation, and apoptosis. It has been suggested that the regulation of cell function by the cell shape is a result of the tension in the cytoskeleton and the distortion of the cell. Here we explore the association between cell-generated mechanical forces and the cell morphology. We hypothesized that the cell contractile force is associated with the degree of cell spreading, in particular with the cell length. We measured traction fields of single human airway smooth muscle cells plated on a polyacrylamide gel, in which fluorescent microbeads were embedded to serve as markers of gel deformation. The traction exerted by the cells at the cell-substrate interface was determined from the measured deformation of the gel. The traction was measured before and after treatment with the contractile agonist histamine, or the relaxing agonist isoproterenol. The relative increase in traction induced by histamine was negatively correlated with the baseline traction. On the contrary, the relative decrease in traction due to isoproterenol was independent of the baseline traction, but it was associated with cell shape: traction decreased more in elongated than in round cells. Maximum cell width, mean cell width, and projected area of the cell were the parameters most tightly coupled to both baseline and histamine-induced traction in this study. Wide and well-spread cells exerted larger traction than slim cells. These results suggest that cell contractility is controlled by cell spreading.

Toloken, S. (2004). "Study: emissions underreported." Plastics News **16**(17): 3-22.

The plastic resin manufacturing industry probably emits five times more of some major pollutants than it reports to the federal government, according to a study from two environmental groups. The June 22 study from the Environmental Integrity Project and a Houston-area group said it took data developed by Texas state regulators about gaps in reporting of air emissions and for the first time applied it nationwide to four industries, including plastic resin manufacturing. The problem, according to the study, is that official emissions figures reported by companies to the U.S. Environmental Protection Agency (EPA) are estimates based on EPA formulas, and are not measurements of actual emissions.

Tolvanen, O. K. (2001). "Airborne bio-aerosols and noise in a dry waste treatment plant in Pietarsaari, Finland." Waste Management & Research **19**(2): 108-114.

Ewapower Ltd in Pietarsaari, Finland produces pellets from paper and plastic waste for burning.

During 1998 and 1999, several measurements were made to determine the dust, particle, microbe and endotoxin concentrations, and also the noise level in the hall where the waste is received and pre-crushed. The noise level exceeded the Finnish recommended level of 85 dBA. The dust and the particle concentrations were low, but the microbe concentrations, especially in the summer and in the autumn, were at a level which may be harmful to health. The total concentration of microbes (both dead and alive) was high--approximately 4.8 million particles m(-3). The concentrations of endotoxins was high in summer and in autumn, from 340 to 1000 ng m(-3) and exceeded recommended values. In the winter, the concentration of the endotoxin was lower, ranging between 4.7 and 33 ng m(-3).

Tomer, A., et al. (2005). "Autoimmune thrombocytopenia: Flow cytometric determination of platelet-associated autoantibodies against platelet-specific receptors." Journal of Thrombosis and Haemostasis **3**(1): 74-78.

Immune thrombocytopenic purpura (ITP) is an autoimmune disorder characterized by antibody-induced platelet destruction. Despite its clinical importance, the diagnosis of ITP is one of exclusion, thus, inevitably associated with potential difficulties. We here describe a feasible diagnostic method using the commonly available technique of flow cytometry. An antigen-specific assay for platelet-associated antibody was developed and tested in 62 adult patients with chronic ITP, 14 patients with thrombocytopenia of decreased production and 60 healthy controls. The method is based on flow cytometric (FCM) detection of autoantibodies reacting with specific platelet receptors immobilized on microbeads. The average fluorescence level in the ITP group calculated as a ratio to normal was 4.07 (range 0.8-31.0), in the non-ITP thrombocytopenic patients 0.9 (range 0.7-1.2), and in the healthy controls 1.0 (range 0.7-1.3). The average assay coefficient of variation was 0.218 [95% confidence interval (CI) 0.213, 0.221]. The difference between the ITP patients and both groups was highly significant (P < 0.001), using a stringent non-parametric analysis. A comparison of the FCM assay with the radioactive immunobead assay previously reported on the same cohort of patients showed significant correlation (R² = 0.71, 95% CI 0.39, 0.53). The overall performance of the FCM assay in discriminating between ITP patients and normals was estimated by the receiver operating characteristic (ROC) plot, showing an area under the curve of 0.96 (maximal value 1.0), with standard error of 0.033. We conclude that the present FCM assay is clinically useful for routine diagnosis and follow-up of ITP. © 2005 International Society on Thrombosis and Haemostasis.

Tommasi, F. (2017). "Microplastics in aquatic and marine habitats: an emerging global environmental health issue." Notiziario dell'Istituto Superiore di Sanita **30**(6): 7-10.

Plastic is one of the most versatile materials invented and developed in the twentieth century. But at the same time, its products, which are often disposable, poorly managed and released into the environment, have become an environmental problem, affecting marine habitats even ubiquitously. Plastic products, prior to degradation, in the sea crumble into smaller form or microplastics, creating ubiquitous and increasing pollution. Microplastics affect all levels of the marine trophic chains: they transport and spread pollutants, reducing fishing stocks, and enter the food chain to humans, with risks to the environment and man.

Tommasi, F. and L. Mancini (2019). "THE ISSUE OF MARINE LITTER FROM A PERSPECTIVE OF

SUSTAINABLE DEVELOPMENT FOR MEDITERRANEAN REGION: A REVIEW." Fresenius Environmental Bulletin **29**(6): 4963-4969.

Plastic is one of the most versatile materials invented and developed in the twentieth century. But at the same time, its products, which are often disposable, poorly managed and released into the environment, have become an environmental problem, affecting marine habitats the Medi-terranean ecosystem area. Plastic products, prior to degradation, in the sea crumble into micro-plastics, creating ubiquitous and increasing pollution. Microplastics (their smallest form) affect all levels of the marine trophic chains: transporting and spreading pollutants, reducing fishing stocks, entering the food chain to humans, with risks to the environment and man. We need economical, eco-systemic and industrial sustainable solution facing up to this growing issue. The only way out is in a sustainable and regulated approach on designing, producing, manaiging and recycling plastic products all along the value chain. We describe most recent proposals and policy management of land-based waste production and recycling. [ABSTRACT FROM AUTHOR]

Tong, M., et al. (2020). "Transport behaviors of plastic particles in saturated quartz sand without and with biochar/Fe₃O₄-biochar amendment." Water Research **169**: 115284.

As an environmentally friendly material, biochar has been widely used to remediate soil/water contaminants such as heavy metals and organic pollutants. The addition of biochar or modified biochar to porous media might affect the retention of plastic particles and thus influence their fate in natural environment. In this study, both biochar and magnetic biochar (Fe₃O₄-biochar) were synthesized via a facile precipitation method at room temperature. To determine the significance of biochar and Fe₃O₄-biochar amendment on the transport and deposition behaviors of plastic particles, the breakthrough curves and retained profiles of three different sized plastic particles (0.02mum nano-plastic particles, and 0.2mum and 2mum micro-plastic particles) in quartz sand were compared with those obtained in quartz sand either with biochar or Fe₃O₄-biochar amendment in both 5mM and 25mM NaCl solutions. The results show that for all three different sized plastic particles under both examined solution conditions, the addition of biochar and Fe₃O₄-biochar in quartz sand decreases the transport and increases the retention of plastic particles in porous media. Fe₃O₄-biochar more effectively inhibits the transport of plastic particles than biochar. We found that the addition of biochar/Fe₃O₄-biochar could change the suspension property and increase the adsorption capacity of porous media (due to the increase of porous media surface roughness and negatively decrease the zeta potentials of porous media), contributing to the enhanced deposition of plastic particles. Moreover, we found that negligible amount of biochar and Fe₃O₄-biochar (<1%) were released from the columns following the plastic particle transport when the columns were eluted with very low ionic strength solution at high flow rate (to simulate a sudden rainstorm). Similarly, small amount of plastic particles were detached from the porous media under this extreme condition (16.5% for quartz sand, 14.6% for quartz sand with biochar amendment, and 7.5% for quartz sand with

Fe₃O₄-biochar amendment). We found that over 74% of the Fe₃O₄-biochar can be recovered from the porous media after the retention of plastic particles by using a magnet and 87% plastic particles could be desorbed from Fe₃O₄-biochar by dispersing the Fe₃O₄-biochar into 10mM NaOH solution. In addition, we found that the amendment of unsaturated porous media with biochar/Fe₃O₄-biochar also decreased the transport of plastic particles. When biochar/Fe₃O₄-biochar were added into porous media as one layer of permeable barrier near to column inlet, the decreased transport of plastic particles could be also obtained. The results of this study indicate that magnetic biochar can be potentially applied to immobilize plastic particles in terrestrial ecosystems such as in soil or groundwater.

Tong, M., et al. (2020). "Cotransport and deposition of biochar with different sized-plastic particles in saturated porous media." Science of the Total Environment **713**: 136387.

Plastic particles recently are reported to be ubiquitous in natural environments, while biochar is widely employed as an amendment into natural environments e.g. soil for pollution remediation. It is highly likely their transport behaviors in porous media would be altered due to interaction with each other. In this study, the cotransport and deposition behaviors of biochar and plastic particles (0.02 mum nanoplastics (NPs), 0.2 mum and 2 mum micrometer-plastics (MPs)) in quartz sand were investigated at both low (5 mM) and high ionic strength (25 mM) in NaCl solutions at pH 6. The results demonstrated that smaller sized plastic particles (0.02 mum NPs and 0.2 mum MPs) increased biochar transport under both 5 and 25 mM NaCl solutions, while large plastic particles (2 mum MPs) increased biochar transport in 5 mM NaCl solutions yet decreased biochar transport in 25 mM NaCl solutions. For all sized plastic particles, biochar significantly decreased their transport at both low (5 mM) and high (25 mM) ionic strengths in NaCl solutions. The change of zeta potentials of biochar due to heteroaggregation with plastic particles, and the steric repulsion induced by the suspended plastic particles contributed to the enhanced biochar transport with the copresence of smaller sized plastic particles (0.02 mum NPs and 0.2 mum MPs). While, the cotransport of biochar with 2 mum MPs due to their heteroaggregation contributed to the varied transport behaviors of biochar observed at low and high ionic strength with the copresence of 2 mum MPs. The formation of plastic particles-biochar heteroaggregates drove to the decreased transport of all three different sized plastic particles with the copresence of biochar. Considering the coexistence of biochar and plastic particles in natural environment, they would interact with each other (form heteroaggregates) and thus lead to the change of transport behaviors in porous media.

Tongesayi, S. and T. Tongesayi (2017). Water Quality and Public Health: Role of Wastewater, Elsevier Inc.**:** 553-596.

The quest to sustain modern civilization and food security amid the world's population explosion has resulted in unprecedented levels of water contamination from anthropogenic sources. Natural phenomena such as climate change are also set to worsen the already grave situation. Public health is under threat from emerging and reemerging water-related illnesses. In developed countries, thriving economies and advances in technology had rendered waterborne illnesses "a-thing-of-the-past". The problem was left for developing countries to deal with but not anymore! The increase in the world's population and the resultant increase in demand- and pollution-driven water stress amid faltering global economies have thrust the issue of water quality to global prominence once again. Donald Hopkins, of the Carter Center once described the situation almost perfectly: "Throughout parts of the developing world, some people work hard "just to get dirty water" for drinking, cooking, and for other personal needs.....Although the overall quality of water is far better, developed countries also face challenges in maintaining drinking water quality standards."[1] Streams of raw wastewater in streets and residential areas are now a common sight in both developed and developing countries, and water is inevitably getting contaminated by a slew of environmental pollutants. William K. Reilly, a former E.P.A. administrator under President George H.W. Bush once said of the United States drinking water: "For years, people said that America has the cleanest drinking water in the world That was true 20. years ago. But people don't realize how many new chemicals have emerged and how much more pollution has occurred. If they did, we would see very different attitudes." [2] This chapter discusses the sources and health impacts of water contaminants. The biogeochemistry, speciation, toxicity of selected heavy metal(loid)s, as influenced by wastewater and microplastics, will also be discussed. 2017 Elsevier Inc. All rights reserved.

Toosky, M. N., et al. (2019). "A rapid, point-of-care antibiotic susceptibility test for urinary tract infections." Journal of medical microbiology. **17**.

Introduction. The alarming rise in urinary tract infection (UTI) antimicrobial resistance has resulted from a combination of high prevalence, low specificity and the lack of a rapid, point-of-care (POC) antibiotic susceptibility test (AST), which has led to the overuse/inappropriate use of antibiotics.Aim. This study aimed to evaluate the performance of a rapid POC phenotypic AST device in reporting susceptibility information within 2 h.Methodology. Instrument calibration was performed with model bacteria and fluorescent microbeads to determine the dynamic range and limit of detection for quantifying concentrations of bacteria and demonstrate the ability to rapidly differentiate susceptible and resistant model bacteria. We then evaluated 30 presumptive UTI-positive patient urine samples in a clinical pilot study using a panel of 5 common UTI antibiotics plus a growth control and compared our results to the hospital standard of care AST.Results. Our device was able to robustly detect and quantify bacteria concentrations from 50 to 105 colony-forming units (c.f.u.) ml-1. The high sensitivity of this measurement technique enabled the device to differentiate between susceptible and resistant model bacteria with 100 % specificity over a 2 h growth period. In the clinical pilot study, an overall categorical agreement (CA) of 90.7 % was observed (sensitivity=91.4 %, specificity=88.9 %, n=97) with performance for individual drugs ranging from 85 % CA (ceftazidime) to 100 % (nitrofurantoin).Conclusions. By reducing the typical timeframe for susceptibility testing from 2-3 days to 2 h, our POC phenotypic AST can provide critical information to clinicians prior to the administration of antibiotic therapy.

Toraman, H. E., et al. (2014). "Detailed compositional characterization of plastic waste pyrolysis oil by comprehensive two-dimensional gas-chromatography coupled to multiple detectors." Journal of Chromatography A **1359**: 237-246.

The detailed compositional characterization of plastic waste pyrolysis oil was performed with comprehensive two-dimensional GC (GC. x. GC) coupled to four different detectors: a flame ionization detector (FID), a sulfur chemiluminescence detector (SCD), a nitrogen chemiluminescence detector (NCD) and a time of flight mass spectrometer (TOF-MS). The performances of different column combinations were assessed in normal i.e. apolar/mid-polar and reversed configurations for the GC. x. GC-NCD and GC. x. GC-SCD analyses. The information obtained from the four detectors and the use of internal standards, i.e. 3-chlorothiophene for the FID and the SCD and 2-chloropyridine for the NCD analysis, enabled the identification and quantification of the pyrolysis oil in terms of both group type and carbon number: hydrocarbon groups (n-paraffins, iso-paraffins, olefins and naphthenes, monoaromatics, naphthenoaromatics, diaromatics, naphthenodiaromatics, triaromatics, naphthenotriaromatics and tetra-aromatics), nitrogen (nitriles, pyridines, quinolines, indole, caprolactam, etc.), sulfur (thiols/sulfides, thiophenes/disulfides, benzothiophenes, dibenzothiophenes, etc.) and oxygen containing compounds (ketones, phenols, aldehydes, ethers, etc.). Quantification of trace impurities is illustrated for indole and caprolactam. The analyzed pyrolysis oil included a significant amount of nitrogen containing compounds (6.4. wt%) and to a lesser extent sulfur containing compounds (0.6. wt%). These nitrogen and sulfur containing compounds described approximately 80% of the total peak volume for respectively the NCD and SCD analysis. TOF-MS indicated the presence of the oxygen containing compounds. However only a part of the oxygen containing compounds (2.5. wt%) was identified because of their low concentrations and possible overlap with the complex hydrocarbon matrix as no selective detector or preparative separation for oxygen compounds was used. © 2014 Elsevier B.V.

Toriumi, D. M., et al. (1996). "Vascular anatomy of the nose and the external rhinoplasty approach." Archives of Otolaryngology -- Head & Neck Surgery **122**(1): 24-34.

OBJECTIVE: To characterize the venous, lymphatic, and arterial blood supply of the nose and determine the effect of the external rhinoplasty approach on this vasculature. We hypothesized that dissection in the areolar tissue plane below the musculoaponeurotic layer of the nose will preserve the nasal vasculature and minimize postoperative nasal tip edema.

DESIGN: The study included preoperative and postoperative clinical evaluation, cadaver dissection, and histologic examination. In the clinical section, lymphoscintigraphy was performed before and after rhinoplasty using the endonasal (transnostril) or external (open) approach. Additionally, nasal tip edema was subjectively quantified at specified interval after surgery. In the cadaver dissection section, 15 fresh cadavers were dissected to identify the venous and arterial vasculature. In the histology section, fresh nasal tissue was examined by light microscopy to verify the anatomy of arteries, veins, and lymphatic vessels.

SETTING: Subjects for the clinical section of the study were volunteers undergoing primary rhinoplasty surgery at the University of Illinois College of Medicine at Chicago.

PATIENTS: Lymphoscintigraphy was performed on nine patients who underwent rhinoplasty surgery. Seven of these patients underwent postoperative lymphoscintigraphy.

INTERVENTIONS: The rhinoplasty procedures included three different methods of exposure of the nasal structures. Two patients underwent an endonasal (transnostril) nondelivery approach using a transcartilaginous incision. Five patients underwent the external approach with three receiving dissection in the areolar tissue plane below the musculoaponeurotic layer (preserving major nasal vasculature) and two undergoing dissection above the musculoaponeurotic layer (disrupting nasal vasculature).

MAIN OUTCOME MEASURES: In the clinical section of the study, the outcome measures were tracer flow as seen on lymphoscintigraphy and tip edema scores subjectively quantitated on a scale from 1 (none) to 4 (maximal).

RESULTS: Clinical Section: Lymphoscintigraphy revealed flow of tracer along the lateral aspect of the nose (cephalic to lateral crura) to the preparotid lymph nodes. Postoperative scans revealed preservation of flow of tracer with the endonasal (transnostril) approach and the external approach with submusculoaponeurotic areolar tissue plane dissection. There was loss of normal flow of tracer with the external approach using dissection that disrupted the musculoaponeurotic layer with supratip debulking. The nasal tip edema scores for the transnostril and external approach using areolar plane dissection were significantly lower than the external approach with disruption of the musculoaponeurotic layer. Cadaver Dissection

Section: Other than the lateral nasal veins, the major arteries, veins, and lymphatic vessels ran superficial to the musculoaponeurotic layer of the nose. The lateral and dorsal nasal and the columellar arteries comprise an alar arcade that provides the major blood supply to the flap elevated in the external rhinoplasty approach. Histologic Section: Light microscopy of plastic resin sections verified the lymphoscintigraphic and cadaver dissection findings. The lymphatic vessels were located primarily in the reticular dermis above the muscle layer.

CONCLUSIONS: The major arterial, venous, and lymphatic vasculature courses in or above the musculoaponeurotic layer of the nose. In the external rhinoplasty approach, dissection in the areolar tissue plane below the musculoaponeurotic layer will minimize tip edema and protect against skin necrosis by preserving the major vascular supply to the nasal tip.

Tormoen, G. W., et al. (2011). "Procoagulant activity of intravascular tissue factor is dependent on carrier burden." Journal of Thrombosis and Haemostasis **2)**: 432.

Background: Tissue factor (TF) is essential for the hemostatic initiation of the extrinsic pathway of blood coagulation. We found that cancer and benign tumor cells have different TF-dependent procoa-gulant activities (PCA). Intravascular microparticle-, cancer-, or other cell-associated TF may initiate thrombosis but circulating TF levels are not necessarily concordant with thrombosis. We investigated the role of TF concentration, carrier number, and fluid transport on coagulation. Method(s): We utilized microbeads and human monocytic-like U937 cells as TF carriers. Microbeads of 1, 5, 10 or 20 im in diameter were coated with a solution of 0.03, 0.1, 0.3 or 1 nM TF. U937 cells were stimulated with endotoxin to induce surface expression of TF. Particle effect on clotting was measured in a closed transport system using a coagulometer. Occlusive thrombus formation was measured in an open transport system using a flow chamber under a constant pressure gradient. Result(s): Initiation of coagulation was more dependent on procoagu-lant surface-sequestered TF carrier burden than overall TF load. TF-coated beads and LPS-stimulated U937 cells were procoagulant in both closed and open systems in a concentration-dependent manner over the range 102-106 carriers/mL. PCA of TF-coated beads were dependent upon the TF-coating concentration and bead number, but not microbead diameter or total TF-load. The PCA of U937 cells was dependent on TF-expression and cell number. In an open system, TF carriers significantly decreased the time to form an occlusive thrombus. The blockade of both tissue factor and the contact pathway was required to abrogate occlusion. Conclusion(s): These findings suggest that threshold levels of localized TF may be necessary for significant PCA and initiation of coagulation. Thus, pathological intravascular surface TF may play a role in thrombogenesis in manner that is largely dependent upon the TF carrier burden rather than overall TF concentration.

Tosetto, L., et al. (2016). "Microplastics on beaches: ingestion and behavioural consequences for beachhoppers." Marine Biology **163**(10).

Microplastics are ubiquitous in the marine environment worldwide, and may cause a physical and chemical risk to marine organisms. Their small size makes them bioavailable to a range of organisms with evidence of ingestion at all levels of the marine ecosystem. Despite an increasing body of research into microplastics, few studies have explored how consumption changes complex behaviours such as predator avoidance and social interactions. Pollutant exposure can result in alterations in behaviour that not only leads to sub optimal conditions for individual organisms but may also serve as a warning sign for wider effects on a system. This research assessed the impacts of microplastics on the ecology of coastal biota using beach hoppers (Platorchestia smithi) as model organisms. We exposed beach hoppers to marine-contaminated microplastics to understand effects on survival and behaviour. Beach hoppers readily ingested

microplastics, and there was evidence for accumulation of microplastics within the organisms. Exposure tests showed that microplastic consumption can affect beach hopper survival. Individuals also displayed reduced jump height and an increase in weight, however, there was no significant difference in time taken to relocate shelter post disturbance. Overall, these results show that short-term ingestion of microplastics have an impact on survival and behaviour of P. smithi. A reduction in the capacity for beach hoppers to survive and function may have flow on effects to their local environment and higher trophic levels.

Tosi, P. F., et al. (1991). "Quantitative immunofluorescent assay of full-length, recombinant CD4 in solution and mapping of its epitopes." Journal of Fluorescence **1**(2): 141-146.

A specific, rapid, and sensitive method for the detection of CD4 in solution was developed using pairs of fluorescently stained monoclonal antibodies which do not cross-compete. The assay is quantitated by flow cytometry using Simply Cellular microbeads (SC beads) as the primary support for the first anti-CD4 mAb. This method uses the standard conditions for anti-CD4 monoclonal antibody binding, washing, detection, and quantitation by flow cytometry of the CD4 antigen either bound to the SC beads or expressed on the cell surface. The monoclonal antibody used (Leu 3a PE) is the standard reference used to evaluate the CD4 concentration. This method differs from ELISA techniques, which need an antigen standard curve and thus can be influenced by the quality and source of the antigen. This type of assay is also a procedure which enables determination of the level of oligomerization of the bound antigen. It can be used for any antigen to which monoclonal antibodies recognizing at least two distinct epitopes are available. The use of soluble or full-length CD4 derivatives as potential therapeutic agents against AIDS, would benefit from a precise quantitation of the CD4 molecules which still have their proper tertiary structure.

Tosin, M., et al. (2012). "Laboratory test methods to determine the degradation of plastics in marine environmental conditions." Frontiers in Microbiology **3**: 225.

In this technology report, three test methods were developed to characterize the degradation of plastic in marine environment. The aim was to outline a test methodology to measure the physical and biological degradation in different habitats where plastic waste can deposit when littered in the sea. Previously, research has focused mainly on the conditions encountered by plastic items when floating in the sea water (pelagic domain). However, this is just one of the possible habitats that plastic waste can be exposed to. Waves and tides tend to wash up plastic waste on the shoreline, which is also a relevant habitat to be studied. Therefore, the degradation of plastic items buried under sand kept wet with sea water has been followed by verifying the disintegration (visual disappearing) as a simulation of the tidal zone. Most biodegradable plastics have higher densities than water and also as a consequence of fouling, they tend to sink and lay on the sea floor. Therefore, the fate of plastic items lying on the sediment has been followed by monitoring the oxygen consumption (biodegradation). Also the effect of a prolonged exposure to the sea water, to simulate the pelagic domain, has been tested by measuring the decay of mechanical properties. The test material (Mater-Bi) was shown to degrade (total disintegration achieved in less than 9 months) when buried in wet sand (simulation test of the tidal zone), to lose mechanical properties but still maintain integrity (tensile strength at break = -66% in 2 years) when exposed to sea water in an aquarium (simulation of pelagic domain), and substantially biodegrade (69% in 236 days; biodegradation relative to paper: 88%) when located at the sediment/sea water interface (simulation of benthic domain). This study is not conclusive as the methodological approach must be completed by also determining degradation occurring in the supralittoral zone, on the deep sea floor, and in the anoxic sediment.

Toto, D. CALL TO ACTION.
The article discusses the highlights of the 2011 Institute of Scrap Recycling Industries Convention & Exposition held at the Los Angeles Convention Center in California on April 5-9. With the theme "Action," the event had an exhibition featuring nearly 300 equipment and service suppliers to the recycling industry. Several sessions were conducted that dwelt on various topics including electronics recycling, plastics recovered from end-of-life electronics and automobiles, and trends in paper recycling.

Toto, D. (2011). "DOMESTIC BLISS." Recycling Today **49**(7): 42-46.
The article discusses the strong domestic price and demand for secondary plastics in the U.S. despite falling prices of primary materials, citing a consumer preference for recycled materials as of July 2011. A wide gap between prices of prime and recycled plastics is analyzed. Exports of recycled materials to China however, have declined due to higher Chinese import duties, increasing wages, and government efforts to curb inflation.

Toumi, H., et al. (2019). "Microplastics in freshwater environment: the first evaluation in sediments from seven water streams surrounding the lagoon of Bizerte (Northern Tunisia)." Environmental Science & Pollution Research **26**(14): 14673-14682.
Microplastic (MP) concentrations were determined, for the first time, in surface sediment of seven streams around the lagoon of Bizerte (Northern Tunisia), using a saturated NaCl flotation technique. Microplastics were categorised according to type, colour and size using a stereoscopic microscope.

Tourinho, P. S., et al. (2019). "Partitioning of chemical contaminants to microplastics: Sorption mechanisms, environmental distribution and effects on toxicity and bioaccumulation." Environmental Pollution **252**(Pt B): 1246-1256.
There is an increasing awareness of the threats posed by the worldwide presence of microplastics (MPs) in the environment. Due to their high persistence, MPs will accumulate in the environment and their quantities tend to increase with time. MPs end up in environments where often also chemical contaminants are present. Since the early 2000s, the number of studies on the sorption of chemicals to plastic particles has exponentially increased. The objective of this study was to critically review the literature to identify the most important factors affecting the sorption of chemical contaminants to MPs. These factors include the physicochemical properties of both the MPs and the chemical contaminants as well as environmental characteristics. A limited number of studies on soil together with an increased notion of the importance of this compartment as a final sink for MPs was observed. Therefore, we assessed the distribution of model chemicals (two PCBs and phenanthrene) in the soil compartment in the presence of MPs using a mass balance model. The results showed a high variation among chemicals and microplastic types. Overall, a higher partitioning to MPs of chemical contaminants in soil is expected in comparison to aquatic environments. As sorption to a large extent determines bioavailability, the effects of combined exposure to chemicals and MPs on the toxicity and bioaccumulation in biota are discussed. Finally, some considerations regarding sorption and toxicity studies using MPs are given.

Toussaint, B., et al. (2019). "Review of micro- and nanoplastic contamination in the food chain." Food Additives & Contaminants. Part A, Chemistry, Analysis, Control, Exposure & Risk Assessment **36**(5):

639-673.

Whereas the dramatic environmental impact of plastic waste rightfully receives considerable attention by scientists, policy makers and public in general, the human health impact of micro- and nanoplastics contamination of our food and beverages remains largely unknown. Indeed, most studies aim at understanding the environmental impact rather than the human health impact of a possible exposure to micro- and nanoplastics. In addition, these papers generally lack a methodological, standardised approach. Furthermore, some studies focus on the damage to and contamination level of animal species collected from the wild environment, and others investigate the rate and biology of microplastic uptake of animals fed with microplastics in laboratory. This review aims at understanding human exposure. Since there is, with few exceptions, no evidence available on the presence of micro- and nanoplastics in a normal diet, this study takes an indirect approach and analyses peer-reviewed publications since 2010 that document the presence of micro- and nanoplastics in those animals (more than 200 species) and food products that are part of the human food chain and that may thus contribute directly or indirectly to the uptake of micro- and nanoplastics via the human diet. It also addresses the question of the definitions, the methodologies and the quality criteria applied to obtain the reported results. This review suggests that, beyond a few estimations and comparisons, precise data to assess the exact exposure of humans to micro- and nanoplastics through their diet cannot be produced until standardised methods and definitions are available.

Townsend, K. R., et al. (2019). "Associations between microplastic pollution and land use in urban wetland sediments." Environmental Science & Pollution Research **26**(22): 22551-22561.

Microplastic pollution is concerning because it is widespread in aquatic environments and there is growing evidence of negative biological effects. Here, we present one of the first studies to examine microplastic pollution (plastic particles < 1 mm) in urban wetlands and investigate relationships between contamination and urban land use. Sediment samples were collected from 20 independent urban wetlands, each with different types of urban land use within their catchments. Microplastics were observed at all wetlands, with an average abundance of around 46 items/kg of dry sediment. Plastic fragments were the most common type of microplastic, accounting for 68.5% of all microplastics found. Consistent with other studies, microplastic abundance was positively correlated with increased catchment urbanisation. On closer examination, plastic fragments and beads correlated with catchment urbanisation. Fragment abundance also increased in wetlands with catchments that had a higher proportion of industrial land use and decreased in catchments with higher residential densities. This study demonstrates the susceptibility of urban wetlands to microplastic pollution, further highlighting the ubiquitous nature of microplastic pollution. The prevalence of microplastic fragments indicates that plastic litter degradation is a significant source of microplastics in urban environments, especially in industrial areas.

Tozzi, C., et al. (2004). "Increased sensitivity of autoantibody determination by coupled-particle light-scattering assay by poly(ethylene glycols)-modified beads." Analytica Chimica Acta **510**(2): 153-161.

New kinds of coatings by using polyethylene glycols were studied and were applied to a qualitative homogeneous immunoassay that exploits the agglutination reaction for the detection of autoimmune antibodies in a complex matrix. We used a piece of new technology, the Copalis^{TM}, which uses a special optical-sizing flow particle analysis and a semiconductor laser as a light source. Polystyrene microbeads coated with the antigen were used as markers and were put in contact with the serum sample. Different polyethylene glycols were synthesised and tested, optimising the experimental parameters. Human serum specimens were evaluated and we obtained a higher sensitivity with good discrimination between negative and positive samples. All the experimental steps are easy, rapid and enable us to process many samples in a short period of time. © 2004 Elsevier B.V. All rights reserved.

Tozzoli, R. (2007). "Recent advances in diagnostic technologies and their impact in autoimmune diseases." Autoimmunity Reviews **6**(6): 334-340.

Conventional immunological methods for the detection of serum autoantibodies have been an essential tool for the diagnosis of autoimmune diseases for 40 years: in the last decade autoantibody tests have become accepted criteria for the diagnosis and classification of the main systemic and organ-specific autoimmune diseases. The high degree of purification reached by the autoantigens used in these methods has allowed high diagnostic sensitivity and specificity, especially in the case of some new autoantibodies of particular clinical significance, such as anti-nucleosome, anti-transglutaminase, anti-TSH receptor and anti-citrullinated protein autoantibodies. In the last 5 years the advent of proteomic technology, which allows the simultaneous measurement of a number of autoantibodies (multiplexing), has opened up new horizons in the diagnosis of autoimmune diseases. Multiplexing is particularly interesting for clinical laboratories, for organisational, logistical/managerial, physiopathological and research reasons. The emerging technologies are represented by systems based on planar or non-planar (suspension) arrays: the latter include methods which use addressable microbeads or nanobarcoded particles. Within a few years, the new methods will allow testing of individual autoantibody profiles, which will probably improve understanding of the physiopathology of autoimmunity, allow early diagnosis (due to the predictive value of autoantibodies), and drive the diffusion of antigen-specific therapies in autoimmune diseases. Trang, T., et al. (2014). "Pancreatic enzyme replacement therapy for pancreatic exocrine insufficiency in the 21(st) century." World Journal of Gastroenterology **20**(33): 11467-11485.

Restitution of normal fat absorption in exocrine pancreatic insufficiency remains an elusive goal. Although many patients achieve satisfactory clinical results with enzyme therapy, few experience normalization of fat absorption, and many, if not most, will require individualized therapy. Increasing the quantity of lipase administered rarely eliminates steatorrhea but increases the cost of therapy. Enteric coated enzyme microbead formulations tend to separate from nutrients in the stomach precluding coordinated emptying of enzymes and nutrients. Unprotected enzymes mix well and empty with nutrients but are inactivated at pH 4 or below. We describe approaches for improving the results of enzyme therapy including changing to, or adding, a different product, adding non-enteric coated enzymes, (e.g., giving unprotected enzymes at the start of the meal and acid-protected formulations later), use of antisecretory drugs and/or antacids, and changing the timing of enzyme administration. Because considerable lipid is emptied in the first postprandial hour, it is prudent to start therapy with enteric coated microbead prior to the meal so that some enzymes are available during that first hour. Patients with hyperacidity may benefit from adjuvant antisecretory therapy to reduce the duodenal acid load and possibly also sodium bicarbonate to prevent duodenal acidity. Comparative studies of clinical effectiveness of different formulations as well as the characteristics of dispersion, emptying, and dissolution of enteric-coated microspheres of different diameter and density are needed; many such studies have been completed but not yet made public. We discuss the history of pancreatic enzyme therapy and describe current use of modern preparations, approaches to overcoming unsatisfactory clinical responses, as well as studies needed to be able to provide reliably effective therapy.

Travagliati, M., et al. (2014). "Acoustofluidics and Whole-Blood Manipulation in Surface Acoustic Wave Counterflow Devices." Analytical Chemistry **86**(21): 10633.

On-chip functional blocks for sample preprocessing are necessary elements for the implementation of fully portable micrototal analysis systems (...TAS). We demonstrate and characterize the microparticle and whole-blood manipulation capabilities of surface acoustic wave (SAW) driven counterflow micropumps. The motion of suspended cells in this system is governed by the two dominant acoustic forces associated with the scattered SAW (of wavelength ...): acoustic-radiation force and acoustic-streaming Stokesian drag force. We show that by reducing the microchannel height (h) beyond a threshold value the balance of these forces is shifted toward the acoustic-radiation force and that this yields control of two different regimes of microparticle dynamics. In the regime dominated by the acoustic radiation force (h ...), microparticles are collected in the seminodes of the partial standing sound-wave arising from reflections off microchannel walls. This enables the complete separation of plasma and corpuscular components of whole blood in periodical predetermined positions without any prior sample dilution. Conversely, in the regime dominated by acoustic streaming (h ...), the microbeads follow vortical streamlines in a pattern characterized by three different phases during microchannel filling. This makes it possible to generate a cell-concentration gradient within whole-blood samples, a behavior not previously reported in any acoustic-streaming device. By careful device design, a new class of SAW pumping devices is presented that allows the manipulation and pretreatment of whole-blood samples for portable and integrable biological chips and is compatible with hand-held battery-operated devices. (ProQuest: ... denotes formulae/symbols omitted.)

Tresset, G. and S. Takeuchi (2004). "A microfluidic device for electrofusion of biological vesicles." Biomedical Microdevices **6**(3): 213-218.

This paper reports a microfabricated device with high aspect-ratio electrodes and low power consumption for the electrofusion of liposomes and cells. The applications may range from gene transfection or cell tracking to biophysical studies of membrane proteins. The device consists of 250 microm thick silicon electrodes bonded to a glass substrate and covered by a PDMS-coated glass slide. Liposomes were first aligned by AC voltage at 300 kHz and then fused with short DC pulses. The fusion yield can reach 75% and is globally better for liposome diameters larger than 10 microm. The encapsulation of microbeads inside liposomes has also been demonstrated and opens up the route towards fusion-based delivery of artificial microstructures into cells.

Trevail, A. M., et al. (2015). "Elevated levels of ingested plastic in a high Arctic seabird, the northern fulmar (Fulmarus glacialis)." Polar Biology **38**(7): 975-981.

Plastic pollution is of worldwide concern; however, increases in international commercial activity in the Arctic are occurring without the knowledge of the existing threat posed to the local marine environment by plastic litter. Here, we quantify plastic ingestion by northern fulmars, Fulmarus glacialis, from Svalbard, at the gateway to future shipping routes in the high Arctic. Plastic ingestion by Svalbard fulmars does not follow the established decreasing trend away from human marine impact. Of 40 sampled individuals, 35 fulmars (87.5%) had plastic in their stomachs, averaging at 0.08 g or 15.3 pieces per individual. Plastic ingestion levels on Svalbard exceed the ecological quality objective defined by OSPAR for European seas. This highlights an urgent need for mitigation of plastic pollution in the Arctic as well as international regulation of future commercial activity.

Trevisan, R., et al. (2019). "Nanoplastics Decrease the Toxicity of a Complex PAH Mixture but Impair

Mitochondrial Energy Production in Developing Zebrafish." Environmental Science & Technology **53**(14): 8405.

Plastics are recognized as a worldwide threat to the environment, possibly affecting human health and wildlife. Small forms of plastics such as micro- and nanoplastics can interact with other organic contaminants, potentially acting as chemical carriers and modulating their toxicity. In this study, we investigated the toxicity of polystyrene nanoparticles (Nano-PS) and a real-world environmental PAH mixture (Elizabeth River Sediment Extract, ERSE, comprised of 36 detected PAHs) to zebrafish embryos and larvae. Embryos were exposed to Nano-PS (0.1–10 ppm) or ERSE (0.1–5% v/v, equivalent to ΣPAH 5.07–25.36 ppb) or coexposed to a combination of both. Larvae exposed to Nano-PS did not exhibit developmental defects, while larvae exposed to ERSE (2–5%) showed classic signs of PAH toxicity such as heart malformation and deformities in the jaw, fin, and tail. ERSE (5%) also impaired vascular development in the brain. When coexposed, Nano-PS decreased the developmental deformities and impaired vascular development caused by ERSE. This was strongly correlated to the lower PAH bioaccumulation detected in the coexposed animals (whole larvae, as well as the yolk sac, brain, and heart). Our data suggest that PAHs are sorbing to the surface of the Nano-PS, decreasing the concentration, uptake, and toxicity of free PAHs during the exposure. Such sorption of PAHs increases the agglomeration rate of Nano-PS during the exposure time, potentially decreasing the uptake of Nano-PS and associated PAHs. Despite that, similar induction of EROD activity was detected in animals exposed to ERSE in the presence or not of Nano-PS, suggesting that enough PAHs were accumulated in the organisms to induce cellular defense mechanisms. Nano-PS exposure (single or combined with ERSE) decreased the mitochondrial coupling efficiency and increased NADH production, suggesting an impairment on ATP production accompanied by a compensatory mechanism. Our data indicate that nanoplastics can sorb contaminants and potentially decrease their uptake due to particle agglomeration. Nanoplastics also target and disrupt mitochondrial energy production and act as vectors for the mitochondrial uptake of sorbed contaminants during embryonic and larval stages. Such negative effects of nanoplastics on energy metabolism and efficiency could be detrimental under multiple-stressors exposures and energy-demanding scenarios, which remains to be validated.

Triebskorn, R., et al. (2019). "Relevance of nano- and microplastics for freshwater ecosystems: A critical review." TrAC - Trends in Analytical Chemistry **110**: 375-392.

The current paper critically reviews the state-of-the-science on (1) microplastics (MP) types and particle concentrations in freshwater ecosystems, (2) MP and nanoplastics (NP) uptake and tissue translocation, (3) MP/NP-induced effects in freshwater organisms, and (4) capabilities of MP/NP to modulate the toxicity of environmental chemicals. The reviewed literature as well as new data on MP and NP concentrations in the river Elbe and on particle uptake into human cells indicate an environmental relevance of small particles in the low nano- and micrometer range higher than that of larger MP. © 2018 Elsevier B.V.

Trifkovic, K. T., et al. (2014). "Chitosan microbeads for encapsulation of thyme (Thymus serpyllum L.) polyphenols." Carbohydrate Polymers **111**: 901-907.

In this work chitosan microbeads were prepared by emulsion technique and loaded with thyme polyphenols by diffusion from an external aqueous solution of Thymus serpyllum L. The effects of concentrations of chitosan (1.5-3% (w/v)) and GA (glutaraldehyde) (0.1-0.4% (v/v)), as a crosslinking agent on the main properties of microbeads were assessed. The obtained microgel beads from ~ 220 to ~ 790 mum in diameter were exposed to controlled drying process at air (at 37 degreeC) after which they contracted to irregular shapes (~ 70-230 mum). The loading of

dried microbeads with polyphenols was achieved by swelling in the acidic medium. The swelling rate of microbeads decreased with the increase in GA concentration. Upon this rehydration, thyme polyphenols were effectively encapsulated (active load of 66-114 mg GAE g(beads)(-1)) and the microbeads recovered a spherical shape. Both, the increase in the amount of the crosslinking agent and the presence of polyphenols, contributed to a more pronounced surface roughness of microbeads. The release of encapsulated polyphenols in simulated gastrointestinal fluids was prolonged to 3h.

Trifuoggi, M., et al. (2019). "Microplastic-induced damage in early embryonal development of sea urchin Sphaerechinus granularis." Environmental Research **179**(Pt A): 108815.

Two microplastic sets, polystyrene (PS) and polymethyl methacrylate (PMMA), were tested for adverse effects on early life stages of Sphaerechinus granularis sea urchins. Microparticulate PS (10, 80 and 230mum diameter) and PMMA (10 and 50mum diameter) were tested on developing S. granularis embryos from 10min post-fertilisation (p-f) to the pluteus larval stage (72h p-f), at concentrations ranging from 0.1 to 5mgL⁻¹. Both PS and PMMA exposures resulted in significant concentration-related increase of developmental defects and of microplastic uptake in plutei. Moreover, embryo exposures to PS and PMMA (5 and 50mgL⁻¹) from 10min to 5h p-f resulted in a significant increase of cytogenetic abnormalities, expressed as significantly increased mitotic aberrations, while mitotoxicity (as % embryos lacking active mitoses) was observed in embryos exposed to PS, though not to PMMA. When S. granularis sperm suspensions were exposed for 10min to PS or to PMMA (0.1-5mgL⁻¹), a significant decrease of fertilisation success was observed following sperm exposure to 0.1mgL⁻¹ PS, though not to higher PS concentrations nor to PMMA. Sperm pretreatment, however, resulted in significant offspring damage, as excess developmental defects in plutei, both following sperm exposure to PS and PMMA, thus suggesting transmissible damage from sperm pronuclei to the offspring. The overall results point to relevant developmental, cytogenetic and genotoxic effects of PS and PMMA microplastics to S. granularis early life stages, warranting further investigations of other microplastics and other target biota.

Trinacty, J., et al. (1999). "Passage and retaining of plastic particles in digestive tract of dry cows." Czech Journal of Animal Science **44**(6): 263-268.

Three crossbred (Czech Pied x Black Pied Friesian) rumen-cannulated dry cows were fed a diet consisting of 6 kg alfalfa hay and 2 kg mixture (32% barley meal, 32% maize meal, 32% wheat meal, 2% mineral supplement and 2% sodium chloride). Plastic cylindrical particles with a specific gravity of 1.25+or-0.05 g/cmsuperscript 3 were applied manually through cannulae into the bottom of the ventral sac, anterior blind sac and reticulum of the rumen. 50 pieces of 8 mm and 50 pieces of 12 mm particles were inserted. Each day, the particles were removed from the stomach, counted, and put back. After 8 days the particles were removed completely. Regurgitated particles and particles in faeces were also counted. The anterior blind sac and reticulum performed a similar role in the passage of the particles through the reticulo-rumen. The particles passed through both parts in one day, and were retained mainly in the bottom of the ventral sac. Regurgitation of 8 mm particles varied from 0 to 2.0%, regurgitation of 12 mm particles was between 8.0 and 11.7%. The particles (10.7 to 21.3%) were retained behind the reticulo-omasal orifice for 9 to 32 days.

Trinacty, J., et al. (2000). "Passage and interactions of large plastic particles applied into lactating cows." Czech Journal of Animal Science **45**(8): 349-354.

Two trials were performed on 2 lactating cows. In the first trial the diet consisted of 5.4 kg maize silage, 3.7 kg lucerne hay and 5.3 kg concentrates (in DM), and the mean milk yield was 17.09 kg. Plastic particles of 6, 8, 10 and 12 mm were used, 50 particles of each size. In the second trial with similar diet the mean milk yield was 22.12 kg, and only particles of 6 and 10 mm (768 and 172 pieces, respectively) were applied separately or together. The specific gravity of particles, which were applied orally, was 1.25+or-0.05 g/cmsuperscript 3. The aim was to determine the recovery and retention time of individual particles, and in the second trial the interaction of 6 and 10 mm particles was also evaluated. Mean cumulative faecal recovery of 6, 8, 10 and 12 mm particles in the first trial was: 98.7, 98.7, 96.0 and 82.7%, and total mean retention time was 39.7, 41.4, 44.5 and 58.4 h, respectively. In the second trial the highest interaction between 6 and 10 mm particles was found when 28 h had elapsed after application, when the cumulative faecal recovery was 60.3 and 54.8%, respectively.

Tripathi, G. and S. Singh (2010). "Formulation and In Vitro evaluation of pH sensitive oil entrapped polymeric blended gellan gum buoyant beads of clarithromycin." Daru: Journal of Faculty of Pharmacy, Tehran University of Medical Sciences **18**(4): 247-253.

BACKGROUND AND THE PURPOSE OF THE STUDY: A gastroretentive pH sensitive system has been a frontier approach to release the drug in controlled manner in stomach and duodenum. The aim of this study was to develop buoyant beads of gellan based, wherein, the oil was entrapped, blended with hydroxypropyl methyl cellulose or carbopol 934 in order to evaluate its potential for targeted sustained delivery of clarithromycin in the gastric region.

METHODS: Buoyant beads of gellan was developed by inotropic gelation technique using calcium carbonate as gas forming agent and the drug polymer dispersion was emulsified with mineral oil. The oil was entrapped and blended with hydroxypropyl methyl cellulose or carbopol 934. The developed beads were evaluated in terms of diameter,% floating, encapsulation efficiency, In vitro drug release, In vivo gastric residence efficacy and clarithromycine concentration in the mucosa of the experimental animal model.

RESULTS: The scanning electron microscope photograph indicated that the prepared beads were spherical in shape and buoyancy, encapsulation efficiency and drug content obtained from all batches were satisfactory. Particle size and percentage buoyancy of the gel beads increased by raising the concentration of calcium carbonate. The formulation exhibited sustained release profile and was best fitted in the Peppas model with $n<0.45$. Subsequent coating of microbeads exhibited zero-order sustained pattern of the drug release up to 8 hrs. Batch B(4) showed comparatively better residence and the drug concentration in the gastric mucosa of the treated animals.

CONCLUSION: The result provides evidence that the prepared optimized formulation may be used effectively for pH sensitive gastric targeted antibiotic such as clarithromycin.

Tripathi, G. K., et al. (2012). "Formulation and In-vitro Evaluation of pH-Sensitive Oil Entrapped Polymeric Blend Amoxicillin Beads for the Eradication of Helicobacter pylori." Iranian Journal of Pharmaceutical Research **11**(2): 447-455.

Oral pH sensitive drug delivery systems are of utmost importance as these systems deliver the drug at specific part of the gastrointestine (GI) as per the pH of GI, resulting in improved patient therapeutic efficacy and compliance. The pH range of fluids in various segments of the GI tract may provide environmental stimuli for drug release. The aim of this study was to design buoyant beads containing amoxicillin (Am) and to evaluate its potential for the eradication of Helicobacter pylori (H. pylori). The gel bead of gellan, wherein the oil was entrapped, was blended with hydroxypropyl methyl cellulose or Carbopol 934. Buoyant beads of gellan were prepared through ionotropic gellation technique to achieve the controlled and pH-sensitive drug release in stomach. The effects of processing variables such as particle size, buoyancy, percent encapsulation efficiency and in-vitro antimicrobial activity were evaluated. The scanning electron micrograph indicated that prepared beads were spherical in shape and all the beads showed satisfactory floating efficiency in the phthalate buffer solution. The diameter of the gel beads was increased through raising the gellan gum and calcium carbonate concentration. The formulation exhibited sustained release profile and was best fitted in the Peppas model with $n < 0.45$. Subsequent coating of microbeads exhibited zero-order sustained pattern of the drug release up to 8 h. In-vitro growth inhibition study showed complete eradication of the isolated H. pylori strain .These results provide evidence that the optimized formulation bearing antibiotics like amoxicillin should be useful in H. pylori treatment.

Trivedi, A., et al. (2018). "CD14 positive selection displays an edge in the isolation of macrophages from induced sputum of COPD patients using immunobead technology." Indian Journal of Physiology and Pharmacology **62**(1): 32-40.

Objectives: Macrophages plays an important role in the pathophysiology of COPD. Sputum induction is a safe and non-invasive method for evaluation of airway inflammation in COPD. The present study aims to evaluate the yield of macrophage isolation from induced sputum of COPD patients by using commercially available immunomagnetic bead based approaches. Method(s): Sputum induction was done in COPD patients (n=13). Cell pellets obtained after the processing of sputum samples (n=11) were subjected to different isolation kits. Macrophages were isolated from cell pellet using positive and negative selection strategies. CD66abce microbead kit, PAN monocyte isolation kit and CD14 microbeads were used in three different combinations for obtaining pure and enriched macrophages from sputum. Result(s): The results obtained from all sets of experiments were compared and per cent purity and enrichment of macrophages was calculated. CD14 positive selection kit when used for isolation yielded maximum enrichment (> 20-folds) and yielded greater purity as compared to negative selection strategies. Conclusion(s): CD14 microbeads based positive selection appeared to be the method of choice for isolating macrophages from induced sputum of COPD patients for various downstream experimental processes. TrOeger, C., et al. (2008). "Ageing of acrylate-based resins for stereolithography: thermal and humidity ageing behaviour studies." Rapid Prototyping Journal **14**(5): 305-317.

Purpose - The purpose of this paper is to describe the ageing behaviour of acrylate-based resins for stereolithography (SL) technology using different test methods and to investigate these effects on polymers. Design-methodology-approach - Controlling the polymer degradation requires an understanding of many different phenomena, including the different chemical mechanisms underlying structural changes in polymer macromolecules, the influences of polymer morphology, the complexities of oxidation chemistry and the complex reaction pathways of polymer additives. Several ageing characterization experiments are given. Findings - The paper covers the ageing process analysis of acrylate-based polymers. An overview of the ageing behaviour is given, along with the bandwidth of material characteristics for a prolonged lifetime of this material class. Research limitations-implications - For research and development in the field of rapid prototyping (RP) materials data about ageing behaviour and environmental effects are crucial. The authors show possible methods for measuring these effects and discuss the consequences in material research using a recently developed biocompatible SL resin as an example. Practical implications - The study of the ageing behaviour of polymers is important for

understanding their usability, storage, lifetime and recycling. The presented polymeric formulations are able to meet the growing demand for both soft and stiff manufacturing resin materials in the engineering and medical fields. Originality-value - The analysis of the ageing behaviour of polymer materials is an important issue for engineering applications, recycling of post-consumer plastic waste, as well as the use of polymers as biological implants and matrices for drug delivery and the lifetime of an article. The paper gives an overview of details involving ageing behaviour and their meaning for applications of acrylate-based SL resins and is therefore of high importance to people with interest in long-term behaviour and ageing of RP materials.

Trojanowska, A., et al. (2015). "Plasmonic-polymer hybrid hollow microbeads for surface-enhanced Raman scattering (SERS) ultradetection." Journal of Colloid & Interface Science **460**: 128-134.

Hybrid composites are known to add functionality to plasmonic nanomaterials. Although these substrates can be produced by common synthetic methods, the percentage of metal loaded into the functional material is usually small. Herein, we exploit a phase inversion precipitation method to incorporate large amounts of silver nanoparticles inside the polymeric matrix of polysulfone microbeads. The composite material combines the high SERS activity resulting from the plasmonic coupling of highly interacting nanoparticles and the ability to accumulate analytes of the polysulfone porous support. This allows for the quantitative SERS detection down to the nanomolar level, with a liner response that extends over an impressive concentration range of five orders of magnitude.

Troost, T. A., et al. (2018). "Do microplastics affect marine ecosystem productivity?" Marine Pollution Bulletin **135**: 17.

Marine and coastal ecosystems are among the largest contributors to the Earth's productivity. Experimental studies have shown negative impacts of microplastics on individual algae or zooplankton organisms. Consequently, primary and secondary productivity may be negatively affected as well. In this study we attempted to estimate the impacts on productivity at ecosystem level based on reported laboratory findings with a modelling approach, using our biogeochemical model for the North Sea (Delft3D-GEM). Although the model predicted that microplastics do not affect the total primary or secondary production of the North Sea as a whole, the spatial patterns of secondary production were altered, showing local changes of ±10%. However, relevant field data on microplastics are scarce, and strong assumptions were required to include the plastic concentrations and their impacts under field conditions into the model. These assumptions reveal the main knowledge gaps that have to be resolved to improve the first estimate above.

Trotter, B., et al. (2019). "Plastic waste interferes with chemical communication in aquatic ecosystems." Scientific Reports **9**(1): 5889.

Environmental pollution with plastic waste has gained increasing attention, as the contamination of aquatic habitats poses a challenge to these ecosystems. Plastic waste has direct negative effects on animals such as reduced growth rate, fecundity or life span. However, the indirect effects of plastic waste, which has the ability to sorb chemicals from the surrounding media, on chemical communication have yet to be investigated. Chemical communication is crucial for aquatic organisms, e.g., to avoid predation. The planktonic water flea Daphnia (Crustacea), an important link between trophic levels, relies on info-chemicals (kairomones) to assess its current predation risk and to form inducible defences. We show that plastic waste, composed of high-density polyethylene (HDPE) and polyethylene terephthalate (PET) interferes with the formation of inducible defences in Daphnia longicephala when exposed

to a combination of kairomones of Notonecta glauca and plastic waste. D. longicephala shows a reduction in all defensive traits, including body length, crest width and time until primiparity, compared to exposure to solely kairomone conditioned media. Plastic waste in the absence of kairomones had no effect on defensive traits. Since it is vital to adjust these defences to the current predation risk, any misperception can have far-reaching ecological consequences. Therefore, plastic waste can have indirect effects on organisms, which may manifest at the community level.

Trucillo, E., et al. (2019). "Growth factor sustained delivery from poly-lactic-co-glycolic acid microcarriers and its mass transfer modeling by finite element in a dynamic and static three-dimensional environment bioengineered with stem cells." Biotechnology & Bioengineering **116**(7): 1777-1794.

Poly-lactic-co-glycolic acid (PLGA) microcarriers (0.8 +/- 0.2 mum) have been fabricated with a load of 20 mug/g_{PLGA} by an emulsion-based-proprietary technology to sustained deliver human bone morphogenetic protein 2 (hBMP2), a growth factor largely used for osteogenic induction. hBMP2 release profile, measured in vitro, showed a moderate "burst" release of 20% of the load in first 3 days, followed by a sustained release of 3% of the load along the following 21 days. PLGA microbeads loaded with fluorescent marker (8 mg/g_{PLGA}) and hydroxyapatite (30 mg/g_{PLGA}) were also fabricated and successfully dispersed within three-dimensional (3D) alginate scaffold (Ca-alginate 2% wt/wt) in a range between 50 and 200 mg/cm³ ; the presence of microcarriers within the scaffold induced a variation of its stiffness between 0.03 and 0.06 MPa; whereas the scaffold surface area was monitored always in the range of 190-200 m² /g. Uniform microcarriers dispersion was obtained up to 200 mg/cm³ ; higher loading values in the 3D scaffold produced large aggregates. The release data and the surface area were, then, used to simulate by finite element modeling the hBMP2 mass transfer within the 3D hydrogel bioengineered with stem cells, in dynamic and static cultivations. The simulation was developed with COMSOL Multiphysics giving a good representation of hBMP2 mass balances along microbeads (bulk eroded) and on cell surface (cell binding). hBMP2 degradation rate was also taken into account in the simulations. hBMP2 concentration of 20 ng/cm³ was set as a target because it has been described as the minimum effective value for stem cells stimulation versus the osteogenic phenotype. The sensitivity analysis suggested the best microbeads/cells ratio in the 3D microenvironment, along 21 days of cultivations in both static and dynamic cultivation (perfusion) conditions. The simulated formulation was so assembled experimentally using human mesenchymal stem cells and an improved scaffold stiffness up to 0.09 MPa (n = 3; p <= 0.01) was monitored after 21 days of cultivation; moreover a uniform extracellular matrix deposition within the 3D system was detected by Von Kossa staining, especially in dynamic conditions. The results indicated that the described tool can be useful for the design of 3D bioengineered microarchitecture by quantitative understanding.

Trufanova, N. A., et al. (2010). "Cryopreservation of human mesenchymal stromal cells in suspension and encapsulated in alginate microbeads by vitrification in multicomponent solutions." Cryobiology **61 (3)**: 407-408.

Mesenchymal stromal cells (MSCs) are a promising cell type for fabrication of tissue engineered constructs due to the high proliferation activity of MSCs, relative easiness of isolation, expansion and ability to differentiation into multiple cell types. Alginate encapsulation is a novel process for manipulation and cryopreservation of MSCs in regenerative medicine. The aim of this study is to investigate the response of single cell suspension and alginate encapsulated human mesenchymal stromal cells to vitrification in multicomponent solution.Human fetal mesodermal tissues and adult dermis derived MSCs were isolated according to Ethical guidelines and expanded in vitro. Two vitrification solutions called DEPS-1 (10% ME<inf>2</inf>SO, 20% EG, 20% 1.2-PD, 0.5 M sucrose) and DEPS-2 (10% ME<inf>2</inf>SO, 15% EG, 15% 1.2-PD, 1 M sucrose) were stepwise added to standard cryovials with MSCs either in suspension or encapsulated in alginate microbeads at room temperature. Samples were frozen by immersion in liquid nitrogen, thawed in a water bath at 40 degreeC and cryoprotectants were washed out in 0.5 M sucrose solution. The glass forming tendency and the stability of the amorphous state were studied by differential scanning calorimetry (DSC). The viability of single cell suspension was assessed by Trypan Blue staining and by cell adhesion test, whereas alginate encapsulated cells by double fluorescein diacetate (FDA) and ethidium bromide (EB) staining. The metabolic activity of MSCs was estimated by the Alamar Blue reduction and MTT-test when cultured for 24 h. Both vitrification solutions during cooling transformed into amorphous state, but DEPS-1 demonstrated higher glass forming tendency than DEPS-2. After vitrification in DEPS-1 viability decreased for 20%, adhesion and metabolic activity - for 40-45% compare to control. After vitrification in DEPS-2 viability and metabolic activity were lower, therefore DEPS-1 was chosen for the further experiments. It was shown that after vitrification in DEPS-1 MSCs demonstrated ability to differentiation into osteogenic and adipogenic lineages. Vitrification of MSCs encapsulated in alginate microbeads by protocol suitable for single cell suspension led to cell

death. Variation of exposure time of MSCs with vitrification solution on each step allowed to significantly improve viability and metabolic activity. The results obtained demonstrate the possibility of using vitrification protocol in standard cryovials for the cryopreservation of MSCs in cell suspension and encapsulated in alginate microbeads for application in cell biology, regenerative medicine and tissue engineering.

Truini, J. (1999). "Bottle bill worries recyclers." Waste News **5**(32): 3.
Reports on recyclers' concern over the impact of California's expanded bottle bill on the quality of scrap plastic in the market. Inclusion of all plastic beverage containers in the state's revised bottle bill; Association of Post-Consumer Plastic Recyclers' concern about contamination; Requirement for businesses to help pay for California's program through processing fees.

Truini, J. (2009). "Plastics recyclers seek voice within ISRI." Waste & Recycling News **14**(28): 14-11NULL.
The article focuses on the hopes pinned by post-consumer plastic packaging recyclers in the U.S., after the move by the Institute of Scrap Recycling Industries to form a plastic recycling council. Though organizations like the Association of Postconsumer Plastic Recyclers already exists, post-consumer plastic recyclers have reportedly complained of the lack of a platform to voice their concerns. Industry members are quoted, who seem much upbeat about the prospects.

Truslow, D. (2017). "MICROBEADS AND THE TOXICS USE REDUCTION ACT: PREVENTING POLLUTION AT ITS SOURCE." Boston College Environmental Affairs Law Review **44**(1): 149-178.
Microbead pollution presents a significant threat to human health and the environment. As a result, Congress enacted a national ban on microbeads in 2015. This ban is a drastic, reactionary measure that fails to address the continued threat posed by already existing pollution. In addition, the ban represents a continued preference for the command-and-control regulatory framework that failed to prevent microbead pollution in the first place. In contrast, pollution prevention, an alternative regulatory technique adopted by Congress as national policy in 1990, more efficiently prevents pollution by focusing on reducing pollution at its source. In 1989, Massachusetts became the first state to successfully implement a comprehensive pollution prevention statute and, as a result, achieved significant pollution reduction throughout the state. If it had applied to microbeads, the pollution prevention model, could have eliminated the need for a national ban and addressed the continued threat posed by already existing pollution. Tsai, C. J., et al. (2009). "The pollution characteristics of odor, volatile organochlorinated compounds and polycyclic aromatic hydrocarbons emitted from plastic waste recycling plants." Chemosphere **74**(8): 1104-1110.
Plastic waste treatment trends toward recycling in many countries; however, the melting process in the facilities which adopt material recycling method for treating plastic waste may emit toxicants and cause sensory annoyance. The objectives of this study were to analyze the pollution characteristics of the emissions from the plastic waste recycling plants, particularly in

harmful volatile organochlorinated compounds, polycyclic aromatic hydrocarbons (PAHs), odor levels and critical odorants. Ten large recycling plants were selected for analysis of odor concentration (OC), volatile organic compounds (VOCs) and PAHs inside and outside the plants using olfactometry, gas chromatography-mass spectrometry and high performance liquid chromatography-fluorescence detector, respectively. The olfactometric results showed that the melting processes used for treating polyethylene/polypropylene (PE/PP) and polyvinyl chloride (PVC) plastic waste significantly produced malodor, and the odor levels at downwind boundaries were 100-229 OC, which all exceeded Taiwan's EPA standard of 50 OC. Toluene, ethylbenzene, 4-methyl-2-pentanone, methyl methacrylate and acrolein accounted for most odors compared to numerous VOCs. Sixteen organochlorinated compounds were measured in the ambient air emitted from the PVC plastic waste recycling plant and total concentrations were 245-553 microg m(-3); most were vinyl chloride, chloroform and trichloroethylene. Concentrations of PAHs inside the PE/PP plant were 8.97-252.16 ng m(-3), in which the maximum level were 20-fold higher than the levels detected from boundaries. Most of these recycling plants simply used filter to treat the melting fumes, and this could not efficiently eliminate the gaseous compounds and malodor. Improved exhaust air pollution control were strongly recommended in these industries.

Tsai, H., et al. (2015). "Detection of rabbit IgG by using functional magnetic particles and an enzyme-conjugated antibody with a homemade magnetic microplate." Chemistry Central Journal **9**: 8.

BACKGROUND: The enzyme-linked immunosorbent assay (ELISA) has been used for diagnosing medical and plant pathologies. In addition, it is used for quality-control evaluations in various industries. The ELISA is the simplest method for obtaining excellent results; however, it is time consuming because the immunoreagents interact only on the contact surfaces. Antibody-labeled magnetic particles can be dispersed in a solution to yield a pseudohomogeneous reaction with antigens which improved the efficiency of immunoreaction, and can be easily separated from the unreactive substances by applying a magnetic force. We used a homemade magnetic microplate, functional magnetic particles (MPs) and enzyme-labeled secondary antibody to perform the sandwich ELISA successfully.

RESULTS: Using antibody-labeled MPs enabled reducing the analysis time to one-third of that required in using a conventional ELISA. The secondary antibody conjugated with horseradish peroxidase (HRP) was affinity-bound to the analyte (IgG in this study). The calibration curve was established according to the measured absorbance of the 3, 3', 5, 5'-tetramethybezidine-HRP reaction products versus the concentrations of standard IgG. The linear range of IgG detection was 114 ng/mL-3.5 ng/mL. The limit of detection (LOD) of IgG was 3.4 ng/mL. The recovery and coefficient of variation were 100% (+/-7%) and 116% (+/-4%) for the spiked concentrations of 56.8 ng/mL and 14.2 ng/mL, respectively.

CONCLUSION: Pseudohomogeneous reactions can be performed using functional MPs and a magnetic microplate. Using antibody-labeled MPs, the analysis time can be reduced to one-third of that required in using a conventional ELISA. The substrate-enzyme reaction products can be easily transferred to another microplate, and their absorbance can be measured without interference by light scattering caused by magnetic microbeads. This method demonstrates great potential for detecting other biomarkers and in biochemical applications. Graphical AbstractA magnetic ELISA with convenient magnetic microplate.

Tsang, Y. Y., et al. (2017). "Microplastic pollution in the marine waters and sediments of Hong Kong." Marine Pollution Bulletin **115**(1-2): 20-28.

The presence of plastic waste with a diameter of less than 5 mm ("microplastics") in marine

environments has prompted increasing concern in recent years, both locally and globally. We conducted seasonal surveys of microplastic pollution in the surface waters and sediments from Deep Bay, Tolo Harbor, Tsing Yi, and Victoria Harbor in Hong Kong between June 2015 and March 2016. The average concentrations of microplastics in local coastal waters and sediments respectively ranged from 51 to 27,909 particles per 100 m³and 49 to 279 particles per kilogram. Microplastics of different shapes (mainly fragments, lines, fibers, and pellets) were identified as polypropylene, low-density polyethylene, high-density polyethylene, a blend of polypropylene and ethylene propylene, and styrene acrylonitrile by means of Attenuated Total Reflectance - Fourier Transform Infrared Spectroscopy. This is the first comprehensive study to assess the spatial and temporal variations of microplastic pollution in Hong Kong coastal regions. Copyright © 2016 Elsevier Ltd

Tsiamis, D. A., et al. (2018). "Role of plastics in decoupling municipal solid waste and economic growth in the U.S." Waste Management **77**: 147-155.

Analysis of data from the US Environmental Protection Agency (EPA) on municipal solid waste (MSW) generation rates correlated to personal consumption expenditure (PCE) uncovers a decoupling event occurring between 1997 and 2000. A comparison of waste generation rates for each material category found in MSW reveals that plastics increased by nearly 84 times from 1960 to 2013 while total MSW increased only 2.9 times. The increase in plastic waste generation coincides with a decrease in glass and metal found in the MSW stream. In addition, calculating the material substitution rates for glass, metal and other materials with plastics in packaging and containers demonstrates an overall reduction by weight and by volume in MSW generation of approximately 58% over the same time period. A quantitative calculation of a scenario where plastics were not used in packaging and containers to replace glass, metal, and other materials demonstrates that MSW generation rate rises equally with PCE. Therefore, this study has determined that the increase of plastic use is a contributing factor to the decoupling of MSW generation from PCE.

Tsirigotis-Maniecka, M., et al. (2017). "Microencapsulation of hesperidin in polyelectrolyte complex microbeads: physico-chemical evaluation and release behavior." Journal of Food Engineering **214**: 104-116.

The aim of the study was to develop and characterize alginate microparticles coated with polyelectrolytes and containing hesperidin - a natural bioflavonoid of great nutritional potential. Hesperidin's solubility is moderate, thus it was essential to develop a stable carrier which enables its targeted delivery to the intestine. The cargo was entrapped in the alginate (ALG) hydrogel matrix by means of the extrusion/external gelation technique. To achieve customized functional properties of microbeads, biopolymers (chitosan, gelatin) and synthetic polymers (PAH/PSS pair) were deposited on the ALG cores. The fabricated microparticles successfully encapsulated hesperidin (>87%) and were compared in terms of moisture content, surface morphology and particle size (SEM). FTIR spectroscopy confirmed the formation of polyelectrolyte complexes and the microsystems were further characterized with DSC. The swelling and release behaviors were studied in detail, including in vitro release experiments. The results obtained indicate that the fabricated microcapsules revealed the desired pH-dependent release ability.

Tsuchida, D., et al. (2011). "Hydrogen sulfide production by sulfate-reducing bacteria utilizing additives eluted from plastic resins." Waste Management & Research **29**(6): 594-601.

In the present study it was demonstrated that organic additives eluted from plastic resins could be utilized as substrates by sulfate-reducing bacteria. Two laboratory-scale experiments, a microcosm experiment and a leaching experiment, were conducted using polyvinyl chloride (PVC) as a model plastic resin. In the former experiment, the conversion of sulfate to sulfide was evident in microcosms that received plasticized PVC as the sole carbon source, but not in those that received PVC homopolymer. Additionally, dissolved organic carbon accumulated only in microcosms that received plasticized PVC, indicating that the dissolved organic carbon originated from additives. In the leaching experiment, phenol and bisphenol A were found in the leached solutions. These results suggest that the disposal of waste plastics in inert waste landfills may result in the production of H(2)S.

Tsuchiya, M., et al. (2019). "Eye-recognizable and repeatable biochemical flexible sensors using low angle-dependent photonic colloidal crystal hydrogel microbeads." Scientific Reports **9**(1): 17059.

This paper presents eye-recognizable and repeatable biochemical flexible sensors using low angle-dependent stimuli-responsive photonic colloidal crystal hydrogel (PCCG) microbeads. Thanks to the stimuli-responsive PCCG microbeads exhibiting structural color, users can obtain sensing information without depending on the viewing angle and the mechanical deformation of the flexible sensor. Temperature-responsive PCCG microbeads and ethanol-responsive PCCG microbeads were fabricated from a pre-gel solution of N-isopropylacrylamide (NIPAM) and N-methylolacrylamide (NMAM) by using a centrifuge-based droplet shooting device (CDSD). As a proof-of-concept of thin and flexible biochemical sensors, temperature- and ethanol-sensing devices were demonstrated. By comparing the structural color of the stimuli-responsive PCCG microbeads and the color chart of the device, sensing information, including skin temperature of the human body and ethanol concentration in alcoholic beverages, was obtained successively. We expect that our device design using low angle-dependent stimuli-responsive PCCG microbeads would contribute to the development of user-friendly biochemical sensor devices for monitoring environmental and healthcare targets.

Tsuchiya, M., et al. (2019). "Sediment sampling with a core sampler equipped with aluminum tubes and an onboard processing protocol to avoid plastic contamination." MethodsX **6**: 2662-2668.

Microplastics are abundant even on the deep-sea floor far from land and the ocean surface where human activities take place. To obtain samples of microplastics from the deep-sea floor, a research vessel and suitable sampling equipment, such as a multiple corer, a box corer, or a push corer manipulated by a remotely operated (ROV) or human occupied vehicle (HOV) are needed. Most such corers use sampling tubes made of plastic, such as polycarbonate, acrylic, or polyvinyl chloride. These plastic tubes are easily scratched by sediment particles, in particular during collection of coarse sandy sediments, and, consequently, the samples may become contaminated with plastic from the tube. Here, we report on the use of aluminum tubes with both a multiple corer and a push corer to prevent such plastic contamination. When compared with plastic tubes, aluminum tubes have the disadvantages of heavier weight and non-transparency. We suggest ways to overcome these problems, and we also present an onboard processing protocol to prevent plastic contamination during sediment core sampling when plastic tubes are used. *Use of a sediment corer with aluminum tubes reduces the risk of plastic contamination in the sediment samples*The proposed method allows undisturbed sediment cores to be retrieved with comparable efficiency to conventional transparent core tubes.

Tsuzuki, Y., et al. (2006). "Differential modulation in the functions of intestinal dendritic cells by long- and medium-chain fatty acids." Journal of Gastroenterology **41**(3): 209-216.

Background: Although dendritic cells (DCs) play significant roles in intestinal immune responses, little is known regarding the direct effects of luminal foods on DC functions in the intestinal mucosa. In this study, we examined the effects of fatty acids (FAs) with various chain length on the phagocytic function, antigen presentation, and chemotaxis of intestinal DCs.

Tue, K. A. and M. M. Thwe (2013). "RECYCLE OF PLASTIC WASTE AND AGRICULTURAL WASTE." Energy Research Journal **4**(1): 24.

Manufacturing of polymer composites using plastic waste is one of the solutions to solve the environmental pollution problems caused by non-biodegradable polymer. In this study, Rice husk fiber Reinforced Polyethylene composites (RhRP) have been fabricated with rice husk fiber and plastic waste (recycle low density polyethylene) by compression molding method. Effect of fiber volume fraction, pressure and temperature on the properties of the composite samples was studied. In addition, mechanical properties, thermal properties and durability of RhRP composites were measured. Moreover, chemical modification of rice husk fiber was done through acid and aqueous alkaline solution. The modified fiber samples exhibit the higher strength as well as the lower water absorption rate compared with the unmodified fiber composite samples. Therefore, the resistance to aging of the composites in aqueous environment improved significantly for the modified composite samples. Furthermore, Scanning Electron Microscope (SEM) was also used to characterize the surface feature and the interfacial adhesion between fiber and matrix polymer. The modified composite samples reveal better interfacial adhesion than the unmodified composite ones. Thermo Gravimetric Analysis (TG/DTA) was employed to determine thermal stability of the composite samples. The modified fiber samples have higher thermal stability than the unmodified composite ones.

Tumino, M., et al. (2016). "ALFA/Beta T AND CD19+ lymphocite depleted hematopoietic stem cell transplantation from haploidentical donors in pediatric patients: A single center experience." Bone Marrow Transplantation **1)**: S352.

Introduction: Transplantation of haploidentical hematopoietic stem cells (haploHSCT) has become an accepted option for pediatric patients with malignant and non malignant diseases (MD, NMD) who lack a matched related or unrelated donor. In order to prevent severe GvHD, many techniques of cells manipulation have been used. In this setting, immune recovery delay and high rate of rejection represent major concerns. Material (or patients) and methods: We retrospective analyzed a cohort of 24 pediatric patients with MD and NMD, who received alphabeta T- and B-cell depleted allografts from haploidentical family donors (haploHSCT alphabeta T- and B-cell depleted). Myeloablative conditioning regimen and serotherapy with ATG were used for the most. Graft manipulation was carried out with anti-TCRalphabeta and anti-CD19 Abs and immunomagnetic microbeads. Gamma/delta T cells, NK, and other cells remained in the grafts. This procedure was compared with standard transplant procedures for each groups: matched sibling donor stem cell transplantation (MSD-SCT: 27 patients) and matched unrelated donor SCT (MUD-SCT: 58 patients). Result(s): In haploHSCT alphabeta T- and B-cell depleted SCT patients, primary engraftment was achieved in all patients, acute GvHD (aGvHD) grade III-IV and chronic GvHD (cGvHD) occurred in 25% and 12% respectively (MSD-SCT primary engraftment, aGvHD III-IV and cGvHD, respectively 100%, 15% and 5%. MUD-SCT primary engraftment, aGvHD III-IV, and cGvHD respectively 100%, 48% and 16%). No differences occurred between three groups in terms of OS, TRM and PFS as both as MD and NMD (MD P-value: OS 0.52, TRM 0.96, PFS 0.29. NMD P-value: OS 0.28, TRM 0.29, PFS 0.13). In the setting of MD, relapses represent the major cause of death, especially in the state of non complete remmission before transplant. Conclusion(s): Compared with standard transplant procedures

(MUD and MFD) we may consider haploHSCT alphabeta T- and B-cell depleted a valid alternative in pediatric MD and NMD. In MD newer cellular approaches are mandatory to controll relapses after transplantation. In this context, prompt availability of the donor such as in the haploidentical procedures represents an advantage.

Tuncan, M., et al. (2003). "The use of waste materials in asphalt concrete mixtures." Waste Management & Research **21**(2): 83-92.

The purpose of this study was to investigate (a) the effects of rubber and plastic concentrations and rubber particle sizes on properties of asphalt cement, (b) on properties of asphalt concrete specimens and (c) the effects of fly ash, marble powder, rubber powder and petroleum contaminated soil as filler materials instead of stone powder in the asphalt concrete specimens. One type of limestone aggregate and one penetration-graded asphalt cement (75-100) were used. Three concentrations of rubber and plastic (i.e. 5%, 10% and 20% of the total weight of asphalt cement), three rubber particle sizes (i.e. No. 4 [4.75mm] - 20 [0.85 mm], No. 20 [0.85mm] - 200 [0.075mm] and No. 4 [4.75mm] - 200 [0.075mm]) and one plastic particle size (i.e. No. 4 [4.75mm] - 10 [2.00mm]) were also used. It was found that while the addition of plastic significantly increased the strength of specimens, the addition of rubber decreased it. No. 4 [4.75mm] - 200 [0.075mm] rubber particles showed the best results with respect to the indirect tensile test. The Marshall stability and indirect tensile strength properties of plastic modified specimens increased. Marble powder and fly ash could be used as filler materials instead of stone powder in the asphalt concrete pavement specimens.

Tuncel, A., et al. (1993). "Cibacron Blue F3G-A-attached monosize poly(vinyl alcohol)-coated polystyrene microspheres for specific albumin adsorption." Journal of Chromatography **634**(2): 161-168.

Monosize polystyrene (PS) microbeads (4 mum in diameter) were produced by phase inversion polymerization of styrene in ethanol-methoxyethanol medium. They were coated with poly(vinyl alcohol) (PVAL) by adsorption and chemical cross-linking to decrease the non-specific protein adsorption. Cibacron Blue F3G-A was then attached for specific protein adsorption. The adsorption conditions were optimized to increase the amount of PVAL by changing the initial concentration of PVAL, and using different types of salts at different ionic strengths. Higher amounts of PVAL (up to 19 mg PVAL/g PS) were loaded by increasing the PVAL initial concentration and by using Na<inf>2</inf>SO<inf>4</inf> at a higher ionic strength (0.2). Bovine serum albumin (BSA) adsorption and desorption on these PS-based microbeads were also investigated under different conditions. PVAL coating prevented the non-specific BSA adsorption. A higher amount of BSA (up to 60 mg BSA/g dye-attached PS/PVAL) was specifically adsorbed on dye-attached PS microbeads, especially around pH 5 and lower ionic strengths (0.01). About 90% of the adsorbed BSA was desorbed in 1 h by using 0.5 M NaSCN.

Tung, S., et al. (2010). "Third party umbilical cord blood regulatory T cells prevents graft versus host disease in a xenogenic murine model." Blood. Conference: 52nd Annual Meeting of the American Society of Hematology, ASH **116**(21).

Background: Umbilical Cord Blood (UUCB) Regulatory T cells (Tregs) co-expressing CD4/CD25 have been shown to inhibit alloreactive T cell function. We hypothesized that prophylactic infusion of 3rd party UCB Tregs can abrogate Graft versus Host Disease (GvHD). Method(s): (a) Treg generation: Naturally occurring CD25+ Tregs, purified from thawed UCB units by magnetic activated cell sorting (MACS) using Miltenyi CD25 reagents (as per manufacturer's instructions), were cultured at 1x106 cells/ml in ExVivo medium (Gibco) containing interleukin (IL)-2 (100 IU/ml) with irradiated K562 cells engineered to express CD86, CD69, CD187c, IL-15, CD64 and

OKT3 (provided by Dr. Laurence Cooper, MDACC) or with microbeads bearing CD3 and CD28 antibodies on their surface (T-Cell Expander, Invitrogen). Cultures were initiated at a ratio of 1 Treg: 4 engineered K562 cells or Invitogen beads and maintained at 1x106 cells/ml over a 14 day period by the addition of fresh medium. Fresh IL-2 was added to maintain 100 IU/ml on an every-other-day basis. Flow cytometry, Western blot analysis and demonstration of ability to reduce in vitro MLR reactions confirmed the Treg phenotype of the expanded cells. (b) Xenogeneic graft vs. host model: On day -1, NOD-SCID IL2Rgnull (NSG) mice were sublethally-irradiated (320 cGy) and received 107 Treg cells intravenously. On day 0, 107 human apheresis PBMCs were injected intravenously. Mice were regularly monitored, weighed and graded according to a GvHD scale developed by Dr. James Ferrara (University of Michigan Comprehensive Cancer Center). Result(s): (a) Ex vivo Treg expansion of up to 700 fold was achieved yielding approximately 2.5x108 Treg cells from an average frozen UCB unit. Analysis of the ex vivo expanded product after 14 days revealed: (i) 95% co-expressed FOXP3/CD4/CD25 (flow cytometry), and (ii) expression of peptidase inhibitor 16, known to be uniquely associated with FOXP3 expression (western blot, Figure 1). Further, addition of UCB Tregs showed suppression of two-way allo-MLR by 93% (measured by tritiated thymidine and CFSE studies). (b) In the NSG GvHD model, mice receiving PBMC showed: (i) a significant (P=0.0002, student's paired t-test) 30% reduction in body weight, (ii) gross evidence of GvHD (average Ferrara score of 6) and (iii) reduced survival, when compared to mice receiving intravenous injection of Tregs on day -1. By comparison, mice receiving Tregs on day -1: (i) did not lose weight, (ii) scored consistently lower on the Ferrara scale (average score of 3) and (iii) had significantly improved survival (70% survival vs. 15%; P < 10-4, figure 2). Xenogenic transplanted mice showed clear histopathological evidence of GvHD in skin, gut, liver, spleen, lung, esophagus, and bone marrow whereas histopathology remained comparable to controls in the Treg rescued mice. (Figure presented) Conclusion(s): Infusion of 3rd party UCB Tregs markedly reduced the severity of xenoGVHD in a mouse transplant model. These preclinical data support the initiation of a phase I/II clinical trial to assess the efficacy of third party allogenic UCB Tregs in a traditional transplant setting.

Tuppo, L., et al. (2013). "Peamaclein--a new peach allergenic protein: similarities, differences and misleading features compared to Pru p 3." Clinical & Experimental Allergy **43**(1): 128-140.

BACKGROUND: Among the peach-derived allergens which are already known, the lipid transfer protein (Pru p 3) seems to be the one to exert severe allergic reactions.

OBJECTIVE: To identify and characterize a new peach allergen causing a clinical picture similar to that of Pru p 3.

METHODS: Patients were selected on the basis of their severe clinical reactivity and negative results to a panel of peach allergens available on the ISAC103 microarray. Several in-house and commercial preparations were compared. Several methods were used to characterize the newly identified molecule. Specific IgE and inhibition assays were performed using the Allergen micro-Beads Array (ABA) assay.

RESULTS: Negative ISAC results to Pru p 3 were confirmed by additional testing in contrast with the positive results obtained by commercial Pru p 3-enriched peach peel extracts. The analyses of one of these preparations led to the identification of Peamaclein, a new allergenic protein. It is a small, basic, cysteine-rich, heat-stable, digestion-resistant protein, homologous to a potato antimicrobial peptide. Peamaclein was able to trigger positive skin test reactions and to bind IgE in the ABA assay. It displays an electrophoretic mobility and chromatographic behaviour similar to that of Pru p 3; therefore, it can be hidden in Pru p 3 preparations. In fact, Pru p 3-enriched peach peel extracts were found to contain both Pru p 3 and Peamaclein by means of comparative in vivo testing, and by biochemical and immunochemical assays. Commercially available anti-Pru p 3 polyclonal antibodies were found to have a double specificity for the two molecules.

CONCLUSIONS AND CLINICAL RELEVANCE: A new allergen from peach belonging to a new family of allergenic proteins has been identified and characterized. This knowledge on Peamaclein will improve our understanding on the clinical aspects of the peach allergy and the quality of diagnostic reagents.

Turco, G., et al. (2011). "Mechanical spectroscopy and relaxometry on alginate hydrogels: a comparative analysis for structural characterization and network mesh size determination." Biomacromolecules **12**(4): 1272-1282.

The structure of calcium-saturated alginate hydrogels has been studied by combining rheological determinations and relaxometry measurements. The mechanical spectroscopy analyses performed on alginate gel cylinders at different polysaccharide concentration allowed estimating their main structural features such as the average mesh size. The calculation was based on the introduction of a front factor in the classical rubber elasticity approach which was correlated to the average length of the Guluronic acid blocks along the polysaccharide chain. Transverse relaxation time (T(2)) determinations performed on the cylinders revealed the presence of two relaxation rates of the water entrapped within the hydrogel network. The cross-correlation of the latter data with the rheological measurements allowed estimating the mesh size distribution of the hydrogel network. The results obtained for the hydrogel cylinders were found to be consistent with the relaxometric analysis performed on the alginate microbeads where, however, only one type of water bound into the network structure was detected. A good correlation was found in the average mesh size determined by means of relaxometric measurements on alginate microbeads and by a statistical analysis performed on TEM micrographs. Finally, the addition of a solution containing calcium ions allowed investigating further the different water relaxation modes within alginate hydrogels.

Turner, A. (2017). "In situ elemental characterisation of marine microplastics by portable XRF." Marine Pollution Bulletin **124**(1): 286-291.

The performance of a portable x-ray fluorescence spectrometer configured in a test stand and coupled to a laptop has been evaluated for the determination of various elements (including Br, Cd, Cl, Cr, Cu, Fe, Pb and Zn) in beached microplastics. Under laboratory conditions, analysis of samples that covered the 3-mm x-ray beam returned concentrations that, on average, were within 20% of concentrations determined by ICP following acid digestion. Analysis of progressively smaller offcuts (to < 1 mm) resulted in corresponding concentrations that were comparable to those determined in original samples but errors and detection limits that progressively increased. When the configuration was deployed in situ with two operators, up to 35 microplastics counted for 60 s each could be processed per hour. Advantages of immediate measurements include the development of an iterative study strategy, rapid compliance-evaluation, and identification of specific materials for further characterisation or study in the laboratory. Turner, A. (2017). "Trace elements in fragments of fishing net and other filamentous plastic litter from two beaches in SW England." Environmental Pollution **224**: 722-728.

Filamentous plastic litter collected from two beaches in south west England has been characterized by FTIR and XRF. The majority of samples were constructed of polyethylene and consisted of twisted or braided strands of a variety of colours that appeared to be derived from commercial fishing nets. A number of different elements were detected among the samples but, from an environmental perspective, the regular occurrence of Cr and Pb and the occasional or isolated occurrence of Br, Cd and Se were of greatest concern. The highest total concentrations of Br (2420 μg g-1), Cd (1460 μg g-1), Cr (909 μg g-1), Pb (3770 μg g-1) and Se (240 μg g-1) were always encountered among orange samples and are attributed to the presence of lead chromates and cadmium sulphoselenide as colourants and to brominated compounds as flame retardants. Element bioaccessibility was evaluated by ICP-MS following an acidic extraction test that mimics the digestive tract of seabirds, with maximum values after a seven-day incubation period and relative to respective total concentrations of 0.2-0.4% for Cd, Cr and Pb and about 7% for Br. In addition to the well-documented impacts on wildlife through entrapment, filamentous plastic waste may act as a significant source of hazardous chemicals into the marine foodchain through ingestion. [ABSTRACT FROM AUTHOR]

Turner, A. (2018). "Black plastics: Linear and circular economies, hazardous additives and marine pollution." <u>Environment International</u> **117**: 308-318.

Black products constitute about 15% of the domestic plastic waste stream, of which the majority is single-use packaging and trays for food. This material is not, however, readily recycled owing to the low sensitivity of black pigments to near infrared radiation used in conventional plastic sorting facilities. Accordingly, there is mounting evidence that the demand for black plastics in consumer products is partly met by sourcing material from the plastic housings of end-of-life waste electronic and electrical equipment (WEEE). Inefficiently sorted WEEE plastic has the potential to introduce restricted and hazardous substances into the recyclate, including brominated flame retardants (BFRs), Sb, a flame retardant synergist, and the heavy metals, Cd, Cr, Hg and Pb. The current paper examines the life cycles of single-use black food packaging and black plastic WEEE in the context of current international regulations and directives and best practices for sorting, disposal and recycling. The discussion is supported by published and unpublished measurements of restricted substances (including Br as a proxy for BFRs) in food packaging, EEE plastic goods and non-EEE plastic products. Specifically, measurements confirm the linear economy of plastic food packaging and demonstrate a complex quasi-circular economy for WEEE plastic that results in significant and widespread contamination of black consumer goods ranging from thermos cups and cutlery to tool handles and grips, and from toys and games to spectacle frames and jewellery. The environmental impacts and human exposure routes arising from WEEE plastic recycling and contamination of consumer goods are described, including those associated with marine pollution. Regarding the latter, a compilation of elemental data on black plastic litter collected from beaches of southwest England reveals a similar chemical signature to that of contaminated consumer goods and blended plastic WEEE recyclate, exemplifying the pervasiveness of the problem.

Turner, A. (2018). "Mobilisation kinetics of hazardous elements in marine plastics subject to an avian physiologically-based extraction test." <u>Environmental Pollution</u> **236**: 1020-1026.

Samples of plastic collected from two beaches in southwest England (n = 185) have been analysed by XRF spectrometry for elements that are hazardous or restricted in synthetic polymers (namely, As, Ba, Br, Cd, Cr, Hg, Pb, Sb and Se). Overall, one or more restricted element was detected in 151 samples, with 15 cases exhibiting non-compliance with respect to the Restriction of Hazardous Substances (RoHS) Directive. Twelve plastics that were RoHS-non-compliant were subsequently processed into microplastic-sized fragments and subjected to an avian physiologically-based extraction test (PBET) that simulates the chemical conditions in the gizzard-proventriculus of the northern fulmar. Kinetic profiles of metal and metalloid mobilisation in the PBET were fitted using a pseudo-first-order diffusion model with rate constants ranging from ~0.02 to 0.5 h^{-1}, while profiles for Br were better fitted with a parabolic diffusion model and rate constants of 7.4–9.5 $(\mu g\ L^{-1})^{-1}\ h^{-1/2}$. Bioaccessibilities, based on maximum or equilibrium concentrations mobilised relative to total (XRF) concentrations, ranged from <1% for Cd and Se in polyethylene and polypropylene to over 10% for Br in a sample of expanded polystyrene and Pb in a sample of PVC. Calculations suggest that ingested plastic could contribute about 6% and 30% of a seabird's exposure to and accumulation of Pb and brominated compounds, respectively. [ABSTRACT FROM AUTHOR]

Turner, A. and M. Filella (2017). "Bromine in plastic consumer products - Evidence for the widespread recycling of electronic waste." Science of the Total Environment **601-602**: 374-379.

A range of plastic consumer products and components thereof have been analysed by x-ray fluorescence (XRF) spectrometry in a low density mode for Br as a surrogate for brominated flame retardant (BFR) content. Bromine was detected in about 42% of 267 analyses performed on electronic (and electrical) samples and 18% of 789 analyses performed on non-electronic samples, with respective concentrations ranging from 1.8 to 171,000mugg⁻¹ and 2.6 to 28,500mugg⁻¹. Amongst the electronic items, the highest concentrations of Br were encountered in relatively small appliances, many of which predated 2005 (e.g. a fan heater, boiler thermostat and smoke detector, and various rechargers, light bulb collars and printed circuit boards), and usually in association with Sb, a component of antimony oxide flame retardant synergists, and Pb, a heavy metal additive and contaminant. Amongst the non-electronic samples, Br concentrations were highest in items of jewellery, a coffee stirrer, a child's puzzle, a picture frame, and various clothes hangers, Christmas decorations and thermos cup lids, and were often associated with the presence of Sb and Pb. These observations, coupled with the presence of Br at concentrations below those required for flame-retardancy in a wider range of electronic and non-electronic items, are consistent with the widespread recycling of electronic plastic waste. That most Br-contaminated items were black suggests the current and recent demand for black plastics in particular is met, at least partially, through this route. Given many Br-contaminated items would evade the attention of the end-user and recycler, their disposal by conventional municipal means affords a course of BFR entry into the environment and, for food-contact items, a means of exposure to humans.

Turner, A. and L. A. Holmes (2015). "Adsorption of trace metals by microplastic pellets in fresh water. (Special Issue: Microplastics in the environment.)." Environmental Chemistry **12**(5): 600-610.

Adsorption of trace metals (Ag, Cd, Co, Cr, Cu, Hg, Ni, Pb, Zn) to new (virgin) and aged (beached) plastic production pellets suspended in river water (pH ~6.5) has been studied under laboratory conditions. Over a 7-day period, reaction kinetics largely conformed to a pseudo-first-order reversible mechanism with forward rate constants that were typically at least an order of magnitude greater for beached pellets than virgin pellets. Adsorption isotherms were defined by a linear model in many cases, with maximum distribution coefficients of ~6 mL g⁻¹ for virgin pellets (Hg and Pb) and of the order of 10² mL g⁻¹ for beached pellets (Ag and Pb). However, more significant fits to the data were obtained using Freundlich or Langmuir models with adsorption constants that were orders of magnitude greater for beached pellets than virgin pellets and, regarding the former, that were greatest for Ag, Hg and Pb. Increasing pH of river water resulted in an increase in adsorption of Ag, Cd, Co, Ni, Pb and Zn, a reduction in adsorption of Cr and no clear trend for Cu or Hg, and adsorption was always greater to beached pellets than virgin pellets. The ability of pellets to adsorb metals was attributed to the modification of the surface through the attachment of organic matter during the experiments and, with regard to beached pellets, their long-term pre-modification through photooxidation and attrition of charged material. Interactions at the pellet surface likely involve metal cations, oxyanions (HCrO₄⁻/CrO₄²⁻) and organic complexes.

Turner, A., et al. (2019). "Identification, origin and characteristics of bio-bead microplastics from beaches in western Europe." Science of the Total Environment **664**: 938-947.

Primary microplastics have been collected from 17 beaches along the Atlantic, English Channel and southern North Sea coasts of western Europe. Based on visual characteristics, these plastics were differentiated as either relatively smooth, lentil- or disc-shaped pre-production pellets (or nurdles), which were usually a few mm in diameter and were mainly white to off-white, or rougher and more irregular pellets that were slightly larger and usually black. The latter appeared to be bio-beads, or plastics that are specifically manufactured for use as biomedia in certain sewage water treatment (SWT) plants and, possibly, in other industrial wastewater treatment applications. Identification of bio-beads was confirmed following the acquisition of identical samples from a SWT plant in southwest England and a French supplier of bio-beads. Infrared and x-ray fluorescence analysis revealed that bio-beads have, at least historically, been constructed of plasticised polyethylene and, unlike pre-production pellets, contained variable quantities of potentially toxic elements: Br, Cd, Cr, Hg, Pb and Sb; with a distinctive Br to Sb ratio indicative of brominated flame retardants and antimony-based retardant synergists. It is asserted that bio-beads have been manufactured from a heterogeneous mix of recycled polyethylene and end-of-life electrical and electronic plastic, with concentrations of Br, Cd, Cr or Pb in about 50 bio-beads (out of 497 analysed) non-compliant or potentially non-compliant with respect to current regulations on hazardous plastic waste. Concentrations of Br, Cd, Cr, Pb and Sb extracted from individual bio-beads by a simulated avian digestive fluid were variable, with maximum values of about 14, 0.8, 1.3, 20 and 1.4 mug g⁻¹, respectively. The presence and, in many cases, dominance of bio-beads among beached primary microplastics is discussed with regard to the classification of microplastics and potential impacts on wildlife. Turner, S., et al. (2019). "A temporal sediment record of microplastics in an urban lake, London, UK." Journal of Paleolimnology **61**(4): 449-462.

A radionuclide-dated (210Pb and 137Cs) sediment core collected from Hampstead Pond No. 1, a North London lake, was used to provide novel data on the historical accumulation of microplastic waste in the urban environment. Microplastics were extracted from sediments by sieving and dense-liquid separation. Fibres of anthropogenic origin dominated the assemblage.

Microplastics were first identified by microscopy before Raman spectroscopy of selected particles was used to determine the composition of synthetic polymers and dyes. Polystyrene microplastic particles were identified, in addition to synthetic fibres of polyacrylonitrile, polyvinyl chloride and fibres containing synthetic dyes. Concentrations of total microplastics in the sediment samples ranged from detection level to 539 particles per kilogram of dried sediment. Proliferation of microplastics is evident in the core from the late 1950s to the present. Relatively low numbers of particles were found in older sediments, comparable to laboratory blanks, highlighting the difficulty of extending a plastic chronostratigraphy back to the early twentieth century. This study shows that, with optimisation, routine extraction of microplastics from radionuclide-dated lake sediments can add an important temporal perspective to our understanding of microplastics in aquatic systems.

Twiss, M. R. (2016). "Standardized methods are required to assess and manage microplastic contamination of the Great Lakes system." Journal of Great Lakes Research **42**(5): 921-925.

Microplastics are products of large plastic item erosion or small (<1 millimeter) manufactured plastic items. When disposed into waste streams microplastics often end up widely dispersed in both freshwater and marine systems worldwide. Most published reports of microplastics in the aquatic systems to date indicate efforts that are unable to properly sample for microplastics. Advances in the science of environmental monitoring of microplastics are necessary. There is a need to standardize sampling procedures, and notably to adopt the use of "clean" techniques to avoid compromising sample integrity, to insure robust, replicable assessments of microplastic pollution. Reliable, standardized methods are of utmost importance for accurately evaluating the amounts of microplastics in aquatic environments and thus enable the assessment and management of these contaminants.

Tyrpekl, V., et al. (2014). "Synthesis of dense yttrium-stabilised hafnia pellets for nuclear applications by spark plasma sintering." Journal of Nuclear Materials **454**(1-3): 398-404.

Dense yttrium-stabilised hafnia pellets (91.35 wt.% Hf sub(O2) and 8.65 wt.% Y sub(2)O sub(3)) were prepared by spark plasma sintering consolidation of micro-beads synthesised by the "external gelation" sol-gel technique. This technique allows a preparation of HfO sub(2)-Y sub(2)O sub(3) beads with homogenous yttria-hafnia solid solution. A sintering time of 5 min at 1600 [degrees]C was sufficient to produce high density pellets (over 90% of the theoretical density) with significant reproducibility. The pellets have been machined in a lathe to the correct dimensions for use as neutron absorbers in an experimental test irradiation in the High Flux Reactor (HFR) in Petten, Holland, in order to investigate the safety of americium based nuclear fuels.

Tziampazis, E. and A. Sambanis (1995). "Tissue engineering of a bioartificial pancreas: Modeling the cell environment and device function." Biotechnology Progress **11**(2): 115-126.

Cell-based implantable artificial tissues are most promising for the long-term treatment of endocrine diseases, such as diabetes. One type of a bioartificial pancreas device consists of calcium alginate microbeads containing insulin-secreting cells and is surrounded by a poly(L-lysine) (PLL) membrane. The membrane is semipermeable, allowing cellular nutrients and metabolites to diffuse through but excluding the antibodies and cytotoxic cells of the host, thus immunoprotecting the cells. The device can be modeled by writing the equations for diffusion of nutrients and metabolites through the polymer and for consumption of the former and production of the latter by the cells. In this paper, we describe the construction and analysis of such a model for alginate/PLL microbeads with insulin-secreting recombinant mouse pituitary

AtT-20 and mouse insulinoma beta TC3 cells. Entrapped AtT-20 cells are a simplified model system, whereas microbeads with beta TC3 cells constitute a realistic artificial pancreatic device. Effective diffusivities of key compounds through the polymer with entrapped, inactivated AtT-20 spheroids were measured first. The kinetics of glucose and oxygen consumption and insulin secretion were modeled next, and the equations for diffusion and reaction were then combined to describe the entire system. The model was used to compute nutrient and metabolite concentration profiles in beads and the bead secretory response for different bead sizes and cell loadings. The size and loading necessary for the cells to be well nourished and for the beads to be rapidly responsive to step-ups and step-downs of secretion stimuli were evaluated. It was shown that if the cells are hypersensitive to glucose, i.e., they do not shut off secretion at the physiological glucose threshold but at a lower one, so are the microbeads. This work demonstrates the usefulness of mechanistic models with representative parameter values in optimizing the design of artificial tissues and in characterizing aspects of their behavior that are of importance for restoring in vivo function.

Ubeda, S., et al. (2019). "Migration of oligomers from a food contact biopolymer based on polylactic acid (PLA) and polyester." Analytical & Bioanalytical Chemistry **411**(16): 3521-3532.

Polylactic acid (PLA) is a biopolymer commonly used in food packaging due to its good characteristics, similar to PET. To evaluate the safety of this material, the analysis of the non-intentionally added substances (NIAS) is required. Oligomers are NIAS and their behavior needs a deep study, especially if they migrate to the food. In this work, the analysis of the polymer and the migration to food simulants was carried out. A total dissolution/precipitation procedure was applied to PLA pellets and films, using dichloromethane and ethanol as solvent and antisolvent system respectively. The migration tests were carried out in three liquid simulants to mimic any kind of food. Since oligomers are not present in the positive list of the Directive 10/2011/EC, their concentration must be below the 0.01 mg/kg of food. UPLC-QTOF-MS, with and without ion mobility (IM), was used for the analysis. Thirty-nine different PLA oligomers made of repeated monomer units of [LA] (C₃H₄O₂) and with different structures were identified. They corresponded to cyclic oligomers with [LA]_n structure and two groups of linear oligomers, one with an hydroxyl group, OH-[LA]_n-H, and the other one with an ethoxy group, CH₃-CH₂-O-[LA]_n-H. Cyclic oligomers only appeared in the material and were not present in migration solutions. Linear oligomers HO-[LA]_n-H were already present in the pellets/film and they migrated in a higher extension to aqueous food simulants (EtOH 10% and AcH 3%). However, linear oligomers CH₃-CH₂-O-[LA]_n-H were not present initially in the pellets/film, but were detected in migration to simulants with ethanol content, EtOH 95% and EtOH 10%. Furthermore, 5 cyclic polyester oligomers were identified in migration. Ethanol 95% and ethanol 10% migration solutions were also analyzed by scanning electron microscopy (SEM), and the presence of microstructures that could be attributed to the oligomers migration was found. They could be seen as microplastics.

Uber, T. H., et al. (2019). "Sorption of non-ionic organic compounds by polystyrene in water." Science of the Total Environment **682**: 348-355.

Polystyrene (PS) is a plastic material that is well known for its use in many different applications, e.g. as shock sensitive packaging. With its prevalence across society, PS contributes significantly to the overall plastic load in aqueous systems. Sorption of organic compounds by the plastics, especially micrometer-sized particles, in the environment has become a concern in the past years. The aim of this study was to improve the understanding of sorption properties of PS, one of the major plastic pollutants in the aqueous environment. Batch experiments with PS film (29mum thickness) were performed for 4days using a diverse set of 24 sorbates to account for varying molecular properties like polarity or molecular volume. Isotherms were evaluated using different sorption models to elucidate the sorption process of PS. Sorption to PS film was non-linear and absorption into the bulk material was the dominant sorption mode. A clear discrimination between the specific and non-specific interactions in the aqueous environment could be shown. The non-linear sorption to PS was shown to be controlled by the molar volume but also by the polarizability/dipolarity parameter (S) of the ppLFER model. The latter is influenced by the aromatic pi-pi-interactions of PS with the sorbate. Similar to other plastics like polyethylene, sorption to PS is driven by hydrophobic interactions but phase descriptors of pristine PS were significantly different than descriptors for other environmental relevant plastics.

Uber, T. H., et al. (2019). "Characterization of sorption properties of high-density polyethylene using the poly-parameter linearfree-energy relationships." Environmental Pollution **248**: 312-319.
High-density polyethylene (HDPE) is a known sorbent for non-ionic organic compounds in technical applications. Nevertheless, there is little information available describing sorption to industrial HDPE for a broad range of compounds. With a better understanding of the sorption properties of synthetic polymers, environmental risk assessment would achieve a higher degree of accuracy, especially for microplastic interactions with organic substances. Therefore, a robust methodology for the determination of sorbent properties for non-ionic organic compounds by HDPE is relevant for the understanding of molecular interactions for both technical use and environmental risk assessment. In this work, sorption properties of HDPE material used for water pipes were characterized using a poly-parameter linear free-energy relationship (ppLFER) approach. Sorption batch experiments with selected probe sorbates were carried out in a three-phase system (air/HDPE/water) covering an aqueous concentration range of at least three orders of magnitude. Sorption in the concentration range below 10−2 of the aqueous solubility was found to be non-linear and the Freundlich model was used to account for this non-linearity. Multiple regression analysis (MRA) using the determined distribution coefficients and literature-tabulated sorbate descriptors was performed to obtain the ppLFER phase descriptors for HDPE. Sorption properties of HDPE were then derived from the ppLFER model and statistical analysis of its robustness was conducted. The derived ppLFER model described sorption more accurately than commonly used single-parameter predictions, based i.e., on log K o/w. The ppLFER predicted distribution data with an error 0.5 log units smaller than the spLFERs. The ppLFER was used for a priori prediction of sorption by the characterized sorbent material. The prediction was then compared to experimental data from literature and this work and demonstrated the strength of the ppLFER, based on the training set over several orders of magnitude. Image 1 • Sorption data were determined for 25 molecular probe compounds. • Sorption to HDPE at two decades below aqueous solubility is non-linear. • Sorption is dependent on polymer density and crystallinity. • The ppLFER model showed to be an improvement over spLFER models without overparameterization. Sorption of non-ionic organic compounds to HDPE in an aquatic environment is non-linear and strongly dependent on polyethylene density and crystallinity. [ABSTRACT FROM AUTHOR]

Ucar, C., et al. (2003). "Investigation of megakaryocyte apoptosis in children with acute and chronic idiopathic thrombocytopenic purpura." European Journal of Haematology **70**(6): 347-352.

OBJECTIVE: Although the platelet destruction shows a primary role in the thrombocytopenia of idiopathic thrombocytopenic purpura (ITP), it has been demonstrated that impaired platelet production may also contribute to the severity of thrombocytopenia in ITP. The present study examined megakaryocyte apoptosis in bone marrow aspirates of children with acute and chronic ITP and investigated the role of megakaryocyte apoptosis in ITP pathophysiology.

METHODS: Thirteen children diagnosed with acute ITP and eight children diagnosed with chronic ITP comprised the study group. Ten children, who were hospitalized for scoliosis operation but healthy otherwise, comprised the control group. In all children, megakaryocytes were isolated from the same amount of bone marrow aspirate samples using MACS CD61 MicroBeads (Miltenyl Biotec, Auburn, CA, USA). Megakaryocyte apoptosis was studied with transferase-mediated d-UTP-bitin nick end-labeling method.

RESULTS: Isolated megakaryocyte counts did not differ significantly between acute ITP, chronic ITP and control groups. The percentage of apoptotic megakaryocytes did not differ significantly between acute ITP group and control group and between chronic ITP group and control group. The percentage of apoptotic megakaryocytes in patients with chronic ITP was significantly lower than the patients with acute ITP. There was no correlation between the percentage of apoptotic megakaryocytes and platelet counts of the cases.

CONCLUSIONS: Increased megakaryocytic apoptosis does not play a role in the pathogenesis of dysmegakaryopoiesis and impaired platelet production in children with ITP. Decreased megakaryocyte apoptosis in cases with chronic ITP may be due to suppression of megakaryocyte maturation, as the terminal phase of the megakaryocyte lifespan is characterized by the onset of apoptosis.

Uchiyama, K., et al. (2004). "Development of a Bio-MEMS for Evaluation of dioxin toxicity by immunoassay method." Sensors and Actuators B: Chemical **B103**(1-2): 200-205.

The Ah-Immunoassay method was developed using a Bio-MEMS approach and applied to the evaluation of dioxin toxicity in this study. The aim of the research is to develop a real time sensing system for the analysis of Dioxins, generated at the air flue by using a novel micro instrument combining the biological field with micro instrumentation. The micro instrument was fabricated from Si and glass, employing photolithographic techniques. A prototype model of the system was established. Micro-beads, coated with Avidine, were used as a reaction medium. The reaction chamber was first filled with the micro-beads and then the receptor immunoassay was carried out in the micro chamber. Poly- aromatic hydrocarbon, having a highly flat structure, was used as a test sample. The reactivity was evaluated using fluorometry, the fluorescence being detected by fluorescent microscopy.

Ueki, S., et al. (2016). "Eosinophil extracellular trap cell death-derived DNA traps: Their presence in secretions and functional attributes." Journal of Allergy & Clinical Immunology **137**(1): 258-267.

BACKGROUND: Activated human eosinophils, as well as neutrophils, can release extracellular chromatin to form DNA traps through cytolytic extracellular trap cell death (ETosis). Although formations of neutrophil DNA traps are recognized in patients with various inflammatory conditions, neither the presence of ETosis-derived eosinophil DNA traps in human allergic diseases nor the characteristics of these DNA traps have been studied.

OBJECTIVE: We investigated the presence of ETosis-derived DNA traps in eosinophil-rich sinus and ear secretions and the functional attributes of ETosis DNA traps.
METHODS: Eosinophil-rich secretions obtained from patients with eosinophilic chronic rhinosinusitis and eosinophilic otitis media were studied microscopically. In vitro studies of ETosis and DNA trap formation used blood-derived eosinophils and neutrophils, and studies of the binding capacities of DNA traps used labeled bacteria and fluorescent microbeads. Stabilities of DNA traps were evaluated by using fluorescence microscopy.
RESULTS: Abundant nuclear histone H1-bearing DNA traps formed in vivo in the eosinophilic secretions and contributed to their increased viscosity. In vitro, after brief shear flow, eosinophil ETosis-elicited DNA traps assembled to form stable aggregates. Eosinophil DNA traps entrapped bacteria and fungi and, through hydrophobic interactions, microbeads. In comparison with neutrophil-derived DNA traps, eosinophil DNA traps ultrastructurally exhibited thicker fibers with globular structures and were less susceptible to leukocyte-derived proteolytic degradation, likely because of the lesser protease activities of eosinophils.
CONCLUSIONS: In human allergic diseases local cytolysis of eosinophils not only releases free eosinophil granules but also generates nuclear-derived DNA traps that are major extracellular structural components within eosinophil-rich secretions.

Uhde, J., et al. (2005). "Viscoelasticity of entangled actin networks studied by long-pulse magnetic bead microrheometry." Physical Review E. Statistical, Nonlinear, & Soft Matter Physics **72**(6 Pt 1): 061916.
We studied the viscoelastic response of entangled actin networks using embedded microbeads driven by force pulses with amplitudes in the range from 3 to 120 pN and durations up to 60 s. We distinguished three regimes in the time dependence of the compliance J(t) of the network. These were characterized by specific power laws J(t) approximately t(alpha)(i) (i=1, 2, 3). In the short-time regime (i=1), we observed the exponent alpha1 approximately 0.75. In the long-time regime (i=3), we find that alpha3 approximately 1. For the intermediate-time interval (i=2), we observed a novel dynamic regime: for all actin concentrations and all applied forces, it was characterized by the exponent alpha3 approximately 0.5. In both regimes i=2 and i=3, the compliance depended upon the actin concentration c, such as J approximately c(-gamma)(i) with gamma2 approximately 1.1 and gamma 3 approximately 1.4. Using these results, we calculated the shear modulus in the frequency domain and found that the intermediate-time regime in the t domain corresponds to its plateau behavior.

Umfress, A., et al. (2014). "Early changes in retinal layers detected in vivo following microbead-induced ocular hypertension." Investigative Ophthalmology and Visual Science **55 (13)**: 2412.
Purpose: Neurodegeneration in glaucoma is characterized by early deficits in retinal ganglion cell axon function in the optic projection. Here, we tested whether optical coherence tomography (OCT) could detect changes in retinal layer thickness in vivo following short-term elevations in ocular pressure in mice induced by microbead injection. Method(s): We induced ocular hypertension (OHT) in 3 month C57 mice (n=10) through microbead occlusion (1 ul) of the anterior chamber and monitored ocular pressure using TonoLab rebound tonometry. The contralateral eye received an equivalent volume saline injection. OCT imaging was performed weekly over 2-3 weeks using the Bioptigen Envisu R2200 VHR Rodent OCT with InVivoVue Clinic Acquisition software. Images were taken in each eye at nine locations using the optic nerve head as register. Data including retinal layer thickness were analyzed with the Bioptigen InVivoVue Diver 2.0 Software using the Retina Template panel. Result(s): Consistent with published results, microbead-injected eyes exhibited an elevation in IOP of about 30% compared to their saline-injected counterparts. Compared to baseline, 2-3 weeks of OHT induced an 8%

increase in retinal nerve fiber layer thickness (p=0.002); thickness in the saline eye remained the same (p=0.10). Over the same period, thickness of the inner plexiform layer varied greatly in both eyes over a range of 38-60 um, with thickness in the OHT retina on average 4% less (p=0.04) Conclusion(s): Our results indicate that even short-term elevations in IOP induced by microbead occlusion are associated with detectable changes in retinal layer thickness as measured by OCT. In particular, prior to axon loss in this model, which occurs after 5-6 weeks of OHT, the retinal nerve fiber layer actually increases in thickness. This change likely reffects early stages of ganglion cell axonopathy and could be utilized as a surrogate biomarker for onset of pathogenesis.

Unice, K. M., et al. (2019). "Characterizing export of land-based microplastics to the estuary - Part II: Sensitivity analysis of an integrated geospatial microplastic transport modeling assessment of tire and road wear particles." Science of the Total Environment **646**: 1650-1659.

Integrated models addressing microplastic (MP) generation, terrestrial distribution, and freshwater transport are useful tools characterizing the export of MP to marine waters. In Part I of this study, a baseline watershed-scale MP mass balance model was developed for tire and road wear particles (TRWP) in the Seine watershed. In Part II, uncertainty and sensitivity analysis (SA) methods were used to identify the parameters that determine the transport of these particles to the estuary. Local differential, local range and global first-order variance-based SA identified similar key parameters. The global SA (1000 Monte Carlo simulations) indicated that most of the variance in TRWP exported to the estuary can be apportioned to TRWP diameter (76%), TRWP density (5.6%), the fraction of TRWP directed to combined sewers with treatment (3.9%), and the fraction of TRWP distributed to runoff (versus roadside soil; 2.2%). The export fraction was relatively insensitive to heteroaggregation processes and the rainfall intensity threshold for road surface washoff. The fraction of TRWP exported to estuary in the probabilistic assessment was centered on the baseline estimate of 2%. This fraction ranged from 1.4 to 4.9% (central tendency defined as 25th to 75th percentile) and 0.97% to 13% (plausible upper bound defined as 10th to 90th percentiles). This study emphasizes the importance of in situ characterization of TRWP diameter and density, and confirms the baseline mass balance presented in Part I, which indicated an appreciable potential for capture of TRWP in freshwater sediment.

Unterleuthner, D., et al. (2017). "An Optimized 3D Coculture Assay for Preclinical Testing of Pro- and Antiangiogenic Drugs." SLAS discovery **22**(5): 602-613.

Angiogenesis is a promising target for anticancer therapies, but also for treating other diseases with pathologic vessel development. Targeting the vascular endothelial growth factor (VEGF) pathway did not proof as effective as expected due to emerging intrinsic resistance mechanisms, as well as stromal contributions leading to drug insensitivity. Therefore, alternative strategies affecting the interaction of endothelial cells (ECs) with other stromal cells seem to be more promising. Human preclinical in vitro angiogenesis models successfully recapitulating these interactions are rare, and two-dimensional (2D) cell cultures cannot mimic tissue architecture in vivo. Consequently, models combining three-dimensionality with heterotypic cell interaction seem to be better suited. Here, we report on an improved human fibroblast-EC coculture assay mimicking sprouting angiogenesis from EC-covered microbeads resembling existing endothelial structures. Culture conditions were optimized to assess pro- and antiangiogenic compounds. Important characteristics of angiogenesis, that is, the number of sprouts and branch points, sprout length protrusion, and overall vessel structure areas, were quantified. Notably, the endothelial sprouts display lumen formation and basal membrane

establishment. In this model, angiogenesis can be inhibited by genetic interference of pro-angiogenic factors expressed in the fibroblasts. Moreover, bona fide antiangiogenic drugs decreased, whereas pro-angiogenic factors increased vessel formation in 24-well and 96-well settings, demonstrating the applicability for screening approaches.

Upadhyay, M., et al. (2018). "Development of biopolymers based interpenetrating polymeric network of capecitabine: A drug delivery vehicle to extend the release of the model drug." International Journal of Biological Macromolecules **115**: 907-919.

The research aims the development and optimization of capecitabine loaded interpenetrating polymeric network by ionotropic gelation method using polymers locust bean gum and sodium alginate by QbD approach. FMEA was performed to recognize the risks influencing CQAs. BBD was applied to study the effect of factors (polymer ratio, amount of cross-linker and curing time) on responses (particle size, % drug entrapment and % drug release). Polynomial equations and 3-D graphs were plotted to relate between factors and responses. The results of the optimized batch viz. particle size (457.92 +/- 1.6 mum), % drug entrapment (74.11 +/- 3.1%) and % drug release (90.23 +/- 2.1%) were close to the predicted values generated by Minitab 17. Characterization techniques SEM, EDX, FTIR, DSC and XRD were also performed for the optimized batch. To study the water transport inside IPN microbeads, swelling study was done. In vitro drug release of optimized batch showed controlled drug release for 12 h. Pharmacokinetic study carried out following oral administration in Albino Wistar rats exhibited that optimized microbeads had better PK parameters than free drug. In vitro cytotoxicity against HT-29 cells revealed significant reduction of the cell growth when treated with optimized formulation indicating IPN microbeads as effective dosage form for treating colon cancer. Copyright © 2018

Upadhyay, M., et al. (2019). "Locust bean gum and sodium alginate based interpenetrating polymeric network microbeads encapsulating Capecitabine: Improved pharmacokinetics, cytotoxicity &in vivo antitumor activity." Materials Science & Engineering. C, Materials for Biological Applications **104**: 109958.

A combination of biopolymers sodium alginate and locust bean gum has been used to prepare an interpenetrating polymeric network of an anticancer drug Capecitabine by ionotropic gelation method. For the optimization 3² levels, a full factorial design was employed to examine the influence of independent factors, i.e. polymer ratio and cross-linker concentration on responses particle size and drug entrapment. The obtained optimized formulation was examined for solid-state characterization, swelling study, in vitro drug release, SRB study, oral toxicity study, in vivo pharmacokinetic and in vivo antitumor study. The results of all the studies performed were found suitable in extending the release of a short elimination half-life drug with improved bioavailability and suggesting it to be safe and effective for oral drug delivery in treating colon cancer.

Upadhye, S. A., et al. (2016). "Fabrication & characterzation of dual cross linked pulsatile beads of diacerein using natural gum." Indian Drugs **53**(3): 60-62.

In the present study, pulsatile dual cross linked beads were prepared by ionotropic gelation method. Diacerein dual crossed linked beads were prepared by dropping dispersed phase of diacerein (DCN), Moringa olifera gum and sodium alginate into dispersed phase of different concentration of calcium chloride solution followed by 5% & 10% Aluminum chloride solution and 2% sodium tripolyphosphate (TPP) solution. In vitro release studies showed lag time of 3-7 h before the release of diacerein from the formulated beads, which were found to be intact for 5

h. Thus, formulated dual cross linked beads when administered at morning time may release the drug when needed most for chronotherapeutics of osteoarthritis in chronic patients.

Urase, T., et al. (2008). "Emission of volatile organic compounds from solid waste disposal sites and importance of heat management." Waste Management & Research **26**(6): 534-538.

The emission of volatile organic compounds (VOCs) from a solid waste disposal site for municipal solid wastes was quantified. The VOCs contained in the landfill gas taken at the site were benzene, toluene, xylenes, ethyl benzenes, and trimethyl benzenes, while the concentrations of chlorinated compounds were very low. The concentration of benzene in the landfill gas samples ranged from below the detection limit to 20 mg m(-3), and the ratio of benzene to toluene ranged from 0.2 to 8. The higher concentrations of VOCs in landfill gas and in leachates were observed with the samples taken at high temperature areas of the target site. Polystyrene plastic waste was identified as one of the sources of VOCs in solid waste disposal sites at a high temperature condition. The appropriate heat management in landfill sites is an important countermeasure to avoid unusually high emission of VOCs because the heat generated by the biodegradation of organic solid wastes may promote the release of VOCs, especially in the case of sites which receive both biodegradable and plastic wastes.

Urbanek, A. K., et al. (2018). "Degradation of plastics and plastic-degrading bacteria in cold marine habitats." Applied Microbiology and Biotechnology **102**(18): 7669-7678.

Synthetic plastics present in everyday materials constitute the main anthropogenic debris entering the Earth’s oceans. The oceans provide important and valuable resources such as food, energy, and water. They are also the main way of international trade and the main stabilizer of the climate. Hence, changes in the marine ecosystem caused by anthropogenic influences such as plastic pollution can have a dramatic impact on a global scale. Although the problem of plastics still remains unsolved, different ways are being considered to reduce their impact on the environment. One of them is to use microorganisms capable of degradation of plastic. A particularly interesting area is the application of microorganisms isolated from cold regions in view of their unique characteristics. Nevertheless, the interactions between plastic and microorganisms are still poorly known. Here, we present a review of current knowledge on plastic degradation and plastic-microorganism interactions in cold marine habitats. Moreover, we highlight the advantages of microorganisms isolated from this environment for eliminating plastic waste from ecosystems.

Urbanek, A. K., et al. (2017). "Isolation and characterization of Arctic microorganisms decomposing bioplastics." AMB Express **7**(1): 148.

The increasing amount of plastic waste causes significant environmental pollution. In this study, screening of Arctic microorganisms which are able to degrade bioplastics was performed. In total, 313 microorganisms were isolated from 52 soil samples from the Arctic region (Spitsbergen). Among the isolated microorganisms, 121 (38.66%) showed biodegradation activity. The ability of clear zone formation on emulsified poly(butylene succinate-co-adipate) (PBSA) was observed for 116 microorganisms (95.87%), on poly(butylene succinate) (PBS) for 73 microorganisms (60.33%), and on poly(e-caprolactone) (PCL) for 102 microorganisms (84.3%). Moreover, the growth of microorganisms on poly(lactic acid) (PLA) agar plates was observed for 56 microorganisms (46.28%). Based on the 16S rRNA sequence, 10 bacterial strains which showed the highest ability for biodegradation were identified as species belonging to Pseudomonas sp. and Rhodococcus sp. The isolated fungal strains were tested for polycaprolactone films and commercial corn and potato starch bags degradation under laboratory conditions. Strains 16G (based on the analysis of a partial 18S rRNA sequence, identified as Clonostachys rosea) and 16H (identified as Trichoderma sp.) showed the highest capability for biodegradation. A particularly high capability for biodegradation was observed for the strain Clonostachys rosea, which showed 100% degradation of starch films and 52.91% degradation of PCL films in a 30-day shake flask experiment. The main advantage of the microorganisms isolated from Arctic environment is the ability to grow at low temperature and efficient biodegradation under this condition. The data suggest that C. rosea can be used in natural and laboratory conditions for degradations of bioplastics.

Urciuolo, F., et al. (2012). "Novel strategies to engineering biological tissue in vitro." Methods in Molecular Biology **811**: 223-244.

Tissue engineering creates biological tissues that aim to improve the function of diseased or damaged tissues. In this chapter, we examine the promise and shortcomings of "top-down" and "bottom-up" approaches for creating engineered biological tissues. In top-down approaches, the cells are expected to populate the scaffold and create the appropriate extracellular matrix and microarchitecture often with the aid of a bioreactor that furnish the set of stimuli required for an optimal cellular viability. Specifically, we survey the role of cell material interaction on oxygen metabolism in three-dimensional (3D) in vitro cultures as well as the time and space evolution of the transport and biophysical properties during the development of de novo synthesized tissue-engineered constructs. We show how to monitor and control the evolution of these parameters that is of crucial importance to process biohybrid constructs in vitro as well as to elaborate reliable mathematical model to forecast tissue growth under specific culture conditions. Furthermore, novel strategies such as bottom-up approaches to build tissue constructs in vitro are examined. In this fashion, tissue building blocks with specific microarchitectural features are used as modular units to engineer biological tissues from the bottom up. In particular, the attention will be focused on the use of cell seeded microbeads as functional building blocks to realize 3D complex tissue. Finally, a challenge will be the potential integration of bottom-up techniques with more traditional top-down approaches to create more complex tissues than are currently achievable using either technique alone by optimizing the advantages of each technique.

Urraca, J. L., et al. (2014). "Multiresidue analysis of fluoroquinolone antimicrobials in chicken meat by molecularly imprinted solid-phase extraction and high performance liquid chromatography." Journal of Chromatography, A: 1-9.

This paper describes the synthesis of novel molecularly imprinted polymer (MIP) micro-beads for the selective extraction (MISPE) of six fluoroquinolone (FQ) antibiotics (enrofloxacin, ciprofloxacin, lomefloxacin, danofloxacin, sarafloxacin and norfloxacin) from chicken muscle samples and further analysis by high-performance liquid chromatography (HPLC) with fluorescence (FLD) or mass spectrometry (MS) detection. A combinatorial screening approach has been applied to select the optimal functional monomer and cross-linker formulation for polymer synthesis. The MIP prepared using enoxacin (ENOX) as the template - a mixture of methacrylic acid (MAA) and trifluoromethacrylic acid (TFMAA) as functional monomers and ethylene glycol dimethacrylate (EDMA) as the cross-linker - showed superior FQ recognition properties than the rest of the materials generated. MIP spherical particles were prepared using silica beads as sacrificial scaffolds. The polymers were packed in solid phase extraction (SPE) cartridges. The optimized MISPE-HPLC method allows the extraction of the antimicrobials from aqueous samples followed by a selective washing with acetonitrile/water (0.005% TFA, pH=3.0), 20:80 (v/v) and elution with 5% trifluoroacetic acid in methanol. Optimum MISPE conditions led

to recoveries of the target FQs in chicken muscle samples ranging between 68 and 102% and precisions in the 3-4% range (RSD, n=18). The method has been validated according to European Union Decision 2002/657/EC, in terms of linearity, accuracy, precision, selectivity, decision limit (CC alpha) and detection capability (CC beta) by HPLC-FLD and HPLC-MS/MS. The limits of detection were improved using HPLC-MS/MS analysis and ranged between 0.2 and 2.7 micro g kg⁻¹ (S/N=3) for all the FQs tested.

Ushijima, T., et al. (2018). "Occurrence of microplastics in digestive tracts of fish with different modes of ingestion in Japanese bays and Lake Biwa." Journal of Japan Society on Water Environment **41**(4): 107-113.

Microplastics pollution has recently drawn worldwide attention, and may have negative effects on ecosystems. Microplastics are plastic smaller than 5 mm. This study documents microplastics larger than 100 micro m in seven fish species from five Japanese bays and Lake Biwa. 197 fish individuals were examined. A total of 140 microplastics particles were found in the digestive tracts of 37.6% of all fish. All species except Sardinella zunasi had ingested microplastics in all areas. The mean number of microplastics particles was 1.89+or-1.41 per individual fish. Most microplastics were polypropylene (40.7%) and polyethylene (35.0%) as identified by Fourier Transform Infrared Spectrometer (FT-IR). The median of the mean sizes of microplastics was 543 micro m as measured using a microscope and digital camera. The fish species were divided into filter feeders and the others on the basis of modes of ingestion. 54.6% of 97 individuals of filter feeders had ingested microplastics, and the total number of particles was 112. The mean number of microplastics particles in filter feeders was 2.11+or-1.54 per individual fish. 21.0% of 100 individuals of the others group had ingested microplastics, and the total number of particles was 28. The mean number of microplastics particles in the others group was 1.33+or-0.80 per individual fish. These results indicated that modes of ingestion influence the fish's ingestion of microplastics.

Ustabasi, G. S. and A. Baysal (2019). "Occurrence and risk assessment of microplastics from various toothpastes." Environmental Monitoring & Assessment **191**(7): 438.

Microplastics have become a major environmental issue; their release from various products affects the aquatic environment. Personal care products such as toothpastes are recently being considered as a significant source of microplastics released to the aquatic environment. This study aims to assess the presence of microplastics found in toothpastes that are available in the drugstores and markets in Istanbul, Turkey. A total of 20 samples were tested. Following the extraction procedure, obtained particles were quantified and then characterized by microscopic evaluation and surface chemistry analysis. Twenty percent of the samples were found to contain microplastics in the structure of polyethylene at concentrations varying between 0.4 and 1%. In order to evaluate the release to environment, a risk assessment was conducted and yearly microplastic emission caused by toothpaste consumption was calculated based on the results.

Ustabasi, G. S. and A. Baysal (2020). "Bacterial interactions of microplastics extracted from toothpaste under controlled conditions and the influence of seawater." Science of the Total Environment **703**: N.PAG-N.PAG.

• Interactions between bacteria and MPs were investigated in both standard and seawater condition. • Environmental relevancy of the growth media significantly impacts on the toxicity. • MPs were affected different bacterium with the media, while the metabolic pathways were the same. • MPs with higher surface charge induced higher inhibition levels. Microplastics have become a global concern due to their increasing use and discharge into the environment. These ubiquitous particles are known to have extremely low degradation rates and accumulate mostly in the marine environment. The evidence for bioaccumulation and indicators of stress linked to microplastics is also stated in the literature. However, the real environmental impact of microplastics has not yet been revealed. Therefore, it is crucial to understand the interaction mechanisms between microplastics and (micro)organisms under controlled (standard) laboratory conditions and environmentally relevant conditions to reflect the true environmental -situation. In this study, we aimed to understand how microplastics extracted from commercially available toothpaste samples interacted with four types of bacteria under both standard and seawater conditions. For this purpose, bacterial inhibitions were examined, and mechanisms of inhibition were evaluated by biochemical parameters (total protein, lipid peroxidase, total antioxidant capacity, and extracellular carbohydrate levels) of bacteria and physicochemical properties (zeta potential, particle size, surface chemistry) of microplastics. Results showed that gram-positive Bacillus subtilis and gram-negative Pseudomonas aeruginosa were affected in controlled and sea water media, respectively. The inhibition of the bacteria relied on the high zeta potentials of the microplastics, and, biochemically, protein and lipid peroxidase activity of bacteria were important in both media. On the other hand, while biochemical responses were similar in both media, the difference between the cell wall and microplastics surface charge was important only in seawater. [ABSTRACT FROM AUTHOR]

Usui, K., et al. (2016). "Monomerization and fibrillation methods for fibrosis peptides using SPPS microbeads." Journal of Peptide Science **22 (Supplement 2)**: S210-S211.

Protein misfolding diseases including Alzheimer's disease and Parkinson's disease are increasingly common in aging populations. These diseases involve the systematic or tissue-localized deposition of fibrillar, beta-sheet rich protein assemblies (amyloid fibrils). These amyloid fibrils are the principal component of extracellular deposits and are regarded as the causative agents of these diseases. To date, many scientists have investigated amyloid aggregation, but monomerization and fibrillation conditions [1-3] have not yet been standardized . In this study, we attempted to suggest a standardized method for monomerization and aggregation of fibrosis peptides using peptide-immobilized microbeads. Immobilization would prevent peptides from aggregating because the immobilized peptides could not interact with each other. In addition, photolabile linker or chemolabile linker could provide standardization of aggregation condition because aggregation reaction could easily start by irradiation of UV light or addition of a cleavage reagent. After optimization of synthesis of peptide-linker-resin, we have checked the monomerization by gel filteration in comparison with conventional methods. Then the fibrillation reaction was checked by ThT fluorescent assay. Finally, using this system, we demonstrated cellular viability assay using the peptides in comparison with conventional methods. This system with substitution of model sequence for other amyloidogenic sequences could be a powerful and fundamental tool for studying the behavior of amyloidogenic peptides. This system would be one of the most promising method for amyloid-related studies toward medicinal and biochemical research fields.

Usui, K., et al. (2018). "Peptidyl microbeads for modification of a direct peptide reactivity assay (DPRA) in skin sensitization assessment." Journal of Peptide Science **24 (Supplement 2)**: S108.

A direct peptide reactivity assay (DPRA) is one of the most promising method as a robust alternative to animal testing for skin sensitization analysis. In DPRA, a chemical substance is mixed with peptides. After 24 h reaction, HPLC is used to measure unreacted peptides, and skin sensitization is predicted based on the percent decrease in unreacted peptides [1]. Since the test substance and peptides are both in aqueous solutions during DPRA, DPRA cannot appropriately assess poorly water-soluble substances. In addition, HPLC measurement has relatively cumbersome procedures. This precludes the ready assessment of numerous types of samples in a short period of time. In this study, we immobilized the DPRA peptides to amphiphilic microbeads. Then using these peptidyl microbeads, two modified skin sensitization assay systems were developed in order to address these limitations in DPRA. We utilized a photo-labile linker [2, 3] and an unreacted peptide sequence as an internal standard in the first system, and thiol or amino group indicators [4, 5] for detecting amount of unreacted peptides were used in the second system. We examined test chemicals including poorly water-soluble substances by our two modified methods. The results indicated that the both two methods were able to appropriately assess all test chemicals including poorly water-soluble substances that conventional DPRA was unable to assess. Additionally, our method offered easy handling and general versatility, and more reproducibility and accuracy than the conventional DPRA. Thus, these studies successfully improved the conventional DPRA. Our method provides a high-throughput testing for skin sensitization with easy handling.

Uurasjarvi, E., et al. (2020). "Microplastic concentrations, size distribution, and polymer types in the surface waters of a northern European lake." Water Environment Research **92**(1): 149-156.

We examined microplastic concentrations, size distributions, and polymer types in surface waters of a northern European dimictic lake. Two sampling methods, a pump sieving water onto filters with different pore sizes (20, 100, and 300 micro m) and a common manta trawl (333 micro m), were utilized to sample surface water from 12 sites at the vicinity of potential sources for microplastic emissions. The number and polymer types of microplastics in the samples were determined with optical microscopy and muFTIR spectroscopy. The average concentrations were 0.27 +/- 0.18 (mean +/- SD) microplastics/m³ in manta trawled samples and 1.8 +/- 2.3 (>300 mum), 12 +/- 17 (100-300 mum) and 155 +/- 73 (20-100 mum) microplastics/m³ in pump filtered samples. The majority (64%) of the identified microplastics (n = 168) were fibers, and the rest were fragments. Materials were identified as polymers commonly used in consumer products, such as polyethylene, polypropylene, and polyethylene terephthalate. Microplastic concentrations were high near the discharge pipe of a wastewater treatment plant, harbors, and snow dumping site. PRACTITIONER POINTS: Samples were taken with a manta trawl (333 mum) and a pump filtration system (300/100/20 mum) With pump filtration, small 20-300 mum particles were more common than >300 mum particles The average concentration of manta trawled samples was 0.27 +/- 0.18 (mean +/- SD) microplastics/m³ FTIR analysis revealed PE, PP, PET, and PAN to be the most common polymers.

Uurasjärvi, E., et al. (2019). "Microplastic concentrations, size distribution, and polymer types in the surface waters of a northern European lake." Water environment research : a research publication of the Water Environment Federation.

Materials were identified as polymers commonly used in consumer products, such as polyethylene, polypropylene, and polyethylene terephthalate. Microplastic concentrations were high near the discharge pipe of a wastewater treatment plant, harbors, and snow dumping site. PRACTITIONER POINTS: Samples were taken with a manta trawl (333 µm) and a pump filtration system (300/100/20 µm) With pump filtration, small 20-300 µm particles were more common than >300 µm particles The average concentration of manta trawled samples was 0.27 ± 0.18 (mean ± SD) microplastics/m3 FTIR analysis revealed PE, PP, PET, and PAN to be the most common polymers.

Uygun, Z. O., et al. (2019). "Development of molecularly imprinted Acrylamide- Acrylamido phenylboronic acid copolymer microbeads for selective glycosaminoglycan separation in children urine." Turkish Journal of Biochemistry **44**(6): 738-744.

Background: In this study, we synthesized molecularly imprinted copolymers for liquid chromatography columns as a separator for glycosaminoglycan (dermatan sulfate; DS and chondroitin sulfate; CS) in urine. Material(s) and Method(s): Acrylamide and acrylamido phenylboronic acid were used as monomers, acrylamide was used for as base monomer to attract negatively charged groups and acrylamido phenylboronic acid (AAPBA) residues used to form diol bonds between sugar and boronic acid residues to strengthen the attraction. These monomers were synthesized by using precipitation polymerization to form uniform spheres, which are more durable for the pressurized chromatographic systems. Trimethylolpropane trimethacrylate and AIBN were used as crosslinker and starter, respectively. Result(s): These GAG selective polymers were filled by pressurized flow into the steel (4.6 mm x 1.6 mm) columns, then imprinted GAGs were extracted and analyzed to calculate binding capacity of each milligram polymer. Calibration curves of the GAG selective columns were obtained 62.5-1000 ng/mL less than 5% coefficient variation, and lower matrix effect. Conclusion(s): Our imprinted columns separated different GAGs from urine specifically and sensitively. Matrix effect was at an ignorable level thus the challenging use. Copyright © 2019 De Gruyter. Uzumkesici, E. S., et al. (1999). Co-processing of single plastic waste streams in low temperature carbonisation, Elsevier Science Ltd., P.O. Box 800 Kidlington Oxford OX5 1DX UK. **78:** 1697-1702.

To investigate the yields of specific compounds and compound classes that can be achieved by co-processing single-stream plastic waste in carbonisation, a series of Gray-King tests have been conducted on blends of Gascoigne Wood (UK high volatile bituminous coal) and both low density polyethene (500 and 600 degree C) and polystyrene (600 degree C). For both polymers the tar yields were found to increase linearly as a function of the amount of polymer used in the coal blend, with the actual and predicted tar yields being identical within experimental error, indicating that no synergism exists between the coal and the polymers under the conditions used. The higher tar yields obtained with increasing polyethene content are accounted for by the increase in the concentration of aliphatics in the tars. Although little variation was evident in the distribution of n-alkanes obtained with increasing polyethene content, average n-alkane/n-alkene ratios for low levels of polymer addition were considerably higher than

predicted, indicating that dehydrogenation of the alkanes may be taking place, with hydrogen transfer to the coal. Furthermore, the presence of coal was found to have a significant effect on the major products derived from polystyrene. Ethylbenzene, as opposed to styrene monomer, was the major product from all coal/polystyrene blends studied, indicating that in the case of coal/polystyrene blends, hydrogen is transferred from the coal to the polymer. A clear advantage of using polyethene and other alkane polymers in low temperature carbonisation processes would be the considerable reductions achieved in the viscosities of the resultant tars which eases handling problems. Further, it was observed in tests that there was no reduction in the quality of the coke (in terms of Gray-King type) until 10 wt% polyethene and 2-3 wt% polystyrene had been added to the coal blend.

Vaclavkova, P., et al. (2006). "A comparison of an anti-CD25 immunotoxin, Ontak and anti-CD25 microbeads for their ability to deplete alloreactive T cells in vitro." Bone Marrow Transplantation **37**(6): 559-567.

Ex vivo depletion of alloreactive CD25(+) T cells from a stem cell transplant (SCT) can reduce the incidence of graft-versus-host disease (GVHD) while preserving antimicrobial and perhaps antileukemia activity. However, the most effective methods for allodepleting T cells prior to transplant have not been determined. In this study, we have compared three agents that deplete CD25(+) activated, alloreactive T cells. These included Ontak (Denileukin Diftitox), an IL-2 fusion toxin, anti-CD25 microbeads (MACS), an anti-CD25 immunotoxin (IT) and a combination of the IT and MACS. Peripheral blood mononuclear cells (PBMCs) activated in a primary mixed lymphocyte reaction (MLR) were allodepleted using optimal amounts of each agent, and the cells were then analyzed by flow cytometry. The treated cells were examined both for remaining alloreactivity and for the preservation of third party reactivity by testing them in a secondary MLR. Our data demonstrate that both the anti-CD25 IT and the anti-CD25 MACS were equally effective in depleting CD4(+)CD25(+) cells and in sparing T cells that were reactive with third party cells. The anti-CD25 IT was, however, superior in depleting alloreactive CD8(+)CD25(+) cells. In contrast, Ontak did not eliminate alloreactive cells and the Ontak-treated cells retained significant reactivity against the original stimulator cells.

Vafajoo, A., et al. (2018). "Multiplexed microarrays based on optically encoded microbeads." Biomedical Microdevices **20**(3): 66.

In recent years, there has been growing interest in optically-encoded or tagged functionalized microbeads as a solid support platform to capture proteins or nucleotides which may serve as biomarkers of various diseases. Multiplexing technologies (suspension array or planar array) based on optically encoded microspheres have made possible the observation of relatively minor changes in biomarkers related to specific diseases. The ability to identify these changes at an early stage may allow the diagnosis of serious diseases (e.g. cancer) at a time-point when curative treatment may still be possible. As the overall accuracy of current diagnostic methods for some diseases is often disappointing, multiplexed assays based on optically encoded microbeads could play an important role to detect biomarkers of diseases in a non-invasive and accurate manner. However, detection systems based on functionalized encoded microbeads are still an emerging technology, and more research needs to be done in the future. This review paper is a preliminary attempt to summarize the state-of-the-art concerning diagnostic microbeads; including microsphere composition, synthesis, encoding technology, detection systems, and applications.

Vafajoo, A., et al. (2018). "Biofunctionalized microbead arrays for early diagnosis of breast cancer."

Biomedical Physics and Engineering Express **4**(6).

A high-performance method is suspension microbead arrays which facilitate HER2 recognition for rapid prognosis in its preliminary stages before cancer reaches to its metastases level or first prevalence of tumor growth. To achieve this goal, we synthesized gelatin microbeads by oil in water (o/w) emulsion method and the size and stability of micro-particles were optimized with different concentrations of glutaraldehyde. The non-toxicity of microbeads was proved by MTT assay. Then the Herceptin was immobilized on the microbeads surface by carbodiimide coupling method. FITC was used as a fluorescent marker for recognizing HER2 receptors on SKBr3 cancer cells (clinical sample) and the recognition was tracked by flow cytometry. Results showed significant discrimination between SKBr3 cancer cells sample concerning HER2 negative cancer cells as a control sample. © 2018 IOP Publishing Ltd.

Vaidya, R., et al. (2010). "Circulating IL-2R, IL-8, IL-15 and CXCL10 levels are independently prognostic in primary myelofibrosis: A comprehensive cytokine profiling study." Blood. Conference: 52nd Annual Meeting of the American Society of Hematology, ASH **116**(21).

Background: Abnormal cytokine expression accompanies the disease process in primary myelofibrosis (PMF) and the levels of proinflammatory cytokines have been shown to be down-regulated by JAK inhibitor therapy. The prognostic relevance of increased cytokine levels in PMF has not been systematically studied. The objectives of the current study were to describe the spectrum of abnormal cytokine expression in PMF and determine its prognostic relevance. Method(s): A multiplex biometric sandwich immunoassay (Invitrogen multiplex assays, Invitrogen Corporation-Carlsbad CA, USA) was used for simultaneous analysis of 30 cytokine levels. Diluted plasma was mixed with fluorescently addressed microbeads bound with anti-cytokine antibodies. Biotin anticytokine secondary antibodies were then added and allowed to bind to cytokine-bead complexes. Total surface fluorescence for each bead was then measured using a Luminex (Luminex Corporation, Austin, TX, USA) fluorescent flow-based detection system. Result(s): Cytokine levels at diagnosis were analyzed for a total of 127 treatment naive patients with PMF, who had stored sera at the time of diagnosis or first referral to the Mayo Clinic. The circulating levels of 30 cytokines in the multiplex assay were compared between PMF patients (n=127) and normal controls (n=31). Significant differences (p<0.05) were evident for 20 of the 30 cytokines: IL-1b, IL-1RA, IL-2R,IL-6, IL-8, IL-10, IL-12, IL-13, IL- 15, TNF-alpha, G-CSF, INF-alpha, INF-gamma, MIP-1alpha, MIP-1beta, HGF, CXCL10, MIG, MCP-1 and VEGF. On univariate analysis, increased levels of 9 of these 20 cytokines were associated with shortened survival (p<0.05): IL-1RA, IL-2R, IL-6, IL-8, IL-12, IL-15, MIP-1alpha, CXCL10 and MIG. On multivariable analysis, 4 of these 9 cytokines maintained their prognostic value for survival: IL-2R (p=0.0011), IL-8 (p<0.0001), IL-15 (p=0.0124) and CXCL10 (p=0.0031). The independent prognostic value of these 4 cytokines was sustained during additional multivariable analysis that included the Dynamic International Prognostic System Score and cytogenetic risk category. Next, we divided the 127 patients into three cytokine risk categories based on the serum levels of IL-2R, IL-8, IL-15 and CXCL10: none elevated, one or two elevated and three or four elevated. The respective median survivals were 69, 37 and 19 months (p=0.01; Figure 1) and such cytokine risk categorization was both DIPSS and cytogenetic risk independent; p values for multivariable analysis including cytokine, DIPSS, cytogenetic risk groups were 0.02, 0.0001 and 0.004, respectively. (Figure Presented) Conclusion(s): Elevated serum levels of IL-2R, IL-8, IL-15 and CXCL10 independently predict shortened survival in PMF and such prognostication appears to be independent of DIPSS and cytogenetic risk category. The current study suggests clinical relevance of multiple cytokines in PMF that could be therapeutically targeted.

Vaidya, S. V., et al. (2007). "Spectral Bar Coding of Polystyrene Microbeads Using Multicolored Quantum Dots." Analytical Chemistry **79**(22): 8520.

This paper focuses on encoding polystyrene microbeads, 10-100 ...m in diameter, with a luminescent spectral bar code composed of mixtures of quantum dots (QDs) emitting at different wavelengths (colors). The QDs are encapsulated in the bead interior during the bead synthesis using a suspension polymerization, and the bar code is constructed by varying both the number of colors included in the bead and, for each color, the number of QDs of that color. Confocal laser scanning microscopy images of the beads demonstrate that the multicolored QDs are pushed together into inclusions within the bead interior. The encoded bead emission spectrum indicates that the peak position of the included colors does not shift relative to the corresponding peaks of the spectra recorded for the nonaggregated QDs at identical loading concentrations. Due to the spatial proximity of the QDs in the inclusions, electronic energy transfer from the lower wavelength emitting QDs to the higher emitting QDs changes the relative intensities of the colors compared to the values in the nonaggregated spectra. We show that this energy transfer does not obscure the spectral uniqueness of the different codes. Ratiometric encoding, in which the bar code is read as relative color intensity, is shown to remove the dependence of the code on the bead size. (ProQuest: ... denotes formulae/symbols omitted.)

Vaidya, V. S., et al. (2009). "A rapid urine test for early detection of kidney injury." Kidney International **76**(1): 108-114.

Kidney injury molecule-1 (Kim-1) has been qualified by the Food and Drug Administration and European Medicines Agency as a highly sensitive and specific urinary biomarker to monitor drug-induced kidney injury in preclinical studies and on a case-by-case basis in clinical trials. Here we report the development and evaluation of a rapid direct immunochromatographic lateral flow 15-min assay for detection of urinary Kim-1 (rat) or KIM-1 (human). The urinary Kim-1 band intensity using the rat Kim-1 dipstick significantly correlated with levels of Kim-1 as measured by a microbead-based assay, histopathological damage, and immunohistochemical assessment of renal Kim-1 in a dose- and time-dependent manner. Kim-1 was detected following kidney injury induced in rats by cadmium, gentamicin, or bilateral renal ischemia/reperfusion. In humans, the urinary KIM-1 band intensity was significantly greater in urine from patients with acute kidney injury than in urine from healthy volunteers. The KIM-1 dipstick also enabled temporal evaluation of kidney injury and recovery in two patients who developed postoperative acute kidney injury following cytoreductive surgery for malignant mesothelioma with intraoperative local cisplatin administration. We hope that future, more extensive studies will confirm the utility of these results, which show that the Kim-1/KIM-1 dipsticks can provide a sensitive and accurate detection of Kim-1/KIM-1, thereby providing a rapid diagnostic assay for kidney damage and facilitating the rapid and early detection of kidney injury in preclinical and clinical studies.

Vajen, T., et al. (2015). "Platelet microvesicles in vascular inflammation." Journal of Thrombosis and Haemostasis **2)**: 895.

Background: Microvesicles are gathering increasing attention as mediators of cell communication and as integral effectors of disease. Platelets present a major source of microvesicles and release these microvesicles either spontaneously or upon activation. Platelet microvesicles (PMVs) retain many features of their parent cells and have been shown to exert modulatory effects on vascular and immune cells. Aim(s): We hypothesize that PMVsinteract with vascular smooth muscle cells (SMCs) and modulate their function in the context of vascular

remodeling. Method(s): PMVs were isolated from stored human platelet-rich plasma by serial centrifugation steps. PMVs were quantified and characterized by flow cytometry using annexin A5/phosphatidylserine and antibodies against CD41a/GPIIb. Size calibrated micro beads were used to quantify the absolute amount of PMVs/mL. Cell migration experiments were performed using a chemotaxis mu-slide. Proliferation of SMCs was measured by the BrdU-cell proliferation kit. Platelet receptors implicated in PMV-SMC interaction were identified by blocking antibodies. Result(s): In the presence of PMVs a gradient was generated that resulted in significant directed migration of the SMCs. Both, the total displacement distance and the velocity of movement of SMCs were significantly increased compared to the control condition without PMVs. The PMV binding to SMCs was specifically abrogated with the integrin alphaIIbbeta3 inhibitor (integrilin) indicating an integrin-dependent mechanism of interaction. A proliferative effect on SMCs was measured after 48 h after incubation with PMVs and this proliferation relied on interactions via integrin alphaMbeta2, CD40 and on P-selectin. Conclusion(s): Isolated PMVs have shown to exert an immunomodulatory activity on various cell types. The present data indicate a role of PMVs in SMC chemotaxis and proliferation, which might contribute to vascular atherogenesis, in particular vascular remodeling.

Vakarelova, M., et al. (2017). "Production of stable food-grade microencapsulated astaxanthin by vibrating nozzle technology." Food Chemistry **221**: 289-295.

Astaxanthin is a carotenoid known for its strong antioxidant and health-promoting characteristics, but it is also highly degradable and thus unsuited for several applications. We developed a sustainable method for the extraction and the production of stable astaxanthin microencapsulates. Nearly 2% astaxanthin was extracted by high-pressure homogenization of dried Haematococcus pluvialis cells in soybean oil. Astaxanthin-enriched oil was encapsulated in alginate and low-methoxyl pectin by Ca²⁺-mediated vibrating-nozzle extrusion technology. The 3% pectin microbeads resulted the best compromise between sphericity and oil retention upon drying. We monitored the stability of these astaxanthin beads under four different conditions of light, temperature and oxygen exposition. After 52weeks, the microbeads showed a total-astaxanthin retention of 94.1+/-4.1% (+4degreeC/-light/+O₂), 83.1+/-3.2% (RT/-light/-O₂), 38.3+/-2.2% (RT/-light/+O2), and 57.0+/-0.4% (RT/+light/+O₂), with different degradation kinetics. Refrigeration, therefore, resulted the optimal storage condition to preserve astaxanthin stability.

Valdespin, C., et al. (2018). "Effect of annexin-V positive sperm-cells removal with magnetic activated cell sorting (MACS) for ICSI procedures in couples with male infertility (teratozoospermia); A randomized controlled trial." Human Reproduction **33 (Supplement 1)**: i28-i29.

Study question: Does the use of MACS and incubation with annexin-V conjugated microbeads (ANMB) before ICSI in couples with male infertility (teratozoospermia) improve the live-birth delivery rate? Summary answer: The use of MACS-ANMB in men with teratozoospermia improves the development and quality of oocytes/embryos, consequently improving fertilization(FR), implantation(IR), pregnancy(PR), and live-birth-delivery rates. What is known already: It is proved that human spermatozoa play an exten-sive role in the reproductive physiology, beginning with the fertilization process, continuing with early and late stages of embryo development, that ultimately impact on implantation and pregnancy rates. The expression of early apoptotic markers as plasma membrane translocation of phosphatidylserine (PS) is associated with abnormal embryo development and suboptimal results of FR, IR and PR. Annexin-V magnetic cell separation of non-apoptotic spermatozoa is simple, fast, inexpensive and highly specific, however, its role in late stages of embryo development and live-birth rate is

unclear. Study design, size, duration: A prospective, randomized, triple-blinded, and controlled trial was conducted using a parallel two-arm study. We included a total of 200 couples with teratozoospermia undergoing ICSI assigned in a 1:1 proportion either to the experimental or the control group. Samples from the study group were prepared by swim-up followed by MACS-ANMB to remove Annexin-V positive sperm cells. The study was conducted from June-2012 to March-2017 in a single reproductive center in Mexico City. Participants/materials, setting, methods: Only those samples exhibiting teratozoospermia (morphology <4% according to Kruger's strict criteria) were included in the study. In addition, patients who presented with poor ovarian response ("Bologna" criteria) were eliminated. Samples were randomized in two groups: i)swim-up followed by MACS-ANMB, and ii)swim-up. All embryos were analyzed until day 5-6 (blastocyst stage) and all transfers were done on the same embryo stage. Statics: Mann-Whitney-test, Fisher-exact-test, and Person's-correlation were done to analyze the results (p < 0.05, significant). Main results and the role of chance: Different results were obtained between groups, however, patients demographics were similar. The Annexin-V positive fraction was negatively correlated with sperm concentration (r =-0.5435 p = <0.0001), progressive motility (r=-0.2975 p = 0.02), and total motility (r =-0.2975 p = 0.02); and was positively correlated with type D morphology (r = 0.4397 p = 0.0006). Regarding embryo development and reproductive results, comparison between MACS-ANMB (n = 100), and control group (n = 100) showed the following results: i) FR of 40.8% (95% IC, 27.4-65.0) versus 45.2% (95% IC, 14.7-69.0) p = 0.04, ii) embryo survival on day-3 of 97.3% (95% IC, 89.7-100) versus 98.9% (95% IC, 96.8-100) Non Significantly (NS), iii) mean quality of embryos on day-3 of 2.9 (95% IC, 2.8-3.0) versus 2.9 (95% IC, 2.9-3.0) NS, iv) blastocyst development on day-5 of 61.2% (95% IC, 51.7-70.6) versus 48.8% (95% IC, 30.2-66.6) p = 0.02, v) quality of embryos on day-5 of 2.8 (95% IC, 2.6-3.1) versus 3.4 (95% IC, 3.3-3.6) p = 0.001, vi) percentage of arrested embryos of 32.9% (95% IC, 23.5-42.3) versus 49.9% (95% IC, 36.8-63.0) p = 0.04, vii) IRof25.5% (95% IC, 12.7-67.1) versus 12.5% (95% IC, 6.2-32.8) p = 0.001, viii) PR of 51.1% (95% IC, 25.5-65.7) versus 26.1% (95% IC, 13.3-34.2) p = 0.001, and ix) live-birth delivery rate 24.5% (95% IC, 12.2-72.0) versus 9.5% (95% IC, 4.7-27.9) p=<0.0001, respectively. Limitations, reasons for caution: In this study, we only included men with teratozoospermia, not evaluating other men with different types of male infertility. Despite the fact that we selected sperm-cells without indicators of apop-tosis and measure its impact on live-birth delivery rate, we didn't evaluate its effect on chromosomal abnormalities. Wider implications of the findings: Through ICSI there is the possibility of injecting a spermatozoon with an apoptotic process that by natural selection would be condemned to die generating suboptimal results in ART; with the help of MACS-ANMB we improve live-birth delivery rate in men with teratozoospermia and type-D motility.

Valente, T., et al. (2019). "Exploring microplastic ingestion by three deep-water elasmobranch species: a case study from the Tyrrhenian Sea." Environmental Pollution **253**: 342-350.

This study analyzes microplastic ingestion by three deep-water elasmobranch species (Galeus melastomus, Scyliorhinus canicula and Etmopterus spinax) from the Tyrrhenian Sea, discriminating between stomach and intestine contents. The absence of significant differences in frequency and abundance of plastic items into stomachs seems to suggest that ecological diversity among the three sharks does not strongly influence the probability of plastic ingestion in the study area. On the other hand, the detected differences in the microplastic content into the intestine might be due to a different retention time of microplastics, suggesting how feeding habits could influence metabolic features, and therefore affect the recovery of ingested plastic items. This information would improve the future development of marine micro-litter monitoring systems, following the MSFD requirements. Moreover, this study shows that all the three examined elasmobranch species can give important information even with relatively small sample sizes (N=30), and they could be used as target species for monitoring micro-litter ingestion in deep-water habitats.

Valenti, G., et al. (2015). "An electrochemiluminescence-supramolecular approach to sarcosine detection for early diagnosis of prostate cancer." Faraday Discussions **185**: 299-309.

Monitoring Prostate Cancer (PCa) biomarkers is an efficient way to diagnosis this disease early, since it improves the therapeutic success rate and suppresses PCa patient mortality: for this reason a powerful analytical technique such as electrochemiluminescence (ECL) is already used for this application, but its widespread usability is still hampered by the high cost of commercial ECL equipment. We describe an innovative approach for the selective and sensitive detection of the PCa biomarker sarcosine, obtained by a synergistic ECL-supramolecular approach, in which the free base form of sarcosine acts as co-reagent in a Ru(bpy)3(2+)-ECL process. We used magnetic micro-beads decorated with a supramolecular tetraphosphonate cavitand (Tiiii) for the selective capture of sarcosine hydrochloride in a complex matrix like urine. Sarcosine determination was then obtained with ECL measurements thanks to the complexation properties of Tiiii, with a protocol involving simple pH changes - to drive the capture-release process of sarcosine from the receptor - and magnetic micro-bead technology. With this approach we were able to measure sarcosine in the muM to mM window, a concentration range that encompasses the diagnostic urinary value of sarcosine in healthy subjects and PCa patients, respectively. These results indicate how this ECL-supramolecular approach is extremely promising for the detection of sarcosine and for PCa diagnosis and monitoring, and for the development of portable and more affordable devices.

Valignat, M. P., et al. (2005). "Reversible self-assembly and directed assembly of DNA-linked micrometer-sized colloids." Proceedings of the National Academy of Sciences of the United States of America **102**(12): 4225-4229.

We present a technique for the directed assembly and self-assembly of micrometer-scale structures based on the control of specific DNA linkages between colloidal particles. The use of DNA links combined with polymer brushes provides an effective way to regulate the range and magnitude of addressable forces between pairs (and further combinations) of different particles. We demonstrate that the autoassembly of alternate microbeads as well as their directed assembly, by using laser tweezers, is reversible. The key to reversibility is preventing the particles from falling into their van der Waals well at close distances. This goal is achieved by the use of adsorbed polymers that limit the number of DNA bridges to one to three between adjacent particles. © 2005 by The National Academy of Sciences of the USA.

Valour, F., et al. (2015). "Delta-toxin production deficiency in Staphylococcus aureus: a diagnostic marker of bone and joint infection chronicity linked with osteoblast invasion and biofilm formation." Clinical Microbiology & Infection **21**(6): 568.e561-511.

Biofilm formation, intra-osteoblastic persistence, small-colony variants (SCVs) and the dysregulation of agr, the major virulence regulon, are possibly involved in staphylococcal bone and joint infection (BJI) pathogenesis. We aimed to investigate the contributions of these mechanisms among a collection of 95 Staphylococcus aureus clinical isolates from 64 acute (67.4%) and 31 chronic (32.6%) first episodes of BJI. The included isolates were compared for internalization rate, cell damage and SCV intracellular emergence using an ex vivo model of human osteoblast infection. Biofilm formation was assessed in a microbead immobilization assay (BioFilm Ring test). Virulence gene profiles were assessed by DNA microarray. Seventeen

different clonal complexes were identified among the screened collection. The staphylococcal internalization rate in osteoblasts was significantly higher for chronic than acute BJI isolates, regardless of the genetic background. Conversely, no differences regarding cytotoxicity, SCV emergence, biofilm formation and virulence gene distribution were observed. Additionally, agr dysfunction, detected by the lack of delta-toxin production using whole-cell matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) analysis (n = 15; 15.8%), was significantly associated with BJI chronicity, osteoblast invasion and biofilm formation. These findings provide new insights into MSSA BJI pathogenesis, suggesting the correlation between chronicity and staphylococcal osteoblast invasion. This adaptive mechanism, along with biofilm formation, is associated with agr dysfunction, which can be routinely assessed by delta-toxin detection using MALDI-TOF spectrum analysis, possibly providing clinicians with a diagnostic marker of BJI chronicity at the time of diagnosis.

Valpione, S., et al. (2015). "A retrospective analysis of 141 patients with liver metastases from uveal melanoma: A two-cohort study comparing transarterial chemoembolization with CPT-11 charged microbeads and historical treatments." Melanoma Research **25**(2): 164-168.

We retrospectively evaluated the benefit of transarterial chemoembolization with CPT-11 charged microbeads (TACE) in 58 of 141 uveal melanoma patients with liver metastases. This was a retrospective analysis of a prospectively maintained database ranging from September 1990 to April 2014. Statistical analyses adjusting for possible confounding effects of extent of liver metastases were carried out using the Cox regression model under the verified hypothesis of proportional hazards. Among 141 patients with liver metastases, 58 were treated with TACE as first-line therapy and 36 were dead at the time of the analysis; 83 patients received other first-line treatments (deaths = 83). The treatment with TACE conferred a survival advantage (median 16.5 vs. 12.2 months, respectively); when the two cohorts were analyzed comparing the two groups according to the percentage of liver involvement, there was significant evidence that patients with worse hepatic involvement benefited most from the treatment (liver metastases = 20-50%: hazard ratio = 0.50, P = 0.048 and liver metastases >=50%: hazard ratio = 0.17, P = 0.009). Liver function tests (transaminases and gamma-glutamyl-transpeptidase) and age were higher in the historic group, and LDH tended to show higher values. There were no high-grade toxicities with TACE. TACE seems to be a tolerable regimen that confers an improvement in the survival of uveal melanoma patients with liver metastases. Confirmation of the clinical efficacy of TACE is recommended in a phase III trial, possibly with the inclusion of a targeted therapy such as a MEK inhibitor. Copyright © 2015 Wolters Kluwer Health, Inc. All rights reserved.

Valpione, S., et al. (2013). "Intra-arterial hepatic chemoembolization with CPT-11 charged microbeads (TACE) combined with systemic fotemustine in metastatic uveal melanoma." European Journal of Cancer **2)**: S860-S861.

Background: Uveal melanoma (UM) is the most frequent tumor of the eye (70%), and represents 5% to 6% of all melanoma diagnoses. Approximately 50% of patients with UM will develop metastatic disease within 15 years from the treatment of primary tumor and the liver is the first or prevalent site of metastatic disease in up to 95% of the recurring patients. Without treatment the median survival time is generally poor: larger published case series reported a median life expectancy from 3.6 to 15 months, with rare cases of long-term survivors. Notwithstanding the efforts made to improve the outcome of metastatic UM, no standard therapy is established so far. Material(s) and Method(s): A total of 143 patients (73 women and 70 men) were identified from a prospectively maintained database queried under IRB approval for uveal metastatic melanoma patients undergoing clinical treatments and procedures for their disease from September 1990 to October 2012. Data of patients who were treated with TACE combined with systemic fotemustine as first line treatment for stage IV disease were analyzed and compared with data of patients who didn't. (Table presented) Results: Out of 143 patients who were treated for metastatic uveal melanoma, 32 received TACE combined with systemic fotemustine as first line therapy. Fotemustine was administrated as outpatient chemotherapy. TACE was performed in day-hospital regimen, patients were usually discharged after an observation of 24 hours. Discharge was delayed after 1st TACE for 6 patients because of infection (N=1), and pain (N=5). Most frequent adverse event related to the procedure was pain (35 patients experimented pain, any grade), that was mostly epigastric and was eased by ranitidine in patients with mild-moderate pain and needed ranitidine plus morphine solphate (up to 40 mg i.v. per day) administration in 5 patients. Nausea and vomiting were controlled with dopamine antagonists. Most serious adverse event was protracted G4 thrombocytopenia, that required transfusion of platelets for 2 patients. We observed 1 case of fever (peak 38.7degreeC) with normal neutrophil count and augment of C reactive protein, the patient was treated with ceftriaxone and discharged after 3 nights. No life-threatening adverse events or procedure-related deaths were observed. Patients who received the combined treatment of TACE and fotemustine had a survival advantage (18.1 vs 14.6 months, p = 0.039). Conclusion(s): Combined treatment with TACE and systemic fotemustine improves survival in metastatic melanoma patients and is well tolerated. It could be proposed for further studies, also combined with new drugs.

Valpione, S., et al. (2012). "Metastatic uveal melanoma: A 22 years single center experience." Annals of Oncology **9)**: ix371.

Uveal melanoma (UM) is the most frequent eye cancer (annual incidence 0.5-0.7:100000), 40% to 60% of patients develop metastases; of them, up to 95% experience liver involvement. Metastatic disease carries a poor prognosis and no standard therapy is established so far. We retrospectively reviewed the medical records of 127 consecutive patients (M/F:61/65) with metastatic UM treated at our institution from September 1990 to February 2012. We collected: gender, age, TNM stage, data and site of primary UM and metastases; LDH, alkaline phosphatase, gGT, transaminases; treatments and outcome. Mean age at diagnosis of primary UM was 56.4 years (median 59.8, 95% CI 53.7-59.1 years). Mean age at diagnosis of first metastasis was 58.8 years (median 62.4, 95% CI 56.1-61.5 years), with a mean disease-free interval (DFI) of 3.6 years (median 1.9, 95% CI 1.9-5.3 years). Ninetynine (78%) patients had liver metastases (LM), 28 (22%) had local or nodal involvement, 9 (7.1%) had lung metastases and 13 (10.2%) had other visceral metastases (CNS, kidney, spleen, adrenal gland, bone), 30 (23.6%) patients had multiple sites of disease. Lung metastases were more frequent in females (OR 9.17, 95% CI 1.11-75.96, p = 0.037). LDH and gGT levels at the first metastasis onset, were inversely correlated with survival (p < 0.05). Survival was significantly poorer in LM bearers (13% versus 55% 1 year survival, p < 0.01). Longer DFI was a prognostic factor for not hepatic recurrence and better prognosis (logistic regression, OR 0.88, 95% CI 0.78-0.99, p < 0.05). Age at diagnosis correlated with age at recurrence and with longer DFI (p < 0.05). Considering all treatments, almost always combining locoregional and systemic therapy with fotemustine, [hepatic intra-arterial fotemustine, radiofrequency, alcoholization, surgery, intra-arterial hepatic chemoembolization with camptothecin charged microbeads (TACE)], only TACE was associated with an improved prognosis (OR 0.17, 95% CI 0.06-0.46, p < 0.01) and with a longer survival after metastasis diagnosis (p= 0.02). Conclusion(s): TACE can be combined with systemic therapy and provides a clinical benefit in UM metastases, this encourages further prospective studies, also in combination with anti-angiogenic drugs and systemic therapies.

Valpione, S., et al. (2014). "Is transhepatic chemoembolization with CPT-11 charged microbeads in combination with systemic fotemustine (f-TACE) effective in uveal melanoma liver metastases? A retrospective analysis of 127 consecutive patients." Journal of Clinical Oncology. Conference **32**(15 SUPPL. 1).

Background: Uveal melanoma is a rare cancer, it represents 5% to 6% of all melanoma diagnoses (annual incidence approximately 0.5-0.7:100000). Up to 50% of patients with UM will develop metastatic disease within 15 years from the treatment of primary tumor. The preferred spread is hematogenous and the liver is the first or prevalent site of metastatic disease in up to 95% of the recurring patients. The median survival time of metastatic uveal melanoma is generally poor, with reported median life expectancy from 3.6 to 15 months and no standard therapy established so far. Method(s): We retrospectively reviewed our database of patients treated at Veneto Region Oncology Research Institute for metastatic uveal melanoma, grouped by liver replacement percentage, to evaluate the benefit of treatment with transarterial chemoembolization with CPT-11 charged microbeads combined with systemic fotemustine (f-TACE) in this set of patients. From 1990 to 2013, 156 patients were treated for metastatic uveal melanoma in our Centre. Among them, 147 patients had liver metastases and 127 had enough information recorded to perform the study and were analyzed. Result(s): Among 127 patients with liver metastases, 49 were treated with f-TACE as first line-therapy. The cohort of patients treated with f-TACE and the cohort that did not receive f-TACE were not significantly different for prognostic factors. The treatment with f-TACE conferred a survival advantage (20.6 vs 14.7 months, respectively; p=.050); the advantage was maintained when analysis was performed with stratification for liver metastatic substitution (HR= 0.58, p=.002). The treatment was not affected by severe toxicities. Conclusion(s): F-TACE seems a tolerable regimen that confers an improvement in survival of uveal melanoma patients with liver metastases. Our data prompt for the conduction of perspective comparative studies confirming the efficacy of f-TACE and, in the future, we advise combination treatments with targeted drugs.

Valverde, A., et al. (2018). "Electrochemical immunosensor for IL-13 Receptor alpha2 determination and discrimination of metastatic colon cancer cells." Biosensors & Bioelectronics **117**: 766-772.

This work describes the first electrochemical immunosensor reported for the determination of IL-13 receptor Ralpha2 (IL-13Ralpha2), an emerging relevant biomarker in metastatic colon cancer. The approach involves the formation of sandwich immunocomplexes using specific capture (CAb) and biotinylated detector antibodies (BDAb) further labeled with an streptavidin-horseradish peroxidase (Strep-HRP) polymer, onto carboxylic acid-modified magnetic microbeads (HOOC-MBs). Amperometric detection at disposable carbon screen-printed electrodes (SPCEs) using the (H₂O₂)/hydroquinone (HQ) system was employed to monitor the affinity reactions. The developed immunosensor exhibits a linear calibration plot over the 3.9-100ngmL⁻¹ concentration range, a LOD of 1.2ngmL⁻¹ and excellent selectivity against other non-target proteins. The amperometric immunosensor was applied successfully to quantify for the first time the IL-13Ralpha2 expression in raw lysates of colon cancer cells and to discriminate the metastatic potential of intact cells through recognition of this target extracellular receptor. In comparison with the commercial Enzyme-Linked ImmunoSorbent Assay (ELISA) kit involving the same immunoreagents, the immunosensor provides a similar LOD in a half-time for the assay.

Van, A., et al. "Persistent organic pollutants in plastic marine debris found on beaches in San Diego,

California." Chemosphere.

Plastic debris were collected from eight beaches around San Diego County, California. Debris collected include: pre-production pellets and post-consumer plastics including fragments, polystyrene (PS) foam, and rubber. A total of n = 2453 pieces were collected ranging from <5 mm to 50 mm in size. The plastic pieces were separated by type, location, and appearance and analyzed for polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), dichlorodiphenyltrichloroethane (DDT) and its breakdown products, and chlordanes. PAH concentrations ranged from 30 ng g⁻¹ to 1900 ng g⁻¹, PCBs from non-detect to 47 ng g⁻¹, chlordanes from 1.8 ng g⁻¹ to 60 ng g⁻¹, and DDTs from non-detect to 76 ng g⁻¹. Consistently higher PAH concentrations found in PS foam samples (300-1900 ng g⁻¹) led us to examine unexposed PS foam packaging materials and PS virgin pellets. Unexposed PS foam contained higher concentrations of PAHs (240-1700 ng g⁻¹) than PS virgin pellets (12-15 ng g⁻¹), suggesting that PAHs may be produced during manufacturing. Temporal trends of debris were investigated at one site, Ocean Beach, where storm events and beach maintenance were found to be important variables influencing debris present at a given time. © 2011 Elsevier Ltd. All rights reserved.

Van Benthum, W. A. J., et al. (1995). "Solids retention time in heterotrophic and nitrifying biofilms in a biofilm airlift suspension reactor." Water Science and Technology **32 (8)**: 53-60.

The solids retention time in biofilms was determined by using fluorescent microbeads as solid tracers. Attachment to and detachment from the biofilms, as well as surface concentration of the microbeads were measured. The surface concentration depended on the surface characteristics of the biofilms. The attachment rate was equal in three experiments and dependent on hydrodynamic conditions in the reactor. In all cases the detachment rate was much smaller than the attachment rate and larger than the average solids retention time of the active biomass. Release of the beads was determined by local, nonuniform detachment phenomena. Microbeads were observed to penetrate into the biofilms. This is not in accordance with conventional biofilm models. Therefore a new biofilm model concept is proposed. The biofilm is a dynamic structure, in which formation of cracks and fissures is taking place continuously. The crevices are filled with fresh biomass rapidly and particulates which are present are entrapped inside the biofilm.

Van Cauwenberghe, L., et al. (2013). "Assessment of marine debris on the Belgian Continental Shelf." Marine Pollution Bulletin **73**(1): 161-169.

A comprehensive assessment of marine litter in three environmental compartments of Belgian coastal waters was performed. Abundance, weight and composition of marine debris, including microplastics, was assessed by performing beach, sea surface and seafloor monitoring campaigns during two consecutive years. Plastic items were the dominant type of macrodebris recorded: over 95% of debris present in the three sampled marine compartments were plastic. In general, concentrations of macrodebris were quite high. Especially the number of beached debris reached very high levels: on average 6429 +/- 6767 items per 100. m were recorded. Microplastic concentrations were determined to assess overall abundance in the different marine compartments of the Belgian Continental Shelf. In terms of weight, macrodebris still dominates the pollution of beaches, but in the water column and in the seafloor microplastics appear to be of higher importance: here, microplastic weight is approximately 100 times and 400 times higher, respectively, than macrodebris weight. © 2013 Elsevier Ltd.

Van Colen, C., et al. (2020). "Does microplastic ingestion by zooplankton affect predator-prey interactions? An experimental study on larviphagy." Environmental Pollution **256**: 113479.

Litter is omnipresent in the ocean where it can be ingested by marine biota. Although ingestion of microplastics (MPs) is abundantly reported, insights into how MP can influence predator-prey interactions currently limits our understanding of the ecological impact of MPs. Here we demonstrate trophic transfer of MPs from zooplankton to benthic filter feeders, through consumption of contaminated prey (i.e. prey with ingested MP). However, predation rates of contaminated prey were significantly lower as compared to predation rates of prey that had no MPs ingested. As filter feeder clearance rates were not affected by consumption of MPs, the lower predation rates of contaminated prey appear to be primarily explained by disruption in zooplankton swimming behaviour that reduces their filtration risk. This is the first study that shows how MPs can change predator-prey interactions that are involved in the coupling between the pelagic and seabed habitat.

van der Hal, N., et al. (2017). "Exceptionally high abundances of microplastics in the oligotrophic Israeli Mediterranean coastal waters." Marine Pollution Bulletin **116**(1-2): 151-155.

Seasonal sea surface microplastic distribution was recorded at 17 sites along the Israeli Mediterranean coast. Microplastics (0.3-5 mm) were found in all samples, with a mean abundance of 7.68 +/- 2.38 particles/m³ or 1,518,340 particles/km². Some areas had higher abundances of microplastics than others, although differences were neither consistent nor statistically significant. In some cases microplastic particles were found floating in large patches. One of these patches contained an extraordinary number of plastic particles; 324 particles/m³ or 64,812,600 particles/km². Microplastic abundances in Israeli coastal waters are disturbingly high; mean values were 1-2 orders of magnitude higher than abundances reported in other parts of the world. Light-colored (white or transparent) fragments were by far more abundant than all other microplastic colors and types. The results of this study underline the need for action to reduce the flux of plastics to the marine environment. Copyright © 2016 Elsevier Ltd

van der Hal, N., et al. (2020). "Uptake and incorporation of PCBs by eastern Mediterranean rabbitfish that consumed microplastics." Marine Pollution Bulletin **150**: 110697.

Two experiments were executed to assess the feasibility of Polychlorinated Biphenyls (PCBs) transfer to fish tissues via MPs as a vector. PCBs that occur in the marine environment were tested for their adsorption to four different MP types. PCB congeners showed the highest adsorption levels to Polypropylene homo-polymer. The uptake of PCBs through MP ingestion was tested in an outdoor mesocosm using the herbivorous rabbitfish, Siganus rivulatus in the eastern Mediterranean Sea. Polypropylene homo-polymer particles (0.3-5.0mm) pre saturated with 11 PCB congeners, in two concentrations (500ng/g and 5000ng/g), were mixed with dough and offered to the fish. PCBs were identified after two weeks in fish muscle tissues, but not in the liver. These results suggest that ingestion of contaminated MP by rabbitfish might harm them in the long run, and perhaps even those who consume them on a regular basis, e.g. rabbitfish predators and humans.

van der Wel, C., et al. (2017). "Microparticle Assembly Pathways on Lipid Membranes." Biophysical Journal **113**(5): 1037-1046.

Understanding interactions between microparticles and lipid membranes is of increasing importance, especially for unraveling the influence of microplastics on our health and environment. Here, we study how a short-ranged adhesive force between microparticles and model lipid membranes causes membrane-mediated particle assembly. Using confocal microscopy, we observe the initial particle attachment to the membrane, then particle wrapping, and in rare cases spontaneous membrane tubulation. In the attached state, we measure that the particle mobility decreases by 26%. If multiple particles adhere to the same vesicle, their initial single-particle state determines their interactions and subsequent assembly pathways: 1) attached particles only aggregate when small adhesive vesicles are present in solution, 2) wrapped particles reversibly attract one another by membrane deformation, and 3) a combination of wrapped and attached particles form membrane-mediated dimers, which further assemble into a variety of complex structures. The experimental observation of distinct assembly pathways, induced only by a short-ranged membrane-particle adhesion, shows that a cytoskeleton or other active components are not required for microparticle aggregation. We suggest that this membrane-mediated microparticle aggregation is a reason behind reported long retention times of polymer microparticles in organisms.

Van Deun, K., et al. (2008). "Short-chain fatty acids and L-lactate as feed additives to control Campylobacter jejuni infections in broilers." Avian Pathology **37**(4): 379-383.

The usefulness of butyrate, acetate, propionate and l-lactate for the control of Campylobacter jejuni infections in broilers was assessed. For this purpose, the effect of these acids on the growth of C. jejuni in broth and intestinal mucous was determined, as well as their influence on the invasiveness of C. jejuni in intestinal epithelial cells. From these in vitro obtained results, one acid was retained for use as a feed additive in an in vivo trial. Butyrate was the most successful of the short-chain fatty acids, with 12.5 mM being bactericidal for C. jejuni at pH 6.0. Propionate and acetate had a bacteriostatic effect at 50 mM. None of the short-chain fatty acids had a bactericidal effect at pH 7.5 at a maximum concentration of 50 mM. Mucous increased the minimum bactericidal concentration of butyrate, but not the bacteriostatic concentrations of propionate or acetate. When C. jejuni was incubated in growth subinhibitory concentrations of butyrate, acetate or propionate or 25 mM L-lactate, no alteration in the invasive capabilities of C. jejuni in Caco-2 cells was observed. The addition of butyrate-coated micro-beads to the feed was unsuccessful to reduce C. jejuni caecal colonization in a seeder model using 2-week-old broilers. In conclusion, despite the marked bactericidal effect of butyrate towards C. jejuni in vitro, butyrate-coated micro-beads do not protect broilers from caecal colonization with C. jejuni in the applied test conditions. This might be partially ascribed to the protective effect of mucous and the rapid absorption of butyrate by the enterocytes.

Van Dommelen, S., et al. (2016). "Exposure of cancer cells to EGFR-inhibitors changes protein composition of extracellular vesicles." Journal of Extracellular Vesicles **5**: 5-6.

Background: Tumour cell-derived extracellular vesicles (EVs) reflect the status of the parental cells. This makes EVs promising candidates for biomarkers, for example to monitor treatment. In this study, we exposed tumour cells to cetuximab (a monoclonal antibody that blocks the activation of epidermal growth factor receptor (EGFR) and erlotinib (a kinase inhibitor blocking EGFR-signal transduction) and examined the effect on extracellular vesicle composition. Method(s): We exposed A431 human epidermoid carcinoma cells to 1 mM erlotinib or 100 mg/ml cetuximab. In one set-up we used ultracentrifugation to isolate extracellular vesicles followed by western blotting of EGFR and phospho-EGFR (pEGFR) and vesicles markers Alix, TSG101 and CD9. In another set-up we captured the extracellular vesicles with magnetic microbeads and isolated them in a magnetic stand. We used fluorescent antibodies to probe the vesiclesurface for EGFR, CD147 and tetraspanins and analysed fluorescence on a flow cytometer. Result(s): Using the ultracentrifugation set-up, we could demonstrate that both

EGFR and pEGFR on the EVs were reduced after cetuximab treatment, reflecting similar changes in the parental cells. Also the expression of the tetraspanin CD9 was reduced. Using density gradient ultracentrifugation, we could observe that cetuximab bound to EVs. EV-associated cetuximab retained its activity. For the magnetic beads conjugated with anti-CD9 antibody we could capture tumour-derived EVs directly from cell culture medium. Analysis by flow cytometry showed marked loss of CD147 and EGFR for EVs form cetuximab treated cells, which was not the case for cells treated with erlotinib. Discussion(s): Cetuximab treatment alters the composition of EVs, reflecting the parental cell status. This indicates that EVs could serve as biomarkers to monitor cetuximab treatment efficacy.

Van Driessche, W., et al. (1993). "An automatic monitoring system for epithelial cell height." Pflugers Archiv - European Journal of Physiology **425**(1-2): 164-171.

This paper describes an automatic method to measure cell height (h) of epithelia grown as monolayers on transparent filter supports. Tissues are mounted in an Ussing-type chamber enabling solution exchange on both sides. The apical and basal side of the epithelial cells are marked with fluorescent beads. The image of the fluospheres is captured with a video camera and processed by a computer-based video imaging system. One basal reference bead in a gelatin layer on the filter support and up to three beads attached at the apical surface are used to monitor changes in cell height of three cells simultaneously. The focusing of the microbeads is done automatically by moving the objective with a piezoelectric device mounted on the nosepiece of the microscope. The algorithm for locating the bead is based on the changes in fluorescent light intensity emitted by the fluospheres. The method has an accuracy higher than 0.1 micron and a time resolution as low as 6 s if measurements are restricted to one bead at the apical side. The method was tested on artificial model systems and used to measure volume changes in renal cultured epithelia (A6) after exposing the serosal surface to hypotonic solutions and replacing cell-impermeable sucrose by an organic compound (glycerol) with a smaller reflection coefficient. Serosal hypotonicity elicited a rapid volume increase followed by regulatory volume decrease, whereas the organic compound replacement caused a steady increase in cell volume.

van Franeker, J. A., et al. (2011). "Monitoring plastic ingestion by the northern fulmar Fulmarus glacialis in the North Sea." Environmental Pollution **159**(10): 2609-2615.

The abundance of plastics in stomachs of northern fulmars from the North Sea is used in the OSPAR Ecological Quality Objective (EcoQO) for marine litter. The preliminary EcoQO defines acceptable ecological quality as the situation where no more than 10% of fulmars exceed a critical level of 0.1 g of plastic in the stomach. During 2003–2007, 95% of 1295 fulmars sampled in the North Sea had plastic in the stomach (on average 35 pieces weighing 0.31 g) and the critical level of 0.1 g of plastic was exceeded by 58% of birds, with regional variations ranging from 48 to 78%. Long term data for the Netherlands since the 1980s show a decrease of industrial, but an increase of user plastics, with shipping and fisheries as the main sources. The EcoQO is now also used as an indicator for Good Environmental Status in the European Marine Strategy Framework Directive. [Copyright &y& Elsevier] van Franeker, J. A., et al. (2018). "Plastic ingestion by harbour porpoises <italic>Phocoena phocoena</italic> in the Netherlands: Establishing a standardised method." AMBIO - A Journal of the Human Environment **47**(4): 387-397.

Stomach contents of harbour porpoises (<italic>Phocoena phocoena</italic>) collected in the Netherlands between 2003 and 2013 were inspected for the presence of plastic and other man-made litter. In 654 stomach samples the frequency of occurrence of plastic litter was 7% with less than 0.5% additional presence of non-synthetic man-made litter. However, we show that when a dedicated standard protocol for the detection of litter is followed, a considerably higher percentage (15% of 81 harbour porpoise stomachs from the period 2010-2013) contained plastic litter. Results thus strongly depended on methods used and time period considered. Occurrence of litter in the stomach was correlated to the presence of other non-food remains like stones, shells, bog-wood, etc., suggesting that litter was often ingested accidentally when the animals foraged close to the bottom. Most items were small and were not considered to have had a major health impact. No evident differences in ingestion were found between sexes or age groups, with the exception that neonates contained no litter. Polyethylene and polypropylene were the most common plastic types encountered. Compared to earlier literature on the harbour porpoise and related species, our results suggest higher levels of ingestion of litter. This is largely due to the lack of dedicated protocols to investigate marine litter ingestion in previous studies. Still, the low frequency of ingestion, and minor number and mass of litter items found in harbour porpoises in the relatively polluted southern North Sea indicates that the species is not a strong candidate for annual monitoring of marine litter trends under the EU marine strategy framework directive. However, for longer-term comparisons and regional differences, with proper dedicated protocols applied, the harbour porpoise has specific use in quantifying litter presence in the, for that specific objective, poorly studied benthic marine habitat. [ABSTRACT FROM AUTHOR]

van Franeker, J. A. and K. L. Law (2015). "Seabirds, gyres and global trends in plastic pollution." Environmental Pollution **203**: 89-96.

Fulmars are effective biological indicators of the abundance of floating plastic marine debris. Long-term data reveal high plastic abundance in the southern North Sea, gradually decreasing to the north at increasing distance from population centres, with lowest levels in high-arctic waters. Since the 1980s, pre-production plastic pellets in North Sea fulmars have decreased by ~75%, while user plastics varied without a strong overall change. Similar trends were found in net-collected floating plastic debris in the North Atlantic subtropical gyre, with a ~75% decrease in plastic pellets and no obvious trend in user plastic. The decreases in pellets suggest that changes in litter input are rapidly visible in the environment not only close to presumed sources, but also far from land. Floating plastic debris is rapidly “lost” from the ocean surface to other as-yet undetermined sinks in the marine environment. [ABSTRACT FROM AUTHOR]

van Leusden, P., et al. (2016). "Structure engineering of filled protein microbeads to tailor release of oil droplets in gastric digestion." Food & Function **7**(8): 3539-3547.

Oil-soluble components can be encapsulated in an O/W1/W2 microsystem, in which they are dissolved in oil droplets dispersed in a gelled microbead (W1), which forms a barrier between the oil droplets and the aqueous continuous phase (W2). We investigated the rate and mechanism of breakdown of protein microbeads in a simulated gastric system, and studied the influence of microbead protein concentration, gelling method (cold-set, slow and fast heat-set), and further processing (freeze-drying), on the breakdown process. Breakdown rate decreased with increasing protein content of the beads, for the same method of production. Due to the porosity of the slowly-heated heat-set beads, breakdown occurred evenly throughout the entire bead. Cold-set microbeads of 10% protein broke down slightly slower than the heat-set microbeads of 15%. The denser surface of the 10% beads slowed down the diffusion of the enzymes into the bead's interior, causing the beads to be broken down from the outside inward. All these beads broke down within one hour. Increasing the rate of temperature increase during the heating step dramatically slowed breakdown. There was no significant breakdown of rapidly heated beads within 138 minutes, even though no difference in microstructure between rapidly and slowly heated beads was visible with electron microscopy. Freeze-drying of the beads also slowed their breakdown. After 132 minutes more than half the measured particle volume of were intact beads. Freeze-drying changed the microstructure of the beads irreversibly: rehydrating the dried beads did not result in a breakdown behaviour similar to that of unprocessed beads.

Van Nguyen, Q., et al. (2019). "Improvement of bio-crude oil properties via co-pyrolysis of pine sawdust and waste polystyrene foam." Journal of Environmental Management **237**: 24-29.

Conversion technology of solid biomass to liquid fuel, named bio-crude oil, has been researched widely for the production of renewable energy to replace fossil fuel oil. As the result of many admirable researches, fast pyrolysis technology for bio-crude oil production is close to commercialization. However, bio-crude oil has unsatisfactory properties compared to general petroleum oil, for instance, low heating value, high water content, and high viscosity. In this study, pine sawdust (SD) biomass was co-pyrolyzed with waste polystyrene foam (WPSF), which was expected to improve the bio-crude oil quality due to high heating value and non-oxygen composition of polystyrene. The co-pyrolysis experiment was conducted in a bubbling fluidized bed reactor under the following conditions: temperature of 500 °C which was chosen based on the results from thermogravimetric analysis of SD and WPSF, nitrogen flow rate of 20–25 L/min., and feeding rate of 200 g/hr. Various mixing ratios of SD/WPSF by weight percentage were tested as follows: 100/0, 95/5, 90/10, 85/15, 80/20, 75/25, 70/30, 60/40, 50/50, 25/75, 0/100. Experimental results showed that in case of only SD feeding the bio-crude oil yield and higher heating value (HHV) were 48.83 wt% and 17.81 MJ/kg respectively. By contrast, oil yield and HHV in case of 25% SD with 75% WPSF mixture were 63.31 wt% and 39.65 MJ/kg respectively. Additional analysis showed that water content, and acetic acid concentration of bio-crude oil from co-pyrolysis of SD/WPSF mixture were decreased almost proportionally with the increasing WPSF ratio. Furthermore, measured values of water content, and acetic acid concentration were lower than the calculated values by linear interpolation, which means that the synergistic effect between SD and WPSF was achieved during the co-pyrolysis. In conclusion, co-pyrolysis of SD

and WPSF was found as a promising solution to improve bio-crude oil quality. With this technology, the industrial growth of bio-crude oil area is expected as well as waste plastic. Highlights • Pine sawdust (SD) biomass was co-pyrolyzed with waste polystyrene foam (WPSF). • HHV of bio-crude oil yield was increased for SD/WPSF mixtures. • The water content, and acetic acid concentration of SD/WPSF mixtures were decreased. van Raamsdonk, L. W. D., et al. (2020). "Current Insights into Monitoring, Bioaccumulation, and Potential Health Effects of Microplastics Present in the Food Chain." Foods **9**(1): 09.

Microplastics (MPs) are considered an emerging issue as environmental pollutants and a potential health threat. This review will focus on recently published data on concentrations in food, possible effects, and monitoring methods. Some data are available on concentrations in seafood (fish, bivalves, and shrimps), water, sugar, salt, and honey, but are lacking for other foods. Bottled water is a considerable source with numbers varying between 2600 and 6300 MPs per liter. Particle size distributions have revealed an abundance of particles smaller than 25 micro m, which are considered to have the highest probability to pass the intestinal border and to enter the systemic circulation of mammals. Some studies with mice and zebrafish with short- or medium-term exposure (up to 42 days) have revealed diverse results with respect to both the type and extent of effects. Most notable modifications have been observed in gut microbiota, lipid metabolism, and oxidative stress. The principal elements of MP monitoring in food are sample preparation, detection, and identification. Identified data gaps include a lack of occurrence data in plant- and animal-derived food, a need for more data on possible effects of different types of microplastics, a lack of in silico models, a lack of harmonized monitoring methods, and a further development of quality assurance.

Van Ta, T., et al. (2019). "The correlation between clinical manifestations and cytokine concentrations in Vietnamese children with dengue hemorrhagic fever." Systematic Reviews in Pharmacy **10**(2): 15-21.

Background: All over the world, dengue hemorrhagic fever (DHF) causes mortality each year. To determine the development and severity of DHF, healthcare professionals usually record and monitor clinical manifestations and the functioning of the immune system. Nevertheless, many issues remain unclear as to the influence of cytokine concentrations on clinical symptoms. Objective(s): This study was aimed at ascertaining the correlation between clinical manifestations and cytokine concentrations in children with DHF. Material(s) and Method(s): A prospective cohort study was conducted involving 234 patients who were serologically diagnosed with dengue virus infection in Tien Giang Hospital. The patients' clinical symptoms, such as fever duration on hospital admission, vomiting, abdominal pain, mucosal bleeding, bleeding under the skin, hepatomegaly, and high bodily temperature, were documented every day from admission to discharge. Cytokine concentrations were detected and measured via multiplex microbead immunoassay. The correlation between cytokine concentration and each clinical manifestation was then identified. Result(s): Interleukin-6 (IL-6) concentration affected the manifestation of abdominal pain in the patients, and high concentrations of IL-2, IL-4, and IL-13 increased the occurrence of hepatomegaly. Temperature was influenced by IL-5, IL-10, and IL-12 concentrations. Conclusion(s): The findings confirmed the correlation between cytokine van Truong, N. and C. beiPing (2019). "Plastic marine debris: sources, impacts and management." International Journal of Environmental Studies **76**(6): 953-973.

Marine plastic has many negative impacts on coastal countries, including Vietnam. Vietnamese waters face problems of marine pollution owing to plastic waste. There are few studies on controlling marine plastic waste generated by marine-based activities. Therefore, this paper aims to provide a general view of marine plastics based on existing academic articles, and the impacts on marine animals and on human health. The paper includes a brief account of the quantity of marine plastic waste on coastal Vietnam and offers some recommendations for Vietnam to minimise and manage plastic waste generated by ships. [ABSTRACT FROM AUTHOR]

Van Vuren, A. J., et al. (2019). "A unique monocyte transcriptome discriminates sickle cell disease from other hereditary hemolytic anemias and shows the particular importance of lipid and interferon signaling." Blood. Conference: 61st Annual Meeting of the American Society of Hematology, ASH **134**(Supplement 1).

Introduction Sickle cell disease (SCD) is a hereditary hemolytic disease characterized by a complex pathophysiology including inflammation and oxidative stress. Intravascular hemolysis leads to release of heme, an erythrocyte-derived Danger Associated Molecular Pattern (e-DAMP) that augments Toll Like Receptor 4 (TLR4) signaling. TLR4 signaling is important in development of acute and chronic complications in SCD. We investigated gene expression profiles of TLR4⁺ cells (by positive selection of its co-receptor CD14) of patients with SCD and other hemolytic anemias to identify differential regulated pathophysiological pathways. Methods Analyses were performed in 60 adults with hereditary hemolytic anemia and 10 healthy controls included in the ZEbRA cohort (UMC Utrecht, [NL5189]). Patients treated with systemic antiinflammatory drugs were excluded (n=1). Deferasirox (DFX)-treated SCD patients were analyzed separately as DFX ameliorated pro-inflammatory effects of heme. CD14⁺ cells were isolated using anti-CD14 microbeads. RNA sequencing was performed on a Nextseq500 platform (Illumina) using a single-end 75bp high-output run. Differentially expressed genes (DEGs) were identified using DESeq2 v1.24.0 in R. To correct for presence of reticulocytes and lymphocytes, data were corrected for expression of 4 hemoglobin (HBA1, HBB, HBG1, HBG2) and 4 T cell specific genes (CD3E, CD3D, CD3G, CD247). A list was constructed from all genes differentially expressed (adj. p<0.01; absolute log2fold change >1) in both the comparisons of SCD without DFX versus other hemolytic anemias and of SCD without DFX versus healthy controls. Pathway enrichment analysis (ReactomePA v1.28.0 in R) was performed with preselected DEGs (adj. p<0.1; absolute log2fold change >0.5). P-values were adjusted with the Benjamini-Hochberg procedure. Results Demographics and hematological values are provided in Table 1. Principal component analysis based on RNA sequencing data separated SCD patients without DFX from hemolytic anemia patients, healthy controls and SCD patients with DFX (Figure 1). Analysis of DEGs discriminating SCD patients from both patients with other hemolytic anemias and healthy controls rendered 29 genes (Figure 2). Heme

oxygenase-1 (HMOX1) was one of these genes (versus healthy controls adj. p=5.6E-13; versus other hemolytic anemias adj. p=3.3E-15) and this is in line with the hypothesis that intravascular free heme is an important effector of gene regulation in monocytes. This sets SCD apart from the other studied hemolytic anemias. The other 28 genes included, PPARG, GUCY1A1, KLF5 and CXCR3 signaling (CXCL9 and CXCL11) which are associated with vascular remodeling and development of pulmonary hypertension. The list of 29 DEGs highlights interesting differences in gene expression of two processes related to immune signaling: CXCR3 signaling by CXCL9 and CXCL11, and lipid metabolism (STARD4, DLC1, SQLE, ME1). Pathway enrichment analysis showed enrichment of genes involved in IFN signaling (type I and II) in SCD versus healthy controls (adj. p=4.4E-16). And, in line with the list of 29 genes, enrichment of genes concerning chemokine signaling in SCD versus both healthy controls and other hemolytic anemias (respectively adj. p=0.06 and adj. p=0.01) and cholesterol biosynthesis in SCD versus other hemolytic anemias (adj. p=0.09). Conclusion Our data shows the unique inflammatory profile of SCD monocytes as opposed to other hemolytic anemias. Moreover, it suggests that lipid metabolism and IFN signaling are important differentiating immune signaling pathways. It is known that alterations in plasma lipid levels in SCD relate to hemolytic severity and vasculopathy. Our data suggests an important role for lipid biology in SCD monocytes. We hypothesize on an important contribution of cholesterol accumulation in enhancement of TLR4 signaling, as lipid rafts accelerated Nf-kB activation in macrophages. (Lee et al., Nat. Commun. 2017; Koseki et al., J. Lip. Res. 2007) The importance of type I and II IFN signaling in SCD sugges s widespread involvement of the immune system. IFNg-inducible cytokines CXCL9 and CXCL11 are associated with Th1 polarization and activation. In summary, the data support the unique role of monocyte immune signaling in SCD. Furthermore, we identified pathways that seem to be relevant for immune regulation and thereby for development of disease complications. (Figure Presented).

van Weert, S., et al. (2019). "Effects of nanoplastics and microplastics on the growth of sediment-rooted macrophytes." Science of the Total Environment **654**: 1040-1047.

Plastic debris of all sizes has been detected in marine, terrestrial and freshwater habitats. Effects of plastic debris on macrophytes have hardly been studied, despite their importance in aquatic ecosystems. We provide the first experimental study exploring nano- and microplastic effects on the growth of sediment-rooted macrophytes. Myriophyllum spicatum and Elodea sp. were exposed to sediments amended with six doses of polystyrene (PS) nanoplastic (50-190nm, up to 3% sediment dry weight) and PS microplastic (20-500mum, up to 10% dry weight) under laboratory conditions. Both macrophyte species were tested for changes in root and shoot dry weight (DW), relative growth rate (RGR), shoot to root ratio (S:R), main shoot length and side shoot length. Microplastics did not produce consistent dose-effect relationships on the endpoints tested, except that main shoot length was reduced for M. spicatum with increasing microplastic concentration. Nanoplastic significantly reduced S:R for both macrophytes as a result of increased root biomass compared to shoot biomass. Nanoplastic also caused a decrease in M. spicatum main shoot length; however, shoot biomass was not affected. Elodea sp. side shoot length, root and shoot biomass and RGR were positively correlated to the nanoplastic concentration. All effects occurred at higher than environmentally realistic concentrations, suggesting no immediate implications for ecological risks. Our study did not aim for the elucidation of the exact mechanistic processes that cause the effects, however, particle size seems to play an important factor. CAPSULE: Nano- and microplastics affect growth of sediment-rooted macrophytes.

van Wezel, A., et al. (2016). "Release of primary microplastics from consumer products to wastewater in the Netherlands." Environmental Toxicology & Chemistry **35**(7): 1627-1631.

The authors estimate the release of primary microplastics from consumer products-cosmetics and personal care products, cleaning agents, and paint and coatings-via sewage effluent as an expected relevant route to the marine environment. Total estimated concentrations in the 3 scenarios are 0.2 mug/L, 2.7 mug/L, and 66 mug/L in sewage-treatment plant (STP) effluent, respectively. All product categories relevantly contribute. Predicted concentrations are compared with reported actual concentrations in STP effluents. Environ Toxicol Chem 2016;35:1627-1631. © 2015 SETAC.

Vancamp, P., et al. (2019). "Gender-specific effects of transthyretin on neural stem cell fate in the subventricular zone of the adult mouse." Scientific Reports **9**(1): 19689.

Choroid plexus epithelial cells produce and secrete transthyretin (TTR). TTR binds and distributes thyroid hormone (TH) to brain cells via the cerebrospinal fluid. The adult murine subventricular zone (SVZ) is in close proximity to the choroid plexus. In the SVZ, TH determines neural stem cell (NSC) fate towards a neuronal or a glial cell. We investigated whether the loss of TTR also disrupted NSC fate choice. Our results show a decreased neurogenic versus oligodendrogenic balance in the lateroventral SVZ of Ttr knockout mice. This balance was also decreased in the dorsal SVZ, but only in Ttr knockout male mice, concomitant with an increased oligodendrocyte precursor density in the corpus callosum. Quantitative RTqPCR analysis following FACS-dissected SVZs, or marked-coupled microbeads sorting of in vitro neurospheres, showed elevated Ttr mRNA levels in neuronal cells, as compared to uncommitted precursor and glial cells. However, TTR protein was undetectable in vivo using immunostaining, and this despite the presence of Ttr mRNA-expressing SVZ cells. Altogether, our data demonstrate that TTR is an important factor in SVZ neuro- and oligodendrogenesis. They also reveal important gender-specific differences and spatial heterogeneity, providing new avenues for stimulating endogenous repair in neurodegenerative diseases.

Vance, D. T., et al. (2013). "Proteomic and functional comparison of phagocytosis by Fc versus oxLDL receptors in human macrophages." FEBS Journal **1)**: 475.

The inflammatory activation of macrophages by solid aggregates of oxidized low density lipoprotein (oxLDL) in the intima of the arteries is a decisive event on the path to coronary artery disease. However the receptor mechanism by which oxLDL aggregates interact with the macrophages to trigger their phagocytosis is not well understood. The role of the receptor signaling complexes in phagocytosis was examined using polystyrene microbeads opsonized with the ligands oxLDL versus immunoglobulin G (IgG). The phagocytosis of 2 lm polystyrene beads opsonized with ox- LDL showed different temporal patterns of internalization and modification by serum factors when compared to that of IgGcoated beads. Actin was observed to polymerize at the site of the ligand-microbead receptors and to form a dense layer that surrounded the particles from the time of binding to engulfment. Liquid chromatography and tandem mass spectrometry were used to characterize the receptor complexes associated with oxLDL- versus IgG-coated beads leading to the identification of a detailed list of actin related proteins, binding factors, and signaling enzymes that were specific to the oxLDL- versus IgGligand. In agreement with the mass spectral results, treatment with pharmacological inhibitors of SRC, PLC and JAK or the actin cytoskeleton prevented the phagocytosis of both oxLDL and IgG microbeads as measured by laser confocal microscopy. Specific isoforms of PI3K, FAK and SYK were strongly associated with the oxLDL receptor complex and the phagocytosis of oxLDL microbeads was more sensitive to inhibition of PI3K, FAK and SYK activity compared to that of IgG. Silencing RNA against SYK inhibited the phagocytosis of oxLDL microbeads but did not inhibit clearance of IgG opsonized beads. The results showed the differential mass spectral analysis of functionally similar receptors and revealed receptor-specific drug targets that were inhibited or silenced to prevent the inflammatory accumulation of oxLDL particles but that did not prevent bacterial clearance by macrophages.

VandenBerg, N. (1991). "Plastic Film Recycling." BioCycle **32**(12): 67.
Film plastics, the thin-gauge plastics used for wrappings and plastic bags, constitue up to 60% of the plastic waste stream and about 3.5% of the solid waste stream, yet little attention has been paid to them in plastic recycling programs. Film plastic recycling efforts must target sources such as commercial and institutional sources, address contamination issues, and develop processing capacities. Final markets for clean film plastic must be developed as well.

Vandermeersch, G., et al. (2015). "A critical view on microplastic quantification in aquatic organisms. (Special Issue: Non-regulated environmental contaminants in seafood: contributions of the ECsafeSEAFOOD EU project.)." Environmental Research **143**(Part B): 46-55.
Microplastics, plastic particles and fragments smaller than 5 mm, are ubiquitous in the marine environment. Ingestion and accumulation of microplastics have previously been demonstrated for diverse marine species ranging from zooplankton to bivalves and fish, implying the potential for microplastics to accumulate in the marine food web. In this way, microplastics can potentially impact food safety and human health. Although a few methods to quantify microplastics in biota have been described, no comparison and/or intercalibration of these techniques have been performed. Here we conducted a literature review on all available extraction and quantification methods. Two of these methods, involving wet acid destruction, were used to evaluate the presence of microplastics in field-collected mussels (Mytilus galloprovincialis) from three different "hotspot" locations in Europe (Po estuary, Italy; Tagus estuary, Portugal; Ebro estuary, Spain). An average of 0.18+or-0.14 total microplastics g⁻¹ w.w. for the Acid mix Method and 0.12+or-0.04 total microplastics g⁻¹ w.w. for the Nitric acid Method was established. Additionally, in a pilot study an average load of 0.13+or-0.14 total microplastics g⁻¹ w.w. was recorded in commercial mussels (Mytilus edulis and M. galloprovincialis) from five European countries (France, Italy, Denmark, Spain and The Netherlands). A detailed analysis and comparison of methods indicated the need for further research to develop a standardised operating protocol for microplastic quantification and monitoring.

Vandermeersch, G., et al. (2015). "Environmental contaminants of emerging concern in seafood--European database on contaminant levels." Environmental Research **143**(Pt B): 29-45.
Marine pollution gives rise to concern not only about the environment itself but also about the impact on food safety and consequently on public health. European authorities and consumers have therefore become increasingly worried about the transfer of contaminants from the marine environment to seafood. So-called "contaminants of emerging concern" are chemical substances for which no maximum levels have been laid down in EU legislation, or substances for which maximum levels have been provided but which require revision. Adequate information on their presence in seafood is often lacking and thus potential risks cannot be excluded. Assessment of food safety issues related to these contaminants has thus become urgent and imperative. A database (www.ecsafeseafooddbase.eu), containing available information on the levels of contaminants of emerging concern in seafood and providing the most recent data to scientists and regulatory authorities, was developed. The present paper reviews a selection of contaminants of emerging concern in seafood including toxic elements,

endocrine disruptors, brominated flame retardants, pharmaceuticals and personal care products, polycyclic aromatic hydrocarbons and derivatives, microplastics and marine toxins. Current status on the knowledge of human exposure, toxicity and legislation are briefly presented and the outcome from scientific publications reporting on the levels of these compounds in seafood is presented and discussed.

Vang, D. P., et al. (2013). "Induction of invasive transitional cell bladder carcinoma in immune intact human MUC1 transgenic mice: a model for immunotherapy development." Journal of Visualized Experiments(80): e50868.

A preclinical model of invasive bladder cancer was developed in human mucin 1 (MUC1) transgenic (MUC1.Tg) mice for the purpose of evaluating immunotherapy and/or cytotoxic chemotherapy. To induce bladder cancer, C57BL/6 mice (MUC1.Tg and wild type) were treated orally with the carcinogen N-butyl-N-(4-hydroxybutyl)nitrosamine (OH-BBN) at 3.0 mg/day, 5 days/week for 12 weeks. To assess the effects of OH-BBN on serum cytokine profile during tumor development, whole blood was collected via submandibular bleeds prior to treatment and every four weeks. In addition, a MUC1-targeted peptide vaccine and placebo were administered to groups of mice weekly for eight weeks. Multiplex fluorometric microbead immunoanalyses of serum cytokines during tumor development and following vaccination were performed. At termination, interferon gamma (IFN-gamma)/interleukin-4 (IL-4) ELISpot analysis for MUC1 specific T-cell immune response and histopathological evaluations of tumor type and grade were performed. The results showed that: (1) the incidence of bladder cancer in both MUC1.Tg and wild type mice was 67%; (2) transitional cell carcinomas (TCC) developed at a 2:1 ratio compared to squamous cell carcinomas (SCC); (3) inflammatory cytokines increased with time during tumor development; and (4) administration of the peptide vaccine induces a Th1-polarized serum cytokine profile and a MUC1 specific T-cell response. All tumors in MUC1.Tg mice were positive for MUC1 expression, and half of all tumors in MUC1.Tg and wild type mice were invasive. In conclusion, using a team approach through the coordination of the efforts of pharmacologists, immunologists, pathologists and molecular biologists, we have developed an immune intact transgenic mouse model of bladder cancer that expresses hMUC1.

Vangipuram, S. D. and W. D. Lyman (2010). "Ethanol alters cell fate of fetal human brain-derived stem and progenitor cells." Alcoholism: Clinical & Experimental Research **34**(9): 1574-1583.

BACKGROUND: Prenatal ethanol (ETOH) exposure can lead to fetal alcohol spectrum disorder (FASD). We previously showed that ETOH alters cell adhesion molecule gene expression and increases neurosphere size in fetal brain-derived neural stem cells (NSC). Here, our aim was to determine the effect of ETOH on the cell fate of NSC, premature glial-committed precursor cells (GCP), and premature neuron-committed progenitor cells (NCP).

METHODS: NSC, GCP, and NCP were isolated from normal second-trimester fetal human brains (n = 3) by positive selection using magnetic microbeads labeled with antibodies to CD133 (NSC), A2B5 (GCP), or PSA-NCAM (NCP). As a result of the small percentage in each brain, NSC were cultured in mitogenic media for 72 hours to produce neurospheres. The neurospheres from NSC and primary isolates of GCP and NCP were used for all experiments. Equal numbers of the 3 cell types were treated either with mitogenic media or with differentiating media, each containing 0 or 100 mM ETOH, for 120 hours. Expression of Map2a, GFAP, and O4 was determined by

immunoflourescence microscopy and western blot analysis. Fluorescence intensities were quantified using Metamorph software by Molecular Devices, and the bands of western blots were quantified using densitometry.

RESULTS: ETOH in mitogenic media promoted formation of neurospheres by NSC, GCP, and NCP. Under control conditions, GCP attached and differentiated, NSC and NCP formed neurospheres that were significantly smaller in size than those in ETOH. Under differentiating conditions, Map2a expression increased significantly in NSC and GCP and reduced significantly in NCP, and GFAP expression reduced significantly in GCP and NCP, and Gal-C expression reduced significantly in all 3 cell types in the presence of ETOH compared to controls.

CONCLUSIONS: This study shows that ETOH alters the cell fate of neuronal stem and progenitor cells. These alterations could contribute to the mechanism for the abnormal brain development in FASD.

Vani, K., et al. (2017). "Analytic Response Curves of Clinical Breast Cancer IHC Tests." Journal of Histochemistry & Cytochemistry **65**(5): 273-283.

An important limitation in the field of immunohistochemistry (IHC) is the inability to correlate stain intensity with specific analyte concentrations. Clinical immunohistochemical tests are not described in terms of analytic response curves, namely, the analyte concentrations in a tissue sample at which an immunohistochemical stain (1) is first visible, (2) increases in proportion to the analyte concentration, and (3) ultimately approaches a maximum color intensity. Using a new immunostaining tool (IHControls), we measured the analytic response curves of the major clinical immunohistochemical tests for human epidermal growth factor receptor type II (HER-2), estrogen receptor (ER), and progesterone receptor (PR). The IHControls comprise the analytes HER-2, ER, and PR at approximately log concentration intervals across the range of biological expression, from 100 to 1,000,000 molecules per test microbead. We stained IHControls of various concentrations using instruments, reagents, and protocols from three major IHC vendors. Stain intensity at each analyte concentration was measured, thereby generating an analytic response curve. We learned that for HER-2 and PR, there is significant variability in test results between clinical kits for samples with analyte concentrations of approximately 10⁴ molecules/microbead. We propose that the characterization of immunostains is an important step toward standardization.

Vanitha, V., et al. (2010). "Polychlorinatedbiphenyls in milk and rumen liquor of stray cattle in Chennai." Tamilnadu Journal of Veterinary and Animal Sciences **6**(2): 71-74.

In this study, milk and rumen liquor of stray cattle were found to contain measurable concentration of PolyChlorinatedBiphenyls (PCB). A notable finding in this study is that stray cattle have high level of PCBs where as the PCB in control group can not be detected. Since, reduction in space in the urban areas has pushed the cattle population to fend themselves in the streets, bovine milk act as a potential source of PCBs for residents in Chennai. To our knowledge, this is the first comprehensive study on exposure of stray cattle to PCBs by intake of plastic waste in India.

Vannela, R. (2012). "Are We "Digging Our Own Grave" Under the Oceans?" Environmental Science & Technology **46**(15): 7932-7933.

The article discusses the threat that plastic debris in marine environments poses to life on earth. Topics include the estimated amount of plastic debris produced annually that ends up in the world's oceans, the expansion of the Great Pacific Garbage Patch, which is an area of intense ocean currents in the Pacific Ocean that accumulates marine debris, and the ecological impact of marine debris on benthic organisms. Also discussed is the allocation of resources to identify pollution sources, compounding effects of El Nino, and the threat of plastic marine debris to earth's entire food chain. The importance of focusing on socio-economic impacts, awareness, and education programs to reduce marine plastic debris is presented.

Varbanov, P. S. (2019). "The policy debate on sustainability: issues and strategy." Clean Technologies & Environmental Policy **21**(8): 1515-1516.

It has been argued in a previous Editorial (Varbanov, P.S., Sikdar, S. & Lee, C.T., Contributing to sustainability: addressing the core problems, Clean Techn Environ Policy (2018) 20: 1121. Of similar magnitude are microplastics pollution (de Souza Machado AA, Kloas W, Zarfl C, et al. (2018) Microplastics as an emerging threat to terrestrial ecosystems. The vertical reef-based facilities for open-sea mussel farming create integrated micro-ecosystems, taking as food the excessive nutrients in the seawater. [Extracted from the article]

Vardar, E., et al. (2018). "Microfluidic production of bioactive fibrin micro-beads embedded in crosslinked collagen used as an injectable bulking agent for urinary incontinence treatment." Acta Biomaterialia **67**: 156-166.

Endoscopic injection of bulking agents has been widely used to treat urinary incontinence, often due to urethral sphincter complex insufficiency. The aim of the study was to develop a novel injectable bioactive collagen-fibrin bulking agent restoring long-term continence by functional muscle tissue regeneration. Fibrin micro-beads were engineered using a droplet microfluidic system. They had an average diameter of 140mum and recombinant fibrin-binding insulin-like growth factor-1 (alpha₂PI₁₋₈-MMP-IGF-1) was covalently conjugated to the beads. A plasmin fibrin degradation assay showed that 72.5% of the initial amount of alpha₂PI₁₋₈-MMP-IGF-1 loaded into the micro-beads was retained within the fibrin micro-beads. In vitro, the growth factor modified fibrin micro-beads enhanced cell attachment and the migration of human urinary tract smooth muscle cells, however, no change of the cellular metabolic activity was seen. These bioactive micro-beads were mixed with genipin-crosslinked homogenized collagen, acting as a carrier. The collagen concentration, the degree of crosslinking, and the mechanical behavior of this bioactive collagen-fibrin injectable were comparable to reference samples. This novel injectable showed no burst release of the growth factor, had a positive effect on cell behavior and may therefore induce smooth muscle regeneration in vivo, necessary for the functional treatment of stress and other urinary incontinences.

STATEMENT OF SIGNIFICANCE: Urinary incontinence is involuntary urine leakage, resulting from a deficient function of the sphincter muscle complex. Yet there is no functional cure for this devastating condition using current treatment options. Applied physical and surgical therapies have limited success. In this study, a novel bioactive injectable bulking agent, triggering new muscle regeneration at the injection site, has been evaluated. This injectable consists of cross-linked collagen and fibrin micro-beads, functionalized with bound insulin-like growth factor-1 (alpha₂PI₁₋₈-MMP-IGF-1). These bioactive fibrin micro-beads induced human smooth muscle cell migration in vitro. Thus, this injectable bulking agent is apt to be a good candidate for regeneration of urethral sphincter muscle, ensuring a long-lasting treatment for urinary incontinence.

Vargas, E., et al. (2018). "Single-Step Incubation Determination of miRNAs in Cancer Cells Using an Amperometric Biosensor Based on Competitive Hybridization onto Magnetic Beads." Sensors **18**(3): 15.

This work reports an amperometric biosensor for the determination of miRNA-21, a relevant oncogene. The methodology involves a competitive DNA-target miRNA hybridization assay performed on the surface of magnetic microbeads (MBs) and amperometric transduction at screen-printed carbon electrodes (SPCEs). The target miRNA competes with a synthetic fluorescein isothiocyanate (FITC)-modified miRNA with an identical sequence for hybridization with a biotinylated and complementary DNA probe (b-Cp) immobilized on the surface of streptavidin-modified MBs (b-Cp-MBs). Upon labeling, the FITC-modified miRNA attached to the MBs with horseradish peroxidase (HRP)-conjugated anti-FITC Fab fragments and magnetic capturing of the MBs onto the working electrode surface of SPCEs. The cathodic current measured at -0.20 V (versus the Ag pseudo-reference electrode) was demonstrated to be inversely proportional to the concentration of the target miRNA. This convenient biosensing method provided a linear range between 0.7 and 10.0 nM and a limit of detection (LOD) of 0.2 nM (5 fmol in 25 muL of sample) for the synthetic target miRNA without any amplification step. An acceptable selectivity towards single-base mismatched oligonucleotides, a high storage stability of the b-Cp-MBs, and usefulness for the accurate determination of miRNA-21 in raw total RNA (RNA_t) extracted from breast cancer cells (MCF-7) were demonstrated.

Vargas, L. F., et al. (2009). "Effect of electron beam treatments on degradation kinetics of polylactic acid (PLA) plastic waste under backyard composting conditions." Packaging Technology & Science **22**(2): 97-106.

The effects of electron beam irradiation on backyard composting behaviour of polylactic acid (PLA) polymer were evaluated. Samples (10 mm² x 0.75 mm) from thermoformed PLA drinking cups were exposed to 10 MeV electron beam irradiation at doses of 0, 72, 144 and 216 kGy. Irradiated PLA samples were placed in heat-sealed, plastic screen and added to organic feedstock in a rotating composter within a computer-controlled environmental chamber for 10 weeks at 35 degrees C. Changes in weight, structural integrity and molecular weight were assessed over time. Results show that irradiation enhanced PLA breakdown. PLA weight decreased by increasing amounts as irradiation dose increased. Sample brittleness increased with irradiation dose and composting time. Finally, PLA molecular weight decreased as irradiation dose and compost time increased. Molecular weight D values for irradiated PLA were found to be about 430 kGy. After 1 week in a typical backyard composter, molecular weight D values increased to about 560 kGy and then fell to about 380 kGy after 2 weeks of composting. Samples irradiated at 216 kGy showed a reduction in weight of 9.4% after 10 weeks of composting, and a reduction of weight-average molecular weight of 93.7% after 6 weeks.

Varney, M. D., et al. (2012). "Methods for diagnostic HLA typing in disease association and drug hypersensitivity." Methods in Molecular Biology **882**: 27-46.

This chapter describes the application of diagnostic HLA typing for disease association and five methods used for specific HLA genotypes. The methods utilise a combination of polymerase chain reaction (PCR) amplification to detect sequence polymorphism by the presence or absence of amplification, nucleotide sequencing of the PCR product, and hybridisation of the PCR product with labelled probes. The probes are specific for sequence polymorphism associated with the genotype and are attached to either a Micro Bead or a Solid Phase. In addition, the

detection of single nucleotide polymorphism(s) which "tag" for the genotype using a real-time PCR is described.

Varo, I., et al. (2019). "Time-dependent effects of polystyrene nanoparticles in brine shrimp Artemia franciscana at physiological, biochemical and molecular levels." Science of the Total Environment **675**: 570-580.

Micro- (<5 mm) and nanoplastics (<1 micro m) are emerging threats for marine ecosystems worldwide. Brine shrimp Artemia is recognized as a suitable model among planktonic species for studying the impact of polystyrene nanoparticles (PS NPs) through short and long-term bioassays. Our study aims to evaluate the time-dependent effects of cationic amino-modified PS-NH₂ (50 nm) in A. franciscana after short- (48 h) and long-term exposure (14 days). For this purpose, nauplii were exposed to a concentration range of PS-NH₂ (0.1, 1, 3 and 10 micro g/mL) in natural sea water (NSW), and physiological, biochemical and molecular responses were investigated. Short-term exposure to PS-NH₂ caused a decrease in nauplii growth and affected the development in a concentration-dependent manner, long-term exposure impaired the survival, but not the growth and feeding behavior. Oxidative stress was detected after short term exposure as the decrease in the activity of antioxidant enzymes, and was fully evident in the long-term as lipid peroxidation, suggesting an accumulative effect. The decrease in Cholinesterase (ChE) activity observed indicates possible neurotoxic action of PS-NH₂. Also, Carboxylesterase (CbE) inhibition by PS-NH_{2,} described for the first time in this study, anticipates potential effects in biotransformation of exogenous and endogenous compounds, being the crustacean juvenile hormone methyl farnesoate (MF) that regulates development and molting, one candidate. Furthermore, short- and long-term exposure to PS-NH₂ affect the expression of genes involved in cell protection, development and molting. Overall, our results reveal that low PS-NH₂ concentrations induce physiological, biochemical and molecular (changes in gene expression) alterations in Artemia, and point at their potential risk for this model organism, supporting the general concern about nanoplastics occurrences in aquatic environments and their ability to represent an ecological threat for aquatic zooplanktonic species.

Varsha, Y. M. and R. Savitha (2011). "Overview on polyhydroxyalkanoates: A promising biopol." Journal of Microbial and Biochemical Technology **3**(5): 99-105.

Plastic pollution is creating the significant environmental and economic burdens since they consume the natural fuels (energy) and other natural resources. Beside this, they have long shelf time, debasing the environment in the numerous ways. The only way to trim down the hazards of plastic pollution is to decrease the use of plastic and thereby reducing its production. Degradations and recycling steps followed to diminish these plastic was of no use since it takes abundant stress (mechanical and chemical) to do so and also considered being costly. Biodegradable plastics became major approach to solve this issue and also became eminent since 1970s. From the inventory of biopolymers acting as bioplastics, PHA has gained major importance because of its analogous behavior to that of petro based plastics. PHAs are the linear polymers produced by the microbes to store energy and carbon. Present review discusses about the PHA production method, recent advances in producing, its degradation and applications of PHA which elucidates the gaining importance in today's industrial world. © 2011 Varsha YM, et al.

Varshney, M. (2006). Immunomagnetic particles and microfluidics based biosensors for rapid detection

of foodborne pathogenic bacteria.

This research investigated immunomagnetic particles and microfluidics based impedance and optical biosensors for detection of foodborne pathogenic bacteria. Magnetic nanoparticles-antibody conjugates (MNAC) based sampling method was developed for the separation and concentration of Escherichia coli O157:H7 in food samples. In pure culture of E. coli O157:H7, MNAC presented minimum capture efficiency (CE) of 94% for bacterial cells ranging from 1.6 x 10 super(1) to 7.2 x 10 super(7) CFU ml super(-1) with an immunoreaction time of 15 min without any enrichment. There was no significant effect (P > 0.05) of mixing on the capture of bacterial cells by MNAC. A label-free, microfluidics and interdigitated array microelectrode (IDAM) based impedance biosensor in combination with MNAC immunoseparation was developed for detection of Escherichia coli O157:H7 in food samples. Flow cell with embedded IDAM was studied to improve the detection limit as compared to open IDAM chip. The open IDAM chip was successfully used for the detection of 7 x 10 super(2) and 6 x 10 super(3) cells of E. coli O157:H7 in pure culture and ground beef samples in a detection volume of 2 kl, respectively. Using a flow cell with embedded IDAM, a minimum of 1.6 x 10 super(2) and 1.2 x 10 super(3) cells of E. coli O157:H7 was detected in pure culture and ground beef samples, respectively, in a detection volume of 60 nl. The total detection time from sampling to measurement in both cases was 35 min. In order to detect low numbers of cells, the bacterial cell growth was measured inside a double IDAM based flow cell. The system could detect a range of E. coli O157:H7 from 8.0 to 8.2 x 10 super(8) CFU ml super(-1) after an enrichment time of 14.7 and 0.8 h, respectively. A chemiluminescence biosensing method combined with microfluidic stepped filter-biochip and immunomagnetic microbeads was investigated and evaluated for detection of E. coli O157:H7. Horseradish peroxidase enzyme labeled anti-E. coli antibodies were used for the generation of chemiluminescence signal. With multi-batch sampling, the filter biochip could detect as few as 34 cells of E. coli O157:H7 inside the reaction microchamber of 12 nl. The total detection time was 90 min. Microfluidics and immunomagnetic separation were effectively synergized for the detection of low numbers of E. coli O157:H7. Moreover, microfluidics based biosensors have the potential to be developed into hand-hold or portable biosensors.

Varshney, M., et al. (2005). "Magnetic nanoparticle-antibody conjugates for the separation of Escherichia coli O157:H7 in ground beef." Journal of Food Protection **68**(9): 1804-1811.

The immunomagnetic separation with magnetic nanoparticle-antibody conjugates (MNCs) was investigated and evaluated for the detection of Escherichia coli O157:H7 in ground beef samples. MNCs were prepared by immobilizing biotin-labeled polyclonal goat anti-E. coli antibodies onto streptavidin-coated magnetic nanoparticles. For bacterial separation, MNCs were mixed with inoculated ground beef samples, then nanoparticle-antibody-E. coli O157:H7 complexes were separated from food matrix with a magnet, washed, and surface plated for microbial enumeration. The capture efficiency was determined by plating cells bound to nanoparticles and unbound cells in the supernatant onto sorbitol MacConkey agar. Key parameters, including the amount of nanoparticles and immunoreaction time, were optimized with different concentrations of E. coli O157:H7 in phosphate-buffered saline. MNCs presented a minimum capture efficiency of 94% for E. coli O157:H7 ranging from 1.6x10¹ to 7.23x10⁷ CFU/ml with an immunoreaction time of 15 min without any enrichment. Capture of E. coli O157:H7 by MNCs did not interfere with other bacteria, including Salmonella enteritidis, Citrobacter freundii, and Listeria monocytogenes. The capture efficiency values of MNCs increased from 69 to 94.5% as E. coli O157:H7 decreased from 3.4x10⁷ to 8.0x10⁰ CFU/ml in the ground beef samples prepared with minimal steps (without filtration and centrifugation). An enrichment of 6 h was done for 8.0x10⁰ and 8.0x10¹ CFU/ml of E. coli O157:H7 in ground beef to increase the number of cells in the sample to a detectable level. The results also indicated that capture efficiencies of MNCs for E. coli O157:H7 with and without mechanical mixing during immunoreaction were not significantly different (P>0.05). Compared with microbeads based immunomagnetic separation, the magnetic nanoparticles showed their advantages in terms of higher capture efficiency, no need for mechanical mixing, and minimal sample preparation.

Vasiadi, M., et al. (2010). "Rupatadine inhibits proinflammatory mediator secretion from human mast cells triggered by different stimuli." International Archives of Allergy and Immunology **151**(1): 38-45.

Background: Mast cells are involved in allergy and inflammation by secreting multiple mediators including histamine, cytokines and platelet-activating factor. Certain histamine 1 receptor antagonists have been reported to inhibit histamine secretion, but the effect on cytokine release from human mast cells triggered by allergic and other stimuli is not well known. We investigated the ability of rupatadine, a potent histamine 1 receptor antagonist that also blocks platelet-activating factor actions, to also inhibit mast cell mediator release. Method(s): Rupatadine (1-50 muM) was used before stimulation by: (1) interleukin (IL)-1 to induce IL-6 from human leukemic mast cells (HMC-1 cells), (2) substance P for histamine, IL-8 and vascular endothelial growth factor release from LAD2 cells, and (3) IgE/anti-IgE for cytokine release from human cord blood-derived cultured mast cells. Mediators were measured in the supernatant fluid by ELISA or by Milliplex microbead arrays. Result(s): Rupatadine (10-50 muM) inhibited IL-6 release (80% at 50 muM) from HMC-1 cells, whether added 10 min or 24 h prior to stimulation. Rupatadine (10-50 muM for 10 min) inhibited IL-8 (80%), vascular endothelial growth factor (73%) and histamine (88%) release from LAD2 cells, as well as IL-6, IL-8, IL-10, IL-13 and tumor necrosis factor release from human cord blood-derived cultured mast cells. Conclusion(s): Rupatadine can inhibit histamine and cytokine secretion from human mast cells in response to allergic, immune and neuropeptide triggers. These actions endow rupatadine with unique properties in treating allergic inflammation, especially perennial rhinitis and idiopathic urticaria. © 2009 S. Karger AG, Basel.

Vasiadi, M., et al. (2013). "Neurotensin serum levels and skin gene expression are increased in atopic dermatitis." British Journal of Dermatology **169**(3): 695-699.

BACKGROUND: Neurotensin (NT) participates in immune responses, but the mechanisms are not known. We have previously shown that NT augments the ability of corticotropin-releasing hormone (CRH) to increase mast-cell-dependent vascular permeability in rodents. We also showed that NT stimulates human mastcell release of vascular endothelial growth factor, and that CRH is increased in the serum of patients with atopic dermatitis (AD), an inflammatory skin condition involving mast cells.

OBJECTIVES: To measure serum levels of NT, and lesional skin expression of NT and the main NT receptor (NTR-1) in AD, and to compare it with skin expression in chronic urticaria (CU) and urticaria pigmentosa (UP).

METHODS: Serum NT was measured with a Milliplex microbead array. Skin NT and NTR-1 gene expression was determined with quantitative polymerase chain reaction. Immunohistochemistry was performed using a mouse monoclonal antibody for NT, and a rabbit polyclonal antibody for NTR-1. Mast cells were counterstained with Leder dye.

RESULTS: Neurotensin is significantly elevated in the serum of patients with AD compared with healthy controls (P = 0.0001). NT gene expression is also significantly increased in lesional skin of patients with AD compared with controls (P = 0.0194). Moreover, immunohistochemistry of AD lesions shows NT > NTR-1 staining of perivascular cells, many of which are identified as mast cells after staining with Leder dye. There was no statistically significant difference in NT and NTR-1 lesional skin gene expression in patients with either CU or UP.

CONCLUSIONS: These results suggest that interactions between NT and mast cells may occur and contribute to AD pathogenesis.

Vasiadi, M., et al. (2012). "Serum neurotensin (NT) is increased in psoriasis and NT induces vascular endothelial growth factor release from human mast cells." British Journal of Dermatology **166**(6): 1349-1352.

BACKGROUND: Psoriasis involves skin inflammation that often worsens with stress, but the mechanism of this effect remains obscure. We have shown that corticotropin-releasing hormone (CRH) is increased in the serum of patients with psoriasis. A peptide, neurotensin (NT), can trigger skin histamine release and augment the ability of CRH to increase skin vascular permeability.

OBJECTIVES: To investigate the serum level of NT, and the expression of genes for NT and NT receptor-1 (NTR-1) in lesional and nonlesional skin of patients with psoriasis, compared with normal controls. Also, to study the effect of NT on human mast cell release of vascular endothelial growth factor (VEGF), which is increased in psoriatic skin.

METHODS: Serum was obtained from patients with psoriasis (n = 56) and controls (n = 33); NT levels were measured with the Milliplex microbead assay. Biopsies were obtained from the lesional and nonlesional skin of patients with chronic plaque psoriasis (n = 40), who had not received any treatment for at least 15 days and were free of any systemic inflammatory diseases. Control skin samples were obtained from healthy subjects (n = 30). Expression of genes for NT and NTR-1 in the skin was evaluated by quantitative reverse transcriptase-polymerase chain reaction. LAD2 human mast cells were stimulated by NT (1 mumol L(-1)) for 24 h and VEGF was measured by enzyme-linked immunosorbent assay.

RESULTS: Serum NT was increased in patients with psoriasis, while expression of genes for NT and NTR-1 in lesional skin was decreased compared with controls. NT induced VEGF release from mast cells and was augmented by interleukin-33.

CONCLUSION: NT may play a role in psoriasis pathogenesis and its worsening by stress, at least in part through activation of skin mast cells.

Vasicek, J., et al. (2011). "Elimination of apoptotic spermatozoa from rabbit insemination dose using annexin V associated with the MACS technique. A preliminary study." Folia Biologica **59**(1/2): 65-69.

The aim of this study was to verify whether the separation and elimination of the apoptotic fraction in rabbit semen using a MACS technique may improve sperm fertility potential and consequently rabbit kindling rate. Semen samples from 25 New ZealandWhite (NZW) rabbit males were collected using an artificial vagina and evaluated using the CASA system for concentration and motility. For artificial insemination the best 11 bucks were chosen based on motility parameters. Their ejaculates were mixed to make a heterospermic pool and routinely diluted in a commercial insemination diluent (MiniTub, Tiefenbach, Germany) at a ratio of 1:6. Diluted heterospermic spermatozoa were filtered through a Sartorius filter to wash out seminal plasma, re-diluted in binding buffer (Annexin V Microbead Kit, Miltenyi Biotec, Germany) at a ratio of 1:3.66 and divided into two groups: an experimental group intended for MACS separation and control group without MACS separation. Then hormonally treated females of NZW rabbits were inseminated with fresh doses of filtered heterospermic semen (n=27; 0.5 ml I.D. per female) and MACS separated semen (n=28; 0.5 ml I.D. per female). Separation and subsequent elimination of apoptotic spermatozoa (positive selection) fromthe insemination dose (after negativeMACS selection) was verified under in vivo conditions on the basis of increased kindling rate in the experimental group in comparison with kindling rate in the control group (81.3% vs. 73.8%). In conclusion, elimination of apoptotic spermatozoa by the use of the MACS technique results in a slight improvement in kindling rate of rabbit does.

Vasileiou, S., et al. (2016). "Evaluation of chimerism in bone marrow enriched CD34+ cells for monitoring of minimal residual disease after allogeneic stem cell transplantation." Bone Marrow Transplantation **1)**: S449-S450.

Introduction: Monitoring of minimal residual disease (MRD) after allogeneic hematopoietic stem cell transplantation (allo- SCT) has become mandatory in the effort to predict the risk of hematologic relapse. The purpose of this study was the evaluation of CD34+ cell donor chimerism as a means of MRD assessment in patients transplanted for myeloid malignancies that lack a reliable molecular marker. Material (or patients) and methods: The study enrolled 10 patients that underwent allo-SCT for myelodysplastic syndrome (MDS, n = 4), de novo/secondary acute myeloid leukemia (AML, n = 5), or myelofibrosis (n = 1). A total of 16 chimerism assays were performed in CD34+ cells, which were enriched from bone marrow (BM) samples either by use of magnetic microbeads coated with anti-CD34 monoclonal antibody (n = 14) or by fluorescence-activated cell sorting (FACS, n = 2). Percentage of CD34+ cells in initial BM samples as well as purity of the resulting CD34+ cell populations were analyzed by flow cytometry. Chimerism was measured by PCRbased analysis of Short Tandem Repeats (STRs). Result(s): The median percentage of CD34+ cells in unprocessed BM mononuclear cells was 0.73% (range: 0.06-3.65%). Enrichment of CD34+ cells resulted in a median purity of 71% (range: 40-93%). Regarding immunomagnetic CD34+ cell separation, purity was superior for BM samples with initial concentrations of CD34+ cells >=1% compared to <1% (88-93% versus 40-73%, respectively). Starting from 1-3 ml whole BM specimens, the yield of total CD34 + cells for chimerism studies ranged from 103 to 2.8x10⁵ (median: 3.7x10⁴). High-level donor CD34+ cell chimerism (94.7-99.4%, median: 97%) was observed in 7 patients, none of whom developed relapse at a median follow-up of 5 (range: 3-17) months. On the other hand, a decline in donor CD34+ cell chimerism was encountered in the 3 remaining patients at a median of 3 (range: 2-5) months post transplant. In one of those 3 patients, low donor CD34+ cell chimerism (5.5%) coincided with early relapse of AML (BM blasts: 12%). In the other 2 patients, decreased values of donor CD34+ cell chimerism (49.5 and 46.4%) were detected while in hematologic complete remission (CR) of the disease (secondary AML and MDS, respectively). All the above 3 patients were treated with salvage or preemptive azacitidine, and showed a response in CD34+ cell donor chimerism (64-95.6%) with achievement or maintenance of hematologic CR. Conclusion(s): Donor chimerism of BM CD34+ cells is a relevant marker of the activity of myeloid malignancies following allo- SCT and may guide to early interventions in the aim of preventing hematologic relapse, particularly with high-risk AML or MDS. Relatively simple and time sparing immunomagnetic selection techniques usually allow for considerable CD34+ cell purity and informative chimerism results, thereby facilitating routine clinical application of the procedure.

Vasylevska, A. S., et al. (2007). "Novel coumarin-based fluorescent pH indicators, probes and membranes covering a broad pH range." Analytical & Bioanalytical Chemistry **387**(6): 2131-2141.

A new family of coumarin-based pH indicators was synthesized. They are sensitive to pH in either weakly acidic or weakly basic solution. The indicators possess moderate to high brightness, excellent photostability and compatibility with light-emitting diodes. The indicators were covalently immobilized on the surface of amino-modified polymer microbeads which in turn were incorporated into a hydrogel matrix to obtain novel pH-sensitive materials. When a mixture of two different microbeads is used, the membranes are capable of optical pH sensing over a very wide range comparable to the dynamic range of the glass electrode (pH 1-11).

Vats, A. and K. Pathak (2013). "Exploiting microspheres as a therapeutic proficient doer for colon delivery: A review." Expert Opinion on Drug Delivery **10**(4): 545-557.

Introduction: Colon-specific drug delivery systems have recently gained importance for delivering a variety of therapeutic agents via oral route. This mode offers the feasibility of treating colonic pathologies with less risk of bioburden to other organs/tissues and has been widely researched for the delivery of challenging drugs. Microspheres targeted to colon have occupied central position on drug delivery due to their small size that offers characteristic intrinsic properties attributable to the carrier. Areas covered: The present deliberation precariously covers the capacious usage of microspheres for the treatment of local colonic pathologies like colon carcinomas, inflammatory bowel disease and parasitic diseases using natural as well as synthetic carriers. The write up also encompasses clinical application of microspheres. Expert opinion: Microspheres have comprehensive potential to be marketed as the patient-friendly formulation, as it would provide direct treatment at the disease site and, consequently, lower dosing and reducing systemic side effects. Wherefore, the major obstacles in delivering drugs to the colon like the absorption and degradation pathways in the proximal part of GIT could be easily overcome, and also a range of pathologies from constipation and diarrhea to the exhaustive inflammatory bowel diseases and colon carcinoma could be cured. © 2013 Informa UK, Ltd.

Vaughan, R., et al. (2017). "Microplastics in the sediments of a UK urban lake." Environmental Pollution **229**: 10-18.

While studies on microplastics in the marine environment show their wide-distribution, persistence and contamination of biota, the freshwater environment remains comparatively neglected. Where studies on freshwaters have been undertaken these have been on riverine systems or very large lakes. We present data on the distribution of microplastic particles in the sediments of Edgbaston Pool, a shallow eutrophic lake in central Birmingham, UK. These data provide, to our knowledge, the first assessment of microplastic concentrations in the sediments of either a small or an urban lake and the first for any lake in the UK. Maximum concentrations reached 25-30 particles per 100 g dried sediment (equivalent to low hundreds kg⁻¹) and hence are comparable with reported river sediment studies. Fibres and films were the most common types of microplastic observed. Spatial distributions appear to be due to similar factors to other lake studies (i.e. location of inflow; prevailing wind directions; propensity for biofouling; distribution of macroplastic debris) and add to the growing burden of evidence for microplastic ubiquity in all environments.

Vazquez, C. M. and R. Pruneda (1978). "Estimation of free intake in grazing animals, comparison of two techniques for estimating digestibility." Ciencia y Tecnica en la Agricultura. Pastos y Forrajes **1**(2): 97-103.

Four Holstein cows grazing on pangola grass were given daily a gel capsule with soluble Cr2O3. Pasture samples were taken from a bull with a rumen fistula to estimate the lignin content and digestibility in vitro. The excreta were identified individually by means of coloured plastic particles, and combined over periods of 5 and 7 days. The digestibility was 53.9 and 69.2% for estimation in vitro and with lignin, respectively. There were no significant differences in faecal production. There were significant differences in consumption, according to the lignin method, and differences among periods. Collection of excreta for 5 and 7 days and digestibility in vitro are recommended.

Vazquez Juiz, M. L., et al. (2018). "Humic acids modify the pulse size distributions in the characterization of plastic microparticles by Tunable Resistive Pulse Sensing." Journal of Contaminant Hydrology **218**: 59-69.

Tunable Resistive Pulse Sensing, TRPS, is an emerging technique used in quantification and measuring the size (particle-by-particle) of viruses, exosomes and engineered colloidal spheres in biological fluids. We study the features of TRPS to enhance size characterization and quantification of submicron-sized microplastics, also called plastic microparticles, MP, in freshwater environments. We report alterations on the detection of the resistive pulses in the TRPS caused by humic acids, HA, during the size measurement of polystyrene microspheres used as MP surrogate. We discuss the alteration of the electric field in the measuring channel of the TRPS apparatus induced by the passage of HA. TRPS is a fast and precise technique for counting and size determination of MP but needs the evaluation of the influence of the organic matter on the current blockades. We show that statistical clustering models of the magnitude distribution of the resistive pulses can help to detect and quantify changes in the pulse size distributions induced by flocculation of humic acids. Conclusions of this study indicate that TRPS can be a valuable tool to improve the knowledge of the MP fate in surface waters, in the vadose zone and groundwater.

Vazquez, Y. and S. Barbosa (2017). "Compatibilization Strategies for Recycling Applications of High Impact Polystyrene/Acrylonitrile Butadiene Blends." Journal of Polymers & the Environment **25**(3): 903-912.

Plastic waste from electrical and electronic equipment (WEEE) is growing up exponentially fast during the last two decades, mainly due to short lifetime of technological products like cellphones or computers. This situation entailed an increase in the accumulation of specific plastic materials such Acrylonitrile-Butadiene-Styrene (ABS), High Impact Polystyrene (HIPS), Polycarbonate, among others. These plastics can be recycled by themselves but their separation by type is neither easy nor economically viable, then recycling them together as a blend is the most economically viable alternative. However, mechanical properties suffer a deterioration and to enhance phase adhesion and add value to this WEEE blend, an adequate compatibilization is needed. To choose a compatibilization route an accurate comprehension of blends behavior has to be done. In this work, a systematical study of the addition compatibilization of HIPS/ABS blends was performed. Besides results were focus to WEEE recycling, in order to comprehend this complex system, virgin base materials were used. Relative amount effect on self-compatibilization was analyzed by two different HIPS/ABS blends, one with major content of HIPS and other with major content of ABS. Also, two different copolymers were used as compatibilizer, Styrene-Acrylonitrile (SAN) and Styrene-Butadiene-Styrene and the concentrations chosen were 2 and 20 wt%. The best performance was achieved for blend with major content of ABS by using 2 % of SAN, obtaining a compatibilized blend with a general improvement of mechanical properties specially toughness in a 350 % and elongation in a 77 % respect to the physical blend. [ABSTRACT FROM AUTHOR]

Vazquez, Y. V. and S. E. Barbosa (2016). "Recycling of mixed plastic waste from electrical and electronic equipment. Added value by compatibilization." Waste Management **53**: 196-203.

Plastic waste from electrical and electronic equipment (WEEE) grows up exponentially fast in the last two decades. Either consumption increase of technological products, like cellphones or computers, or the short lifetime of this products contributes to this rise generating an accumulation of specific plastic materials such ABS (Acrylonitrile-Butadiene-Styrene), HIPS (High impact Polystyrene), PC (Polycarbonate), among others. All of they can be recycled by themselves. However, to separate them by type is neither easy nor economically viable, then an alternative is recycling them together as a blend. Taking into account that could be a deterioration in final properties, to enhance phase adhesion and add value to a new plastic WEEE blend a compatibilization is needed. In this work, a systematical study of different compatibilizers for blends of HIPS and ABS from WEEE was performed. A screening analysis was carried out by adding two different compatibilizer concentration (2wt% and 20wt%) on a HIPS/ABS physical blend 80/20 proportion from plastic e-waste. Three copolymers were selected as possible compatibilizers by their possible affinity with initial plastic WEEE. A complete characterization of each WEEE was performed and compatibilization efficiency was evaluated by comparing either mechanical or morphological blends aspects. Considering blends analyzed in this work, the best performance was achieved by using 2% of styrene-acrylonitrile rubber, obtaining a compatibilized blend with double ultimate strength and modulus respect to the physical blend, and also improve mechanical properties of initial WEEE plastics. The proposed way is a promise route to improve benefit of e-scrap with sustainable, low costs and easy handling process. Consequently, social recycling interest will be encouraged by both ecological and economical points of view.

Vazquez-Tello, A., et al. (2010). "Expression of IL-17a and IL-17F cytokines in B lymphocytes." American Journal of Respiratory and Critical Care Medicine. Conference: American Thoracic Society International Conference, ATS **181**(1 MeetingAbstracts).

INTRODUCTION IL-17A and F cytokines are regarded as promoters of autoimmune conditions such as inflammatory bowel disease, rheumatoid arthritis, and multiple sclerosis. There is a body of evidence suggesting that IL-17A and F are produced primarily by CD4⁺ Th-17 lymphocytes. However, recent reports suggest that other cells including CD8⁺, NKT and Treg cells also express IL-17A and IL-17F and may contribute to the production of these cytokines in immunologically-mediated diseases. B lymphocytes are known to be important cytokine sources in inflammation and play a significant role in a number of chronic immunological diseases including allergic and autoimmune diseases. We therefore investigated the potential of human B lymphocytes to produce IL-17A and IL-17F. METHODS Tonsillar and peripheral B lymphocytes were purified by a procedure that included the sequential removal of contaminating T lymphocytes and monocytes, followed by a positive selection of CD19+ cells using magnetic microbeads coated with anti-CD19 antibodies. The purified CD19+ cells were confirmed to be >97% positive for the CD20 B cell marker by flow cytometry. The CD19+/CD20+ B cells in culture were stimulated with IL-4, IFN-gamma, IL-6, IL-23, and TGF-beta and analyzed the expression of both IL-17A and F in response to stimulation by real-time RT-PCR, western blot, immunocytochemistry and ELISA. RESULTS Freshly purified B cells from tonsils and from blood express detectable amounts of the mRNA and protein of IL-17A and F. When B cells were stimulated with IL-6, IL-23 and TGF-beta, the mRNA and protein expression of both IL-17A and F was significantly increased. (n=3; P<=0.001) In contrast, stimulation with IL-4 alone or in

combination with anti-CD40 antibody, decreased the expression of IL-17A and F in cultured B cells (n=3; P<=0.001). CONCLUSIONS These novel findings provide evidence that B lymphocytes could be a significant source of IL-17A and IL-17F cytokines and support the notion that B lymphocytes actively participate in immune responses via a mechanism in addition to the classic release of antibodies. Moreover, our results also set the stage for investigating the role of the B cells-IL-17 interaction in autoimmune diseases.

Vecchiatini, R., et al. (2015). "Effect of dynamic three-dimensional culture on osteogenic potential of human periodontal ligament-derived mesenchymal stem cells entrapped in alginate microbeads." Journal of Periodontal Research **50**(4): 544-553.

BACKGROUND AND OBJECTIVE: Bioreactors are devices that efficiently create an environment that enables cell cultures to grow in a three-dimensional (3D) context mimicking in vivo conditions. In this study, we investigate the effect of dynamic fluid flow on the osteogenic potential of human mesenchymal stem cells obtained from periodontal ligament and entrapped in alginate microbeads.

MATERIAL AND METHODS: After proper immunophenotyping, cells were encapsulated in barium alginate, cultured in 3D static or 3D dynamic conditions represented by a bioreactor system. Calcein-AM/propidium iodide staining was used to assess cellular viability. Quantitative real-time polymerase chain reaction was used to analyze the expression of osteogenic markers (Runx2 and COL1). Alizarin Red S staining and the Fourier transform infrared spectroscopy were used to assess mineral matrix deposition.

RESULTS: Optimal encapsulation procedure, in terms of polymer pumping rate, distance from droplet generator to the gelling bath and atomizing airflow was assessed. Cell viability was not affected by encapsulation in alginate microbeads. Bioreactor cell exposure was effective in anticipating osteogenic differentiation and improving mineral matrix deposition.

CONCLUSION: For the first time human mesenchymal stem cells obtained from periodontal ligaments encapsulated in alginate microbeads were cultured in a bioreactor system. This combination could represent a promising strategy to create a cell-based smart system with enhanced osteogenic potential useful for many different dental applications.

Vedolin, M. C., et al. (2018). "Spatial variability in the concentrations of metals in beached microplastics." Marine Pollution Bulletin **129**(2): 487-493.

Heavy metals and microplastics have been considered as threats to the marine environment and the interactions between these two pollutants are poorly understood. This study investigates the interactions between metals adsorbed in pellets collected randomly from 19 beaches along the coast of Sao Paulo State in southeastern Brazil, comparing these levels with those in virgin pellets. The samples were analyzed for Al, Cr, Cu, Fe, Mn, Sn, Ti and Zn by inductively coupled plasma optical emission spectroscopy (ICP-OES). The polymers were solubilized via acid digestion. The highest levels occurred with Fe (227.78 mg kg^{- 1} - Itaguare) and Al (45.27 mg kg^{- 1} - Guarau) in the same areas, which are closer to the Port of Santos. The metal adsorption on pellets collected is greater than that on virgin pellets. In this context, pellets can be considered to be a carrier for the transport of metals in the environment, even in small quantities. Copyright © 2017 Elsevier Ltd

Veerasingam, S., et al. (2016). "Characteristics, seasonal distribution and surface degradation features of microplastic pellets along the Goa coast, India." Chemosphere **159**: 496-505.

Microplastic pellets (MPPs) are ubiquitous contaminants, recognised as a serious threat to the biota in coastal, estuarine and marine environment. The distribution, abundance, weathering and chemical characteristics of MPPs on the beaches of Goa, and their transport to the coast during the southwest (SW) monsoon are discussed in this paper. MPP samples collected from six sandy beaches were categorised based on colour and polymer types using Stereoscope microscope and FTIR-ATR spectroscopy, respectively. White colour MPPs were the most abundant, and Polyethylene (PE) and Polypropylene (PP) were the dominant polymer types of MPPs deposited on all the beaches. Carbonyl index values showed that MPPs collected in June 2015 (representing SW monsoon) were 'new', whereas the MPPs collected in January 2015 were 'aged', showing that MPPs are arriving at Goa coast only during SW monsoon due to conducive hydrodynamic conditions. Characteristics of MPPs suggest that they could be originated primarily from ocean-based sources. The winds and surface currents during SW monsoon are the driving forces for the transportation and deposition of MPPs on the Goa beaches. The results of this study will be useful to the National 'Clean India' program for effective plastic debris removal management.

Vehlow, J., et al. (2003). "Bromine in waste incineration: partitioning and influence on metal volatilisation." Environmental Science & Pollution Research **10**(5): 329-334.

INTENTION, GOAL, SCOPE, BACKGROUND: The halogen bromine is far less abundant than chlorine, but it can be found at high concentrations in special materials like flame retarded plastics. The fate and effects of Br in waste incineration are not well understood. It may have similar implications like Cl for the volatilisation of heavy metals and the formation of low volatile organic compounds. Due to its lower oxidation potential, there is a risk of formation of elementary Br_2 in the offgas.

OBJECTIVE: Co-combustion tests of different types of Br containing plastic waste materials (up to 22%) and MSW in the TAMARA pilot plant for waste incineration were conducted to investigate the Br partitioning and the influence of Br on metal volatilisation.

METHODS: The Br inventory of the fuel mix was elevated to approx. 1 wt-%. All input and output mass flows of the furnace have been sampled and the partitioning of Cl, Br, S, and a number of heavy metals, has been calculated on the basis of closed mass balances.

RESULTS AND DISCUSSION: Organically-bound Br was typically released to more than 90% into the raw gas. Elementary Br_2 was detected at high Br levels. Its presence was always analysed when all SO_2 in the raw gas was oxidised to SO_3. Br enhances the volatilisation of metals like K, Zn, Cd, Sn, Sb, and Pb out of the fuel bed principally in the same way as Cl. The tests gave strong indication that the promoting influence of the halogens on metal volatilisation is more pronounced than that of the fuel bed temperature. The volatilised metals are condensated on the fly ashes and are discharged along with the filter ashes.

CONCLUSIONS: As long as a surplus of SO_2 is present in the raw gas no Br_2 is formed. Although the halogen induced transfer out of the fuel bed causes high concentrations of volatile metals in the filter ashes, a recovery is not economically feasible for the time being. The volatilisation gives no rise to metal emission problems as long as efficient dedusting is achieved.

RECOMMENDATION AND OUTLOOK: If there is a risk of Br_2 formation, in wet scrubbing a reducing agent has to be added to the neutral scrubber for efficient abatement. Filter ashes should be disposed of in a way that enables access for recovery in the future. The exact volatilisation characteristics of the various metals have to be studied in future using specifically tailored experiments.

Vejerano, E. P., et al. (2013). "Emissions of Polycyclic Aromatic Hydrocarbons, Polychlorinated Dibenzo-p-Dioxins, and Dibenzofurans from Incineration of Nanomaterials." Environmental Science & Technology **47**(9): 4866-4874.

Disposal of some nanomaterial-laden waste through incineration is inevitable, and

nanomaterials' influence on combustion byproduct formation under high-temperature, oxidative conditions is not well understood This work reports the formation of polycyclic aromatic hydrocarbons (PAHs) and polychlorinated-dibenzo-p-dioxins and dibenzofurans (PCDD/Fs) from incineration of paper and plastic waste containing various nanomaterials, including titania, nickel oxide, silver, ceria, iron oxide, quantum dots, and CgQ-fullerene, in a laboratory-scale furnace. The presence of nanomaterials in the waste stream resulted in higher emissions of some PAH species and lower emissions of others, depending on the type of waste. The major PAH species formed were phenanthrene and anthracene, and emissions were sensitive to the amount or nanomaterials in the waste, tienerally, there were no significant duterences in emission factors for the larger PAH species when nanomaterials were added to the waste. The total PAH emission factors were on average ∼6 times higher for waste spiked widi nanomaterials v. uSeir bulk counterparts. Emissions of chlorinated dioxins from poly(vinyl chloride) (PVC) waste were not detected; however, chlorinated furans were formed at elevated concentrations with wastes containing silver and titania nanomaterials, and toxicity was attributable mainly to 2,3,4,7,8-pentachlorodibenzofuran. The combination of high specific surface area and catalytic, including electrocatalytic, properties of nanomaterials might be responsible for affecting die formation of toxic pollutants during incineration. [ABSTRACT FROM AUTHOR]

Velez, J. F. M., et al. (2018). "Considerations on the use of equilibrium models for the characterisation of HOC-microplastic interactions in vector studies." Chemosphere **210**: 359-365.

The association of hydrophobic organic contaminants (HOCs) to microplastics (MPs) in the aquatic environment and the possible perturbation of how biota and HOCs interact (i.e. 'MP vector effect') is a much researched topic in the emergent field of aquatic MP pollution. Consensus on whether the vector-effect is relevant can in part be ascertained using laboratory experimentation. Such studies, of which there are now many examples, have as a mandatory component a characterisation of the HOC-MP interaction. However, important considerations must be made when planning and executing such laboratory experiments, and subsequently when choosing equilibria models to fit sorption curves, as it is necessary to recognize that simplified conceptual models (i.e. Freundlich or Langmuir models) do not fit all HOC-MP interactions under all circumstances. The sorption equilibrium of HOCs to most plastic particles occurs as a combination of surface adsorption in the crystalline regions of the polymer (typically characterized by Langmuir models) and internal partition into amorphous regions (modelled with Freundlich relations), but this is rarely recognized. In this discussion we highlight some considerations needed when both characterizing the interactions between MPs and HOCs and improving the environmental realism of vector studies through the use of, for instance, weathered particles, adequate time for HOC-MP equilibria to be reached and working at lower concentrations. Increasing environmental realism of vector studies corresponds to a greater complexity in the equilibria model, but ultimately allows better understanding of any potential HOC-MP vector effect in nature. Velez, N., et al. (2019). "A baseline assessment of beach macrolitter and microplastics along

northeastern Atlantic shores." Marine Pollution Bulletin **149 (no pagination)**(110649).

Marine litter is widely dispersed throughout coastal environments. Assessing the distribution and accumulation of such contaminants is crucial to understand their environmental impacts. This study presents a baseline for the monitoring of litter and microplastics in intertidal sediments along the Atlantic shores of southern Portugal and Morocco and identifies potential sources of contamination. Although variable, distribution and composition of both litter and microplastics did not follow a latitudinal pattern. Most of the litter had an undifferentiated source. Within the identifiable sources of litter, food packaging, fishing and tobacco were the most abundant, with variable contributions among sites. Over 97% of marine litter retrieved was plastic. Fragments and filaments were the most abundant categories of plastics at sites with the highest and lowest microplastic abundance respectively. Filaments were mainly made of Polypropylene (PP,50%) and Polyethylene terephthalate (PET,29%) while the predominant polymers for fragments were Polyethene (PE, 75%) and PP (25%). Vélez, S. L. P. and A. R. Vélez (2017). "RECYCLING ALTERNATIVES TO TREATING PLASTIC WASTE, ENVIRONMENTAL, SOCIAL AND ECONOMIC EFFECTS: A LITERATURE REVIEW." The Journal of Solid Waste Technology and Management(2).

Plastic waste is a problem not only for the environment, but also for the municipal solid waste management. In order to get new raw materials, further natural resources are being exploited. Moreover, plastic refuse that could be reintroduced into the production process is wasted. One important strategy to treat this waste is recycling. The importance lies in the fact that the plastic recycling process reduces the amount of waste going to landfills, and also because it permits a reduction in the consumption of virgin material and resources used to produce original polymers. Recycled plastic could be used as an input in the cycle production of new products, which is the case for concrete, car industry and textiles. Therefore, recycling could be considered an ecofriendly method for the treatment of plastic waste and a good opportunity for reducing the environmental impact, considering that the energy demands of recycling and reusing plastics are much lower than the energy inputs required to deal with virgin materials. This paper carries out a review of the relevant scientific research in the field of plastic recycling in order to make an overview of this practice and its impact on the environment.

Veli, M. and A. Ozcan (2018). "Computational Sensing of Staphylococcus aureus on Contact Lenses Using 3D Imaging of Curved Surfaces and Machine Learning." Acs Nano **12**(3): 2554-2559.

We present a cost-effective and portable platform based on contact lenses for noninvasively detecting Staphylococcus aureus, which is part of the human ocular microbiome and resides on the cornea and conjunctiva. Using S. aureus-specific antibodies and a surface chemistry protocol that is compatible with human tears, contact lenses are designed to specifically capture S. aureus. After the bacteria capture on the lens and right before its imaging, the captured bacteria are tagged with surface-functionalized polystyrene microparticles. These microbeads provide sufficient signal-to-noise ratio for the quantification of the captured bacteria on the contact lens, without any fluorescent labels, by 3D imaging of the curved surface of each lens using only one hologram taken with a lens-free on-chip microscope. After the 3D surface of the contact lens is computationally reconstructed using rotational field transformations and holographic digital focusing, a machine learning algorithm is employed to automatically count the number of beads on the lens surface, revealing the count of the captured bacteria. To demonstrate its proof-of-concept, we created a field-portable and cost-effective holographic microscope, which weighs 77 g, controlled by a laptop. Using daily contact lenses that are spiked with bacteria, we demonstrated that this computational sensing platform provides a detection limit of ~16

bacteria/muL. This contact-lens-based wearable sensor can be broadly applicable to detect various bacteria, viruses, and analytes in tears using a cost-effective and portable computational imager that might be used even at home by consumers.

Velzeboer, I., et al. (2014). "Strong sorption of PCBs to nanoplastics, microplastics, carbon nanotubes, and fullerenes." Environmental Science & Technology **48**(9): 4869-4876.

The presence of microplastic and carbon-based nanoparticles in the environment may have implications for the fate and effects of traditional hydrophobic chemicals. Here we present parameters for the sorption of 17 CB congeners to 10-180 mum sized polyethylene (micro-PE), 70 nm polystyrene (nano-PS), multiwalled carbon nanotubes (MWCNT), fullerene (C60), and a natural sediment in the environmentally relevant 10(-5)-10(-1) mug L(-1) concentration range. Effects of salinity and sediment organic matter fouling were assessed by measuring the isotherms in fresh- and seawater, with and without sediment present. Sorption to the "bulk" sorbents sediment organic matter (OM) and micro-PE occurred through linear hydrophobic partitioning with OM and micro-PE having similar sorption affinity. Sorption to MWCNT and nano-PS was nonlinear. PCB sorption to MWCNT and C60 was 3-4 orders of magnitude stronger than to OM and micro-PE. Sorption to nano-PS was 1-2 orders of magnitude stronger than to micro-PE, which was attributed to the higher aromaticity and surface-volume ratio of nano-PS. Organic matter effects varied among sorbents, with the largest OM fouling effect observed for the high surface sorbents MWCNT and nano-PS. Salinity decreased sorption for sediment and MWCNT but increased sorption for the polymers nano-PS and micro-PE. The exceptionally strong sorption of (planar) PCBs to C60, MWCNT, and nano-PS may imply increased hazards upon membrane transfer of these particles.

Venancio, C., et al. (2019). "The effects of nanoplastics on marine plankton: a case study with polymethylmethacrylate." Ecotoxicology and Environmental Safety **184**(109632).

Marine biota is currently exposed to plastic pollution. The biological effects of plastics may vary according to polymer types (e.g. polystyrene, polyethylene, acrylate), size of particles (macro, micro or nanoparticles) and their shape. There is a considerable lack of knowledge in terms of effects of nanoplastics (NP) to marine biota particularly of polymers like polymethylmethacrylate (PMMA). Thus, this study aimed to assess its ecotoxicological effects using a battery of standard monospecific bioassays with four marine microalgae (Tetraselmis chuii, Nannochloropsis gaditana, Isochrysis galbana and Thalassiosira weissflogii) and a marine rotifer species (Brachionus plicatilis). The tested PMMA-NP concentrations allowed the estimation of median effect concentrations for all microalgae species. T. weissflogii and T. chuii were respectively the most sensitive (EC_{50,96 h} of 83.75 mg/L) and least sensitive species (EC_{50,96 h} of 132.52 mg/L). The PMMA-NP were also able to induce mortality in rotifers at concentrations higher than 4.69 mg/L with an estimated 48 h median lethal concentration of 13.27 mg/L. A species sensitivity distribution curve (SSD), constructed based on data available in the literature and the data obtained in this study, reveal that PMMA-NP appears as less harmful to marine biota than other polymers like polystyrene.

Vendel, A. L., et al. (2017). "Widespread microplastic ingestion by fish assemblages in tropical estuaries subjected to anthropogenic pressures." Marine Pollution Bulletin **117**(1/2): 448-455.

Our aim was to quantify microplastic ingestion by fish assemblages in two tropical Brazilian estuaries and to evaluate whether biological and ecological factors influence the ingestion of microplastics by fish species. Of 2233 fish from both estuaries (from 69 species) examined in this study, 9% of the individuals (24 species) had microplastics in their gut contents. Microplastic

ingestion occurred irrespective of fish size and functional group. The diet of fish species was analyzed based on prey items identified in the fish's full stomach contents and five feeding guilds were defined. Microplastics were common throughout all feeding guilds. Low (average ingestion values 1.06+or-0.30 items/total fish) but widespread occurrence among estuaries also indicates proliferation of microplastic pollution. Our findings highlight the need to focus on assemblage level studies to understand the real magnitude of the problem and emphasize the urgency of mitigation measures directed at microplastic pollution in estuarine ecosystems.

Veneman, W. J., et al. (2017). "Pathway analysis of systemic transcriptome responses to injected polystyrene particles in zebrafish larvae." Aquatic Toxicology **190**: 112-120.

Microplastics are a contaminant of emergent concern in the environment, however, to date there is a limited understanding on their movement within organisms and the response of organisms. In the current study zebrafish embryos at different development stages were exposed to 700 nm fluorescent polystyrene (PS) particles and the response pathway after exposure was investigated using imaging and transcriptomics. Our results show limited spreading of particles within the larvae after injection during the blastula stage. This is in contrast to injection of PS particles in the yolk of 2-day old embryos, which resulted in redistribution of the PS particles throughout the bloodstream, and accumulation in the heart region. Although injection was local, the transcriptome profiling showed strong responses of zebrafish embryos exposed to PS particle, indicating a systemic response. We found several biological pathways activated which are related to an immune response in the PS exposed zebrafish larvae. Most notably the complement system was enriched as indicated by upregulation of genes in the alternative complement pathway (e.g. cfhl3, cfhl4, cfb and c9). The fact that complement pathway is activated indicates that plastic microparticles are integrated in immunological recognition processes. This was supported by fluorescence microscopy results, in which we observed co-localisation of neutrophils and macrophages around the PS particles. Identifying these key events can be a first building block to the development of an adverse outcome pathway (AOP). These data subsequently can be used within ecological and human risk assessment.

Venkata Ramana Reddy, K. and M. V. Nagabhushanam (2019). "STudy on the effect of alginate, type of cross linkers, and mucoadhesive polymers on drug release from lovastatin-loaded mucoadhesive cross-linked microbeads." Asian Journal of Pharmaceutical and Clinical Research **12**(12): 246-256.

Objective: The aim of the current study is to prepare and lovastatin-loaded alginate microbeads were prepared using emulsification gelation internal method by the use of different cross-linking agents, polymer effect in different concentrations on drug release and its combination with hydrophilic polymers on drug release. Method(s): The effect of sodium alginate concentration and its combination with other hydrophilic polymers on particle size and shape, scanning electron microscopy (SEM) studies, entrapment efficiency, Fourier transform infrared (FTIR) analysis (FTIR), differential scanning calorimetry (DSC) studies, and X-ray diffraction (XRD) studies conducted to determine compatibility of drug and used excipients and in vitro drug release was studied. The efficiency of mucoadhesion strength of microbeads is determined by wash-off study. Result(s): The optimum condition for preparation alginate beads and produces sustained release manner was occurred at 3% polymer mixture. Infrared spectroscopic study confirmed the presence of compatibility between drug-polymer additives, good drug entrapment, and SEM studies prove microbeads were in spherical and rough particles. XRD and DSC were used to confirm successful entrapment of drugs into the alginates microbeads. The in vitro release profile could be altered notably by changing formulation parameters to give a sustained release of drug from the microbeads. Conclusion(s): The kinetic modeling of the release data indicate that drug release from the microbeads follow anomalous transport mechanism and super Case-II transport mechanism and drug release is controlled by both swelling and relaxation of the polymer chains. It was found to be drug release is pH dependent. This will help in overcoming the drawbacks of lovastatin with a short half-life, improves the bioavailability. The release kinetics of drug from the alginate beads followed zero order. Copyright © 2019 The Authors.

Venkatesh, D. N., et al. (2019). "Enhanced oral bioavailability of tenofovir from ionotropically gelled microbeads." International Journal of Applied Pharmaceutics **11**(4): 242-250.

Objective: The main objective of the present investigation was to develop the microbeads of tenofovir. Tenofovir, a BCS class III drug has a poor bioavailability of 25%, and it is administered 300 mg once a day. By incorporating the drug into a microparticulate carrier, it is expected that the dissolution profile and the oral bioavailability may be increased. Method(s): Reinforced gellan-chitosan and calcium chloride beads of tenofovir were prepared by ionotropic gelation method employing various different concentrations of gellan, chitosan, calcium chloride and tenofovir. The beads were evaluated for various physicochemical parameters such as particle size determination, drug entrapment efficiency, swelling studies, infrared spectroscopy study, differential scanning calorimetry, x-ray diffraction analysis, scanning electron microscopy, in vitro drug release study, cytotoxicity study and in vivo oral bioavailability studies. Result(s): From the results, it can be concluded that the formulation TB-III exhibited higher drug entrapment efficiency (46.09+/-0.21), a higher swelling index, sustained drug release for a period of 24 h. The pharmacokinetic profile of the drug from microbeads exhibited an increased oral bioavailability (1.25 times higher than that of the pure drug), decreased elimination rate (1.32 times lesser for the drug in microbeads) with prolonged elimination half-life (1.32 times higher than pure tenofovir). Conclusion(s): Tenofovir loaded microbeads demonstrated as a better delivery system for the modified release of drug and also to navigate the drawbacks associated with conventional therapy. Venkateshwar Reddy, A. and S. Maduri (2012). "Formulation and evaluation of low cost sustained release floating alginate beads." International Journal of Research in Pharmaceutical Sciences **3**(3): 398-403.

Floating beads are the micro-beads/ spheres prepared by ionic gelation technique. They can be either of sustained release or immediate release type. Sustained release type of floating drug delivery systems generally employ a high viscosity polymer like the hydroxyl propyl methyl cellulose (HPMC) or ethyl cellulose as the matrixing agent. These polymers are generally very expensive, and their use in the formulation leads to increased cost of the for-mulation, which is the main reason that limits the wide-spread usage of this dosage form. In this study, we have tried to produce low cost floating alginate beads by substituting high-cost polymers like HPMC with low cost po-lymer like carboxy methyl cellulose (CMC). Comparative studies were carried out to determine the efficacy of for-mulations containing CMC with that of formulations containing HPMC as the matrixing agent. We have also stu-died the effect of physicochemical properties of the drugs on the drug release pattern of the dosage form i.e. floating alginate beads. © JK Welfare & Pharmascope Foundation.

Venugopal, S. P. (2017). "A survey of marine pollution based on oil spill, air and land pollutions." Journal of Engineering and Applied Sciences **12**(16): 4161-4164.

In this study, the marine ecosystem polluted by a huge amount of oil spills, industries outlet

wastages to rivers, lakes and those toxic evaporation polluting sea living organisms like penguins, birds, mammals, etc., even air polluting marine ecosystem by carrying lot of dusts from industries which outlets burned gases in open atmosphere. Most ships offshore may sink sometime with a load of oil or leakage happens on the sea, these spreads oil surrounding environment of sea and shores where animals get affected due to oil coated with furs and cause liver or lung damage, poison, die within 2 days. Oil spilling not only affected marine ecosystem animal but it also evaporates toxic gas in open atmosphere which is inhaled by human beings, cause liver, respiratory diseases. Land junks, plastic wastes, ship wastages are all thrown in seas to make them more polluted which leads to the toxic environment where no one will survive the environment is completely out of hands. © Medwell Journals, 2017.

Verdesoto, S., et al. (2015). "Plasma cells negative selection technique in samples of plasma cell dyscrasia patients." Haematologica **1)**: 500-501.

Background:A 15-20% of plasma cells (PCs) is the main prerequisite for diagnosis of genetic abnormalities by FISH techniques in bone marrow interphase plasma cell dyscrasia patients. Plasma cells (PCs) enrichment from bone marrow samples patients are frequently performed by the traditional method of immunomagnetic separation (magnetic activated cell sorting, MACS) using anti-CD138 MicroBeads. The main inconveniences of the MACS method are: its high cost, it is unsuccessful if the percentage of PCs in the initial sample is less than 5% and the PCs positive selection affect to the quality of the cells. RosetteSep Human Multiple Myeloma Enrichment Cocktail The RosetteSep enrichment cocktail cross-links unwanted cells in human bone marrow to multiple red blood cells (RBCs) using Tetrameric Antibody Complexes (TAC), forming immunorosettes. This increases the density of the unwanted cells, in such a way that they pellet along with the free RBCs when centrifuged over Ficoll- Paque PLUS. Desired cells are never labeled with antibodies and are easily collected as a highly enriched population at the interface between the plasma and Ficoll-Paque PLUS. With this above negative selection cells technique, it obtain a great quantity and high quality cells. Aim(s): The aim of this paper is to find the optimal algorithm, results and advantages in cost and pure and quality cell populations of the RosetteSep separation technique for samples of 50 bone marrow plasma cell dyscrasia patients with various percentages of neoplastic cells for applying FISH methods in these diseases. Method(s): Specimens: We analysed 76 heparinized bone marrow aspirates with known PCs dyscrasias for FISH diagnosis of genetic abnormalities. The percentage of monoclonal PCs varied between 0.48 and 73.5% (mean 14.39%) according to flow cytometry analysis on the previous study before PCs selection. The cytology analysis was used when the percentage was between 3 to 4%, to determine the PCs infiltration, when there was an infiltration >=7% or presence of cell nests the sample was processed. Cell separation: RosetteSep technique was used for separation of PCs in all specimens. Briefly, we added RosetteSep Multiple Myeloma Enrichment Cocktail at 50 mul/ml of bone marrow aspirate sample, incubated 20 minutes at room temperature and diluted it with an equal volume of Ficoll-Paque PLUS. After centrifuging for 20 minutes at 1200xg at room temperature we removed and washed the enriched cells from the density medium (plasma interface). For all cases, enrichment was accomplished. Flow cytometry analysis: It was proved the percentage of PCs before and after the separation. Enriched sample was stained with CD38-FITC and CD45-V450 and acquired using a BD FACSCanto II. Percentage of PCs among non-erythroid cells was obtained by Infinicyt software (Cytognos). FISH analysis: FISH analysis was carried out following standard procedures on interphase cells. The number of interphase cells analyzed were 200. Result(s): 76 bone marrow samples were analyzed from patients with a range age between 38-89 years old (mean 67 years old). 19 sample patients with <=5% of preselected PCS by flow cytometry (0.48%>4.9%) showed

hemodilution (1 cases). Cytology analysis were carried out in spite of do the PCs selection in the rest of the bone marrow samples with <=5% PCs (6 cases); the PCs selection was realized when the samples showed a >=7% of PCs and/or nest cells by cytology. All samples were successfully separated. The median of PCs after enrichment was 60.5% (range 45.93- 86.75%). We obtained results in all of 77 FISH samples analyzed. Summary and Conclusion(s): The introduction of RosetteSep contributed markedly in increasing the effectiveness of plasma cell separation from bone marrow samples, mainly in samples with low plasma cell content where the MACS method is not unsuccessful (<5%), its negative selection strategy enabled us to obtain sufficient amounts of highly purified and quality PCs required for subsequent diagnosis techniques proposed. On the other hand, the above technique has a low cost as opposed to MACS. The increase in the PCs concentration permits better FISH results incrementing the genetic abnormality detections which have a high prognosis value in these pathologies.

Verespej, M. (2009). "ASTM: Changes likelyfor SPI resin ID codes." Plastics News **21**(34): 1-1NULL.
The article informs that some possible changes have been developed by ASTM International Inc. to the plastics industry resin identification code. The code was developed in 1988 by Society of the Plastics Industry (SPI), but the task of possibly changing elements of the code has been given to ASTM. The resin identification code is used by consumers and municipalities to identify plastic products for recycling.

Verespej, M. (2012). "Center petition seeking to set plastic pollution limits in water." Plastics News **24**(24): 0004-0004.
The article reports that the U.S. Center for Biological Diversity has requested that the U.S. Environmental Protection Agency (EPA) issue regulations limiting plastic pollution in ocean waters. Topics include the Clean Water Act of the EPA and the health risks to marine life posed by plastics pollution.

Verespej, M. (2012). "Health-care recycling council begins study." Plastics News **24**(23): 0020-0020.
The article discusses a 2012 study that will be conducted by the Healthcare Plastics Recycling Council (HPRC) to analyze the types and amount of plastic waste generated at Stanford Hospital & Clinics healthcare facility in Palo Alto, California. According to the article, the HPRC also released Design for Recycling hospital plastics recycling guidelines in November, 2011.

Verma, S. B., et al. (1979). "A comparison of temperature fluctuations measured by a microbead thermistor and a fine wire thermocouple over a crop surface." Agricultural Meteorology **20**(4): 281-289.
A microbead thermistor and a fine wire thermocouple were tested for rapid-response air temp. measurements over a lucerne crop. The turbulent statistics (the standard deviations of temp. fluctuations, and the covariances of temp. and vertical velocity fluctuations) and spectra measured with the 2 sensors under different thermal stratification conditions compared reasonably well. Coherence computations also indicated a fairly high degree of agreement between the time series measured with the microbead thermistor and the fine wire thermocouple.

Vertova, A., et al. (2019). "Chlorine Dioxide Degradation Issues on Metal and Plastic Water Pipes Tested in Parallel in a Semi-Closed System." International Journal of Environmental Research & Public Health [Electronic Resource] **16**(22): 19.
Chlorine dioxide (ClO₂) has been widely used as a disinfectant in drinking water in the past but its effects on water pipes have not been investigated deeply, mainly due to the

difficult experimental set-up required to simulate real-life water pipe conditions. In the present paper, four different kinds of water pipes, two based on plastics, namely random polypropylene (PPR) and polyethylene of raised temperature (PERT/aluminum multilayer), and two made of metals, i.e., copper and galvanized steel, were put in a semi-closed system where ClO₂ was dosed continuously. The semi-closed system allowed for the simulation of real ClO₂ concentrations in common water distribution systems and to simulate the presence of pipes made with different materials from the source of water to the tap.

Verykiou, S., et al. (2017). "Modulation of autophagy reduces survival of trametinib-resistant, CD271-expressing melanoma subpopulations." British Journal of Dermatology **176 (4)**: e44.

Acquired resistance of BRAF-mutant melanoma to targeted BRAF/mitogen-activated protein kinase kinase (MEK) inhibition is associated with increased expression of the neurotrophin receptor CD271 and the activation of prosurvival mechanisms including autophagy. The aim of the present study was to further define the relationship between CD271 expression and autophagy, and to determine the impact of CD271 inhibition or autophagy modulation on the potential resensitization of metastatic melanoma cells to MEK inhibition with trametinib. Semiquantitative immunohistochemical analysis (IHC) of CD271 expression in five benign naevi and 17 primary cutaneous melanomas of differing American Joint Committee on Cancer stages with 13 patient-matched metastatic lymph node tumours demonstrated a significant stepwise increase in CD271 expression with disease progression (P = 0.002). Additionally, autophagic activity (assessed by p62 IHC analysis) was increased in metastatic lymph nodes compared with patient-matched primary melanomas. Treatment of WM35/A375 BRAF^{V600E} mutant melanoma cell lines with trametinib for 9 days resulted in increased CD271 expression, as well as LC3-II accumulation and reduced p62 expression (P < 0.001), both hallmarks of increased autophagy. Inhibition of autophagy using the lysosomal inhibitor chloroquine in trametinib-resistant CD271-expressing WM35/A375 cells resulted in significant inhibition of cell viability and reduction in colony-forming capacity, suggesting a prosurvival role of autophagy in the development of drug resistance. Furthermore, chloroquine also specifically inhibited the viability of CD271-positive WM35/A375 cells following selection with magnetic microbeads, indicating a direct correlation between CD271 expression and prosurvival autophagic activity. Alternatively, promoting cytotoxic autophagy in trametinibresistant CD271-expressing melanoma subpopulations with D9- tetrahydrocannabinol also resulted in significant inhibition of cell viability (P < 0.05). Therefore, collectively these data underpin the prosurvival role of autophagy and suggest that targeting autophagy modulation represents a viable therapeutic strategy through which to overcome MEK inhibitor-induced, CD271-mediated drug resistance of metastatic melanoma.

Vethaak, A. D. and H. A. Leslie (2016). "Plastic Debris Is a Human Health Issue." Environmental Science & Technology **50**(13): 6825-6826.

Viana, K. F., et al. (2013). "Analysis using canine peripheral blood for establishing in vitro conditions for monocyte differentiation into macrophages for Leishmania chagasi infection and T-cell subset purification." Veterinary Parasitology **198**(1/2): 62-71.

Canine visceral leishmaniasis (CVL) is a parasitic disease endemic in many countries, and dogs present as the major natural reservoir of the parasite, Leishmania chagasi (syn. L. infantum). Biomarkers in the canine immune system is an important technique in the course of developing vaccines and treatment strategies against CVL. New methodologies for studying the immune response of dogs during Leishmania infection and after receiving vaccines and treatments against CVL would be useful. In this context, we used peripheral blood mononuclear cells (PBMCs) from healthy dogs to evaluate procedures related to (i) establishment of in vitro conditions of monocytes differentiated into macrophages infected with L. chagasi and (ii) purification procedures of T-cell subsets (CD4⁺ and CD8⁺) using microbeads. Our data demonstrated that after 5 days of differentiation, macrophages were able to induce significant phagocytic and microbicidal activity after L. chagasi infection and also showed increased frequency of parasitism and a higher parasite load. Although N-acetyl- beta -D-glucosaminidase (NAG) levels presented similar levels of macrophage culture and L. chagasi infection, a progressive decrease in myeloperoxidase (MPO) levels was a hallmark over 5 days of culture. High purity levels (>90%) of CD4 and CD8 T cells were obtained on a magnetic separation column. We concluded that monocytes differentiated into macrophages at 5 days and displayed an intermediate frequency of parasitism and parasite load 72 h after L. chagasi infection. Furthermore, the purification system using canine T-lymphocyte subsets obtained after 5 days of monocyte differentiation proved efficient for CD4 or CD8 T-cell purification (>=90%). The in vitro analysis using L. chagasi-infected macrophages and purified T cells presented a prospective methodology that could be incorporated in CVL vaccine and treatment studies that aim to analyze the microbicidal potential induced by specific CD4⁺ and/or CD8⁺ T cells.

Vianello, A., et al. (2018). "First evaluation of floating microplastics in the Northwestern Adriatic Sea." Environmental science and pollution research international **25**(28): 28546-28561.

Plastic pollution in the marine environment is becoming a problem of global concern, and the Mediterranean is believed to be one of the worst affected regional seas. The present study presents data on floating microplastics in the Northwestern Adriatic Sea in order to evaluate the possible contribution of two significant potential sources: the lagoon of Venice and the Po River. Samples were collected in March and April 2014 along two transects located off Pellestrina Island (Venice) and the Po Delta, each consisting of four sampling stations at 0.5, 3, 10, and 20 km from the shoreline. Microplastics were quantified and classified according to their colors and shapes and analyzed by micro-attenuated total reflection-FT-IR. Microplastics were found in all samples, albeit with high spatial and temporal variability. The highest concentrations were observed in March at the offshore station of the Pellestrina transect (10.4 particles m−2) and the two landward stations off the Po Delta (2.1 and 4.3 particles m−2), highlighting the influence of various factors, such as surface circulation and river discharges, in determining specific accumulation patterns. The most common polymers were polyethylene and polypropylene, and most of the particles were secondary microplastics (83.5%). The patchy distribution of microplastics observed in the study area is driven by hydrodynamic and meteorological factors acting on short time scales.

Vianello, A., et al. (2019). "Simulating human exposure to indoor airborne microplastics using a Breathing Thermal Manikin." Scientific Reports **9**(1): 8670.

Humans are potentially exposed to microplastics through food, drink, and air. The first two pathways have received quite some scientific attention, while little is known about the latter. We address the exposure of humans to indoor airborne microplastics using a Breathing Thermal Manikin. Three apartments were investigated, and samples analysed through FPA-micro FTIR-Imaging spectroscopy followed by automatic analyses down to 11 micro m particle size. All samples were contaminated with microplastics, with concentrations between 1.7 and 16.2 particles m⁻³. Synthetic fragments and fibres accounted, on average, for 4% of the total identified particles, while nonsynthetic particles of protein and cellulose constituted 91%

and 4%, respectively. Polyester was the predominant synthetic polymer in all samples (81%), followed by polyethylene (5%), and nylon (3%). Microplastics were typically of smaller size than nonsynthetic particles. As the identified microplastics can be inhaled, these results highlight the potential direct human exposure to microplastic contamination via indoor air.

Vicentini, D. S., et al. (2019). "Toxicological Evaluation and Quantification of Ingested Metal-Core Nanoplastic by Daphnia magna Through Fluorescence and Inductively Coupled Plasma-Mass Spectrometric Methods." Environmental Toxicology & Chemistry **38**(10): 2101-2110.

There are few studies on nanoplastic that propose quantification of the amount ingested combined with evaluation of the toxic effects on aquatic organisms. We propose 2 methods to quantify the amount of polystyrene nanoplastic (PSNP) ingested by Daphnia magna: fluorescence intensity, where a fluorescent monomer (F) is added to the PSNP and quantified through fluorescence light microscopy, and total aluminum quantification, where PSNP is synthesized with Al2O3 metal-core nanoparticles and used for quantification of the nanoplastic ingested by the organism Daphnia magna using inductively coupled plasma-mass spectrometry. In addition, the PSNP was functionalized with palmitic acid to simulate the environmental conditions leading to biological and chemical transformations. Acute and chronic toxicity tests were performed with fluorescent PSNP (PSNP/F) and palmitic acid-functionalized PSNP/F (PSNP/F-PA). The ingestion quantified was higher by factors of 2.8 and 3.0 for PSNP/F-PA and 1.9 and 1.7 for PSNP/F applying the fluorescence intensity and total Al quantifying methods, respectively, when compared to PSNP. These results are consistent with the data obtained in the toxicity tests, which showed an approximately 3 times increase in the adverse effect of PSNP/F-PA on the mobility and reproduction of the organisms. Thus, the strong inhibition of D. magna reproduction caused by PSNP/F-PA in the chronic toxicity tests could be associated with a greater amount of this nanoplastic being ingested by the organisms. Vidal, J. C., et al. (2012). "An electrochemical immunosensor for ochratoxin A determination in wines based on a monoclonal antibody and paramagnetic microbeads." Analytical and bioanalytical chemistry **403**(6): 1585-1593.

We report a direct competitive immunosensor for the rapid determination of ochratoxin A (OTA) in wine samples. Magnetic beads (1+or-0.5 micro m diameter) covered with streptavidin were functionalized with a monoclonal antibody against OTA, and then left to incubate in a solution of tracer (ochratoxin conjugated to the enzyme peroxidase) and a range of OTA concentrations (10⁻⁴ to 1,000 ng mL⁻¹). After washing and separation steps helped with a magnetic field, a volume of the dispersion was put on screen-printed electrodes under a magnet, and after adding the substrate the p-benzoquinone generated enzymatically was detected by differential-pulse voltammetry. Wine samples (2 mL) were easily prepared simply by adjusting to pH=7.5 with diluted NaOH and by adding polyvinylpyrrolidone for complexing polyphenols, without any other clean-up or preconcentration steps. The limit of detection for detecting OTA in wines was of 0.11+or-0.01 ng L⁻¹, well below the permitted content of the mycotoxin by the European Union (<2 ng mL⁻¹). Spiked wines were subjected to immunosensor calibrations to study the matrix effects. OTA concentrations measured with the immunosensor were compared with those obtained by high-performance liquid chromatography coupled to fluorescence detection (AOAC official method 2001.01). The OTA levels from two red wines of "Campo de Borja", Spain, ranged from about 0.027 to 0.033 ng mL⁻¹ of OTA.

Vidyasakar, A., et al. (2018). "Macrodebris and microplastic distribution in the beaches of Rameswaram Coral Island, Gulf of Mannar, Southeast coast of India: A first report." Marine Pollution Bulletin **137**: 610-616.

This is the first study on the distribution and characteristics of plastic debris found in the sediments of Rameswaram Island, Gulf of Mannar, India. Studies on the distribution of plastics and microplastic content in highly populated coral islands and their impact on the coral ecosystem are very scarce. For this purpose, marine sediment samples were collected from 20 locations along the coastal areas of the study region. The distribution and characterization study was carried out by visual examination followed by FTIR spectroscopy. The results showed abundance of white-colored and irregular-shaped plastic debris in this study area. Polypropylene was identified as a dominant polymer variety, followed by polyethylene, polystyrene, nylon, and polyvinyl chloride. Tourist activities and fishing practices were found to be the possible sources of the microplastic debris. Additionally, the distribution of the plastics was found to be dominantly controlled by the aeolian process and the nature of the coast. Copyright © 2018

Vigneron, A., et al. (2019). "Immune Defenses of a Beneficial Pest: The Mealworm Beetle, Tenebrio molitor." Frontiers in Physiology **10**: 138.

The mealworm beetle, Tenebrio molitor, is currently considered as a pest when infesting stored grains or grain products. However, mealworms are now being promoted as a beneficial insect because their high nutrient content makes them a viable food source and because they are capable of degrading polystyrene and plastic waste. These attributes make T. molitor attractive for mass rearing, which may promote disease transmission within the insect colonies. Disease resistance is of paramount importance for both the control and the culture of mealworms, and several biotic and abiotic environmental factors affect the success of their anti-parasitic defenses, both positively and negatively. After providing a detailed description of T. molitor's anti-parasitic defenses, we review the main biotic and abiotic environmental factors that alter their presentation, and we discuss their implications for the purpose of controlling the development and health of this insect.

Viirlaid, E., et al. (2019). "Immunoassay for rapid on-site detection of glyphosate herbicide." Environmental Monitoring & Assessment **191**(8): 507.

Glyphosate is the most widespread herbicide and its global use is steadily increasing. Although glyphosate is considered to have low toxicity, its wide application has raised concerns about its effects on human health. The extensive use of glyphosate has risen a need of its continuous monitoring in drinking and surface waters to assure in accordance with the set standards. Within the present study, we have developed a novel assay for the on-site detection of glyphosate by combining flow-through technology with the high specificity of immunorecognition. The proposed biosensing system was based on the detection of fluorescence signal generated by the quantitative replacement of glyphosate in antigen-antibody complex with IgY-type anti-glyphosate antibodies on microbeads by synthetic 5-carboxytetramethylrhodamine (5-TAMRA) conjugated glyphosate. The working range of this assay was in low millimolar range and the time required for glyphosate detection around 0.5 h. The applicability of the immunoassay for glyphosate detection in surface water was tested and the biosensor results were validated with high-performance liquid chromatography.

Villaret, J., et al. (2018). "Adaptation of a microbead assay for the easy evaluation of traditional anti-sickling medicines: application to DREPANOSTAT and FACA." Pharmaceutical Biology **56**(1): 385-392.

CONTEXT: Sickle cell disease is a common inherited blood disorder affecting millions of people worldwide. Due to lack of progress in drug discovery for a suitable treatment, sufferers often turn to traditional medicines that take advantage of the plant extracts activity used by traditional healers.

OBJECTIVE: This study optimizes an anti-sickling screening test to identify preparations capable of reverting sickle cells back to the morphology of normal red blood cells. We focused on the miniaturization and practicability of the assay, so that it can be adapted to the laboratory conditions commonly found in less developed countries.

MATERIALS AND METHODS: We tested two traditional anti-sickling herbal medicines, FACA and DREPANOSTAT, composed of Zanthoxylum zanthoxyloides (Lam.) Zepern. & Timler (Rutaceae) and Calotropis procera (Aiton) Dryand. (Apocynaceae) at screening concentrations of hydroethanol extracts from 0.2 to 1 mg/mL. Potential bioactive molecules present in the extracts were profiled using Ultra High Performance Liquid Chromatography coupled with High Resolution Mass Spectrometry (UHPLC-HRMS/MS) method, identified through HRMS, MS/MS spectra and in silico fragmentation tools.

RESULTS: Hydroethanol extracts of FACA and DREPANOSTAT showed low anti-sickling activity, inhibiting less than 10% of the sickling process. The UHPLC-HRMS/MS profiles identified 28 compounds (18 in FACA and 15 in DREPANOSTAT, including common compounds) among which l-phenylalanine is already described as potential anti-sickling agent. When used as positive control, 7 mg/mL

phenylalanine reduced the sickled RBC to 52%.
DISCUSSION AND CONCLUSIONS: This assay has been optimized for the easy screening of plant extracts or extracted compounds from bioassay guided fractionation, valuable to laboratories from less developed countries.

Vinatzer, B. A., et al. (1998). "Construction and characterization of a bacterial artificial chromosome library of apple." Theoretical and Applied Genetics **97**(7): 1183-1190.
A bacterial artificial chromosome (BAC) library has been constructed from apple (Malus x domestica [M. pumila]) using the variety Florina, which is resistant to scab (Venturia inaequalis) by virtue of the Vf gene. Since apple leaves are rich in polyphenols, high-molecular-weight DNA was extracted from leaf nuclei with a protocol adapted to apple. The nuclei were then embedded in agarose microbeads and partially digested by varying ratios of EcoRI to EcoRI methylase. The resulting DNA fragments were size-selected by pulsed-field gel electrophoresis, ligated to the BAC cloning vector pECBAC1 and transformed into Escherichia coli cells by electroporation. A total of 36 864 recombinant clones (BACs) were obtained. The library has an average insert size of 120 kb and represents approximately 5 x apple haploid-genome equivalents. It was screened with six cDNA probes using the chemiluminescent DIG system. An average of 4.4 clones was detected for each locus. The apple BAC library will be used to isolate the Vf scab resistance gene through map-based cloning. In this connection the library was screened with a marker closely linked to the Vf gene and six positive clones have been isolated. This library should thus be well suited for map-based gene cloning, in particular for the isolation of the Vf gene and for the construction of a physical map of the apple genome.

Vinson, B. T., et al. (2017). "Laser direct-write based fabrication of a spatially-defined, biomimetic construct as a potential model for breast cancer cell invasion into adipose tissue." Biofabrication **9**(2): 025013.
Epithelial-adipose interaction is an integral step in breast cancer cell invasion and progression towards lethal metastatic disease. Understanding the physiological contribution of obesity, a major contributor to breast cancer risk and negative prognosis in post-menopausal patients, on cancer cell invasion requires detailed co-culture constructs that reflect mammary microarchitecture. Using laser direct-write, a laser-based CAD/CAM bioprinting technique, we have demonstrated the ability to construct breast cancer cell-laden hydrogel microbeads into spatially defined patterns in hydrogel matrices containing differentiated adipocytes. Z-stack imaging confirmed the three-dimensional nature of the constructs, as well as incorporation of cancer cell-laden microbeads into the adipose matrix. Preliminary data was gathered to support the construct as a potential model for breast cancer cell invasion into adipose tissue. MCF-7 and MDA-MB-231 breast cancer cell invasion was tracked over 2 weeks in an optically transparent hydrogel scaffold in the presence of differentiated adipocytes obtained from normal weight or obese patient tissue. Our model successfully integrates adipocytes and gives us the potential to study cellular and tissue-level interactions towards the early detection of cancer cell invasion into adipose tissue.

Virsek, M. K., et al. (2017). "Microplastics as a vector for the transport of the bacterial fish pathogen species Aeromonas salmonicida." Marine Pollution Bulletin **125**(1-2): 301-309.
Microplastics is widespread in the marine environment where it can cause numerous negative effects. It can provide space for the growth of organisms and serves as a vector for the long distance transfer of marine microorganisms. In this study, we examined the sea surface concentrations of microplastics in the North Adriatic and characterized bacterial communities

living on the microplastics. DNA from microplastics particles was isolated by three different methods, followed by PCR amplification of 16S rDNA, clone libraries preparation and phylogenetic analysis. 28 bacterial species were identified on the microplastics particles including Aeromonas spp. and hydrocarbon-degrading bacterial species. Based on the 16S rDNA sequences the pathogenic fish bacteria Aeromonas salmonicida was identified for the first time on microplastics. Because A. salmonicida is responsible for illnesses in fish, it is crucial to get answers if and how microplastics pollution is responsible for spreading of diseases. Copyright © 2017 Elsevier Ltd

Visani, G., et al. (2009). "Identification of novel cryptic chromosomal abnormalities in primary myelofibrosis by single-nucleotide polymorphism oligonucleotide microarray." Blood. Conference: 51st Annual Meeting of the American Society of Hematology, ASH. New Orleans, LA United States. Conference Publication: **114**(22).

Background.: Primary myelofibrosis (PMF) is a clonal myeloproliferative neoplasm (MPN) characterised by a proliferation of predominantly megakaryocytes and granulocytes in bone marrow that in fully developed disease is replaced by fibrous tissue. At molecular level, no specific defect has been identified yet. Cytogenetic abnormalities occur in up to 30% of patients, the commonest including del(13)(q12-22), der(6)t(1;6)(q21-23;p21.3), del (20q), and partial trisomy 1q. In addition, approximately 50% of patients with PMF exhibit a single, recurrent, somatic mutation in the gene encoding the cytoplasmic tyrosine kinase Janus kinase 2 (JAK2). However, such mutation is not specific, also occurring in other MPN. Recently a couple of reports dealt with single-nucleotide polymorphism (SNP) array karyotyping of MPD, including some PMF. Importantly, such studies could identify previously uncovered genetic lesions, highlighting the importance of novel high resolution technologies for the detection of formerly unknown, cryptic aberrations. In this study we performed high resolution karyotyping by SNP oligonucleotide microarray by using the most updated Affymetrix array (Genome-Wide Human SNP Array 6.0) in 20 cases of myelofibrosis (MF) in order to identify novel cryptic genomic aberrations. Methods.: DNA (500 ng) was extracted from peripheral blood cells (PBMNC) of 14 primary and 6 secondary MF patients. PBMNC were depleted from lymphocytes by magnetic beads. Briefly, CD3+ cells were labeled with anti-CD3 MoAb directly coupled to magnetic microbeads (Miltenyi Biotech), washed and subsequently purified using Mini-MACS technology. After selection, cell present in the positive (CD3) and negative (PBMNC) fractions were counted and submitted to flow cytometry analysis. DNA was processed and hybridized to the Affymetrix SNP arrays 6.0 as for manufacturer instruction. A whole-genome copy number variation (CNV), genotyping, loss of heterozygosity (LOH) and uniparental disomy (UPD) analyses were performed using the Partek Suite 6.0. Ten lab-specific as well as 90 HapMap samples relative to Caucasian healthy donor were used as control reference. Genomic abnormalities were defined as recurrent when occurring in at least 25% of cases. JAK2 mutational status was assessed as reported, by alle-specific PCR. Clinical information and complete follow up were retrieved for all cases. Direct sequencing, FISH, qPCR and immunohistochemistry (IHC) has been chosen for validation. Results.: In all patients we could detect several CNV. The median number of CNV was 60 (range, 34-72), including 46 amplifications (A) and 14 deletions (D). All commonest previously described abnormalities were detected. In addition, several formerly uncovered recurrent lesions were identified, mainly involving 1p, 1q, 2p, 4p, 4q, 5q, 6p, 6q, 7q, 8p, 9q 10q, 11p 11q, 12p, 14q, 15q, 16p, 16q, 17q, 18q, 19q, 20p, 22q. The median size of such CNV was 424,582 Kbp (1,379 Kbp-71,277 Mbp). We then compared JAK2+ vs. JAK2- cases. Of note, we found numerous definite aberrations (A or D) distinguishing the two groups and specifically affecting 16q23.1, 1p36.13, 3q26, 14q13.2, 5q33.2, 6q14.1, 7q33, 8p23.1, and 9p11.2. Grippingly, several

genes of potential interest for PMF pathogenesis were identified within the involved loci, including RET, SCAPER, WWOX and SIRPB1. Among others, the product of such genes has been selected for validation by IHC. Similarly, many miRNA were recognized, which may deserve further investigation. Conclusions.: By using a newly developed highly sensitive array we identified novel cryptic lesions in patients affected by MF. Future studies on larger series, as well as functional analyses will definitely assess their role in the pathogenesis of the disease. Of note, consistent differences were recorded in JAK2+ vs. JAK2-, supporting the hypothesis of different genetic mechanisms occurring in the two sub-groups.

Viscidi, R. and F. Rossi (2013). "Are B lymphocytes a reservoir of JC virus?" Journal of NeuroVirology **19 (3)**: 300-301.

Whether B cells are a reservoir for JC virus (JCV) is controversial, with widely ranging reports of JCV DNA detection in B cells/PBMC and conflicting data on susceptibility of B cell lines to JCV infection, the association of natalizumab with PML and the perturbations of B cell populations by the drug have stimulated renewed interest in the question whether B cells are susceptible to JCV infection. We purified primary B cells from healthy donor PBMC using flow cytometry cell sorting into naive (CD19+/CD27-/CD38-) and memory (CD19+ /CD27+/CD38-) B cells, transitional B cells (CD19+/CD27-/CD24+ /CD38+) and differentiated plasma-like cells (CD19+/CD27+/CD38+ /CD24-). Purified populations were transfected with pBJC (rearranged) or pJCCY (archetype) plasmid DNA (gift of Jennifer Gordon) using the Amaxa B cell Nucleofector kit. In addition, the cells were infected with JCV from lysates of 293TT cells cultured for 7 days after transfection with the above plasmids, following the method of Broekema and Imperiale for production of infectious JC virus. Four days posttransfection and 7 days post-infection, we did not detect JCVearly gene mRNAexpression by TaqMan PCR.However, the cells were negative for GFP expression using a control plasmid, raising concerns about efficiency of transfection of sorted cells. As an alternative approach, B cells were purified by Miltenyi microbead separation into CD19+/CD27-/CD10- cells (naive), CD19+/CD27-/CD10+ (transitional), CD19+/CD27+ /CD138- (memory), and CD19+/CD27+/CD138+ (plasma) sub populations. Cells recovered by microbead separation were capable of being transfected with a GFP control plasmid. Results of transfection/infection experiments with JC virus plasmids/TT293 lysates will be reported.

Vladisavljevic, G. T. and R. A. Williams (2005). "Recent developments in manufacturing emulsions and particulate products using membranes." Advances in Colloid & Interface Science **113**(1): 1-20.

Membrane emulsification (ME) is a relatively new technique for the highly controlled production of particulates. This review focuses on the recent developments in this area, ranging from the production of simple oil-in-water (O/W) or water-in-oil (W/O) emulsions to multiple emulsions of different types, solid-in-oil-in-water (S/O/W) dispersions, coherent solids (silica particles, solid lipid microspheres, solder metal powder) and structured solids (solid lipid microcarriers, gel microbeads, polymeric microspheres, core-shell microcapsules and hollow polymeric microparticles). Other emerging technologies that extend the capabilities into different membrane materials and operation methods (such as rotating membranes, repeated membrane extrusion of coarsely pre-emulsified feeds) are introduced. The results of experimental work carried out by cited researchers in the field together with those of the current authors are presented in a tabular form in a rigorous and systematic manner. These demonstrate a wide range of products that can be manufactured using different membrane approaches. Opportunities for creation of new and novel entities are highlighted for low throughput applications (medical diagnostics, healthcare) and for large-scale productions (consumer and personal products). Vlietstra, L. S. and J. A. Parga (2002). "Long-term changes in the type, but not amount, of ingested plastic particles in short-tailed shearwaters in the southeastern Bering Sea." Marine Pollution Bulletin **44**(9): 945-955.

We report the current (1997-1999, 2001) incidence and amount of ingested plastic in short-tailed shearwaters (Puffinus tenuirostris) in the southeastern Bering Sea and compare our results with plastic reported in shearwaters during 1970-1978. We also examine correlations between plastic loads and shearwater body mass. We found that 84% (N = 330) of shearwaters sampled in 1997-1999 and 2001 contained plastic. The incidence and amount of ingested plastic have not significantly changed since the 1970s. In contrast, the predominant type of plastic has changed over time, from industrial plastic to user plastic. S,asonal patterns in the incidence and amount of ingested plastic also changed from peak levels during early and late summer in the 1970s to mid summer in the late 1990s and 2001. We suggest that the availability of neuston plastic to seabirds in the Bering Sea has undergone a shift in composition since the 1970s. Shearwater body mass appears little if at all impaired by plastic, at least at present levels of consumption.

Volkmann, E. R., et al. (2018). "Specific pneumoproteins predict progression of interstitial lung disease in systemic sclerosis patients undergoing treatment with immunosuppression." Arthritis and Rheumatology **70 (Supplement 9)**: 2093-2094.

Background/Purpose: Interstitial lung disease (ILD) is the leading cause of death in systemic sclerosis (SSc). While some SSc-ILD patients are stable or improve with immunosuppressive therapy, others have progressive decline and currently available clinical parameters do not reliably predict outcomes. We investigated whether two specific pneumoproteins, Krebs von den Lungen-6 [KL-6] and CC chemokine ligand 2 [CCL18]) predict response to immunosuppression with cyclophosphamide (CYC) and mycophenolate(MMF) in SSc-ILD. Method(s): 142 patients in Scleroderma Lung Study (SLS) II were randomized to receive either mycophenolate (MMF) for 2 years or oral CYC for 1 year followed by 1 year of placebo. All available serum baseline and 12-month samples were investigated. CCL18 was assayed by commercially available ELISA while KL-6 was measured using antibody coated latex microbeads and an automated analyzer. The forced vital capacity (FVC) and the diffusing capacity for carbon monoxide (DLCO) were measured every 3 months. Quantitaive Lung fibrosis (QLF) and Quantitative ILD (QILD) scores for whole lung (WL) and zone of maximum involvement (ZM) were measured at baseline. To investigate the relationship between baseline CCL18 and KL-6 and progression of ILD, joint models were created with the outcomes of the course of the FVC and DLCO over 1 year. Result(s): Baseline serum KL-6 and CCL18 correlated with extent of ILD. KL-6 levels correlated with (r, P-value):DLCO (- 0.3; 0.0002) QLF-WL (0.5; <0.0001) QLF-ZM(0.4; <0.0001), and QILD-WL(0.5; <0.0001), QILD-ZM (0.5; <0.0001); Baseline CCL18 levels were correlated with QILD-WL (r=0.2; p=0.04) and QILD-ZM (r=0.3; p=0.009), but not with the FVC or DLCO. CCL18 and KL6 levels declined significantly in the first year in both arms (Figure 1). After adjusting for baseline disease severity, higher baseline KL6 levels predicted progression of ILD as measured by the course of the FVC (CYC/MMF: Estimate-0.31/-0.74; P=0.024/<0.001) and DLCO (CYC/MMF: Estimate -1.30/-1.29; P<0.001/<0.001) over 1 year for both treatment arms. Similarly, higher baseline CCL18 levels predicted progression of ILD as measured by the course of the FVC (CYC/MMF: Estimate -1.24/-0.35; P<0.001; 0.007) and DLCO (CYC/MMF: Estimate -1.87/-1.24; P=0.001/0.002) over 1 year for both treatment arms. Conclusion(s): In the context of a rigorously conducted clinical trial for SSc-ILD, baseline KL-6 and CCL18 levels correlated with several surrogate measures of ILD severity. Patients with higher baseline KL-6 and CCL18 levels

were more likely to experience disease progression despite treatment with CYC and MMF. KL-6 and CCL18 could be used to identify patients with progressive ILD that require closer monitoring in clinical practice. KL-6 and CCL18 may also be used to enrich SSc- ILD clinical trials with those at risk of accelerated ILD progression with conventional immunosuppressive therapy. (Figure Presented).

Volkov, V. A., et al. (2014). "Preparation of segmented microtubules to study motions driven by the disassembling microtubule ends." Journal of Visualized Experiments **85**: 15.

Microtubule depolymerization can provide force to transport different protein complexes and protein-coated beads in vitro. The underlying mechanisms are thought to play a vital role in the microtubule-dependent chromosome motions during cell division, but the relevant proteins and their exact roles are ill-defined. Thus, there is a growing need to develop assays with which to study such motility in vitro using purified components and defined biochemical milieu. Microtubules, however, are inherently unstable polymers; their switching between growth and shortening is stochastic and difficult to control. The protocols we describe here take advantage of the segmented microtubules that are made with the photoablatable stabilizing caps. Depolymerization of such segmented microtubules can be triggered with high temporal and spatial resolution, thereby assisting studies of motility at the disassembling microtubule ends. This technique can be used to carry out a quantitative analysis of the number of molecules in the fluorescently-labeled protein complexes, which move processively with dynamic microtubule ends. To optimize a signal-to-noise ratio in this and other quantitative fluorescent assays, coverslips should be treated to reduce nonspecific absorption of soluble fluorescently-labeled proteins. Detailed protocols are provided to take into account the unevenness of fluorescent illumination, and determine the intensity of a single fluorophore using equidistant Gaussian fit. Finally, we describe the use of segmented microtubules to study microtubule-dependent motions of the protein-coated microbeads, providing insights into the ability of different motor and nonmotor proteins to couple microtubule depolymerization to processive cargo motion.

Vollenkle, C., et al. (2004). "Construction of a functional S-layer fusion protein comprising an immunoglobulin G-binding domain for development of specific adsorbents for extracorporeal blood purification." Applied & Environmental Microbiology **70**(3): 1514-1521.

The chimeric gene encoding a C-terminally-truncated form of the S-layer protein SbpA from Bacillus sphaericus CCM 2177 and two copies of the Fc-binding Z-domain was constructed, cloned, and heterologously expressed in Escherichia coli HMS174(DE3). The Z-domain is a synthetic analogue of the B-domain of protein A, capable of binding the Fc part of immunoglobulin G (IgG). The S-layer fusion protein rSbpA(31-1068)/ZZ retained the specific properties of the S-layer protein moiety to self-assemble in suspension and to recrystallize on supports precoated with secondary cell wall polymer (SCWP), which is the natural anchoring molecule for the S-layer protein in the bacterial cell wall. Due to the construction principle of the S-layer fusion protein, the ZZ-domains remained exposed on the outermost surface of the protein lattice. The binding capacity of the native or cross-linked monolayer for human IgG was determined by surface plasmon resonance measurements. For batch adsorption experiments, 3-microm-diameter, biocompatible cellulose-based, SCWP-coated microbeads were used for recrystallization of the S-layer fusion protein. In the case of the native monolayer, the binding capacity for human IgG was 5.1 ng/mm(2), whereas after cross-linking with dimethyl pimelimidate, 4.4 ng of IgG/mm(2) was bound. This corresponded to 78 and 65% of the theoretical saturation capacity of a planar surface for IgGs aligned in the upright position,

respectively. Compared to commercial particles used as immunoadsorbents to remove autoantibodies from sera of patients suffering from an autoimmune disease, the IgG binding capacity of the S-layer fusion protein-coated microbeads was at least 20 times higher. For that reason, this novel type of microbeads should find application in the microsphere-based detoxification system.

von Friesen, L. W., et al. (2019). "An efficient and gentle enzymatic digestion protocol for the extraction of microplastics from bivalve tissue." Marine Pollution Bulletin **142**: 129-134.

Standardized methods for the digestion of biota for microplastic analysis are currently lacking. Chemical methods can be effective, but can also cause damage to some polymers. Enzymatic methods are known to be gentler, but often laborious, expensive and time consuming. A novel tissue digestion method with pancreatic enzymes and a pH buffer (Tris) is here presented in a comparison to a commonly applied digestion protocol with potassium hydroxide. The novel protocol demonstrates a highly efficient removal of bivalve tissue (97.7 +/- 0.2% dry weight loss) already over-night. Furthermore, it induces no impairment in terms of ability to correctly identify four pre-weathered plastic polymers and six textile fiber polymers by Fourier transform infrared spectroscopy after exposure. The high-throughput protocol requires minimal handling, is of low cost and does not pose risk to the performer or the environment. It is therefore suggested as a candidate for a standardized digestion protocol, enabling successful analysis of microplastics ingested by bivalves. Copyright © 2019 Elsevier Ltd

Von Keudell, G., et al. (2013). "Pilot study of regulatory T cell depletion in the setting of autologous stem cell transplantation for multiple myeloma." Blood. Conference: 55th Annual Meeting of the American Society of Hematology, ASH **122**(21).

Although autologous stem cell transplantation (ASCT) is effective for patients with multiple myeloma (MM), disease relapse remains problematic. Despite significant advances in therapeutics for MM, it remains mostly incurable. Following ASCT, a majority of MM patients are in a minimal residual disease state, at which time delivery of immunotherapy may be most effective. Regulatory T cells (Tregs) are a naturally-suppressive CD4+ T cell population (CD4+CD25+FoxP3+ T cells) that expand in MM patients, and strongly inhibit anti-tumor immune responses. In pre-clinical models Treg depletion enhanced the function of tumor antigen-specific T cells. Effective strategies to deplete Tregs in humans are being investigated. We initiated pilot study to test 2 methods of Treg depletion in MM patients undergoing ASCT. In the first approach, an anti-CD25 monoclonal antibody (basiliximab) was administered day +1 following ASCT (in vivo Treg depletion). The second method involved depleting CD4+CD25+ Tregs from autologous stem cell (ASC) grafts with clinical-grade anti-CD25 microbeads and the CliniMACS device (Miltenyi) (ex vivo Treg depletion). A control arm consisted of patients in which no Treg-depleting maneuver was performed. To date, 10 patients with symptomatic MM have been enrolled and randomly assigned to 1 of 3 study arms (arm 1 - standard ASCT; arm 2 - in vivo Treg depletion; arm 3 - ex vivo Treg depletion). Primary endpoints included: a) efficacy of ex vivo Treg depletion from ASC grafts, b) kinetics of Treg depletion and recovery in each study arm, and c) assessment of toxicity associated with Treg depletion. Secondary endpoints included time to engraftment following ASCT and disease response. The overall goal of the study was to identify a superior strategy with regard to depth and durability of Treg depletion. Ten patients (median age 59; range 46-68) have been enrolled. 4 were enrolled onto arm 1, 3 onto arm 2 and 3 onto arm 3. One patient enrolled on arm 2 was removed from study due to ASC mobilization failure. ASC were collected following neupogen and plexifor, and conditioning for ASCT consisted of melphalan (200mg/m2). Typical serious adverse events associated with ASCT were observed in

all study arms, with neutropenic fever being the most common (n=2 arm 1, n=1 arm 2 and n=2 arm 3). Autoimmune complications, such as autologous graft-versus-host disease, were not observed. All patients engrafted post-ASCT with normal kinetics. Too few patients have been treated to make conclusions regarding clinical efficacy. Depletion of CD4+CD25+ Tregs from ASC grafts in arm 3 (ex vivo Treg depletion) was effective. As shown in Figure 1, 90.1% +/- 6% of CD4+25+ Tregs were depleted from 3 ASC grafts following the procedure. Baseline frequencies of peripheral blood (PB) CD4+FoxP3+ Tregs were similar between patients in all arms (p = n.s.). At least a 2-fold reduction in PB Treg frequency was observed at days +28 and + 60 following ASCT (Figure 2). At day +28, mean numbers (+/- SD) of CD4+FoxP3+ PB Tregs were 8.58% +/- 4.52%, 2.48% +/- 1.77%, and 3.28% +/- 1.12% in arms 1, 2 and 3, respectively (p = 0.08 arm 1 vs arm 2; p = 0.05 arm 1 vs arm 3; p = .57 arm 2 vs arm 3). These data suggest that both the in vivo and ex vivo Treg depletion may be effective at mediating effective and durable Treg depletion (Figure Presented) Treg are effectively depleted ex vivo with CD25 microbeads and the Clinimacs device. A FACS plots showing frequency of CD4 +CD25 + Tregs before (left) and after (right) ex vivo Treg depletion procedure (arm 3). B Mean CD4+CD25+ Treg frequencies before and after ex vivo Treg depletion (*p= 0.05). Kinetics of Treg depletion following ASCT. Mean (+/- SD) frequency of CD4+FoxP3+ Tregs before and after ASCT in each study arm are displayed. In conclusion, both the in vivo or ex vivo method of Treg depletion appear to be effective based on small patient numbers. Treg depletion in MM patients undergoing ASCT is safe and does not delay engraftment. Additional patients will need to be treated to make conclusions regarding clin cal efficacy. Future studies of Treg depletion in combination with other immunotherapeutic strategies are being considered.

Vonk, G., et al. (2019). "Analysis of pollutants in the product gas of a pilot scale downdraft gasifier fed with wood, or mixtures of wood and waste materials." Biomass and Bioenergy **125**: 139-150.

Small scale gasification of Solid Recovered Fuels (SRF) in downdraft reactors could be an alternative to large scale waste-to-energy schemes. In this perspective, the assessment of the pollutant emissions at pilot scale is necessary. This work compares pollutant emissions from wood and SRF air gasification in a downdraft fixed bed gasifier. Five fuels have been studied: Poplar wood, SRF wood, and three different mixtures containing mass fractions of 80% SRF wood with 20% of either tire, plastic waste or sewage sludge. Air gasification was performed in a pilot scale reactor in fed-batch mode using a fuel mass ranging from 5 to 8 kg and an air inlet flow of 170-180 L min⁻¹ (at 0 degrees C and 101 325 Pa). Depending on the fuel, Equivalence Ratios (ER) ranged from 0.22 to 0.29 and gasification temperatures from 690 to 850 degrees C. Emissions analyses were performed on product gas, condensable species and remaining chars, with a particular focus on sulfur, nitrogen and heavy metals. Regarding sulfur, wood and SRF wood led to low H₂S contents (6-8 micro mol mol⁻¹), when SRF mixes led to higher concentrations (44-96 micro mol mol⁻¹) in addition to of up to 11 heavier sulfur compounds. Regarding nitrogen, SRF produced higher ammonia concentrations (2.1-7.6 mmol mol⁻¹) than Wood (619 micro mol mol⁻¹), as a result of initial nitrogen mass fractions 17 to 27 times higher in the SRF mixes. Heavy metals analyzed in remaining solids after gasification showed low recovery rates (<0.4%), and tend to accumulate in fine particles, as a result of their volatility.

Vos, A. C., et al. (2012). "Anti-TNF induced regulatory macrophages display high levels of autophagy." Gastroenterology **1)**: S889.

Background One of the most exciting developments in IBD therapy has been the introduction of anti-TNF agents. Although originally believed to function through neutralization of soluble TNF,

we have previously shown that anti-TNF agents induce regulatory macrophages which have immune-suppressive and wound healing capacity (Vos et al, Gastroenterology 2010). How these cells exert their effects has not been established thus far. Over the past few years, genome-wide association studies have shown a correlation between Crohn's Disease (CD) and a number of autophagy-related genes, implicating a role for autophagy dysfunction in the pathogenesis. We evaluated the induction of autophagy in anti-TNF induced macrophages. Methods Mixed lymphocyte reactions were established using PBMC from two healthy donors in a 1:1 ratio and treated with anti-TNF or IgG control. Subsequently, macrophages were isolated from the cultures using CD14-microbeads. Levels of autophagy were determined by enumeration of LC3+ spots and quantification of LC3-I/LC3-II ratio's. In addition, expression levels of various autophagy-related genes were studied by gene array. Results Anti- TNF induced regulatory macrophages displayed increased numbers of autophagosomes as indicated by LC3+ spots. In addition, conversion of the autophagosomal protein LC3 was increased in anti-TNF treated cultures compared to IgG treated cultures. Finally, expression of a number of autophagy related genes including atg5, atg7, atg9 and atg16l2 were upregulated in the induced regulatory macrophages in comparison to inflammatory M1 type macrophages. Conclusion Regulatory macrophages induced by anti-TNF therapy display increased levels of autophagy compared to IgG-induced or inflammatory macrophages. Given the role for impaired autophagy in the pathogenesis of CD, this may be an addition mechanism by which anti-TNF compounds exert their beneficial effects.

Vos, J. G. M. and N. Sumarni (1997). "Integrated crop management of hot pepper (Capsicum spp.) under tropical lowland conditions: effects of mulch on crop performance and production." Journal of Horticultural Science **72**(3): 415-424.

The effects of mulches were investigated within integrated crop management (ICM) of hot pepper at tropical lowland sites in Indonesia. Mulching materials consisted of rice straw and white or silvery plastic film. Mulches affected soil temperature, light reflection, and soil nutrient concentrations after the last harvest. Rice straw mulch reduced soil temperature, induced faster plant growth, advanced mid-fruiting time, and resulted in higher K contents in leaves, but had no effect on yield. Plastic mulches increased soil temperature, induced faster plant growth and earlier fruiting, reduced P concentration in leaves and fruits, and increased N concentration in leaves and fruits. Yield and mean fruit weight of healthy fruits were increased and earliness of harvesting was enhanced. Improved crop performance and production with increase in fertilizer efficiency, control of evaporation, leaching and soil erosion makes plastic mulches suitable for use in ICM. To minimize the negative side-effect of plastic waste on the environment, further improvement of mulch technology is required. Preliminary field results and a tentative cost-benefit analysis are in favour of the application of plastic mulch in hot pepper under tropical lowland conditions.

Vossier, L., et al. (2019). "Combining culture and microbead-based immunoassay for the early and generic detection of bacteria in platelet concentrates." Transfusion **59**(1): 277-286.

BACKGROUND: Despite current preventive strategies, bacterial contamination of platelets is the highest residual infectious risk in transfusion. Bacteria can grow from an initial concentration of 0.03-0.3 colony-forming units (CFUs)/mL up to 10⁸ to 10⁹ CFUs/mL over the product shelf life. The aim of this study was to develop a cost-effective approach for an early, rapid, sensitive, and generic detection of bacteria in platelet concentrates.

STUDY DESIGN AND METHODS: A large panel of bacteria involved in transfusion reactions, including clinical isolates and reference strains, was established. Sampling was performed 24 hours after

platelet spiking. After an optimized culture step for increasing bacterial growth, a microbead-based immunoassay allowed the generic detection of bacteria. Antibody production and immunoassay development took place exclusively with bacteria spiked in fresh platelet concentrates to improve the specificity of the test.
RESULTS: Antibodies for the generic detection of either gram-negative or gram-positive bacteria were selected for the microbead-based immunoassay. Our approach, combining the improved culture step with the immunoassay, allowed sensitive detection of 1 to 10 CFUs/mL for gram-negative and 1 to 10² CFUs/mL for gram-positive species.
CONCLUSION: In this study, a new approach combining bacterial culture with immunoassay was developed for the generic and sensitive detection of bacteria in platelet concentrates. This efficient and easily automatable approach allows tested platelets to be used on Day 2 after collection and could represent an alternative strategy for reducing the risk of transfusion-transmitted bacterial infections. This strategy could be adapted for the detection of bacteria in other cellular products.

Vossier, L., et al. (2019). "Combining culture and microbead-based immunoassay for the early and generic detection of bacteria in platelet concentrates." Transfusion **59**(1): 277-286.

BACKGROUNDDespite current preventive strategies, bacterial contamination of platelets is the highest residual infectious risk in transfusion. Bacteria can grow from an initial concentration of 0.03–0.3 colony-forming units (CFUs)/mL up to 108 to 109 CFUs/mL over the product shelf life. Vox, G., et al. (2016). "Mapping of agriculture plastic waste." Agriculture and Agricultural Science Procedia **8**: 583-591.

The current intensification of the use of plastic materials in agriculture, although has increased significantly the productivity, is also generating growing adverse effects on the environment of the agro-ecosystem. The agriculture is responsible for a massive use of plastic materials, in addition to energy and water inputs, chemical fertilizer and pesticides. Besides the pollution generated during the manufacture, at the end of their lifetime plastic materials used for crop covering, soil mulching, packaging, containers, pots, irrigation and drainage pipes, may became a pollution source when improperly disposed, leaved on the ground or burned. Instead the agricultural plastic waste (APW), if correctly collected, can be used as a new secondary raw material or as an energy source. An adequate APW management can prevent economical losses and environmental damages. The territory of the Barletta, Andria, Trani Province (BAT), in the Apulia Region, South Italy, is an agricultural area characterized by vineyards, olive groves, orchards and vegetables; it represents an area of intense production of plastic wastes and with a widespread problem linked to the application of unacceptable disposal practices. The goal of this study is to define and quantify the different types of plastic waste produced by the agricultural practice in a restricted area of the municipal area of Trani and Barletta, to localize the points where the most remarkable quantities of them are generated, and to provide the local Authorities and the decision makers of a useful tool for implementing an efficient and effective waste management. A dedicated geo-referenced database was designed using land use maps in a GIS environment and applying a methodology that can be functional for any kind of agricultural plastic waste. The resulting database gives updated and complete information on the plastic waste generation, over the land, related to the cultivation kind.

Vral, A., et al. (2001). "A higher micronucleus yield in B-versus T-cells after low-dose gamma-irradiation is not linked with defective Ku86 protein." International Journal of Radiation Biology **77**(3): 329-339.

PURPOSE: To elaborate the B-cell micronucleus (MN) response in the low-dose region in detail and to investigate the postulated deficiency in DNA-PK in B-cells.

MATERIALS AND METHODS: Lymphocytes of five healthy volunteers were irradiated with low LET gamma-rays and high LET fast neutrons with doses ranging between 0.01 and 2 Gy. After post-irradiation incubation, B- and T-cells were isolated via CD3 and CD19 immunomagnetic microbeads. MN were analysed in both subpopulations. To study the underlying mechanism of chromosomal radiosensitivity, cell extracts prepared from purified B- and T-cells were subjected to SDS-electrophoresis and electroblotting using antibodies directed against the DNA-PK repair enzymes Ku70/86 and DNA-PKcs. Activity measurements were performed using the SignaTECT DNA-dependent protein kinase assay. DNA double-strand break (DSB) induction and rejoining was determined using constant-field gel electrophoresis.

RESULTS: For low LET gamma-rays a higher MN yield was observed in B-cells than in T-cells, but only in those samples exposed to doses < 1 Gy. For 1 Gy, the MN yields were comparable and for 2Gy even lower in B-cells compared with T-cells. After high LET neutron irradiation no significant differences in MN yields were observed between both subsets. The results of the DNA-PK experiments demonstrate that there is no difference between T- and B-cells in the basal expression and activity of DNA-PK repair proteins. No differences in DNA DSB induction and rejoining were found between T- and B-cells using constant-field gel electrophoresis.

CONCLUSIONS: From the results, it was concluded that the enhanced chromosomal radiosensitivity in B-cells is restricted to low doses (<1 Gy) of low LET radiation and that the chromosomal behaviour of B-cells to low LET radiation cannot be attributed to aberrant forms of the DNA-PK components. A type of chromosomal induced radioresistance (IRR) may be a possible explanation for the observed effect.

Vrana, N. E., et al. (2011). "Hybrid titanium/biodegradable polymer implants with an hierarchical pore structure as a means to control selective cell movement." PLoS ONE [Electronic Resource] **6**(5): e20480.

UNLABELLED: In order to improve implant success rate, it is important to enhance their responsiveness to the prevailing conditions following implantation. Uncontrolled movement of inflammatory cells and fibroblasts is one of these in vivo problems and the porosity properties of the implant have a strong effect on these. Here, we describe a hybrid system composed of a macroporous titanium structure filled with a microporous biodegradable polymer. This polymer matrix has a distinct porosity gradient to accommodate different cell types (fibroblasts and

epithelial cells). The main clinical application of this system will be the prevention of restenosis due to excessive fibroblast migration and proliferation in the case of tracheal implants.
METHODOLOGY/PRINCIPAL FINDINGS: A microbead-based titanium template was filled with a porous Poly (L-lactic acid) (PLLA) body by freeze-extraction method. A distinct porosity difference was obtained between the inner and outer surfaces of the implant as characterized by image analysis and Mercury porosimetry (9.8+/-2.2 micro m vs. 36.7+/-11.4 micro m, p<=0.05). On top, a thin PLLA film was added to optimize the growth of epithelial cells, which was confirmed by using human respiratory epithelial cells. To check the control of fibroblast movement, PKH26 labeled fibroblasts were seeded onto Titanium and Titanium/PLLA implants. The cell movement was quantified by confocal microscopy: in one week cells moved deeper in Ti samples compared to Ti/PLLA.
CONCLUSIONS: In vitro experiments showed that this new implant is effective for guiding different kind of cells it will contact upon implantation. Overall, this system would enable spatial and temporal control over cell migration by a gradient ranging from macroporosity to nanoporosity within a tracheal implant. Moreover, mechanical properties will be dependent mainly on the titanium frame. This will make it possible to create a polymeric environment which is suitable for cells without the need to meet mechanical requirements with the polymeric structure.

Vroom, R. J. E., et al. (2017). "Aging of microplastics promotes their ingestion by marine zooplankton." Environmental Pollution **231**(Part 1): 987-996.

Microplastics (<5 mm) are ubiquitous in the marine environment and are ingested by zooplankton with possible negative effects on survival, feeding, and fecundity. The majority of laboratory studies has used new and pristine microplastics to test their impacts, while aging processes such as weathering and biofouling alter the characteristics of plastic particles in the marine environment. We investigated zooplankton ingestion of polystyrene beads (15 and 30 micro m) and fragments (<=30 micro m), and tested the hypothesis that microplastics previously exposed to marine conditions (aged) are ingested at higher rates than pristine microplastics. Polystyrene beads were aged by soaking in natural local seawater for three weeks. Three zooplankton taxa ingested microplastics, excluding the copepod Pseudocalanus spp., but the proportions of individuals ingesting plastic and the number of particles ingested were taxon and life stage specific and dependent on plastic size. All stages of Calanus finmarchicus ingested polystyrene fragments. Aged microbeads were preferred over pristine ones by females of Acartia longiremis as well as juvenile copepodites CV and adults of Calanus finmarchicus. The preference for aged microplastics may be attributed to the formation of a biofilm. Such a coating, made up of natural microbes, may contain similar prey as the copepods feed on in the water column and secrete chemical exudates that aid chemodetection and thus increase the attractiveness of the particles as food items. Much of the ingested plastic was, however, egested within a short time period (2-4 h) and the survival of adult Calanus females was not affected in an 11-day exposure. Negative effects of microplastics ingestion were thus limited. Our findings emphasize, however, that aging plays an important role in the transformation of microplastics at sea and ingestion by grazers, and should thus be considered in future microplastics ingestion studies and estimates of microplastics transfer into the marine food web.

Vu, D., et al. (2018). A system designed to convert plastic waste product into utilitarian artifacts. 125th ASEE Annual Conference and Exposition, June 23, 2018 - December 27, 2018, Salt Lake City, UT, United states, American Society for Engineering Education.

The paper expounds a senior design project that was undertaken to convert plastic waste into utilitarian artifacts. The paper presents here the practice followed by the authors in their respective Department of Electrical Engineering Technology at Duy Tan University, Da Nang, Vietnam and Purdue University Northwest, Hammond, Indiana. This paper describes the following promising solution: (a) set up and organize a system for collecting plastic used for water and soda bottles, (b) design and manufacture production line for automatically processing plastic bottles to make plastic ribbons of various sizes, (c) use the plastic ribbon to make a prototype of useful products like tables, chairs, roofing, decorations, etc. This paper covers the design details of three machines that are core in the successful implementation of the project. The first machine converts waste plastic into plastic ribbon. The second machine is for the straightening of the plastic ribbon. The third machine is for kneading straight plastic ribbon into various artifacts of choice. The paper brings forth the projects economic and social benefits. On the economical side, this will minimize all expenditures for waste processing related to disposition of the plastic waste, create more jobs, especially in rural areas, and providing plastic products with reasonable price for low income population. On the social side, this will improve environmental conditions, reduce landfill waste, and eliminate spreading of disease due to contamination from burning and melting of plastics. The project enhances students' awareness of ecology, and the environmental protection of community. The pedagogy of the course delivery is based on "Interactive Learning Model". The paper elaborates the benefits derived through the pedagogical approaches of keeping the learner actively engaged in all aspects of discovery and design. The course interactively involves the learner in directing and defining the material under discourse. The paper presents the fine points of pedagogical approach that were implemented in successful completion of this course. American Society for Engineering Education, 2018.

Wadhwa, A., et al. (2012). "Bead-based microfluidic immunoassay for diagnosis of Johne's disease." Journal of Immunological Methods **382**(1-2): 196-202.

Microfluidics technology offers a platform for development of point-of-care diagnostic devices for various infectious diseases. In this study, we examined whether serodiagnosis of Johne's disease (JD) can be conducted in a bead-based microfluidic assay system. Magnetic micro-beads were coated with antigens of the causative agent of JD, Mycobacterium avium subsp. paratuberculosis. The antigen-coated beads were incubated with serum samples of JD-positive or negative serum samples and then with a fluorescently-labeled secondary antibody (SAB). To confirm binding of serum antibodies to the antigen, the beads were subjected to flow cytometric analysis. Different conditions (dilutions of serum and SAB, types of SAB, and types of magnetic beads) were optimized for a large degree of differentiation between the JD-negative and JD-positive samples. Using the optimized conditions, we tested a well-classified set of 155 serum samples from JD-negative and JD-positive cattle by using the bead-based flow cytometric assay. Of 105 JD-positive samples, 63 samples (60%) showed higher antibody binding levels than a cut-off value determined by using antibody binding levels of JD-negative samples. In contrast, only 43-49 JD-positive samples showed higher antibody binding levels than the cut-off value when the samples were tested using commercially-available immunoassays. Microfluidic assays were performed by magnetically immobilizing a number of beads within a microchannel of a glass microchip and detecting antibody on the collected beads using laser-induced fluorescence. Antigen-coated magnetic beads treated with the bovine serum sample and fluorescently-labeled SAB were loaded into a microchannel to measure the fluorescence (reflecting level of antibody binding) on the beads in the microfluidic system. When the results of five bovine serum samples with the microfluidic system were compared to those analyzed with the flow cytometer, a high level of correlation (linear regression, r²=0.994) was observed. In a further experiment, we magnetically immobilized antigen-coated beads in a microchannel, reacted the beads with serum and SAB in the channel, and detected antibody binding to the beads in the microfluidic system. A strong antibody binding in JD-positive serum was detected, whereas there was only negligible binding in negative control experiments. Our data suggest that the bead-based microfluidic system may form a basis for development of an on-site serodiagnosis of JD. © 2012 Elsevier B.V.

Wagner, J., et al. (2019). "Nondestructive Extraction and Identification of Microplastics from Freshwater Sport Fish Stomachs." Environmental Science & Technology **53**(24): 14496-14506.

Microplastics were extracted from freshwater sport fish stomachs containing substantial biomass and identified using optical microscopy, scanning electron microscopy plus energy-dispersive X-ray spectroscopy (SEM/EDS), and Fourier transform infrared (FTIR) micro-spectroscopy with automated spectral mapping. An extraction method is presented that uses a negatively pressurized sieve stack and purified water to preserve plastic surface characteristics and any adsorbed persistent organic pollutants (POPs). This nondestructive extraction method for large predators' stomachs enables multiple trophic-level studies from one fish sampling event and provides other dietary and behavioral data. FTIR-identified microplastics 50-1500 mum, including polyethylene (two with plastic additive POPs), styrene acrylonitrile, polystyrene, and nylon and polyethylene terephthalate fibers 10-50 mum wide. SEM/EDS revealed characteristic surface weathering on the plastic surfaces. The nylon fibers appear to be from human fishing activities, suggesting options for management. Some particles visually identified as potential plastics were revealed by micro-spectroscopy to be mineralized, natural polyamide proteins, or nonplastic shell pieces. A low-cost, reflective sample preparation method with stable particle mounting was developed to enable automated mapping, improved FTIR throughput, and lower detection size limit. This study yielded 37 intact prey items set aside for future analyses.

Wagner, M., et al. (2014). "Microplastics in freshwater ecosystems: what we know and what we need to know." Environmental Sciences Europe **26**(1): 12.

BACKGROUND: While the use of plastic materials has generated huge societal benefits, the 'plastic age' comes with downsides: One issue of emerging concern is the accumulation of plastics in the aquatic environment. Here, so-called microplastics (MP), fragments smaller than 5 mm, are of special concern because they can be ingested throughout the food web more readily than larger particles. Focusing on freshwater MP, we briefly review the state of the science to identify gaps of knowledge and deduce research needs.

STATE OF THE SCIENCE: Environmental scientists started investigating marine (micro)plastics in the early 2000s. Today, a wealth of studies demonstrates that MP have ubiquitously permeated the marine ecosystem, including the polar regions and the deep sea. MP ingestion has been documented for an increasing number of marine species. However, to date, only few studies investigate their biological effects. The majority of marine plastics are considered to originate from land-based sources, including surface waters. Although they may be important transport pathways of MP, data from freshwater ecosystems is scarce. So far, only few studies provide evidence for the presence of MP in rivers and lakes. Data on MP uptake by freshwater invertebrates and fish is very limited.

KNOWLEDGE GAPS: While the research on marine MP is more advanced, there are immense gaps of knowledge regarding freshwater MP. Data on their abundance is fragmentary for large and absent for small surface waters. Likewise, relevant sources and the environmental fate remain to be investigated. Data on the biological effects of MP in freshwater species is completely lacking. The accumulation of other freshwater contaminants on MP is of special interest because

ingestion might increase the chemical exposure. Again, data is unavailable on this important issue.

CONCLUSIONS: MP represent freshwater contaminants of emerging concern. However, to assess the environmental risk associated with MP, comprehensive data on their abundance, fate, sources, and biological effects in freshwater ecosystems are needed. Establishing such data critically depends on a collaborative effort by environmental scientists from diverse disciplines (chemistry, hydrology, ecotoxicology, etc.) and, unsurprisingly, on the allocation of sufficient public funding.

Wagner, S., et al. (2018). "Tire wear particles in the aquatic environment - A review on generation, analysis, occurrence, fate and effects." Water Research **139**: 83-100.

Tire wear particles (TWP), generated from tire material during use on roads have gained increasing attention as part of organic particulate contaminants, such as microplastic, in aquatic environments. The available information on properties and generation of TWP, analytical techniques to determine TWP, emissions, occurrence and behavior and ecotoxicological effects of TWP are reviewed with a focus on surface water as a potential receptor. TWP emissions are traffic related and contribute 5-30% to non-exhaust emissions from traffic. The mass of TWP generated is estimated at 1,327,000 t/a for the European Union, 1,120,000 t/a for the United States and 133,000 t/a for Germany. For Germany, this is equivalent to four times the amount of pesticides used. The mass of TWP ultimately entering the aquatic environment strongly depends on the extent of collection and treatment of road runoff, which is highly variable. For the German highways it is estimated that up to 11,000 t/a of TWP reach surface waters. Data on TWP concentrations in the environment, including surface waters are fragmentary, which is also due to the lack of suitable analytical methods for their determination. Information on TWP properties such as density and size distribution are missing; this hampers assessing the fate of TWP in the aquatic environment. Effects in the aquatic environment may stem from TWP itself or from compounds released from TWP. It is concluded that reliable knowledge on transport mechanism to surface waters, concentrations in surface waters and sediments, effects of aging, environmental half-lives of TWP as well as effects on aquatic organisms are missing. These aspects need to be addressed to allow for the assessment of risk of TWP in an aquatic environment. Copyright © 2018 Elsevier Ltd

Wagner, S., et al. (2019). "Relationship between Discharge and River Plastic Concentrations in a Rural and an Urban Catchment." Environmental Science & Technology **53**(17): 10082-10091.

Rivers play a major role in the transport of plastic debris from inland sources such as urban areas into the marine environment. The present study examined plastic particle concentrations and loads (>500 mum) upstream and downstream of an urban subcatchment over 15 months and investigated the relationship between river water discharge (Q) and plastic concentration (C). The plastic particle concentration increases by 0.8 g/1000 m³ or 79 n/1000m³ from the rural to the urban subcatchment. In the rural subcatchment, C does not increase with increasing Q (p = 0.57), whereas a positive relationship between C and Q exists downstream of the urban catchment (p = 0.00003). Combined sewer overflows likely contribute additional plastic loads during high flow conditions. Based on the C-Q relationship, we estimate the total plastic export in 2016 from the entire catchment to be 3.0 x 10⁶ n/year or 2.6 x 10⁴ n/(km² year) and 15 n/(cap year). Because of the positive C-Q relationship, 90% of the plastic load is transported during 20% of the time. The analysis of time-resolved plastic concentration data in rivers provides a data-driven tool to better estimate plastic loads and to better understand the catchment controls of plastic

in rivers.

Wahlqvist, M. L. (2017). "Enabling and disabling health systems through food systems." Annals of Nutrition and Metabolism **71 (Supplement 2)**: 14-15.

Health is more dependent on the prevailing food system than acknowledged. This is for several reasons. First, it may or may not be available Second, it may not be safe. Third, it may not be acceptable. Fourth, it may not be affordable. Fifth, food itself is much more complicated than nutrient composition would suggest or aberrant nutrient intake might contribute to pathophysiology (Wahlqvist Food & Function 2016). Sixth, food plays a sociological as well as physiological role. Seventh, it is eaten at the end of an intricate system of production, transport, processing, packaging, storage and marketing any one of which may have health effects downstream. Eighth, it has effects on every body organ and system, not just the cardiovascular, gastrointestinal, musculoskeletal or immune system, for example. Ninth, it alters gene expression (epigenetics), and heretofore we have over-stated what is genetic inheritance and underestimated the intra-and inter-generational effects of food. Tenth, the growing understanding of our microbiomes provides for explanatory models of food-health associations previously arcane. Finally, we are ecological creatures and not separate from our environment whether through biorhythms, sensory inputs, energy regulation, microbiomic pathways, endocrine-phytonutrient linkages, locomotor activity, eco-immunology, and more (Wahlqvist ML ,Ann Nutr Metab 2016). The recognition of these food system inputs into human biology offers potentially greater cost-effectiveness in health care systems. We now know that a greater emphasis on plant-derived foods and food biodiversity reduces the prevailing burden of disease and its costs (Lo et al Amer J Managed Care 2013). In addition, the availability of public open space (POS) and gardens is associated with better mental health, longer lives and less so-called chronic disease (Mitchell and Popham, Lancet 2014). Better health outcomes are possible even in the face of risk factors like cognitive impairment, hypertension and obesity with a biodiverse diet, physical activity and POS (Wahlqvist APJCN, 2014). A deeper understanding of food and health would be represented by an ecosystem health disorder nomenclature (EHD) (Wahlqvist, APJCN, 2014). It has been suggested that we increasingly suffer what might be termed 'nature deficit disorders'. Given that modest exercise is necessary to access nature, and is associated with healthier and longer lives (Wen CP et al Lancet, 2011), the combination of a biodiverse diet, the social role of food and walking among nature and gardens has the prospects of health and economic advantage. Yet new health risks and costs loom as ecosystems are lost and food systems compromised. One of the most pressing is that of oceanic contamination with microplastics, much of it derived from food and beverage packaging. They are now found in deep sea and coastal seafood whose health risk and benefit must therefore come under review. An innovative food and health workforce with systems awareness could take a more socio-ecological approach to mitigate the challenges of climate change. Axiomatic will be that we need to appreciate how little we need and not seek how much we can get, in the interests of our ecological selves and a habitable planet.

Waite, H. R., et al. (2018). "Quantity and types of microplastics in the organic tissues of the eastern oyster Crassostrea virginica and Atlantic mud crab Panopeus herbstii from a Florida estuary." Marine Pollution Bulletin **129**(1): 179-185.

This study determined the quantity and diversity of microplastics in water and soft tissues of eastern oysters (Crassostrea virginica) and Atlantic mud crabs (Panopeus herbstii) in Mosquito Lagoon, a shallow, microtidal estuary along the east coast of central Florida. One-liter water samples had an average of 23.1 microplastic pieces (n=15). Crabs (n=90) had an average of 4.2

pieces in tissues/individual plus an average of 20.3 pieces/individual temporarily entangled in exposed surfaces and released within 5 days in tanks. Adult oysters (n=90) had an average of 16.5 microplastic pieces/individual. Fibers, mostly royal/dark blue in color, dominated our collections. When compared per gram of tissue, crabs had two orders of magnitude more microplastic pieces than oysters. Our numbers were higher than previous studies on invertebrate microplastics; this is potentially the result of extensive urbanization, limited flushing, and intensive recreational usage of Mosquito Lagoon.

Waldschlager, K. and H. Schuttrumpf (2019). "Erosion Behavior of Different Microplastic Particles in Comparison to Natural Sediments." Environmental Science & Technology **53**(22): 13219-13227.
Microplastic (MP) has been detected in marine, limnic, terrestrial, and atmospheric environments. However, rivers are often only seen as transport paths for MPs from inland sources to the oceans, although transport rates in rivers can hardly be determined yet. MP in rivers can either be transported, or it settles to the bottom of the river and either remains there or is remobilized again at higher flow velocities. This remobilization, also known as erosion, depends on the critical shear stress of a particle and is influenced by the particle properties and the sediment bed. In this study, the critical shear stresses of 14 MP particles with different shapes, densities, and particle sizes on different sediment beds were experimentally determined and subsequently compared with the basic principles of erosion from sediment transport. Critical shear stresses of the MP particles were between 0.002 and 0.233 N/m², depending on particle and sediment properties. Furthermore, the hiding-exposure effect was transferred to MPs and an equation was developed to determine the critical shear stress of different MP particles on natural sediment beds.

Waldschläger, K. and H. Schüttrumpf (2019). "Effects of Particle Properties on the Settling and Rise Velocities of Microplastics in Freshwater under Laboratory Conditions." Environmental Science & Technology **53**(4): 1958.
Microplastic (MP) contaminates terrestrial, aquatic, and atmospheric environments. Although the number of river sampling studies with regard to MP concentrations is increasing, comprehension of the predominant transport processes of MP in the watercourse is still very limited. In order to gain a better process understanding, around 500 physical experiments were conducted to shed more light on the effects of particle shape, size and density on the rise and settling velocities of MP. The determined velocities ranged between 0.39 cm/s for polyamide fibers (settling) and 31.4 cm/s for expanded polystyrene pellets (rise). Subsequently, the determined velocities were compared with formulas from sediment transport and, as there were large differences between theoretically and experimentally determined velocities, own formulas were developed to describe settling and rise velocities of MP particles with a large variety of shapes, sizes and densities. This study shows that MP differs significantly from sediment in its behavior and that a transfer of common sediment transport formulas should be treated with caution. Furthermore, the established formulas can now be used in numerical simulations to describe the settling and rising of MP more precisely.

Walek, K. M., et al. (2011). "The assessment of autoantibodies from patients with primary immune thrombocytopenia using platelet phagocytosis assay." Transfusion Medicine and Hemotherapy **1)**: 7-8.
Background: Primary Immune thrombocytopenia (ITP) is a bleeding disorder caused by platelet specific autoantibodies (PLT-AAbs). Although PLT-Abs are frequently detected using serological laboratory investigations, little is know about the effector function of these antibodies. In this study, the phagocytic activity of PLT-AAbs was analyzed in vitro using phagocytosis assay.

Method(s): Monocytes were isolated from healthy donors using CD 14-microbeads. Autologous PLTs were isolated by centrifugation and labeled using an intra- cellular FITC-dye. Labeled PLTs were then opsonized with purified IgG from ITP- and non-immune thrombocytopenic patients and introduced to isolated monocytes. After incubation, antibody phagocytic activity was determined using flow cytometry as the percentage of FITC-positive monocytes out of all gated monocytes. To exclude non-specific positive signal from antibody- independent PLT-monocytes interactions, investigations using confocal microscope were performed in parallel. Result(s): By testing IgG-fraction from non-immune thrombocytopenic patients, no phagocytic activity was observed (median: 3.1%) indicating the high specificity of the phagocytosis assay. The phagocytosis induced by AAbs was significantly higher using platelets obtained from citrated than from EDTA- blood samples (21,33% vs. 10,33%, p = 0.0013). The phagocytic activity of AAbs was largely, but not completely, inhibited by adding ivIgG at high concentration (660 [xg/ml), suggesting that other mechanisms than engaging Fc gamma receptors may contribute to platelet destruction in ITP-patients. Conclusion(s): Better conditions for the effector function of PLT-AAbs can be provided using citrated blood samples. This finding could have a huge impact on laboratory investigations of ITP where a better sensitivity may be obtained using citrated blood samples. The phagocytosis assay allows better understanding of the pathophysiology of ITP and may be used to investigate new therapies.

Walker, T. R. (2018). "China's ban could curb plastic waste." Nature **553**(7689): 405.

Walkinshaw, C., et al. (2020). "Microplastics and seafood: lower trophic organisms at highest risk of contamination." Ecotoxicology & Environmental Safety **190**: 110066.

Microplastic debris is a prevalent global pollutant that poses a risk to marine organisms and ecological processes. It is also suspected to pose a risk to marine food security; however, these risks are currently poorly understood. In this review, we seek to understand the current knowledge pertaining to the contamination of commercially important fished and farmed marine organisms with microplastics, with the aim of answering the question "Does microplastic pollution pose a risk to marine food security?". A semi-systematic review of studies investigating the number of microplastics found in commercially important organisms of different trophic levels suggests that microplastics do not biomagnify, and that organisms at lower trophic levels are more likely to contaminated by microplastic pollution than apex predators. We address the factors that influence microplastic consumption and retention by organisms. This research has implications for food safety and highlights the risks of microplastics to fisheries and aquaculture, and identifies current knowledge gaps within this research field.

Wall, T., et al. (2017). "Optofluidic Lab-on-a-Chip Fluorescence Sensor Using Integrated Buried ARROW (bARROW) Waveguides." Micromachines **8**(8).

Optofluidic, lab-on-a-chip fluorescence sensors were fabricated using buried anti-resonant reflecting optical waveguides (bARROWs). The bARROWs are impervious to the negative water absorption effects that typically occur in waveguides made using hygroscopic, plasma-enhanced chemical vapor deposition (PECVD) oxides. These sensors were used to detect fluorescent microbeads and had an average signal-to-noise ratio (SNR) that was 81.3% higher than that of single-oxide ARROW fluorescence sensors. While the single-oxide ARROW sensors were annealed at 300 degreeC to drive moisture out of the waveguides, the bARROW sensors required no annealing process to obtain a high SNR.

Waller, C. L., et al. (2017). "Microplastics in the Antarctic marine system: An emerging area of research."

Science of the Total Environment **598**: 220-227.

It was thought that the Southern Ocean was relatively free of microplastic contamination; however, recent studies and citizen science projects in the Southern Ocean have reported microplastics in deep-sea sediments and surface waters. Here we reviewed available information on microplastics (including macroplastics as a source of microplastics) in the Southern Ocean. We estimated primary microplastic concentrations from personal care products and laundry, and identified potential sources and routes of transmission into the region. Estimates showed the levels of microplastic pollution released into the region from ships and scientific research stations were likely to be negligible at the scale of the Southern Ocean, but may be significant on a local scale. This was demonstrated by the detection of the first microplastics in shallow benthic sediments close to a number of research stations on King George Island. Furthermore, our predictions of primary microplastic concentrations from local sources were five orders of magnitude lower than levels reported in published sampling surveys (assuming an even dispersal at the ocean surface). Sea surface transfer from lower latitudes may contribute, at an as yet unknown level, to Southern Ocean plastic concentrations. Acknowledging the lack of data describing microplastic origins, concentrations, distribution and impacts in the Southern Ocean, we highlight the urgent need for research, and call for routine, standardised monitoring in the Antarctic marine system.

Waller, C. L. and K. A. Hughes (2018). "Plastics in the Southern Ocean." Antarctic Science **30**(5): 269.

With the CCAMLR beach survey documenting plastics litter now for many years, and published reports of ingestion of plastics by a range of birds from petrels to albatross and penguins, there has already been a major attempt to report on the problem. The recent Greenpeace Antarctic cruise found microplastics in most of their limited number of water samples but the much more wide-ranging Antarctic Circumpolar Expedition of 2016–17 recorded microplastics in every surface sample taken all around the Antarctic, and even in remote locations like the Mertz Polynya. The cross disciplinary group will assess the occurrence, distribution, source and fates of plastics in the Southern Ocean and the impacts on physical environments and biological communities, co-ordinating with other groups like CCAMLR, IAATO and SCOR.

Walpitagama, M., et al. (2019). "Additives migrating from 3D-printed plastic induce developmental toxicity and neuro-behavioural alterations in early life zebrafish (Danio rerio)." Aquatic Toxicology **213**(105227).

The environmental impact of exposure to 3D-printed plastics as well as potential migration of toxic chemicals from 3D-printed plastics remains largely unexplored. In this work we applied leachates from plastics fabricated using a stereolithography (SLA) process to early developmental stages of zebrafish (Danio rerio) to investigate developmental toxicity and neurotoxicity. Migration of unpolymerized photoinitiator, 1-hydroxycyclohexyl phenyl ketone (1-HCHPK) from a plastic solid phase to aqueous media at up to 200 mg/L in the first 24 h was detected using gas chromatography-mass spectrometry. Both plastic extracts (LC₅₀ 22.25% v/v) and 1-HCHPK (LC₅₀ 60 mg/L) induced mortality and teratogenicity within 48 h of exposure. Developmental toxicity correlated with in situ generation of reactive oxygen species (ROS), an increase in lipid peroxidation and protein carbonylation markers and enhanced activity of superoxide dismutase (SOD) and glutathione-S-transferase (GST) in embryos exposed to concentrations as low as 20% v/v for plastic extracts and 16 mg/L for 1-HCHPK. ROS-induced cellular damage led to induction of caspase-dependent apoptosis which could be pharmacologically inhibited with both antioxidant ascorbic acid and a pan-caspase inhibitor. Neuro-behavioral analysis showed that exposure to plastic leachates reduced spontaneous embryonic movement in 24-36 hpf embryos. Plastic extracts in concentrations above 20% v/v induced rapid retardation of locomotion, changes in photomotor response and habituation to photic stimuli with progressive paralysis in 120 hpf larvae. Significantly decreased acetylcholinesterase (AChE) activity with lack of any CNS-specific apoptotic phenotypes as well as lack of changes in motor neuron density, axonal growth, muscle segment integrity or presence of myoseptal defects were detected upon exposure to plastic extracts during embryogenesis. Considering implications of the results for environmental risk assessment and the growing usage of 3D-printing technologies, we speculate that some 3D-printed plastic waste may represent a significant and yet very poorly uncharacterized environmental hazard that merits further investigation on a range of aquatic and terrestrial species.

Walter, P., et al. (2013). "Innate immune cell expression of pattern recognition receptors from transfused thalassemia major patients during intensive combination chelation therapy." American Journal of Hematology **88 (5)**: E95.

Introduction: Despite improved chelation therapies, thalassemia major patients endure iron overload, chronic inflammation, organ failure, infection and oxidative stress, resulting in elevated levels of pro- and anti-inflammatory proteins and pro-apoptotic proteins. Infection is the second most common cause of death in thalassemia. The innate immune system provides the first line of defense against infection and its specificity depends on pattern recognition receptors (PRRs) specific to microbial pathogens. One class of PRR called the toll-like receptors (TLRs) interacts with CD14 on innate immune cells transducing the signal for bacterial Lipopolysaccharide (LPS), resulting in cytokine production. The role iron plays in thalassemia in determining expression level of PRRs is unknown. Thus, the goal in these studies is to investigate the relationship of iron overload and chelation to innate immune cell expression of PRRs in thalassemia. Patients and Methods: Eighteen transfusion dependent thalassemia patients (11 - 29 yrs old) participating in the combination trial of deferasirox and deferoxamine (Novartis sponsored CICL670AUS24T) were enrolled in a substudy investigating innate immunology (Novartis sponsored CICL670AUS42T). Fasting blood samples were obtained i) at baseline after a 72 hr. washout of chelator, and ii) at 6 and 12 months on study. Fourteen healthy controls (10 - 35 yrs old) were also enrolled. Peripheral blood mononuclear cells (PBMCs) were isolated from blood samples and then monocytes and granulocytes were purified using antibody-linked magnetic microbeads (Miltenyi Biotec Inc). Highly enriched populations of CD14+ monocytes and CD15+ granulocytes were verified by flow cytometry. CD15 is not a PRR, but a trisaccharide adhesion molecule, used by granulocytes to mediate phagocytosis and chemotaxis. The expression level of CD14 and CD15 in PBMCs and TLR4 in purified cells was determined and reported as the median fluorescent intensity (MFI). Liver iron concentration (LIC) was determined by biomagnetic susceptibility ("SQUID", Ferritometer) in patients with thalassemia; healthy controls were shown to have normal ferritin. Result(s): In PBMCs from thalassemia patients at baseline, the expression of monocyte CD14 and TLR4 were significantly increased 22% and 27% respectively compared to healthy controls ($p < 0.05$). Granulocytes from patients with thalassemia were also found to have a 50% and 23% higher expression of TLR4 and CD15 respectively at baseline compared to controls. In longitudinal analysis markers of iron burden and the expression of TLR4 on granulocytes all significantly decreased in the follow-up period in thalassemia patients receiving intensive combination chelator therapy ($p<0.05$). Conclusion(s): These studies support the hypothesis that iron burden influences the innate immune response in thalassemia as demonstrated by the increased monocyte and granulocyte expression of TLR4 at baseline. Also increased at baseline were the expression of monocyte CD14 and granulocyte CD15. All of these changes are likely to contribute to the chronic inflammation in thalassemia and could also contribute to the commonly observed susceptibility to infection. After intensive chelation, the levels of TLR4 decreased, indicating that decreased iron overload with chelation may improve chronic inflammation in thalassemia. These changes in CD14 and TLR4 may be able to restore proper innate immune function in thalassemia patients.

Walter, P. B., et al. (2012). "Innate immune cell expression of pattern recognition receptors from beta-thalassemia patients during intensive combination chelation therapy." Blood. Conference: 54th Annual Meeting of the American Society of Hematology, ASH **120**(21).

Introduction: Thalassemia major patients endure chronic RBC transfusions, high levels of tissue iron, iron chelation and organ injury. Patients with thalassemia also have reduced immune function and are at risk for infection. Infection is in fact the second most common cause of death in thalassemia. The innate immune system provides the first line of defense against infection and it specificity depends on pattern recognition receptors (PRRs) specific to microbial pathogens. One class of PRR called the toll-like receptors (TLRs) interact with CD14 on innate immune cells transducing the signal for bacterial Lipopolysaccharide (LPS), resulting in cytokine production. The role iron plays in thalassemia in determining expression level of PRRs is unknown. Thus, the goal in these studies is to investigate the relationship of iron overload and its chelation to innate immune cell expression of PRRs in thalassemia. Patients and Methods: Eighteen transfusion dependent thalassemia patients (11 - 29 yrs old) participating in the combination trial of deferasirox and deferoxamine (Novartis sponsored CICL670AUS24T) were enrolled in a substudy investigating innate immunology (Novartis sponsored CICL670AUS42T). Fasting blood samples were obtained i) at baseline after a 72 hr. washout of chelator, and ii) at 6 and 12 months on study. Fourteen healthy controls (10 - 35 yrs old) were also enrolled. Peripheral blood mononuclear cells (PBMCs) were isolated from blood samples and then from these cells monocytes and granulocytes were purified using antibody-linked magnetic microbeads (Miltenyi Biotec Inc). Highly enriched populations of CD14+ monocytes and CD15+ granulocytes were verified by flow cytometry. The expression level of CD14 and CD15 in PBMCs and TLR4 in purified cells were determined and reported as the median fluorescent intensity (MFI). Liver iron concentration (LIC) was determined by biomagnetic susceptibility ("SQUID", Ferritometer) in patients with thalassemia; healthy controls were shown to have normal ferritin. Result(s): In PBMCs from thalassemia patients at baseline, the expression of monocyte CD14 and TLR4 were significantly increased 22% and 6.5% respectively compared to healthy controls ($p < 0.05$). Granulocytes from patients with thalassemia at baseline were also found to have a 50% higher expression of TLR4 compared to controls. Markers of iron burden, such as LIC and ferritin also significantly correlated with the expression of monocyte TLR4. In longitudinal analysis markers of iron burden, the expression of TLR4 on monocytes and granulocytes all significantly decreased in the follow-up period in thalassemia patients receiving intensive combination chelator therapy ($p<0.05$). Conclusion(s): These studies support the hypothesis that iron burden influences the innate immune response in thalassemia as demonstrated by the increased monocyte expression of both CD14 and TLR4 at baseline, both of which likely contribute to the commonly observed susceptibility to infection. After intensive chelation, the levels of CD14 and TLR4 decreased, indicating that decreased iron overload with chelation may improve innate immune responsiveness. These changes in CD14 and TLR4 may be able to restore proper innate immune function in thalassemia patients.

Walter, P. B., et al. (2009). "Iron overload diminishes the effectiveness of the innate immune response in thalassemia major: A possible mechanism for increased infection risk." Blood. Conference: 51st Annual Meeting of the American Society of Hematology, ASH. New Orleans, LA United States. Conference

Publication: **114**(22).

Introduction: Infection is the second most common cause of death in thalassemia. The innate immune system provides a first line of defense against infection and specificity depends on pattern recognition receptors (PRRs) specific to microbial pathogens. One class of PRR called the toll-like receptors (TLRs) are important for transducing the signal for bacterial Lipopolysaccharide (LPS), resulting not only in cytokine production, but also in the control of extracellular iron levels through production of neutrophil gelatinase associated Lipocalin (NGAL). However, the exact role that NGAL plays and the expression level of PRRs are unknown in thalassemia. Thus, the goal in these studies is to investigate the relationship of iron overload to the innate immune cell expression of PRRs and NGAL in thalassemia. Patients and Methods: Fifteen transfusion dependent thalassemia patients (11 - 29 yrs old) participating in the combination trial of deferasirox (an oral iron chelator) and deferoxamine were enrolled (Novartis sponsored CICL670AUS24T). Fasting blood samples were obtained i) at baseline after a 72 hr washout of chelator, and ii) at 6 and 12 months on study. Five healthy controls (13 - 18 yrs old) were also enrolled. Fresh monocytes were isolated using antibody-linked magnetic microbeads (Miltenyi Biotec Inc). Highly enriched populations of CD14+ monocytes were verified by flow cytometry. The expression of TLR4, also examined by flow cytometry is reported as the mean fluorescent intensity (MFI). In patients with thalassemia, liver iron concentration (LIC) was analyzed by biomagnetic susceptibility ("SQUID", Ferritometer). The plasma levels of NGAL were analyzed by ELISA. Result(s): At baseline the expression of monocyte TLR4 (mean 18.8 +/- 3.5 MFI) was reduced 30% compared to the healthy controls (mean 26.9 +/- 7.6 MFI, p<0.05). The expression of TLR4 over the follow-up period of 52 weeks in patients receiving intensive combination chelator therapy significantly increased 27% / year (7 MFI / year, p=0.005). Interestingly the expression of monocyte TLR4 was negatively correlated with LIC (r=-0.6, p=0.04). Finally, thalassemia patients at baseline have significantly higher levels of NGAL (80 +/- 20 ng/ml) compared to controls (42 +/- 15 ng/ml, p=0.01). Conclusion(s): These preliminary studies support the hypothesis that iron burden has a negative impact on the innate immune response in thalassemia as demonstrated by the decreased expression of TLR4. After intensive chelation, the levels of TLR4 increased, indicating that decreased iron overload with chelation may improve innate immune responsiveness. Finally, the iron transport protein NGAL is significantly elevated in thalassemia possibly acting to prevent essential iron uptake by pathogenic bacteria.

Walter, P. B., et al. (2013). "Association of cardiac iron by T2* with innate immune markers in transfusion-dependent thalassemia patients undergoing combined chelation therapy." Blood. Conference: 55th Annual Meeting of the American Society of Hematology, ASH **122**(21).

Introduction The thalassemias are inherited anemias sometimes characterized by severe transfusion dependence that can lead to extra-hepatic cardiac iron overload, causing cardiomyopathy. Despite improved chelation therapies, patients with transfusion-dependent thalassemia still endure cardiomyopathy and chronic inflammation. The innate immune system provides the first line of defense against infection and specificity depends on pattern recognition receptors (PRRs) specific to microbial pathogens. One class of PRR called the toll-like receptors (TLRs) interacts with CD14 on innate immune cells transducing the signal for bacterial lipopolysaccharide. Another cell surface protein that is not a PRR, but aids phagocytosis and is important in granulocytes function and chemotaxis is the adhesive polysaccharide antigen, CD15. The role that excess iron plays in determining expression level of these innate immune proteins is unknown. Thus, the goal in these studies is to investigate the relationship of cardiac iron overload and its chelation to innate immune cell expression of TLR4 and CD15 in patients

with transfusion-dependent thalassemia. Patients and Methods Eighteen patients with transfusion dependent thalassemia (11 - 29 years old) (participating in the Novartis sponsored CICL670AUS24T) were enrolled in a substudy investigating innate immunology (Novartis sponsored CICL670AUS42T). Patients were investigated at baseline, then after 6 months and one year of combined chelation therapy with deferasirox and deferoxamine. Fasting blood samples were obtained after a 72 hr washout with no chelators. Fourteen healthy controls (10 - 35 yrs old) were also enrolled. Changes in LIC (ferritometer), cardiac function (MRI) and myocardial iron (MRI T2*) were monitored. Peripheral blood mononuclear cells (PBMCs) and granulocytes were isolated from blood samples using density gradients. Monocytes and granulocytes were further purified using antibody-linked magnetic microbeads. Highly enriched populations of CD14+ monocytes and CD15+ granulocytes were verified by flow cytometry. The expression level of CD15 and TLR4 was determined. Results Previously we found that transfusion-dependent thalassemia patients had 37% higher TLR4+ neutrophils than control patients and a smaller percentage of CD15+ neutrophils. We have also observed a decrease in TLR4 expression during the course of combined chelation therapy on neutrophils but not monocytes, indicating that TLR4 is differentially modulated on neutrophils compared to monocytes. Now we find that these flow cytometry parameters show significant relationships to markers of iron burden. The percentage of TLR4+ monocytes was related to liver iron concentration ($r=- 0.49$, $p = 0.039$), ferritin concentration ($r=-0.47$, $p = 0.049$), serum iron level ($r=0.61$, $p = 0.008$), and total iron binding capacity (TIBC; $r=0.51$, $p = 0.021$), while the percentage of CD15 positive neutrophils predicted myocardial iron, as measured by MRI T2* ($r= 0.69$, $p<0.001$), and left ventricular ejection fraction (LVEF; $r=0.50$, $p = 0.022$). Lastly, analysis of covariance, controlling for age and gender, revealed that the number of CD15+ neutrophils increased significantly from baseline (90.84%) to 52 weeks (95.09%) of combined chelation therapy ($p = 0.007$). Conclusions This study found evidence that the innate immune system may be modulating iron trafficking not only to the liver but to the heart as well. The negative correlation between LIC and TLR4 expression suggests that severe iron overload may lead to heptocellular damage causing monocyte dysfunction, the pathology of which could be due to altered TLR4 expression. This relationship may also be driving the positive correlation observed between TLR4 expression and TIBC. CD15 seems to play an important role in cardiac health as it is positively correlated to LVEF and MRI T2*. This relationship is further validated by our previous finding that transfusion-dependent thalassemia patients had a smaller percentage of CD15+ neutrophils, which we now show improved during one year of combi ation chelation therapy. Taken together, this suggests that chelation therapy may enhance cardiac health by increasing the percentage of CD15+ neutrophils.

Walther, B. A., et al. (2018). "Type and quantity of coastal debris pollution in Taiwan: A 12-year nationwide assessment using citizen science data." Marine Pollution Bulletin **135**: 862-872.

Man-made coastal debris pollution is a growing concern for Taiwan. In 2004, Taiwanese environmental organizations led by the "Society of Wilderness" began gathering data on 19 categories of debris items collected during cleanup events. We present our analysis of the resulting 12-year dataset collated from 541 events held between October 2004 and December 2016. In total, 904,302 items weighing 131,358.3kg were collected, and 63.6% and 27.2% of items were made of either plastic or plastic mixed with other materials, respectively. The five most commonly recorded debris categories were plastic shopping bags, plastic bottle caps, disposable tablewares, fishing equipment, and plastic drinking straws. We estimated that during the 12-year period on average between 3.7 and 7.9 million items weighing 560-1110metrictons polluted Taiwan's coastline. We offer recommendations for improving the quality of data

collected during Taiwan's cleanup events and report some policy changes due partly to previous reports of this dataset.

Wan, T., et al. (2019). "A spectroscopic and theoretical investigation of interaction mechanisms of tetracycline and polystyrene nanospheres under different conditions." Environmental Pollution **249**: 398-405.

Interaction mechanisms of tetracycline (TC, as a typical antibiotic) on polystyrene microsphere (PSs, as a typical nanoplastic) were conducted by the batch, spectroscopic and theoretical techniques. The batch results showed that Na⁺ and K⁺ had no obvious effects on TC adsorption towards PSs, whereas Mg²⁺ significantly inhibited TC adsorption at pH>5.0 due to its induced aggregations of PSs. The maximum TC adsorption capacity of PSs in the presence of humic acid (50.99mg/g) was higher than that of PSs (44.77mg/g) at pH 6.0. The highly effective adsorption was attributed to electrostatic attraction, pi-pi interaction and hydrophobic effect, which was determined by FT-IR and XPS analysis. According to DFT (density functional theory) calculations, the adsorption energy of TC/TC⁺ on PSs (1.52eV) was significantly higher than that of negative TC⁻ (0.57eV), whereas minimum distance of TC on PSs (3.684A) was shorter than that of TC⁻ on PSs (3.988A). The results of theoretical calculations indicated that TC was more preferably adsorbed on PSs with more stable configuration compared to TC⁻. These findings indicated that PSs can be used as a promising adsorbent for immobilization and pre-concentration of TC from aqueous solutions.

Wan, W., et al. (2016). "Occurrence and distribution of organophosphorus esters in soils and wheat plants in a plastic waste treatment area in China." Environmental Pollution **214**: 349-353.

This study for the first time reported the occurrence, distribution and concentrations of organophosphate esters (OPEs) in soils caused by plastic waste treatment, as well as their influence on OPE accumulation in wheat (Triticum aestivum L.). Eight OPEs were detected with the total concentrations of 38-1250 ng/g dry weight in the soils from the treatment sites, and tributoxyethyl phosphate and tri(2-chloroethyl) phosphate present as the dominant OPEs. There were similar distribution patterns of OPEs and significant correlations between the total OPE concentrations in the soils from the plastic waste treatment sites with those in the nearby farmlands (P < 0.005), indicating that plastic waste treatment caused the OPE contamination of farmland soils. The uptake and translocation of OPEs by wheat were determined, with OPEs of high hydrophobicity more easily taken up from soils and OPEs with low hydrophobicity more liable to be translocated acropetally.

Wan, Y., et al. (2019). "Effects of plastic contamination on water evaporation and desiccation cracking in soil." Science of the Total Environment **654**: 576-582.

Environmental contamination of plastics is becoming an issue of concern globally. Detection of plastics, particularly microplastics, has been increasingly reported in both marine environments and inland waters. Recent work has indicated that soil in terrestrial environments has also been contaminated by plastics. Research has also shown that plastics can have adverse effects on soil biota. However, the impact of plastics on soil physical properties is still unclear. In this work, effects of plastic film of different sizes at environmental relevant concentrations on water evaporation and desiccation cracking in two clay soils were studied. The results showed that the presence of plastics in soil significantly increased the rate of soil water evaporation by creating channels for water movement. The effect was more pronounced in soils treated with 2mm plastics than in soils treated with 5 and 10mm plastics, and increased with increasing plastic

content. Desiccation cracking was observed on the surface of soil treated with 5 and 10mm plastics likely due to the destruction of soil structural integrity. While 2mm plastics increased the rate of desiccation shrinkage, the shrinkage ratio was reduced at the residual stage.

Wan, Z., et al. (2019). "Effects of polystyrene microplastics on the composition of the microbiome and metabolism in larval zebrafish." Chemosphere **217**: 646-658.

Microplastics are major pollutants in marine environment and may have health effects on aquatic organisms. In this study, we used two sizes (5 and 50 micro m diameter) of fluorescent and virgin polystyrene microplastics to analyze the adverse effects on larval zebrafish. In our study, we evaluated the effects on larval zebrafish after exposure to 100 and 1000 micro g/L of two sizes of polystyrene microplastics for 7 days. Our results show that polystyrene microplastics could cause alterations in the microbiome at the phylum and genus levels in larval zebrafish, including changes in abundance and diversity of the microbiome. In addition, metabolomic analysis suggested that exposure to polystyrene microplastics induced alterations of metabolic profiles in larval zebrafish, and differential metabolites were involved in energy metabolism, glycolipid metabolism, inflammatory response, neurotoxic response, nucleic acid metabolism, oxidative stress. Polystyrene microplastics also significantly decreased the activities of catalase and the content of glutathione. In addition, the results of gene transcription analysis showed that exposure to polystyrene microplastics induced changes in glycolysis-related genes and lipid metabolism-related genes, confirming that polystyrene microplastics disturbed glycolipid and energy metabolism. Taken together, the results obtained in the present study indicated that the potential effects of environmental microplastics on aquatic organisms should not be ignored.

Wang, A. R., et al. (2015). "Fatal fulminant accelerated rejection in a cardiac transplant recipient with natural killer cell infiltrate." Journal of Heart and Lung Transplantation **1)**: S18-S19.

Introduction: Accelerated rejection is uncommon in cardiac transplantation. The mechanism is believed to be mediated by cytotoxic T cells and/or anti-HLA alloantibodies resulting from a memory response to the donor allograft in sensitized patients. However, animal studies suggest a role for innate immune responses in rejection. We report a case of fatal fulminant accelerated rejection with a predominant natural killer (NK) cell infiltrate in a woman five days after orthotopic heart transplantation. Case Report: A 37-year-old, gravida 4, para 2, female with peripartum cardiomyopathy underwent a bicaval orthotopic heart transplant with a blood group compatible donor. No donor specific anti-HLA class I or class II antibodies were detected prior to transplant using flow cytometry microbead assays and Flow cytometry T and B cell crossmatches. Her initial postoperative course was uneventful. However, on postoperative day five, she was found unresponsive, pulseless, and expired despite extensive resuscitative measures. An autopsy revealed left ventricular subendocardial and intramyocardial hemorrhage with diffuse lymphocytic infiltrates and myocyte damage, consistent with ISHLT Grade 4 rejection. Immunohistochemistry demonstrated CD57+ cytotoxic lymphocytes, consistent with a predominant NK cell population. Recipient genotyping of the killer IgG receptor (KIR) revealed the presence of activating KIR (2DS2, and 2DS3 of KIR B haplotypes), and 2DS4 with its cognate HLA-C1 and C2 ligands in the donor. Summary: This is the first case report of a fatal, accelerated rejection occurring in the context of a predominantly natural killer cell infiltrate in a transplant recipient following a peripartum cardiomyopathy. Since activating KIRs can decrease the influence of the 'strong' inhibitory forms of KIR carried by A haplotypes, this case suggests that the interaction of patient's activating KIR with donor HLA-C1/C2 ligands may have contributed to NK cell activation and allograft rejection. In support of this hypothesis, recent studies indicated that KIR2DS4/HLA-C ligands increase the risk of early acute rejection in liver transplant recipients. Several mechanisms exist by which NK cell activation may have led to rejection in this case, including ischemia time, viral pathogens, and KIR/HLA class I ligands interaction.

Wang, B., et al. (2019). "Gold-nanorod-enhanced Raman spectroscopy encoded micro-quartz pieces for the multiplex detection of biomolecules." Analytical & Bioanalytical Chemistry **411**(21): 5509-5518.

The rapid analysis and detection of biomolecules has become increasingly important in biological research. Hence, here we propose a novel suspension array method that is based on gold nanorod (AuNR)-enhanced Raman spectroscopy and uses micro-quartz pieces (MQPs) as microcarriers. AuNRs and Raman reporter molecules are coupled together by Au-S bonds to obtain surface-enhanced Raman scattering labels (SERS labels). The SERS labels are then assembled on the surfaces of the MQPs via electrostatic interactions, yielding encoded MQPs. Experimental results showed that the encoded MQPs could be decoded using a Raman spectrometer. A multiplex immunoassay experiment demonstrated the validity and specificity of these encoded MQPs when they were used for bioanalysis. In concentration gradient experiments, the proposed method was found to give a linear concentration response to the target biomolecule at target concentrations of 0.46875-30 nM, and the detection limit was calculated to be 1.78 nM. The proposed method utilizes MQPs as carriers rather than conventional microbeads, which allows the interference caused by the background fluorescence of microbeads to be eliminated. The fluorescence of the encoded MQPs can be simply, rapidly, and inexpensively quantified using fluorescence microscopy. By dividing the quantitative and qualitative detection of biomolecules into two independent channels, crosstalk between the encoded signal and the labeled signal is averted and high decoding accuracy and detection sensitivity are guaranteed. Graphical abstract.

Wang, B. D., et al. (2019). "[Effects of Microplastics on Membrane Fouling During a Shortened Ultrafiltration Membrane Process]." Huanjing Kexue/Environmental Science **40**(11): 4996-5001.

Microplastics have garnered much attention worldwide as a new emerging pollutant. As they are gradually detected in freshwaters, understanding how microplastics will behave during current drinking water treatment processes is urgently needed. In recent years, the shortened process with an ultrafiltration (UF) membrane has shown excellent performance because of its low land use and high water purification efficiency. In this work, the membrane performance induced by microplastics was investigated with a shortened UF membrane process. The results showed that membrane fouling was always induced by the cake layer before and after coagulating with microplastics. Owing to the small UF membrane pore size (d<0.1 mum), slight membrane fouling was caused by microplastics (d<5 mm) alone. However, although the loose cake layer was formed because of the existence of flocs, the cyberspace formed by flocs was easily entered by small microplastics with increasing coagulant dosage. As a result, server membrane fouling was induced because of the formation of a dense cake layer. It was shown that the specific membrane flux induced by flocs alone was 0.82 and 0.76 in the presence of 0.1 mmol.L⁻¹ and 0.9 mmol.L⁻¹ FeCl₃.6H₂O, respectively. However, after coagulation the specific membrane fouling induced by the 0.1 g small microplastics (d<0.5 mm) was 0.76 and 0.62 with 0.1 mmol.L⁻¹ and 0.9 mmol.L⁻¹ FeCl₃.6H₂O, respectively. In addition, microplastics were always negatively charged in water. In comparison with alkaline conditions, Fe-based flocs were positively charged under acidic conditions, which were also much smaller. Therefore, microplastics were more easily adsorbed by Fe-based flocs under acidic conditions, leading to severe membrane fouling because of the dense cake layer formed. After coagulating

with 0.3 mmol.L⁻¹ FeCl₃.6H₂O, the specific membrane flux induced by 0.1 g small microplastics (d<0.5 mm) was 0.55 and 0.79 at pH 6.0 and 8.0, respectively.

Wang, C., et al. (2018). "Review of microplastics detection from marine organisms and their harms." Journal of Food Safety and Quality **9**(11): 2678-2683.

Microplastic (or mesoplastic) in the ocean is the general term for all plastics with dimensions less than 5 mm. The microplastic widely exists in various sea areas and has become a pollutant in the global marine ecological environment system. Marine organisms are also polluted with microplastics, which has seriously affected the safety of seafood. This paper reviewed the existing national and international researches from the following 4 aspects: the species of marine organisms containing microplastic, the extraction methods of microplastic, the appearance characteristics of microplastic, and the nondestructive identification methods of microplastic. At the same time, the harms caused by microplastics to marine organisms were summarized. In view of the existing problems of the microplastics testing standards could not be unified, the main directions of future researches were also proposed.

Wang, C., et al. (2020). "Structure of the global plastic waste trade network and the impact of China's import Ban." Resources, Conservation & Recycling **153**: N.PAG-N.PAG.

• Global plastic waste trade networks (GPWTNs) from 1988 to 2017 are established. • The spatiotemporal evolution of the GPWTNs is analyzed. • The direct and indirect impacts of China's import ban on the GPWTNs are evaluated. • Practical implications are given according to analysis of the GPWTNs. Millions of tonnes (teragrams) of plastic waste are traded around the world every year, which plays an important role in partially substituting virgin plastics as a source of raw materials in plastic product manufacturing. In this paper, global plastic waste trade networks (GPWTNs) from 1988 to 2017 are established using the UN-Comtrade database. The spatiotemporal evolution of the GPWTNs is analyzed. Attention is given to the country ranks, inter- and intra-continental trade flows, and geo-visual communities in the GPWTNs. We also evaluate the direct and indirect impacts of China's plastic waste import ban on the GPWTNs. The results show that the GPWTNs have small-world and scale-free properties and a core-periphery structure. The geography of the plastic waste trade is structured by Asia as the dominant importer and North America and Europe as the largest sources of plastic waste. China is the unrivaled colossus in the global plastic waste trade. After China's import ban, the plastic waste trade flows have been largely redirected to Southeast Asian countries. Compared with import countries, export countries are more important for the robustness of GPWTNs. Clearly, developed countries will not announce bans on plastic waste exports; these countries have strong motivation to continue to shift plastic waste to poorer countries. However, the import bans from developing countries will compel developed countries to build new disposal facilities and deal with their plastic waste domestically. [ABSTRACT FROM AUTHOR]

Wang, C. W., et al. (2015). "Integration of acoustic radiation force and optical imaging for blood plasma clot stiffness measurement." PLoS ONE [Electronic Resource] **10**(6): e0128799.

Despite the life-preserving function blood clotting serves in the body, inadequate or excessive blood clot stiffness has been associated with life-threatening diseases such as stroke, hemorrhage, and heart attack. The relationship between blood clot stiffness and vascular diseases underscores the importance of quantifying the magnitude and kinetics of blood's transformation from a fluid to a viscoelastic solid. To measure blood plasma clot stiffness, we have developed a method that uses ultrasound acoustic radiation force (ARF) to induce micron-scaled displacements (1-500 mum) on microbeads suspended in blood plasma. The displacements were detected by optical microscopy and took place within a micro-liter sized clot region formed within a larger volume (2 mL sample) to minimize container surface effects. Modulation of the ultrasound generated acoustic radiation force allowed stiffness measurements to be made in blood plasma from before its gel point to the stage where it was a fully developed viscoelastic solid. A 0.5 wt % agarose hydrogel was 9.8-fold stiffer than the plasma (platelet-rich) clot at 1 h post-kaolin stimulus. The acoustic radiation force microbead method was sensitive to the presence of platelets and strength of coagulation stimulus. Platelet depletion reduced clot stiffness 6.9 fold relative to platelet rich plasma. The sensitivity of acoustic radiation force based stiffness assessment may allow for studying platelet regulation of both incipient and mature clot mechanical properties.

Wang, D., et al. (2012). "A liquid optical phantom with tissue-like heterogeneities for confocal microscopy." Biomedical Optics Express **3**(12): 3153-3160.

Phantoms play an important role in the development, standardization, and calibration of biomedical imaging devices in laboratory and clinical settings, serving as standards to assess the performance of such devices. Here we present the design of a liquid optical phantom to facilitate the assessment of optical-sectioning microscopes that are being developed to enable point-of-care pathology. This phantom, composed of silica microbeads in an Intralipid base, is specifically designed to characterize a reflectance-based dual-axis confocal (DAC) microscope for skin imaging. The phantom mimics the scattering properties of normal human epithelial tissue in terms of an effective scattering coefficient and a depth-dependent degradation in spatial resolution due to beam steering caused by tissue micro-architectural heterogeneities.

Wang, D., et al. (2014). "A CD8 T cell/indoleamine 2,3-dioxygenase axis is required for mesenchymal stem cell suppression of human systemic lupus erythematosus." Arthritis & Rheumatology **66**(8): 2234-2245.

OBJECTIVE: Allogeneic mesenchymal stem cells (MSCs) exhibit therapeutic effects in human autoimmune diseases such as systemic lupus erythematosus (SLE), but the underlying mechanisms remain largely unknown. The aim of this study was to investigate how allogeneic MSCs mediate immunosuppression in lupus patients.

METHODS: The effects of allogeneic umbilical cord-derived MSCs (UC-MSCs) on inhibition of T cell proliferation were determined. MSC functional molecules were stimulated with peripheral blood mononuclear cells from healthy controls and SLE patients and examined by real-time polymerase chain reaction. CD4+ and CD8+ T cells were purified using microbeads to stimulate MSCs in order to determine cytokine expression by MSCs and to further determine which cell subset(s) or which molecule(s) is involved in inhibition of MSC-mediated T cell proliferation. The related signaling pathways were assessed. We determined levels of serum cytokines in lupus patients before and after UC-MSC transplantation.

RESULTS: Allogeneic UC-MSCs suppressed T cell proliferation in lupus patients by secreting large amounts of indoleamine 2,3-dioxygenase (IDO). We further found that interferon-gamma (IFNgamma), which is produced predominantly by lupus CD8+ T cells, is the key factor that

enhances IDO activity in allogeneic MSCs and that it is associated with IFNGR1/JAK-2/STAT signaling pathways. Intriguingly, bone marrow-derived MSCs from patients with active lupus demonstrated defective IDO production in response to IFNgamma and allogeneic CD8+ T cell stimulation. After allogeneic UC-MSC transplantation, serum IDO activity increased in lupus patients.

CONCLUSION: We found a previously unrecognized CD8+ T cell/IFNgamma/IDO axis that mediates the therapeutic effects of allogeneic MSCs in lupus patients.

Wang, D., et al. (2013). "A CD8 T cell-IFN-gamma-IDO axis is required for mesenchymal stem cell suppression of human SLE." Arthritis and Rheumatism **10)**: S674-S675.

Background/Purpose: Stem cell-based regenerative medicine is a promising approach in tissue reconstruction. Mesenchymal stem cells (MSC) show therapeutic effects on human autoimmune diseases including systemic lupus erythematosus (SLE), but the underlying mechanisms remain largely unknown. Method(s): The effects on inhibiting T cell proliferation by allogenic umbilical cord derived MSC were determined. Then MSC functional molecules were examined by real-time PCR under the stimulation of peripheral blood mononuclear cells (PBMC) from healthy controls and SLE patients, respectively. CB4+ and CB8+T cell were purified by microbeads to stimulate MSC, respectively, to determine IDO expression as well as supernatant cytokines, to further get to know which cell subset(s) or which molecule(s) involved in MSC mediated T cell proliferation inhibition. Meanwhile, the possible signaling pathways were assessed. Moreover, we analyzed the correlation between baseline serum cytokines and clinical response of MSC transplantation (MSCT). Result(s): UC MSC efficiently inhibited T cell proliferation in both healthy controls and lupus patients, with a more inhibitory effect in lupus T cell. In vitro activated lupus PBMC significantly induced MSC to secret TGF-beta1, IDO, HGF and IL-6, with a more than 200-fold increase of IDO. The addition of IDO inhibitor could almost completely abrogate MSC mediated T cell proliferation inhibition. Moreover, we found that lupus peripheral CB8+T cell markedly stimulated MSC to secret IDO and supernatant IFN-gamma significant increased. The addition of anti-IFN-gamma monoclonal antibody could inhibit IDO activity and similarly abrogate inhibition of T cell proliferation by MSC. We further found that lupus CB8+T cell secreted predominant intracellular IFN-gamma compared to CB4+T cell or compared to healthy CB8+ or CB4+T cell subsets. Furthermore, in the presence of lupus CB8+T cell, IFNGR/JAK/ STATs signaling pathways were activated, then to induce MSC to secret IDO and upregulate IDO activity. However, bone marrow MSC from lupus patients are less response to allogenic CB8+T cell or recombinant IFN-gamma stimulation and produce far less IDO, consequently fail to efficiently inhibit T cell proliferation. In the last, clinical analysis showed that lupus patients had significant higher proportion and absolute number of CB3+CD4-CB8+T cell than healthy controls, and serum IFN-gamma markedly increased. Predominant IFN-gamma in lupus patients was mainly secreted by CB8+T cell. Baseline serum IFN-gamma as well as CB8+T cell levels were significant higher in good responders than in poor responders who underwent UC MSC transplantation. Conclusion(s): We uncovered a previously unrecognized CB8+T cell-IFN- gamma-IDO axis that mediates the immunotherapy by allogenic MSC in lupus patients.

Wang, D., et al. (2012). "Regulatory role of umbilical cord mesenchymal stem cells on Treg and Th17 cells in patients with systemic lupus erythematosus." International Journal of Rheumatic Diseases **1)**: 26-27.

Objective: To investigate the regulatory effect of umbilical cord mesenchymal stem cells (UC-MSC) on regulatory T cells (Treg) and Th17 cells in patients with systemic lupus erythematosus (SLE). Method(s): Human UC-MSC were isolated, expanded, identified and infused into 15 refractory SLE patients (NCT00698191, phase II). Clinical efficacy was evaluated. The percentages of Treg and Th17 cells in peripheral blood were detected by flow cytometry. Peripheral cytokines were determined by ELISA and real time PCR, respectively. Peripheral blood mononuclear cells (PBMC) from 11 active SLE were co-cultured with UC-MSC to examine the changes of Treg and Th17 cells and supernatant cytokines. Patient peripheral blood naturally occurring Treg (nTreg) were isolated and co-cultured with UC-MSC in vitro in the presence of anti CD3/28 microbeads and recombinant IL-2. Result(s): Significant clinical efficacy was found by UC-MSC transplantation. Peripheral blood CD4+CD25+Foxp3+T cells percentage showed obvious increase at 1 week (2.32 +/- 1.40%), 1 month (2.03 +/- 1.30%), 3 months (2.41 +/- 2.06%) and 6 months (2.81 +/- 0.69%) visit (all P < 0.05 versus pre-MSCT 1.58 +/- 1.02%), in parallel with significant decline of CD3+CD8-IL17A+T cells after MSCT (1.30 +/- 1.02% at 1 week, 0.73 +/- 0.60% at 1 month, 0.56 +/- 0.60% at 3 months, 0.52 +/- 0.40% at 6 months, all P < 0.05 versus pre- MSCT 1.69 +/- 1.13%). Real time PCR showed that gene expression of RORct decreased, while TGF-b1 increased significantly 1 week after transplantation. Plasma concentration of TNF-alpha and IL17A decreased while TGF-b1 increased. The co-culture of UC-MSC with SLE PBMC resulted in a statistical increase of CD4+CD25+Foxp3+T cells and reduce of CD3+CD8-IL17A+T cells (all P < 0.05 at UC-MSC: PBMC 1:1, 1:10, 1:50 ratio), but without a dose dependent manner. Supernatant TGF-b1 and IL-6 increased but TNF-alpha decreased significantly in the co-culture system. The addition of TGF-b1 or PGE2 inhibitor to the culture system statistically abrogated the upregulation of Treg, while only PGE2 inhibitor significantly abrogated inhibitory role of Th17 cells by UC MSC. The addition of IL-6 or IDO inhibitor in the co-culture system had no effect on Treg and Th17 cells percentage. The absolute number of nTreg in the presence of UC-MSC increased compared to that of nTreg alone, and showed significant enhanced expression of Foxp3 and GITR. Additionally, CFSE dilution suggested that UC-MSC can obviously promote the proliferation of SLE nTreg in vitro. Conclusion(s): UC-MSC transplantation markedly and PGE2 dependently regulate Treg and Th17 cells in SLE patients, which may be one of the mechanisms for its therapeutic potential in refractory SLE.

Wang, D., et al. (2009). "[Detection of multiple gene mutations in non-small-cell lung cancer by suspension microarray]." Chung-Hua i Hsueh Tsa Chih [Chinese Medical Journal] **89**(48): 3393-3396.

OBJECTIVE: To construct a high-throughput suspension microarray for detecting the hotspot gene mutations of p53, p16, retinoblastoma (Rb) and epidermal growth factor receptor (EGFR) and to investigate the significance of this multimarker panel in molecular diagnosis of non-small-cell lung cancer (NSCLC).

METHODS: The specific probes of normal or mutated sequences targeting the hotspot mutation sites of p53, p16, Rb and EGFR were designed and immobilized to carboxylated Luminex microspheres (micro-beads). Genomic DNA was extracted from 65 specimens of cancer tissues and 20 adjacent normal lung tissues. p53, p16, Rb and EGFR genes were amplified by PCR, hybridized with the specific probes on the beads and measured using Luminex 100.

RESULTS: The single gene mutations of p53, p16, Rb or EGFR in NSCLC specimens were 53.8% (35/65), 20.0% (13/65), 7.7% (5/65) or 35.4% (23/65) respectively. The para-tumor normal tissue specimens were 5.0% (1/20), 5.0%(1/20), 0 and 0 respectively. For combined detections of four genes, the sensitivity, specificity and accuracy were 81.5% (53/65), 90.0% (18/20) and 83.5%(71/85) respectively. The mutation rates of this panel in stage I, stage II and stage III were 78.3% (18/23), 80.0% (16/20) and 86.4% (19/22) respectively.

CONCLUSIONS: A high-throughput suspension microarray with a higher specificity and sensitivity has been built. It may be used to simultaneously detect the gene mutations of p53, p16, Rb or EGFR in NSCLC specimens. This suspension microarray is helpful to improve the sensitivity of

molecular diagnosis of NSCLC and guide the molecular targeting therapy of NSCLC.

Wang, D.-E., et al. (2015). "Polydiacetylene liposome-encapsulated alginate hydrogel beads for Pb2+ detection with enhanced sensitivity." Journal of materials chemistry. A, Materials for energy and sustainability **3**(43): 21690-21698.

The development of a novel and simple method to trace lead ions (Pb2+) has received great attention due to its high toxicity to human health and the environment. In this paper, we describe a new polydiacetylene (PDA)-based liposome sensor for the colorimetric and fluorometric detection of Pb2+ in aqueous solution and in alginate hydrogel microbeads. In the sensor system, a dopamine group was rationally introduced into a diacetylene monomer to work as a strong binding site for Pb2+. The dopamine-functionalized monomer and 10,12-pentacosadiynoic acid (PCDA) were then incorporated into PDA liposomes in aqueous solution. After UV light-induced polymerization, deep blue colored liposome solutions were obtained. Upon the addition of various metal ions into the liposome solution, only Pb2+ could cause a distinct color change from blue to red and a dramatic fluorescence enhancement. To further improve its sensitivity and address its intrinsic aggregation, we then developed a liposome-immobilized detection system by encapsulating PDA-DA liposomes into alginate hydrogel beads through a microfluidic droplet-based method. The results showed that the PDA-DA liposome-containing hybrid hydrogel beads possessed excellent stability and high sensitivity. These interesting findings demonstrated that the PDA liposome system developed in the current study may offer a new method for Pb2+ recognition in a more efficient manner.

Wang, D. I., et al. (1984). "Penicillin fermentation in a 200-liter tower fermentor using cells confined to microbeads." Applied Biochemistry & Biotechnology **9**(1): 105-116.

The scale-up of the penicillin fermentation through cell confinement in a 200-L tower fermentor is described. P. chrysogenum spores were adsorbed into Celite microbeads having diameters greater than 180 microns. Fed-batch fermentations were performed using both free and confined cells. Cell growth and penicillin concentrations were measured during the fermentation. In addition, the oxygen transfer rate, the aeration rate, and the level of dissolved oxygen were also measured. Significant improvement in the mass transfer coefficient was found when the cells were anchored onto the microbeads. This improved oxygen transfer rate was accompanied by higher production of penicillin at a lower aeration rate. Besides the improved oxygen transfer rate into the mycelial broth, a reduction of the energy input for the oxygen transfer was observed. The confinement of the cells to this microcarrier furthermore allowed the intermittent harvesting of fermentation broth without reducing the cell mass in the fermentor.

Wang, F., et al. (2015). "The partition behavior of perfluorooctanesulfonate (PFOS) and perfluorooctanesulfonamide (FOSA) on microplastics." Chemosphere **119**: 841-847.

Microplastics have been recognized as transport vectors for heavy metals and organic pollutants to marine animals. Thus, the sorption behavior of contaminant on microplastic is crucial to their transport in marine system. In this study, the sorption behavior of PFOS and FOSA (two perfluorochemicals) on three kinds of microplastics (PE, PS, and PVC) are reported. The isotherm study showed that the sorption of PFOS and FOSA on microplastics is highly linear, and it indicated that partition by hydrophobic interaction is the predominant sorption mechanism. The K_d values of FOSA on three kinds of microplastics are all higher than those of PFOS, and the reason is attributed to their different functional groups. The K_d value of FOSA on three types of microplastics followed the order as: PE > PVC > PS. Such finding may

indicate that the molecule composition and structure of microplastics play important roles in their sorption processes of organic pollutants. The PFOS sorption levels on PE and PS particles were increased with the increase of NaCl and CaCl₂ concentrations, while the ion concentrations have no effect on FOSA sorption. The study on the pH effects on PFOS and FOSA sorption indicated FOSA could partition under various pH conditions on three types of microplastics while PFOS sorption on PE and PS were favored with lower pH.

Wang, F., et al. (2019). "Adsorption characteristics of cadmium onto microplastics from aqueous solutions." Chemosphere **235**: 1073-1080.

As one of emerging contaminants, microplastics (MPs) can enter the environment and adsorb toxic metals such as cadmium (Cd), thereby causing potential environmental risks. However, adsorption characteristics of MPs are poorly understood. Herein, batch experiments were performed to investigate the adsorption characteristics of Cd onto high-density polyethylene (HDPE) MPs with different particle sizes, that is, 1-2mm, 0.6-1mm, and 100-154mum. The adsorption of Cd was quite rapid initially, and the equilibrium time was approximately 90min. An increase in the pH of the Cd solution led to an increase in Cd adsorption. MPs with particle size of 100-154mum had the highest adsorption capacity. Addition of 1, 10, and 100mg/L NaCl all significantly decreased Cd adsorption. Adsorption kinetics fitted the pseudo-second-order model. Adsorption isotherm followed the Langmuir model and, to a lesser extent, the Freundlich model, with estimated maximum adsorption capacity of 30.5mug/g. The adsorbed Cd easily desorbed from the MPs. Energy-dispersive X-ray spectroscopy (EDS) analysis confirmed Cd adsorption to and desorption from MPs. Fourier transform infrared (FTIR) spectroscopy analysis showed no new functional groups formed during the adsorption and desorption processes, suggesting physical interaction may dominate the Cd adsorption onto MPs. The present study findings provide evidence that MPs can accumulate Cd, and the adsorbed Cd may be highly available, thus posing risks to the organisms exposed to these MPs.

Wang, G., et al. (2012). "Molecular distribution and stable carbon isotopic composition of dicarboxylic acids, ketocarboxylic acids, and alpha-dicarbonyls in size-resolved atmospheric particles from Xi'an City, China." Environmental Science & Technology **46**(9): 4783-4791.

Size-resolved airborne particles (9-stages) in urban Xi'an, China, during summer and winter were measured for molecular distributions and stable carbon isotopic compositions of dicarboxylic acids, ketocarboxylic acids, and alpha-dicarbonyls. To our best knowledge, we report for the first time the size-resolved differences in stable carbon isotopic compositions of diacids and related compounds in continental organic aerosols. High ambient concentrations of terephthalic (tPh, 379 +/- 200 ng m(-3)) and glyoxylic acids (omegaC(2), 235 +/- 134 ng m(-3)) in Xi'an aerosols during winter compared to those in other Chinese cities suggest significant emissions from plastic waste burning and coal combustions. Most of the target compounds are enriched in the fine mode (<2.1 mum) in both seasons peaking at 0.7-2.1 mum. However, summertime concentrations of malonic (C(3)), succinic (C(4)), azelaic (C(9)), phthalic (Ph), pyruvic (Pyr), 4-oxobutanoic (omegaC(4)), and 9-oxononanoic (omegaC(9)) acids, and glyoxal (Gly) in the coarse mode (>2.1 mum) are comparable to and even higher than those in the fine mode (<2.1 mum). Stable carbon isotopic compositions of the major organics are higher in winter than in summer, except oxalic acid (C(2)), omegaC(4), and Ph. delta(13)C of C(2) showed a clear difference in sizes during summer, with higher values in fine mode (ranging from -22.8 to -21.9) and lower values in coarse mode (-27.1 to -23.6). The lower delta(13)C of C(2) in coarse particles indicate that coarse mode of the compound originates from evaporation from fine mode and subsequent condensation/adsorption onto pre-existing coarse particles. Positive linear

correlations of C(2), sulfate and omegaC(2) and their delta(13)C values suggest that omegaC(2) is a key intermediate, which is formed in aqueous-phase via photooxidation of precursors (e.g., Gly and Pyr), followed by a further oxidation to produce C(2).

Wang, G., et al. (2019). "Occurrence and pollution characteristics of microplastics in surface water of the Manas River Basin, China." Science of the Total Environment **710**: 136099.

Microplastics, as a new type of pollutant, are widely found in various environmental media, and their effects on organisms are of great concern to society. However, research on the characteristics of microplastic pollution in inland rivers in China is still rare. The Manas River, which is located in the interior of Northeast China, was selected as the research object. The occurrence and pollution characteristics of microplastics in the surface water of the river were explored. The range of abundance of microplastics in the Manas River Basin was 21 +/- 3-49 +/- 3 items/L. Fibrous microplastics were dominant in all sites (88.0%); their size was mainly distributed between 0.1 and 1.0 mm (82.6%), and white and black were the dominant colours (82.9%). In addition, the size range of flaky-type microplastics were investigated in this study, which was principally between 2.5 x 10³-9.0 x 10⁴ mum² (84.5%). Infrared spectral analysis revealed that most of the selected particles were identified as microplastics, and polymer types of microplastics were dominated by polypropylene and polyethylene terephthalate (48.3%). This study can be used as a reference to better understand the contamination features of microplastics in inland rivers.

Wang, G., et al. (2017). "Comparison of the purity and vitality of natural killer cells with different isolation kits." Experimental & Therapeutic Medicine **13**(5): 1875-1883.

Natural killer (NK) cells are innate lymphocytes that aid in the protection of the host from infectious diseases and cancer. In vitro studies of NK cells have provided a foundation for developing clinical adoptive NK-cell transferred immunotherapy against human tumors. To elucidate the functions and mechanisms of NK cell populations, it is important to develop an optimal, highly reproducible and reliable isolation method. The present comparative study was performed with four different NK cell isolation kits of magnetic bead labeling made by Miltenyi and Stemcell companies, including positive selection kits [cluster of differentiation (CD)-49b, using the monoclonal antibody DX5) MicroBeads] and negative selection kits. In addition, the viability of NK cells isinterleukin-2 (IL-2)-dependent in vitro and thus the concentration of IL-2 is critical for maintaining longer cell viability of NK cells. NK cell purity and viability after culturing, for 24, 48 or 72 h, with or without IL-2 (0, 100, 300 or 500 U/ml) was investigated in the present study. Purity of NK cells varied depending on the purification kit used, despite the same method being applied. Furthermore, more granulocytes were present in purified NK cells using Miltenyi sorting kits, particularly when using the negative selection kit. The main disadvantage of DX5-positive selection using the Stemcell and Miltenyi kits was that a high percentage of CD3epsilon⁺ cells were mixed into the isolated NK cells. Additionally, a significant difference of NK cell purity (P=0.003) was observed while purification was performed using different surface markers. As a consequence, the use of the positive selection kit was modified and subsequently a significantly higher purity (P=0.002) and yield (P=0.004) of NK cells was obtained. Moreover, the purity of NK cells and viability with or without a range of concentrations of IL-2 was compared.

Wang, H., et al. (2019). "Diagnosis of Invasive Nonfunctional Pituitary Adenomas by Serum Extracellular Vesicles." Analytical Chemistry **91**(15): 9580-9589.

The invasiveness evaluation of nonfunctional pituitary adenoma (NFPAs) is crucial for the prediction of the malignant potential and for making surgical plans of NFPAs. Current invasiveness evaluation of NFPAs is based on neuroimaging, which can hardly predict the invasive potential and dynamically monitor disease progress. Here we used microbead-assisted flow cytometry to detect and analyze the serum extracellular vesicles (EVs) from 30 NFPAs patients (15 invasive and 15 noninvasive). Lower expressions of folate receptor 1 (FOLR1) and epithelial cell adhesion molecule (EpCAM) were found in serum EVs from the invasive NFPAs patients compared to the noninvasive ones [area under the curve (AUC) of 0.94 for FOLR1 and 0.88 for EpCAM]. Meanwhile, increased mRNA expression of vimentin and N-cadherin, two mesenchymal markers, was found in serum EVs from the invasive NFPAs patients compared to the noninvasive ones. Consistent results were observed in the tumor tissue that invasive NFPAs have lower expression of the epithelial markers while higher expression of the mesenchymal markers. These results suggested the possible role of epithelial-mesenchymal transition (EMT) in the invasiveness of NFPAs. Pituitary tumor transforming gene 1 (PTTG1) mRNA in serum EVs was also found to be an indicator for invasive NFPAs and is related with EMT. These results provide a method for the blood-based diagnosis and invasiveness evaluation of NFPAs and would be beneficial to the diagnosis, prognosis prediction, and surgical risk evaluation of NFPAs.

Wang, H., et al. (2012). "Application of dissolved air flotation on separation of waste plastics ABS and PS." Waste Management **32**(7): 1297-1305.

The aim of this research was to separate waste plastics acrylonitrile butadiene styrene (ABS) and polystyrene (PS) by dissolved air flotation in a self-designed dissolved air flotation apparatus. The effects of wetting agents, frother, conditioning time and flotation time on flotation behavior of waste plastics ABS (w-ABS) and PS (w-PS) were investigated and the optimized separation conditions were obtained. The results showed that when using 25 mgL(-1) tannic acid, 5 mgL(-1) terpineol, 15 min conditioning time and 15 min flotation time, mixtures of w-ABS and w-PS were separated successfully by dissolved air flotation in two stages, the results revealed that the purity and recovery rate of w-PS in the floated products were 90.12% and 97.45%, respectively, and the purity and recovery rate of w-ABS in the depressed products were 97.24% and 89.38%, respectively. Based on the studies of wetting mechanism of plastic flotation, it is found that the electrostatic force and hydrophobic attraction cannot be the main factor of the interaction between wetting agent molecules and plastic particles, which can be completed through water molecules as a mesophase, and a hydrogen bonding adsorption model with hydration shell as a mesophase was proposed.

Wang, H., et al. (2019). "Exposure to microplastics lowers arsenic accumulation and alters gut bacterial communities of earthworm Metaphire californica." Environmental Pollution **251**: 110-116.

Ubiquitous contamination of microplastics and arsenic in soil ecosystems can induce many health issues to nontarget soil organisms, and will also cause many potential threats to the gut bacterial communities of soil fauna. However, the changes in the gut bacterial communities of soil fauna after exposure to both microplastics and arsenic remain unknown. In this study, the toxicity and effects on the gut microbiota of earthworm Metaphire californica caused by the combined exposure of microplastics and arsenic were examined by using arsenic species analysis and high throughput sequencing of gut microbiota. Results showed that total arsenic and arsenic species in the earthworm gut and body tissues after exposure to combination of microplastics with arsenate (As(V)) were significantly different from that treated with As(V) alone. Microplastics lessened the accumulation of total arsenic and the transformation rate of As(V) to arsenite (As(III)). Microplastics alleviated the effect of arsenic on the gut microbiota possibly via adsorbing/binding As(V) and lowering arsenic bioavailability, thus prevented the reduction of As(V) and accumulation of total arsenic in the gut which resulted in a lower toxicity on the earthworm. The study broadens our understanding of the ecotoxicity of microplastics with other pollutants on the soil animals and on their gut microbiota.

Wang, H., et al. (2019). "Evaluation of serum extracellular vesicles as noninvasive diagnostic markers of glioma." Theranostics **9**(18): 5347-5358.

Rationale: Glioma is the most common malignant primary brain tumor in the central nervous system (CNS). The lack of reliable noninvasive diagnostic and prognostic methods is one of the main reasons for the high mortality of glioma. Serum has become a useful biomarker for the diagnosis and prognosis prediction of glioma because extracellular vesicles (EVs) carry molecular components from their parental cells. Method(s): To detect EVs and perform molecular analysis of serum EVs, we established and optimized a microbead-assisted method based on flow cytometry and estimated the efficacy of EGFR protein expression and NLGN3 and PTTG1 mRNA in serum EVs from glioma patients (n=23) and healthy individuals (n=12). We evaluated the ability of EGFR⁺ EVs to differentiate high-grade and low-grade glioma patients and checked the correlation between EGFR in EVs and the ki-67 labeling index (LI) in the tumor tissue. Result(s): We demonstrated that EGFR⁺ EVs are effective diagnostic and prognostic markers of glioma. The expression of EGFR in serum EVs can accurately differentiate high-grade and low-grade glioma patients, and EGFR in EVs positively correlates with ki-67 LI in the tumor tissue. We also showed the potential of NLGN3 and PTTG1 mRNA in EVs for detecting glioma patients. Conclusion(s): We demonstrate that the protein expression of EGFR in serum EVs is an effective diagnostic marker of glioma. EGFR in EVs highly correlates with the malignancy of glioma. We also show the potential of NLGN3 and PTTG1 in EVs for detecting glioma. The optimized flow cytometry with the aid of microbead-based EV enrichment show its potential as a noninvasive method for the detection of glioma and will be beneficial to the management of glioma. Wang, H., et al. (2014). "Multiplex profiling of glycoproteins using a novel bead-based lectin array." Proteomics **14**(1): 78-86.

Lectin array is becoming important in profiling targeted glycan/glycoprotein, but weak interaction between lectin and glycan causes low sensitivity of the approach. This study aims to develop a bead-based lectin array for improving the sensitivity of glycosylation profiling. Lectins are chemically coupled to fluorescent dye coated microbeads, and glycan-lectin recognition is carried out three dimensionally. The performance of this platform was evaluated, and the LOD of lectin Ricinus communis agglutinin 120 (RCA120) was 50 pg/mL (1 pM) of asialofetuin, providing the bead-based lectin microarray with the highest sensitivity among the reported lectin microarrays. Furthermore, multiplexed assay was performed, which allowed the simultaneous detection of multiple carbohydrate epitopes in a single reaction vessel. The glycosylation patterns of hepatocellular carcinoma associated immunoglobulin G were analyzed, and increased (alpha-1,6) core fucosylation and (alpha-2,6) sialylation patterns were observed, which may provide significant clinical evidence for disease diagnosis.

Wang, H., et al. (2001). "[Non-invasive prenatal diagnosis of fetal Down syndrome by dual-color fluorescence in situ hybridization with co-denaturation]." Chung-Hua Fu Chan Ko Tsa Chih [Chinese Journal of Obstetrics & Gynecology] **36**(6): 338-340.

OBJECTIVE: To explore the possibility of non-invasive prenatal diagnosis of Down syndrome by dual color fluorescence in situ hybridization with co-denaturation.

METHODS: Fetal nucleated red blood cells labeled by anti-glycophorin a monoclonal immunomagnetic

microbeads were enriched from maternal peripheral blood by magnetic activated cell sorting. The ploidy of chromosome 21 and sex of fetuses were determined using two-color fluorescence in situ hybridization with 21 and Y chromosome probes denatured by codenaturation. The accuracy of prediction was verified according to the karyotype of fetuses by analysis of amniotic cells.

RESULTS: The ploidy of chromosome 21 of fetuses from 11 pregnant women was predicted normal. The results were correctly identified by the fetal karyotypes. 5 pregnant women were predicted carrying male fetuses. The number and mean number of male fetal nucleated red blood cells were 9-65 and 25 per 2 ml, respectively. The purity of male fetal erythrocytes enriched from maternal peripheral blood was 1.4%-18.8%; 6 pregnant women were predicted carrying female fetuses, and no male fetal nucleated red blood cell was found. The results of sex prediction were consistent with the kayotypes of fetuses by analysis of amniotic cells.

CONCLUSION: It is possible to predict the ploidy of chromosome 21 and the sex of fetuses when fetal nucleated erythrocytes enriched by direct immunomagnetic labeling followed by magnetic activated cell sorting are analyzed using two-color fluorescence in situ hybridization with Y and 21 chromosome probes through codenaturation.

Wang, H., et al. (2019). "Insights into removal mechanisms of bisphenol A and its analogues in municipal wastewater treatment plants." <u>Science of the Total Environment</u> **692**: 107-116.

The occurrence and removal mechanisms of bisphenol A (BPA) and its analogues in municipal WWTPs were critically reviewed in this article. BPA appeared to be the dominant bisphenol, and the removal efficiency of bisphenols was in the order of bisphenol AP > bisphenol P > bisphenol F > bisphenol Z > bisphenol C > bisphenol S > bisphenol B > BPA > bisphenol E > bisphenol AF. It was also found that BPA removal showed linear relationships to those of its analogues, which have been proven by BPA vs BPS or BPF. BPA removal performances in different treatment processes ranked from low to high are primary treatment, lagoon process, biological aerated filter, and activated sludge. Lab-scale studies showed that >50% BPA can be removed by sewage sludge estimated with the BPA solid water distribution coefficients, which showed that sludge adsorption played an important role on BPA removal. The theoretically predicted removal of BPA in municipal WWTP showed that it is readily biodegradable, which deviate from its on-site investigations. Existence of BPA conjugates in raw municipal wastewater as well as newly produced BPA degraded or migrated from microplastic materials are possible two main reasons. Copyright © 2019 Elsevier B.V.

Wang, H., et al. (2011). "The separation, purification and identification of mouse interstitial dendritic cells in lung." <u>Chinese Journal of Immunology</u> **27**(9): 814-817.

Objective: To establish the methods to separate and purify pulmonary interstitial dendritic cells (DCs) of mice in order to provide experimental base for the related study on them.

Wang, H., et al. (2018). "Visible-light-driven removal of tetracycline antibiotics and reclamation of hydrogen energy from natural water matrices and wastewater by polymeric carbon nitride foam." <u>Water Research</u> **144**: 215-225.

Water and energy are key sustainability issues that need to be addressed. Photocatalysis represents an attractive means to not only remediate polluted waters, but also harness solar energy. Unfortunately, the employment of photocatalysts remains a practical challenge in terms of high cost, low efficiency, secondary pollution and unexploited water matrices influence. This study investigated the feasibility of photocatalysis to both treat water and produce hydrogen with practical water systems. Polymeric carbon nitride foam (CNF) with large surface area and

mesoporous structure was successfully prepared via the bubble-template effect of ammonium chloride decomposition during thermal condensation. The reaction kinetics, mechanisms, and effect of natural water matrices and wastewater on CNF-based photocatalytic removal of tetracycline hydrochloride (TC-HCl) were systematically investigated. Furthermore, the efficiency of clean hydrogen energy from natural water matrices and wastewater was also evaluated. It was found that the photocatalytic performance of CNF for TC-HCl removal was principally affected by calcination temperature in the presence of NH₄Cl. The degradation rates of CNF-4 (calcined at 550degreeC) were approximately 1.84, 2.49 and 7.47 times than that of the CNF-2 (calcined at 600degreeC), CNF-1 (calcined at 500degreeC) and GCN (without NH₄Cl), respectively.

Wang, H., et al. (2012). "Identification of env-specific monoclonal antibodies from Chinese HIV-1 infected person by B cell activation and RT-PCR cloning." Chinese Journal of Virology **28**(4): 358-365.
To obtain protective human monoclonal antibody from HIV-1 infected person, we adapted a technology for isolating antigen specific monoclonal antibody from human memory B cells through in vitro B cell activation coupled with RT-PCT and expression cloning. Human B cells were purified by negative sorting from PBMCs of HIV-1 infected individuals and memory B cells were further enriched using anti-CD27 microbeads. Two hundred memory B cells per well were cultured in 96-well round-bottom plates with feeder cells in medium containing EBV and CpG. Env-specific antibodies in supernatants were screened by ELISA after 1-2 weeks' culture. Cells from positive wells of Env-specific antibody were harvested and total RNA was isolated. Human VH and V kappa or V lambda genes were amplified by RT-PCR and cloned into IgG1 and kappa or lambda expressing vectors. Functional VH and V kappa or V lambda were identified by cotransfecting 293T cells with individual heavy chain and light chain clones followed by analysis of culture supernatants by ELISA for Env-specific antibodies. Finally, corresponding mAb was produced by transient transfection of 293T cells with the identified VH and V kappa / lambda pair and purified by protein A affinity chromatography. Purified monocolonal antibodies were used for HIV-1 specific antibody-dependent cell-mediated cytotoxicity (ADCC) and neutralizing activity assay. Four monocolonal Env-specific antibodies were isolated from one HIV-1 subtype B' infected individual. Two of them showed strong ADCC activity and one showed weak neutralizing activity against HIV-1. Its further studies on their application in therapeutic or prophylactic vaccines against HIV-1 should be grounded.

Wang, H. Q., et al. (2007). "A feasible and quantitative encoding method for microbeads with multicolor quantum dots." Journal of Fluorescence **17**(2): 133-138.
Multicolor encoded beads were achieved by incorporating two color core-shell quantum dots (QDs) (CdSe/ZnS) to commercial polystyrene (PS) beads. By controlling the concentration ratios of the two quantum dots (QDs) in doping solutions, a series of codes with different intensity ratios were obtained. Based on the multiple encoded carboxylic modified polystyrene beads, fluorescent dyes labeled antibodies were distinguished successfully on the beads' surface. It suggests that the encoded beads from this method have the practicability in biological applications and chemical analysis.

Wang, J., et al. (2019). "Negligible effects of microplastics on animal fitness and HOC bioaccumulation in earthworm Eisenia fetida in soil." Environmental Pollution **249**: 776-784.
As one type of the most widespread and long-lasting anthropogenic contaminants, microplastics have become a global environmental concern. While numerous studies have demonstrated effects of microplastics on aquatic organisms, the potential influence on terrestrial faunas is

relatively less known, even though soil is a primary recipient and sink of plastics. In this study, earthworm Eisenia fetida was exposed to different levels (0, 1, 5, 10, and 20% d.w.) of polyethylene (PE, <=300 micro m) and polystyrene (PS, <=250 micro m) particles in an agricultural soil to evaluate the oxidative stress. Fluorescence imaging, after dying with Nile Red, clearly indicated the ingestion of PE and PS particles by E. fetida. Exposure to PE or PS particles at the highest rate (20%) for 14 d significantly (p<0.05) increased the activity of catalase and peroxidase and the level of lipid peroxidation, while inhibited the activity of superoxide dismutase and glutathione S-transferase in E. fetida. However, no discernible effect was detected at amendment rates <=10% for the majority of biochemical endpoints, suggesting that microplastic-induced oxidative stress would not occur in E. fetida under most environmental conditions. The influence of microplastics on bioaccumulation of PAHs and PCBs was also evaluated in E. fetida exposed to different levels (0, 0.1, 1, 5, and 10% d.w.) of PE and PS particles. The tissue concentrations of PAHs and PCBs were reduced in the presence of microplastics at amendment rates >=1%, suggesting that microplastics did not act as a carrier to enhance contaminant uptake. This was attributed to competitive sorption of microplastics for contaminants and the specific feeding behavior of earthworm. Biodynamic model analysis confirmed that ingestion of microplastics contributed negligibly to contaminant bioaccumulation. Findings of this study suggested that under environmentally relevant conditions, microplastics should not cause significant toxic effects to E. fetida, nor enhance its accumulation of hydrophobic contaminants.

Wang, J., et al. (2014). "[Investigation and analysis of factors that affect the health of children in the plastic recycling and regeneration processing region]." Zhonghua Lao Dong Wei Sheng Zhi Ye Bing Za Zhi/Zhonghua Laodong Weisheng Zhiyebing Zazhi/Chinese Journal of Industrial Hygiene & Occupational Diseases **32**(9): 690-692.

OBJECTIVE: To investigate the main influential factors for the health of children in the plastic waste recovery and recycling area.

METHODS: A cross-sectional survey was performed among children aged 9~17 years from three natural villages engaged in plastic waste recovery and recycling and four control villages engaged in planting. The health status of children was investigated by random household survey using a face-to-face questionnaire, and the main influential factors were analyzed accordingly.

RESULTS: The incidence rates of respiratory symptoms (cough and expectoration, nasal congestion, and sore throat) (78.4%, 69/88) and digestive diseases (gastrointestinal disease and liver disease) (14.8%, 13/88) in the waste processing area were significantly higher than those in the control area (64.0%, 71/111; 6.3%, 7/111) (P < 0.05).

CONCLUSION: Multivariate logistic regression analysis indicated that skin diseases are related to whether plastic can be smelt around the residential area.

Wang, J., et al. (2019). "Polystyrene microplastics cause tissue damages, sex-specific reproductive disruption and transgenerational effects in marine medaka (Oryzias melastigma)." Environmental Pollution **254**(Part B).

The ubiquity of microplastics in the world's ocean has aroused great concern. However, the ecological effects of microplastics at environmentally realistic concentrations are unclear. Here we showed that exposure of marine medaka (Oryzias melastigma) to environmentally relevant concentrations of 10 micro m polystyrene microplastics for 60 days not only led to microplastic accumulation in the gill, intestine, and liver, but also caused oxidative stress and histological changes. Moreover, 2, 20, and 200 micro g/L microplastics delayed gonad maturation and decreased the fecundity of female fish. Alterations of the hypothalamus-pituitary-gonadal (HPG)

axis were investigated to reveal the underlying mechanisms, and gene transcription analysis showed that microplastic exposure had significantly negative regulatory effects in female HPG axis. Transcription of genes involved in the steroidogenesis pathway in females were also downregulated. This disruption resulted in decreased concentrations of 17 beta -estradiol (E₂) and testosterone (T) in female plasma. Furthermore, parental exposure to 20 micro g/L microplastics postponed the incubation time and decreased the hatching rate, heart rate, and body length of the offspring. Overall, the present study demonstrated for the first time that environmentally relevant concentrations of microplastics had adverse effects on the reproduction of marine medaka and might pose a potential threat to marine fish populations.

Wang, J., et al. (2018). "Separation of acrylonitrile-butadiene-styrene and polystyrene waste plastics after surface modification using potassium ferrate by froth flotation." Waste Management **78**: 829-840.

This work develops a simple and practical process for separation of acrylonitrile–butadienestyrene (ABS) and polystyrene (PS) waste plastics by froth flotation after surface modification using potassium ferrate. ABS plastics containing brominated flame retardants (BFRs) can release hazardous emissions during the process of disposal. Moreover, ABS and PS are typical styrene plastics with similar properties, posing severe restrictions on their separation for recycling. Thus, potassium ferrate modification was investigated and found to decrease selectively the floatability of ABS, providing available process for separation of ABS and PS. Contact angle measurements, FT-IR, XPS and SEM characterization analysis confirmed that potassium ferrate modification can induce the desired changes in the surface properties of ABS. With consideration to separation of ABS and PS, the optimum conditions are potassium ferrate concentration 0.15 M/L, modification time 15 min, temperature 60 °C, stirring rate 200 rpm, frother concentration 14.50 mg/L and flotation time 2 min. Under optimum conditions, separation of ABS and PS with different mixing ratios was accomplished with a recovery and purity of 98.60% and 98.62% respectively. Moreover, reusing of potassium ferrate solution is feasible, further eliminating emissions and cost of this process. Consequently, surface modification using potassium ferrate can be applied for facilitating flotation separation of ABS and PS waste plastics. © 2018 Elsevier Ltd

Wang, J., et al. (2019). "Microplastics as contaminants in the soil environment: A mini-review." Science of the Total Environment **691**: 848-857.

Microplastics (MPs) have become a global environmental concern because of their ubiquitous presence. While extensive microplastic researches have focused on the marine environment, pervasive MPs contamination in soil and their detrimental impacts have been largely overlooked. Excessive concentrations of MPs and additives have been found in soil derived from the use of plastic mulches and the application of sewage sludge to fields. They may pose directly or indirectly as adverse effects on flora and fauna. The objectives of this review are (1) to summarize the abundance, sources, and properties of MPs in soil; (2) to analyze combined effects of MPs and various other environmental pollutants on soil system; and (3) to discuss the possible risks posed by MPs to soil biodiversity, food safety and human health. This review will highlight key future research areas for scientists and policymakers, and increase overall understanding of soil MPs pollution and its potential environmental impacts.

Wang, J., et al. (2019). "Sorption behaviors of phenanthrene, nitrobenzene, and naphthalene on mesoplastics and microplastics." Environmental science and pollution research international **26**(12): 12563-12573.

The occurrence of plastic particles in aquatic environment has led to enormous concern in the past few years. The sorption behaviors of harmful organic compounds by plastic particles can increase their concentrations by several orders of magnitude influencing their global transport in the marine environment. Five types of mesoplastics (5–20 mm) and five types of microplastics (< 5 mm) were selected to investigate the sorption behaviors of three typical organic compounds (phenanthrene, nitrobenzene, and naphthalene). For phenanthrene, most microplastics have stronger sorption ability than that of mesoplastics due to the higher specific surface area (SSA). However, the sorption ability of nitrobenzene on low-density polyethylene (LDPE) mesoplastics was higher than that on LDPE microplastics, and the sorption ability of naphthalene on polyvinyl chloride (PVC) mesoplastics was higher than that on PVC microplastics, which were attributed to the presence of functional groups on the surface of mesoplastics, induced by adding slip agents, lubricant, plasticizer, stabilizer, etc. during film production. Talcum-filled polypropylene (PP) microplastics had strongest sorption ability to nitrobenzene and naphthalene due to the presence of talcum and high SSA. For unmodified microplastics, the sorption abilities of phenanthrene, nitrobenzene, and naphthalene were all followed the order of high-density polyethylene (HDPE) > polystyrene (PS) > LDPE > PVC after SSA normalization. Thus, SSA and the functional groups on the surface of plastic particles should be considered when the sorption behaviors of harmful organic compounds on plastic particles are studied.

Wang, J., et al. (2019). "Size effect of polystyrene microplastics on sorption of phenanthrene and nitrobenzene." Ecotoxicology and Environmental Safety **173**: 331-338.

Microplastics can have strong sorption capacity for many contaminants, thus greatly influencing the fate, transport and bioavailability of those contaminants in the environment. However, the effect of particle size on contaminant sorption by microplastics is still poorly understood. This study investigated the sorption of phenanthrene and nitrobenzene to micron-, submicron- and nano-sized polystyrene microplastics of 170 micro m, 102 micro m, 50 micro m, 30 micro m, 800 nm, 235 nm or 50 nm. All phenanthrene sorption isotherms and most nitrobenzene sorption isotherms were linear because of the strong sorption capacity of microplastics and the hydrophobic partitioning. The log K_d values ranged between 3.07-4.20 and 1.58-3.14 log (L/kg) for phenanthrene and nitrobenzene, respectively. The log K_d values of phenanthrene and nitrobenzene both increased with decreasing particle size for micron-sized polystyrenes (micro-polystyrene) and submicron-sized polystyrenes (submicro-polystyrene). However, in comparison with 235 nm submicro-polystyrene, the log K_d values of 50 nm nano-polystyrene were significantly lower for phenanthrene and comparable for nitrobenzene because its aggregation greatly reduced the effective surface area accessible for sorption. The results improved our understanding of the fate and risks of microplastics associated with the two typical organic contaminants in the micrometer to nanometer scale.

Wang, J., et al. (2019). "Typhoons increase the abundance of microplastics in the marine environment and cultured organisms: a case study in Sanggou Bay, China." Science of the Total Environment **667**: 1-8.

Microplastic contamination in the ocean has emerged as an environmental issue of global importance. The most effective strategy to control microplastic pollution is to reduce the terrestrial input, but severe weather conditions make it difficult. This study investigated microplastic abundance and characteristics in the seawater, sediments, and cultured oysters (Crassostrea gigas) of Sanggou Bay (China) before and after two typhoons with an average rainfall of 19.2 mm/d over 8 days. Prior to the typhoons, microplastic levels in the seawater, sediment, and oysters were 63.6+or-37.4 items/L, 2178+or-369 items/kg, and 41.0+or-15.5 items/individual, with fibers being the predominant shape. Typhoons increased the average

concentrations of microplastics in the seawater and sediments by approximately 40%, and the proportions of fragments, spherules, and granules in the sediments increased by 9.6%, 4.0%, and 4.3%, respectively. The majority of microplastics in seawater, sediments, and oysters collected before the typhoons could be grouped into sizes of 0.1-0.5 mm (36.7%), 0.05-0.1 mm (42.6%), and 0.1-0.5 mm (47.1%), respectively. After the typhoons, the most abundant size classes of microplastics in the three environmental compartments were 0.05-0.1 mm (39.2%) for seawater, 0.1-0.5 mm (37.1%) for sediments, and 0.05-0.1 mm (29.9%) for oysters. The typhoons also altered color distribution of microplastics and increased the proportions of polypropylene, polystyrene, and polyethylene terephthalate in seawater. Scanning electron microscopy/energy dispersive spectroscopy showed that organic matter and heavy metals were present on the microplastics collected from oysters. Our results suggest that weather conditions should be considered when investigating marine microplastics.

Wang, J., et al. (2019). "A simple protocol for isolating mouse lung endothelial cells." Scientific Reports **9**(1): 1458.

Endothelial dysfunction is the common molecular basis of multiple human diseases, such as atherosclerosis, diabetes, hypertension, and acute lung injury. Therefore, primary isolation of high-purity endothelial cells (ECs) is crucial to study the mechanisms of endothelial function and disease pathogenesis. Mouse lung ECs (MLECs) are widely used in vascular biology and lung cell biology studies such as pulmonary inflammation, angiogenesis, vessel permeability, leukocyte/EC interaction, nitric oxide production, and mechanotransduction. Thus, in this paper, we describe a simple, and reproducible protocol for the isolation and culture of MLECs from adult mice using collagenase I-based enzymatic digestion, followed by sequential sorting with PECAM1 (also known as CD31)- and ICAM2 (also known as CD102)-coated microbeads. The morphology of isolated MLECs were observed with phase contrast microscope. MLECs were authenticated by CD31 immunoblotting, and immunofluorescent staining of established EC markers VE-cadherin and von Willebrand factor (vWF). Cultured MLECs also showed functional characteristics of ECs, evidenced by DiI-oxLDL uptake assay and THP-1 monocyte adhesion assay. Finally, we used MLECs from endothelium-specific enhancer of zeste homolog 2 (EZH2) knockout mice to show the general applicability of our protocol. To conclude, we describe here a simple and reproducible protocol to isolate highly pure and functional ECs from adult mouse lungs. Isolation of ECs from genetically engineered mice is important for downstream phenotypic, genetic, or proteomic studies.

Wang, J., et al. (2017). "Microplastics in the surface sediments from the Beijiang River littoral zone: Composition, abundance, surface textures and interaction with heavy metals." Chemosphere **171**: 248-258.

While large quantities of studies on microplastics in the marine environment have been widely carried out, few were available in the freshwater environment. The occurrence and characteristics, including composition, abundance, surface texture and interaction with heavy metals, of microplastics in the surface sediments from Beijiang River littoral zone were investigated. The concentrations of microplastics ranged from 178 ± 69 to 544 ± 107 items/kg sediment. SEM images illustrated that pits, fractures, flakes and adhering particles were the common patterns of degradation. Chemical weathering of microplastics was also observed and confirmed by μ-FTIR. EDS spectra displayed difference in the elemental types of metals on the different surface sites of individual microplastic, indicating that some metals carried by microplastics were not inherent but were derived from the environment. The content of metals (Ni, Cd, Pb, Cu, Zn and Ti) in microplastics after ultrasonic cleaning has been analyzed by ICP-MS.

Based on data from the long-term sorption of metals by microplastics and a comparison of metal burden between microplastics, macroplastics and fresh plastic products, we suggested that the majority of heavy metals carried by microplastics were derived from inherent load. [ABSTRACT FROM AUTHOR]

Wang, J., et al. (2016). "The behaviors of microplastics in the marine environment." Marine Environmental Research **113**: 7-17.

Despite the pollution of microplastics being internationally recognized, the understanding of their behaviors in marine environment is still developing. Microplastics are ubiquitous in the marine environment, with the potential to cause harm to marine ecosystem. Here, we would classify the behaviors of microplastics as physical behaviors (i.e. migration, sedimentation and accumulation), chemical behaviors (i.e. degradation and adsorption) and biobehaviors (i.e. ingestion, translocation and biodegradation), and a further discussion on their behavioral mechanisms were presented to better understand their impacts for the marine environment. Copyright © 2015 Elsevier Ltd.

Wang, J., et al. (2019). "High levels of microplastic pollution in the sediments and benthic organisms of the South Yellow Sea, China." Science of the Total Environment **651**(Part 2): 1661-1669.

Microplastics, emerging contaminants in the ocean, are thought to sink and accumulate in sediments, and thus may pose a potential ecological risk to benthic communities. In this study, abundances and characteristics of microplastics in sediments and benthic organisms from the South Yellow Sea were investigated. First, we optimized the sediment sampling for microplastic analysis and found that the top layer (0-5 cm) had the highest abundance, and microplastic abundances decreased significantly with increase in sediment depth. The abundance of microplastics was 560-4205 n/kg dry weight in the surface sediments (the topmost 3 cm) of 14 sites and 1.7-47.0 n/g wet weight in the tissues of benthic organisms. Moreover, microplastic abundances in sediments and benthic organisms were both positively correlated with water depth. Fibers, transparent microplastics, and small microplastics (<0.5 mm) were the most dominant types in sediments and organisms. FTIR analysis showed that polypropylene (PP, 31%), polyester (PE, 24%), nylon (19%), and polystyrene (PS, 15%) were the most abundant polymers in sediments. The results of SEM showed rough surfaces and obvious cracks on the microplastics isolated from sediments. In addition, characteristics of microplastics in Ophiura sarsii, Crangon affinis, and Acila mirabilis were compared. Our results demonstrate that a comprehensive investigation of microplastics in sediments and benthic communities will help to fully understand the ecological risk of microplastic pollution.

Wang, J., et al. (2009). "Carboxylated magnetic microbead-assisted fluoroimmunoassay for early biomarkers of acute myocardial infarction." Colloids & Surfaces B: Biointerfaces **72**(1): 112-120.

A carboxylated superparamagnetic microbead-assisted sandwich fluoroimmunoassay was successfully demonstrated for the analysis of the early protein markers, myoglobin and human heart-type fatty acid-binding protein (H-FABP), associated with acute myocardial infarction. This assay approach consisted of the preparation of superparamagnetic polymer microbeads using a dispersion polymerization, followed by grafting of capture antibodies (monoclonal anti-H-FABP 10E1 and anti-myoglobin 7C3) onto the polymer microbeads using EDC-NHS protocol, and then a sequential sandwich fluoroimmunoassay using detection antibodies (FITC-labeled anti-H-FABP 9F3 and FITC-labeled anti-myoglobin 4E2). The Fe(3)O(4) nanoparticles and carboxylated Fe(3)O(4)-polymer microbeads were characterized by scanning electron microscopy, transmission electron microscopy, Fourier transform infrared spectrophotometry, vibrating sample magnetometry, and X-ray diffraction. The fluoroimmunoassay images were recorded using a confocal laser-scanning microscope, and the average fluorescence intensity of the microbeads was found to correspond to the concentration of each cardiac marker, in agreement with the results obtained by a spectrofluorophotometer. The carboxylated magnetic microbead-assisted protocol could be utilized to semi-quantitatively detect both myoglobin and H-FABP.

Wang, J., et al. (2018). "A critical review on the sources and instruments of marine microplastics and prospects on the relevant management in China." Waste Management & Research **36**(10): 898-911.

The world's oceans are suffering a constant and unprecedented accumulation of emerging plastic contaminants known as microplastics with a particle diameter smaller than 5mm. Microplastics exhibit a widespread distribution in various habitats from land to the oceans, and even reach the most remote regions - the deep sea and the polar, receiving attention exponentially in the past few years. Owing to their small size, marine species risk getting ingested and entangled in microplastics, causing suffocation, starvation, physical trauma or damage from chemicals, which poses vast and growing threats to biodiversity and the food web. This review article focuses on the various sources attributed to marine microplastics, the latest international, regional and national countermeasures to combat marine litter, as well as the status quo of microplastics pollution, legislation and regulations in China, and furthermore provides improving proposals/solutions on key research gaps, governance and management for future environmental control and policymaking in China.

Wang, J. C., et al. (2018). "Label-Free Monitoring of Microorganisms and Their Responses to Antibiotics Based on Self-Powered Microbead Sensors." ACS Sensors **3**(10): 2182-2190.

Rapid detection of bacteria and their susceptibility to specific antibiotics plays a vital role in microbial infection treatments. Antimicrobial susceptibility testing (AST) is a common measure to select effective drugs. However, the conventional practices, such as broth dilution, E-test, and disk diffusion, in clinical applications require a long turnaround time (~3 days), thereby compromising treatments and increasing mortality. This study presents self-powered sensors for on-site microorganism monitoring and rapid AST based on functionalized microbeads. The microbead sensors are driven by Brownian motion, rendering external power unnecessary. Fluorescent microbeads (d_p = 2 mum) were coated with vancomycin to capture bacteria. The growth and responses of Gram-negative Escherichia coli and Gram-positive Staphylococcus aureus under antibiotic treatment were evaluated. The method showed stable selective binding despite the presence of some interferential substances, such as proteins and cells. Diffusivity change was strongly related to bacterial concentration. Accordingly, the diffusivity values of microbeads bound with motile and nonmotile bacteria exhibited specific patterns because of extra motility from microbes and increased particle diameter. Only a drop of microbead-bacteria suspension (~5 muL) was needed in a microchip for each measurement. The microchip provided a steady environment for measurement over a few hours. By distinguishing the slope of the last four data points in the temporal diffusivity curve, bacterial susceptibility or resistance to specific antibiotics could be determined within a time frame of 2

h. The study provides insights into saving more lives by using a fast and robust AST technique in future clinical practice.

Wang, J. L. and L. L. Wang (2011). "Catalytic Pyrolysis of Municipal Plastic Waste to Fuel with Nickel-loaded Silica-alumina Catalysts." Energy Sources Part A: Recovery, Utilization & Environmental Effects **33**(21): 1940-1948.

Three nickel-loaded silica-alumina (Ni/Si-Al) catalysts of varying Si/Al molar ratio (Si/Al ratio) were prepared for catalytic pyrolysis of municipal waste plastic. Acid properties of the catalysts have been analyzed by Fourier transform infrared spectroscopy, and the results showed that the total acid amount increased with the decrease of Si/Al ratio. The temperature and the catalyst acidity have a significant effect on the lump (gas, gasoline fraction, heavy oil fraction, and residue) yields. In addition, the gasoline fraction products that evolved have been analyzed by gas chromatography spectrometer. It showed that the gasoline fraction has higher iso-paraffins and a smaller concentration of olefins and aromatics for a lower Si/Al ratio and higher acidity of catalyst. These results suggested that the proper selection of the Si/Al ratio makes it possible to control the composition distribution, yields, and gasoline fractions of fuel. [ABSTRACT FROM AUTHOR]

Wang, J. W. (2013). "Starch-Based Biodegradable Packaging Materials of Antimicrobial." Applied Mechanics and Materials **457-458**(Frontiers of Mechanical Engineering and Materials Engineering II): 231-235.

With the gradual increase of the global environmental awareness and environmentally friendly voice rising, the deal with the problem of plastic waste has become the focus of public opinion around the world has also become a hot topic of scientific research. This paper can be made of polystyrene as main raw material, adding starch and antibacterial agents containing silver nanoscale titanium dioxide, and by the synthesis of biodegradable packaging materials performance. The results showed that: 0.25mm sheet of polystyrene made of the thickness of the main raw material by injection molding process, and factors affecting the performance of the sheet, the better the performance of the film material process parameters. According to the definition of the GB/T1040-92 national standards of the People's Republic of China "plastic tensile properties of test methods and GB/T20197-2006 degradable plastics, classification, marking, and degradation of the performance requirements" and GB4789.3-94 "State Microbiological examination of coli form bacteria in the standard of food hygiene as determined by experimental methods for testing. The orthogonal experiment results show that the expandable polystyrene Dosage: 80%; starch dosage: 2%; toluene, acetone and put ratio: 3:2 .The mechanics of materials, degradation, and antimicrobial properties.

Wang, J. Y., et al. (2019). "Sensitive tear screening of diabetic retinopathy with dual biomarkers enabled using a rapid electrokinetic patterning platform." Lab on a Chip **18**: 18.

Bead-based immunosensors have intrigued the scientific community over the past decades due to their rapid and multiplexed capabilities in the detection of various biological targets. Nevertheless, their use in the detection of low-abundance analytes remains a continuing

challenge because of their limited number of active enrichment approaches. To this end, our research presents a delicate microbead enrichment technique using an optoelectrokinetic platform, followed by the detection of dual biomarkers for the sensitive screening of an eye disease termed diabetic retinopathy (DR). In this study, microbeads turned fluorescent as their surfaces formed sandwiched immunocomplexes in the presence of target antigens. The tiny fluorescent dots were then concentrated using the optoelectrokinetic platform for the enhancement of their signals. The signal rapidly escalated in 10 s, and the optimal limit of detection was nearly 100 pg mL-1. For practical DR screening, two biomarkers, lipocalin 1 (LCN1) and vascular endothelial growth factor (VEGF), were used. Approximately 20 muL of analytes were collected from the tear samples of the tested patients. The concentrations of both biomarkers showed escalating trends with the severity of DR. Two concentration thresholds of LCN1 and VEGF that indicate proliferative DR were determined out of 24 clinical samples based on the receiver operating characteristic curves. For verification, a single-blind test was conducted with additional clinical tear samples from five random subjects. The final outcome of this evaluation showed an accuracy of >80%. This non-invasive screening provides a potential means for the early diagnosis of DR and may increase the screening rate among the high-risk diabetic population in the future.

Wang, L., et al. (2017). "Enhancing anti-microbial properties of wood-plastic composites produced from timber and plastic wastes." Environmental Science & Pollution Research **24**(13): 12227-12237.

Considering the resource waste and environmental burden for timber and plastic materials ending up at landfills, this study proposed upcycling wood and plastic waste into value-added wood-plastic composites (WPCs), complying with the standard requirements of flexural strength, thickness swelling, water absorption and thermal insulation. Biological deterioration is a major concern of WPCs. Bacterial survival, fungal attack and algal growth of bactericide-treated WPCs were holistically analysed. Melamine resin was adopted for impregnating anti-microbial agents on the surface. All the agents showed excellent bactericidal rate (Escherichia coli), yet poly-diallyl-dimethyl-ammonium chloride (PolyDADMAC) and silver had the lowest minimum inhibitory concentrations. In terms of weight loss and strength reduction due to fungal decay (Coriolus versicolor), PolyDADMAC, silver and cetyltrimethylammonium bromide (CTAB) imparted the highest resistance on the WPCs. Moreover, PolyDADMAC and copper provided the most protection against algal growth (Chlorella vulgaris), and the former presented durable inhibitory effect. This study presents a value-added solution to wood/plastic waste recycling.

Wang, L., et al. (2019). "Photocatalytic TiO₂ Micromotors for Removal of Microplastics and Suspended Matter." Acs Applied Materials & Interfaces **11**(36): 32937-32944.

Environmental contamination is a major global challenge, and the effects of contamination are found in most habitats. In recent times, the pollution by microplastics has come to the global attention and their removal displays an extraordinary challenge with no reasonable solutions presented so far. One of the new technologies holding many promises for environmental remediation on the microscale are self-propelled micromotors. They present several properties that are of academic and technical interest, such as the ability to overcome the diffusion limitation in catalytic processes, as well as their phoretic interaction with their environment. Here, we present two novel strategies for the elimination of microplastics using photocatalytic Au@Ni@TiO₂-based micromotors. We show that individual catalytic particles as well as assembled chains show excellent collection and removal of suspended matter and microplastics from environmental water samples.

Wang, L., et al. (2008). "A MEMS Thermal Biosensor for Metabolic Monitoring Applications." Journal of Microelectromechanical Systems **17**(2).

This paper presents a microelectromechanical systems (MEMS) differential thermal biosensor integrated with microfluidics for metabolite measurements in either flow-injection or flow-through mode. The MEMS device consists of two identical freestanding polymer diaphragms, resistive heaters, and a thermopile between the diaphragms. Integrated with polymer-based microfluidic measurement chambers, the device allows sensitive measurement of small volumes of liquid samples. Enzymes specific to a metabolic analyte system are immobilized on microbeads packed in the chambers. When a sample solution containing the analyte is introduced to the device, the heat released from the enzymatic reactions of the analyte is detected by the thermopile. The device has been tested with glucose solutions at physiologically relevant concentrations. In flow-injection mode, the device demonstrates a sensitivity of approximately 2.1 muV/mM and a resolution of about 0.025 mM. In flow-through mode with a perfusion flow rate of 0.5 mL/h, the sensitivity and resolution of the device are determined to be approximately 0.24 muV/mM and 0.4 mM, respectively. These results illustrate that the device, when integrated with subcutaneous sampling methods, can potentially allow for continuous monitoring of glucose and other metabolites.

Wang, L., et al. (2018). "Interpretation of safety standard and inspection of plastic packaging products for food contact." Journal of Food Safety and Quality **9**(24): 6345-6354.

Plastic products for food contact are closely related to health and safety. After the release of the new version of food safety standards, some issues related to safety standards and the inspection process of their products have attracted people's attention. This paper compared and analyzed the main differences between old and new versions of food safety standards of plastic products for food exposure, elaborated the main technical requirements and inspection items of GB 4806.6-2016 National standard for food safety plastic resin for food exposure and GB 4806.7-2016 National standard for food safety plastic materials and products for food exposure. Taking polyethylene terephthalate (PET) without steam beverage bottles, polyethylene (PE) food bags, and melamine sauce cans as examples, the selection of transfer test conditions during the inspection process was discussed in detail, so as to provide references for the production enterprises and inspection agencies of plastic products for food contact.

Wang, L., et al. (2011). "Increased oxidative DNA damage in workers exposed to external environmental di(2-ethylhexyl) phthalate (DEHP) in a waste plastic recycle area in China." Epidemiology **1)**: S296-S297.

Background/Aims: Di(2-ethylhexyl)phthalate (DEHP) is a generalpurpose plasticizer for polyvinyl chloride and has become a ubiquitous environmental contaminant. It is suspected to be an endocrine disrupting/modulating substance in humans. China has already been the second county of plastic production and consumption in the whole world. As the universal application and high-out rates of plastics in our daily life, plastics recycling and processing industry have emerged. A large number of abandoned plastic products have been collected and transport to waste plastic recycle areas. According to statistics, the number of plastics recycling businesses in China is up to 10,000 or so, developing a number of large-scale plastics recycling markets and processing areas. The amount of recycling waste plastics of an annual is about more than 600 million tons. However, with the lack of effective market regulation, backward technology and poorly equipped of plastics recycling businesses, the aggravation environment problems and people's health in these areas have become a social issue of common concern, especially burning and depositing plastic waste. The aims of the study were to perform the monitoring of

levels ofDEHP in the water samples and 5 PAEs in the soil samples, which were collected from the exposure region and the control region; to measure the levels of oxidative stress and the extent of deoxyribonucleic acid DNA oxidative damage by the biomarkers including levels of malondialdehyde (MDA), super oxide dismutase (SOD), and glutathione peroxides in sera samples and 8-OHdG in the urine samples from the workers who engaged plastic recycle and plastic reclaim, and to analyze the risk factors relating to these biomarkers. Method(s): The exposure region was a plastic recycling centers in the Southern city where has had over 20 years in plastics recycle and the control region was 50 km far away from exposure region where it is without known sources of pollution related. The 157 workers in exposure region and 157 residents in control region were selected based on gender and age matched, and the basic information was collected by uniform questionnaire. DEHP levels of collected water samples from the sites (including the river, wells, ponds, tap water, and industrial effluent) in the exposure region and the control region were detected using the solidphase extraction and gas chromatography method. The column chromatography and gas chromatography techniques were applied to determine the concentrations of DEHP and other PAEs in soil samples. The chemical colorimetric was used to determine serum MDA, glutathione peroxides, and SOD in exposure and control population, which is served as an oxidative stress index of DNA damage. The electrochemical-high performance liquid chromatography was applied to test the level of urinary 8-OHdG, which is served as an index of the extent of DNA oxidative damage. The demography data and related medical index in exposure and control were analyzed by using significance test. Logistic regression was performed to analyze the DNA damage. Result(s): The average DEHP level in the river water samples from the polluted section (mean: 2.05 mug/L) was 6.4 fold compared with that from the control section (0.32 mug/L). Average DEHP level in the pond (135.68 mug/L) and the well (14.20 mug/L) water samples from the exposure region were 18 fold and 215 fold compared with those (0.79 mug/L and 0.37 mug/L) in the control region, respectively. The DEHP level in industrial effluent sample ranged from 0.36 mug/L to 161.86 mug/L. The dibutyl phthalate (DBP) (0.94 -24.09 mg/kg) and DEHP (0.85-37.23 mg/kg) were indentified in all soil samples from exposure and control regions. In 5 PAEs determined, the DEHP and DBP concentration is the highest one, following by diethyl phthalate, di-n-octyl phthalate (DnOP), and dimethyl phthalate. The average of 5 PAEs in soil of exposure region was 1-19 times of that in control region. The contents of DBP (mean: 9.46 mg/kg) and DEHP (mean: 13.07 mg/kg) in exposure region soil were the 19 and 16 times of that in control region. The detection rate of DBP (range, 0.94 -24.09 mg/kg) and DEHP (range, 0.85-37.23 mg/kg) in the exposed soil are 100%. The medians of serum SOD in exposed population and control population were 111.80 U/mL (range, 31.71-167.69 U/mL) and 124.16 U/mL (range, 78.88 -181.46 U/mL) respectively, with a significant difference between the 2 groups (P < 0.01). Conclusion(s): The study results showed that DEHP exposure concentrations in water and soil samples in plastic recycling centers where occupational workers lived were higher than that where the control residents live. The demological study results showed that the occupational exposure was the main factor, which affects the levels of serum SOD, MDA, GAH-Px, and urine 8-OHdG. Although Urine 8-OHdG levels may be affected by other pollutants from plastic recycling center, the exposure population has shown the oxidative DNA damage.

Wang, M., et al. (2013). "Minimizing the severity of rhBMP-2-induced inflammation and heterotopic ossification with a polyelectrolyte carrier incorporating heparin on microbead templates." Spine **38**(17): 1452-1458.

STUDY DESIGN: A rodent model of posterior spinal fusion.
OBJECTIVE: The aim of this study was to evaluate the efficacy of low-dose recombinant human bone

morphogenetic protein-2 (rhBMP-2) delivered with a heparin based polylectrolyte complex (PEC) carrier in facilitating posterior spinal fusion while concurrently minimizing seroma and heterotopic ossification.

SUMMARY OF BACKGROUND DATA: rhBMP-2 is being used to augment spinal fusion. However, complications such as heterotopic ossification and local soft tissue swellings have been reported. These are attributed to supraphysiological amount of rhBMP-2 and the poor modulation capacity of absorbable collagen sponge.

METHODS: Forty rats were randomized into 6 groups as follows. Group I: absorbable collagen sponge without rhBMP-2 (n = 4); group II: positive control, absorbable collagen sponge + 10 mug rhBMP-2 (n = 4); group III: alginate-(poly-L-lysine)-heparin (PEC) without rhBMP-2 (n = 8); group IV: PEC + 4.5 mug rhBMP-2 (n = 8); group V: PEC + 1.5 mug rhBMP-2 (n = 8); group VI: PEC + 0.5 mug rhBMP-2 (n = 8).

RESULTS: Between postoperative days 5 and 7, seroma was observed in all rhBMP-2 implanted groups irrespective of carrier and dose. However, the rate and size of seroma differed considerably. Although all animals (100%) in positive control group showed seroma, only one animal (12.5%) in group VI developed seroma at the implant site. The size of seroma in group VI was significantly smaller than that in positive control group. Micro-computed tomography evaluation revealed comparable mean fusion scores in all rhBMP-2 implanted groups. More importantly, although new bone was well contained within the cage in group VI, heterotopic ossification beyond the cage was observed in positive control group.

CONCLUSION: A new carrier has demonstrated capacity to minimize seroma formation as well as heterotopic ossification associated with rhBMP-2 by reducing the efficacious dose needed for consistent fusion. The results of this study indicate that PEC alginate microbeads may represent a new opportunity to define an efficient rhBMP-2 carrier.

Wang, M., et al. (2015). "Pipette-tip solid-phase extraction by use of a sol-gel hybrid adsorbent: a new pretreatment strategy for rapid screening of cucumbers for cyanazine and atrazine." Analytical and bioanalytical chemistry **407**(4): 1231-1239.

Issue Title: A different way of looking at vibrational hyperspectral data/Micellar extraction for the analysis of Alzheimer's disease brain proteome/Quantification of polyolefin microplastics in personal-care products/Removal of Triton X-100 by microdialysis A pipette-tip solid-phase extraction (PT-SPE) method using a sol-gel hybrid adsorbent has been developed. The method could be used for rapid screening of vegetable matrices for cyanazine and atrazine; assay of cucumbers is reported as an example. The sol-gel hybrid adsorbent was synthesized from tetraethyl orthosilicate (TEOS) as the precursor and γ-(methacryloyloxy)propyltrimethoxysilane (KH570) as both surface modifying agent and monomer for the polymerization. Under the optimized conditions, good calibration linearity was obtained in the range 0.022-1.65 [mu]g g^sup -1^ with correlation coefficients (r) [greater than or equal to]0.9996. Recovery at three spike levels ranged from 87.6 to 93.8 % with relative standard deviations [less than or equal to]7.8 %. This extraction strategy has several advantages, for example ease of assembly, low cost, and high extraction efficiency, and is a potential pretreatment strategy for rapid screening of cyanazine and atrazine in vegetables. [Figure not available: see fulltext.]

Wang, M. H., et al. (2019). "Research and management of plastic pollution in coastal environments of China." Environmental Pollution **248**: 898-905.

Marine plastic waste has become an ever-increasing environmental threat in the world's ocean largely due to their unique properties and ubiquitous occurrence. They include diverse forms of land- and ocean-based sources of plastics and are estimated to account for up to 85% of marine debris worldwide. As secondary pollutants, marine microplastic particles (<5mm) are derived from pellet loss and degradation of macroplastics. Up to now, several reports have proposed negative impacts of both macro-sized and micro-sized plastics on marine biota. As one of the rapidly growing economies, China is the topmost contributor of plastic waste in the world. China's massive impact on the plastic levels of the ocean are a definite cause of concern and is developing multiple economic, environmental and biological complications. The research of plastics impact on coastal environments in China is only incipient. Here we review the available information on plastic waste, their impacts on marine biota and human health, and Chinese government policies and management initiatives. Although Chinese coastal environments (surface water, coastal sediments, water column) are affected by microplastics pollution, both from land-based and sea-based activities, their impacts on marine biota remain to be elucidated. Though national-level policies are modern and well suited for minimizing the impacts of plastic pollution, there is hardly any legislation for containment of microplastic pollution. Our objective is to review and summarize the information about the occurrence, impacts, and management of plastic pollution in the Chinese coastal environments in order to comprehend their widespread repercussions. MAIN FINDING: Microplastics are increasingly being detected and quantified in Chinese coastal environments and legislation for containment of such pollution is highly recommended.

Wang, M.-X., et al. (2012). "A portable instrument for rapid field test of E. coli based on bioluminescent magnetic immunoassay." Nami Jishu yu Jingmi Gongcheng/Nanotechnology and Precision Engineering **10**(6): 514-519.

A portable instrument was designed for rapid field specific test of Escherichia coli (E. coli) based on bioluminescent magnetic immunoassay, which consisted of photon counting unit, central processing unit, temperature control unit and power supply unit. The temperature control unit supplied a constant temperature of 37C, which is suitable for incubation and convenient for field test. An improved simplified coupling method was presented, in which immunomagnetic microbeads coupled with biotinylated rabbit-anti-E. coli antibody could capture E. coli directly by one step. The detecting result of E. coli showed a good linear relationship in lg-lg domain between the intensity of luminescence and the concentration of E. coli obtained through plate counting in the range from 23.00 CFU/mL to 2.25 107 CFU/mL, with a correlation coefficient of 0.9657. The sensitivity of the detecting system was 0.4787. In the reproducibility test, the coefficient of variation was 4.48%. The instrument integrated with constant temperature control is portable, easy to operate and low in cost, which will provide potential applications in food hygiene and safety, environmental monitoring and disease diagnosis.

Wang, Q., et al. (2011). "Increased urinary 8-hydroxy-2'-deoxyguanosine levels in workers exposed to di-(2-ethylhexyl) phthalate in a waste plastic recycling site in China." Environmental Science & Pollution Research **18**(6): 987-996.

BACKGROUND: Di-(2-ethylhexyl) phthalate (DEHP) is a common plasticizer used in industrial and diverse consumer products. Animal studies indicate DEHP caused developmental, reproductive, and hepatic toxicities. However, human studies of the potential effects of DEHP are limited.

METHODS: The exposed site with a history of over 20 years of waste plastic recycling was located in Hunan Province, China. The reference site without known DEHP pollution source was about 50 km far away from the exposed site. In this study, 181 workers working in plastic waste recycling and 160 gender-age matched farmers were recruited. DEHP concentrations in water and cultivated soil samples, serum thyroid-stimulating hormone, malondialdehyde (MDA), superoxide dismutase (SOD), urinary 8-hydroxy-2'-deoxyguanosine (8-OHdG), and micronuclei

frequency in human capillary blood lymphocytes were analyzed.
RESULTS: Mean levels of DEHP were greater in environment at the recycling site than at reference site (industry wastewater for the exposed: 42.43 mug/l; well water: 14.20 vs. 0.79 mug/l, pond water: 135.68 vs. 0.37 mug/l, cultivated soil: 13.07 vs. 0.81 mg/kg, $p < 0.05$ for all). The workers had higher median levels of MDA (3.80 vs. 3.14 nmol/ml) and urinary 8-OHdG (340.37 vs. 268.18 mumol/mol creatinine) and decreased SOD activities (112.15 vs. 123.82 U/ml) than the reference group ($p < 0.01$ for all). Multivariate analysis revealed that the history of working in waste plastic recycling was an independent risk factor for the increased urinary 8-OHdG levels in the male workers ($p < 0.01$).
CONCLUSIONS: The occupational DEHP exposure might contribute to oxidative deoxyribonucleic acid damage in the male workers.

Wang, Q., et al. (2017). "Plastic Classification with X-ray Absorption Spectroscopy Based on Back Propagation Neural Network." Applied Spectroscopy **71**(11): 2538-2548.

Currently, spectral analysis methods used in the classification of plastics have limitations that do not apply to opaque plastics or the stability of experimental results is not strong. In this paper, X-ray absorption spectroscopy (XAS) has been applied to classify plastics due to its strong penetrability and stability. Fifteen kinds of plastics are selected as specimens. X-ray, which is excited by a voltage of 60 kV, penetrated these specimens. The spectral data acquired by CdTe X-ray detector are processed by principal component analysis (PCA) and other data analysis methods. Then the back propagation neural networks (BPNN) algorithm is used to classify the processed data. The average recognition rate reached 96.95% and classification results of all types of plastic results were analyzed in detail. It indicates that XAS has the potential to classify plastics and that XAS can be used in some fields such as plastic waste sorting and recycling. At the same time, the technology of XAS, in the future, can also be used to classify more substances.

Wang, S., et al. (2020). "Selectively enrichment of antibiotics and ARGs by microplastics in river, estuary and marine waters." Science of the Total Environment **708**: 134594.

The partition of antibiotics and antibiotic resistant genes (ARGs) between the microplastics (MPs) and the surrounding water with various salinity are still unclear. In this study, we hypothesized that adsorption of antibiotics on MPs might cause a significant change of the structure of microbial communities, diversity and abundance of ARGs on MPs and this might be further affected by change of salinity. In this study, we investigated adsorption of four common antibiotics (sulfamerazine, tetracycline, chloramphenicol and tylosin) to polyethylene (PE) MPs in river, estuary and marine waters, and the differences of antibiotic resistant genes (ARGs) and bacterial communities on MPs and in the three waters. The results showed that MPs can enrich antibiotics, ARGs and microbes from the surrounding water. Elevated salinity could reduce adsorption of antibiotics to MPs and the abundance of ARGs. For example, MPs can concentrate more antibiotics and ARGs in the fresh river water than in the estuary and the marine waters. In addition, ARGs and bacterial communities on MPs at various salinity were significantly different under the pressure of four antibiotics. On MPs, sul1, sulA/folP-01, tetA, tetC, tetX and ermE increased significantly but a few new ARGs such as sulA/folP-01 and tetA appeared. The structure of the bacterial communities on MPs was different from the surrounding water since some bacteria species found on MPs were barely detected in the surrounding water while some genera on MPs vanished after exposure to antibiotics. As the antibiotics adsorbed and the ARGs on MPs decreased with the water salinity, the structure of the communities on MPs thus varied with salinity change. These findings are important to understand the effects of MPs on the

transport, fate and ecological risk of antibiotics and ARGs in different aquatic environments.

Wang, S.-c., et al. (2019). "Toxicity research progress of microplastics on microalgae." Haiyang Huanjing Kexue = Marine Environmental Science(2): 192.

Microplastics(MPs) pollution has become a global environmental problem. A few papers reported that MPs could have toxic effect on microalgae. Moreover,due to their strong binding ability,MPs may induce joint toxicity with other contaminants. As microalgae are the most primary producers in water system,the toxic effect is likely to influence the stability of food chains in water and further bring potential risks to human beings. The present paper reviewed the current research achievements and possible toxicity mechanisms,including physical damage,shielding effect,oxidative stress,adsorption and hetero-aggregation. In addition,future research directions were also proposed and discussed.

Wang, S. Y., et al. (2018). "Research on principle of benzoxazole derivative PO-291 inhibiting T cell proliferation. [Chinese]." Chinese Pharmacological Bulletin **34**(7): 925-933.

Objective To investigate the immunosuppressive activity of benzoxazole derivative PO-291 in inhibiting human activated T cell proliferation and function. Methods Human T cells were isolated and purified by the immunomagnetic microbeads and activated by anti-CD3/anti-CD28 mAbs or alloantigen. Cell proliferation, the expression of CD25 and CD69, cell cycle and apoptosis were measured by flow cytometry. Secretion levels, including IL-2, IL-4, IL-6, IL-10, IL-17 and IFN-7 were determined by ELISA. The expression and phosphorylation of STAT5 and p70S6K of activated T cells were detected by Western blot. Results PO-291 significantly inhibited human T cell proliferation with anti-CD3/anti-CD28 mAbs or alloantigen stimulation without obvious cytotoxicity. PO-291 did not affect CD25, CD69 and IL-2 expression, but induced T cell cycle arrest in G0/G, phase. PO-291 significantly inhibited IL-17, IFN-7 and IL-6 expression, but not IL-2, ILA and IL-10. PO-291 did not affect STAT5 and p70S6K expression, but inhibited STAT5 phosphorylation and enhanced p70S6K phosphorylation. Conclusions PO-291 inhibits human activated T cell proliferation by affecting the JAK3/STAT5 pathway. PO-291 represents a potential lead compound for the design and development of new immunosuppressive drugs for the treatment of organ transplantation and autoimmune diseases. Wang, T., et al. (2018). "The research progress in migration, distribution, biological effects and analytical methods of microplastics." Kexue Tongbao/Chinese Science Bulletin **63**(4): 385-395.

Microplastics (MPs) are synthetic organic polymers. The particle sizes of MPs range from approximately 0.01 to 5 nm. The photodegradation of MPs is more difficult than that of bulk plastics. Therefore, MPs are regarded as potential persistent organic pollutants. Researches of MPs have become a hot spot, and lots of MPs studies were reported recently. Although there are a lot of studies on the migration, distribution, biological effects and analytical methods of MPs in natural environments, systematic and comprehensive review articles are emergent, especially for the recent literatures. The present work summarized the researches involving the migration, distribution, biological effects and analytical methods of MPs in recent years. MPs are generally divided into two types, primary MPs and secondary MPs. Primary MPs are intentionally designed and produced for certain purposes, while secondary MPs generate from the fragmentations of bulk plastics and the breakage of clothes fibers. Currently, researches of MPs distribution focus on in marine environments, and found that MPs distributed throughout the ocean, even in the north and south poles, driven by the flow of sea water. However, researches of on MPs distribution in fresh water and terrene are limited. Researches also showed that MPs could migrate among terrestrial, freshwater and marine environments, where freshwater environments affected the migration and interaction of MPs between terrene and marine environments. Studies of biological effects of MPs focus on two parts, ingestion effects and combined effects with organic contaminants. Ingestion of MPs damages living beings and then MPs transfer through food chains. The responses of living beings to MPs are mainly related to sublethal effects at environmental-relevant concentrations. The inhibition of individual growth and reproduction, disturbance of proteins and genes, and reduction of nutrition uptake were reported for specific physiological effects of MPs. Some researches proposed that MPs could be accumulated in living organisms. Therefore, humans, as a part of the food chains, will inevitably be affected by MPs. The organic contaminants combine with the MPs released from the plasticizers in the production of MPs and then are adsorbed in the natural environments. MPs have been found in seafood. As a result, MPs become one medium of human exposure to organic pollutants. The analysis and identification of MPs are critical to other researches, such as environmental behaviors and toxicity. In general, the analytical methods of plastic include physical and chemical characterizations. Physical characterizations involve visual, microscopy and spectroscopy methods. Chemical characterization methods, such as differential scanning calorimetry (DSC), gas chromatography mass spectrometry (GC-MS), scanning electron microscope and energy disperse spectroscopy (SEM-EDS), and thermal desorption gas chromatography mass spectrometry (TDS-GC-MS) are frequently used in chemical characterizations. Although lots of analytical methods were proposed by researchers, there are still some shortcomings and limitations, for example, the influence from environmental or biological matrices. It is necessary to develop effective and accurate methods for the analysis of MPs. Through many researches of MPs were reported recently, the information of source, migration, distribution, biological effects and analytical methods of MPs is not enough to scientifically evaluate their environmental and health risks. Consequently, the present review also proposes some perspectives for MPs researches. It is worth to study the distribution of MPs in terrestrial and freshwater environments, the biological effects at individual level, the prevention and control of MPs pollution and the environmental behavior of nanoplastics. Integrating the data of MPs source, distribution, behavior and toxicity is necessary to the scientific evaluations of MPs risks. This review provides insights in the control techniques and theoretical researches of MPs. 2018, Science Pr ss. All right reserved.

Wang, T., et al. (2019). "Emission of primary microplastics in mainland China: Invisible but not negligible." Water Research **162**: 214-224.

Primary microplastics are mostly produced as part of the daily plastic product use. The emission process is often invisible but poses potential ecological hazards. Thus, primary microplastics deserve public attention. Due to China's huge population base and its rapid economic development, primary microplastics emissions are of both regional and global significance. This study is the first to establish the emission inventory of primary microplastics in mainland China. It was estimated that the primary microplastic waste from mainland China amounts to 737.29 Gg, and one-sixth of this amount entered the aquatic environment in 2015. The highest proportion of this waste was attributable to tire dust and synthetic fiber, accounting for 53.91% and 28.77% of the total respectively, in mainland China. The primary microplastics emissions mainly depend on the population, followed by the level of economic development. It was roughly estimated that 538 g of microplastics is produced by each person in China. At the grid scale, the spatial difference in the total primary microplastics emissions in mainland China primarily depends on the population density distribution and transportation network. We studied the entire life cycle of several sources of microplastics, from production to discharge into the aquatic environment. We suggested different control measures under different nodes. Increasing microplastics treatment in sewage treatment plants should be a short-term viable way to achieve some measure of reduction in their entry to the environment in mainland China. Our research can not only raise public awareness about primary microplastics, but can also guide the development of environmental policies to reduce plastic pollution. Copyright © 2019 Elsevier Ltd

Wang, T., et al. (2019). "Adsorption behavior and mechanism of five pesticides on microplastics from agricultural polyethylene films." Chemosphere **244**: 125491.

Polyethylene (PE) agricultural soil films are easily embrittled and decomposed to microplastics (MPs) in environment. As widely used pesticides in vegetable farmland, carbendazim, dipterex, diflubenzuron, malathion, difenoconazole have potential environmental and human safety risks. They are often coexisting with MPs in the environment, and may cause consequential pollution to the ecosystem. Studying the adsorption behavior between pesticides and PE agricultural soil films MPs would be helpful for the risk assessment of co-exposure of pesticides and MPs. Herein, a systematic study on batch adsorption experiments was performed to determine the adsorption process of pesticides on MPs, the environmental factors on adsorption capacity were evaluated, and the adsorption mechanisms were discussed.

Wang, W., et al. (2010). "Target ultrasonography detection of IBMIR induced by pig islets." Transplantation **1)**: 1008.

Introduction: Islet transplantation will induce immediately blood-mediated inflammatory reaction (IBMIR) when grafts are exposed to recipient's blood. IBMIR is a critical reason resulting to portal vein thrombosis and graft failure. Thrombus can be a mark of extent and degree of IBMIR.The aim of this study is to develop a KGDS-target ultrasound contrast agent(MBK) to bind to GPIIb/IIIa on activated platelets specifically and assess its specificity of binding effect on thrombus in IBMIR models in vitro and in vivo. Material(s) and Method(s): Neonatal Porcine islet(NPI) was mixed with human blood in tubing loops as IBMIR model in vitro. Affinity of MBK to GPIIb/IIIa receptors in activated platelets was assessed with immunocytochemical and immunofluorescence technique. Contrast-enhanced US imaging was performed with MBK and non-target microbubbles(MBN) respectively. Twenty SD rats were divided into 4 groups. Contrast-enhanced US imaging with MBK or MBN was performed in 4 groups of rats respectively (Group A: transplantation of NPI via portal vein + MBK , Group B: NPI +MBN ; Group C: implantation of alginate microbeads via portal vein +MBK, Group D: alginate microbead +MBN). The size of alginate microbeads was similar as NPI. Result(s): NPIs trigged the activation of coagulation system and platelets in tubing loops IBMIR model after islet mixed with human blood. The MBK was shown high affinity to the GPIIb/IIIa in platelets activated by NPI in IMBIR model in vitrol. Adherence of MBk on thrombus was significantly higher than that of MBN($P<0.001$). Contrast-enhanced US imaging showed high-echo ring surrounding the thrombus with MBk. Otherwise, MBN was just shown thrombus as anechoic filling defect in tubing loops IMBIR model, no enhancement of thrombus was shown in US image with MBN. Further more, the liver of rats in Group A was shown contrast-enhanced US image with MBK, average video intensity was significantly higher than Group B ($P<0.001$). Both MBK and MBN not showed ultrasonic contrast enhancement in alginate microbeads groups (Group C and D). Results of immunohistochemical assay confirmed GPIIb/IIIa expression of thrombus surrounding NPI, and fluorescence assay also shown MBK attached to thrombus surrounding NPI. Conclusion(s): US with GPIIb/IIIa targeted contrast agent shown a potential ability of real-time and dynamic detection for IBMIR in pig islet xenotransplantation.

Wang, W., et al. (2019). "The ecotoxicological effects of microplastics on aquatic food web, from primary producer to human: A review." Ecotoxicology & Environmental Safety **173**: 110-117.

The prevalence of microplastics in global waters raises the concern about their potential effects on aquatic biota. In aquatic environment, microplastics are almost ubiquitously present in all compartments from surface water to benthic sediment, making them accessible to a wide range of aquatic biota occupying different habitats. Exposure to microplastics may induce detrimental implications to the health of aquatic organisms. This review describes the wide occurrence of microplastics ingestion by aquatic fauna and evaluates the ecotoxicological effects of microplastics as well as the associated chemicals on aquatic biota including phytoplankton and fauna from both freshwater and marine environments. Trophic transfer of microplastics and associated contaminants along the aquatic food chain and potential impacts on human health are also discussed. Finally, this review emphasizes the current knowledge gaps and gives recommendations for the future work.

Wang, W., et al. (2020). "Bioavailability and toxicity of microplastics to fish species: A review." Ecotoxicology & Environmental Safety **189**: 109913.

The prevalence of microplastics in aquatic environments has raised concerns about their availability and risks to aquatic biota. Since fish is an important source of animal protein for human beings, the occurrence and potential impacts of microplastics in fishes deserve special attention. Although there have been an increasing number of studies concerning microplastics ingestion and effects in fish, review papers specifically focusing on this issue are few. This review summarized the current knowledge about the bioavailability and toxicity of microplastics to fish species. By collating literatures, it can be concluded that microplastics contamination could occur in almost all types of aquatic habitats around the globe. Both field and laboratory studies suggest that fishes are very susceptible to microplastics ingestion. Compared with marine species, freshwater fishes have been less studied. Microplastics alone or in combination with other contaminants could cause various health problems to fish after exposure. There still exist some debates over the environmental relevance of the laboratory-based effect studies and the relative contribution of microplastics in increasing the exposure of fish to hazardous chemicals. Hopefully, this review could extend the current knowledge on the ecotoxicological impacts of microplastics contamination to fish and provide guidance for future research.

Wang, W., et al. (2020). "Environmental fate and impacts of microplastics in soil ecosystems: Progress and perspective." Science of the Total Environment **708**: 134841.

The wide and intensive application of plastics and their derived products has resulted in global environmental contamination of plastic waste. Large-sized plastic litter can be fragmented into microplastics (<5 mm), which have attracted increasing concerns from the general public and scientific communities worldwide. Until recently, the majority of microplastics research reported in literatures has been focusing on the aquatic settings, especially the marine environment, while information about microplastics contamination in terrestrial soil systems is highly insufficient. In this paper, we reviewed the latest data regarding the occurrence of microplastics in terrestrial soils and discussed their potential pathways into the soil environment. We also summarized the currently used methodologies for extraction and characterization of microplastics in soil matrices and evaluated their advantages and limitations. Additionally, we assessed the ecotoxicological consequences of microplastics contamination on soil ecosystems, including the effects on soil physiochemical properties, terrestrial plants, soil fauna, and soil microbes. Finally, based on the most current progress summarized in this review, we suggested several directions for future research on microplastics in soil ecosystems.

Wang, W., et al. (2017). "Microplastics pollution in inland freshwaters of China: A case study in urban surface waters of Wuhan, China." Science of the Total Environment **575**: 1369-1374.

Microplastics have been considered as an emerging pollutant in the aquatic environment. However, research about microplastic pollution in inland freshwaters of China is insufficient. The present study investigated the levels of microplastics in surface water of 20 urban lakes and urban reaches of the Hanjiang River and Yangtze River of Wuhan, the largest city in central China. Microplastic concentrations ranged from 1660.0+/-639.1 to 8925+/-1591n/m³ for the studied waters, with the highest concentration found in Bei Lake. Microplastic abundance in lakes varied markedly in space, and negatively correlated with the distance from the city center (p<0.001), which confirmed the important role of anthropogenic factors in microplastic distribution. Urban reaches of the Hanjiang River and Yangtze River were found to have relatively lower levels of microplastics than most of the studied lakes. The major type of microplastics among the studied waters was colored plastic, with fiber being the most frequent shape. More than 80% of microplastics in number had a size of <2mm. Polyethylene terephthalate and polypropylene were the dominant polymer-types of microplastics analyzed. This study provided important reference for better understanding microplastic levels in inland freshwaters.

Wang, W. and J. Wang (2018). "Different partition of polycyclic aromatic hydrocarbon on environmental particulates in freshwater: Microplastics in comparison to natural sediment." Ecotoxicology & Environmental Safety **147**: 648-655.

Microplastics pollution in the aquatic ecosystems has aroused increasing concerns in recent years. Though microplastics are known to sorb organic contaminants from water, the interaction mechanisms between microplastics and organic chemicals are not yet well understood. Here we investigated the partition characteristics of phenanthrene (Phe) in three mass-produced plastic particles, including polyethylene (PE), polystyrene (PS) and polyvinylchloride (PVC), and one natural sediment, as a comparison. The sorption kinetics of Phe onto microplastics and natural sediment were successfully described by the pseudo-second-order model (R² > 0.992), while the equilibrium data were best-fitted to the Langmuir isotherm (R² > 0.995). Compared with natural sediment, microplastics exhibited higher capacities for Phe which followed an order of PE > PS > PVC. As the aqueous concentration of pyrene (Pyr) increased, both uptakes and distribution coefficients (K_d) of Phe within the solids decreased, with natural sediment giving the largest decline. Although proportions of Phe desorbed from the contaminated microplastics were low, due to the high Phe uptake, microplastics released larger amounts of the sorbed Phe to water than the natural sediment during the desorption process. Given their minimal abundance relative to natural sediment, microplastics may play a less important role in the transport of organic pollutants in a natural aquatic environment.

Wang, W., et al. (2013). "Co-extrusion encapsulation of canola oil with alginate: effect of quercetin addition to oil core and pectin addition to alginate shell on oil stability." Food Research International **54**(1): 837-851.

This study investigates the feasibility of encapsulating antioxidant-fortified canola oil via co-extrusion using 0.67% alginate (0.67%A), 1% alginate (1%A) or high methoxyl (HM) pectin-enhanced alginate (A-P) as the encapsulant. Results show that encapsulation conditions especially the core-shell flow rates and shell wall formulation, influenced oil bead characteristics, core oil stability and retained phenolic content. Optical and scanning electron

microscopy revealed that the 3 types of co-extruded oil beads were spherically shaped with the A-P beads having the largest bead size. All beads were physically and chemically robust, and remained intact after being treated in acidified water at pH 3 for 2 h. Storage trials at 20 and 38 degrees C for 30 or 60 days revealed the interplay between shell formulations and storage conditions on oil primary and secondary oxidation, hydrolytic rancidity and total phenolic content of the encapsulated canola oils. Quercetin added to the oil core was more effective than vitamin E or BHT in suppressing oil oxidation at 38 degrees C. High performance liquid chromatography analyses indicated different decomposition pathways for quercetin in these beads during storage. FT-IR studies confirmed the chemical composition and chemical stability of the 3 types of quercetin-containing oil beads. 1%A and A-P shells are both acceptable and comparable for preserving quercetin-containing canola oil, with A-P and 1%A being slightly better for 30 and 60 day storage periods, respectively. Thus, it is feasible and beneficial to deliver unsaturated oil and phenolic antioxidants in the form of pectin fibre-enhanced alginate microbeads.

Wang, W., et al. (2018). "Microplastics in surface waters of Dongting Lake and Hong Lake, China." Science of the Total Environment **633**: 539-545.

Microplastics pollution is an environmental issue of increasing concern. Much work has been done on the microplastics pollution in the marine environments. Although freshwaters are potential sources and transport pathways of plastic debris to the oceans, there is a lack of knowledge regarding the presence of microplastics in freshwater systems, especially in China, the world's largest producer of plastics. This study investigated the occurrence and properties of microplastics in surface waters of two important lakes in the middle reaches of the Yangtze River. The concentration ranges of microplastics in Dongting Lake and Hong Lake were 900-2800 and 1250-4650n/m³, respectively. Fiber was the dominant shape. Colored items occupied the majority. Particles with a size of <330mum comprised >20% of total microplastics collected in both lakes. Most of the selected particles were identified as plastics, with polyethylene (PE) and polypropylene (PP) being the major components. This study can provide valuable reference for better understanding the microplastics pollution in inland freshwater ecosystems.

Wang, W.-l., et al. (2019). "Microplastics characteristic in Yundang Wastewater Treatment Plant of Xiamen." Haiyang Huanjing Kexue = Marine Environmental Science(2): 205.

Wastewater treatment plants in coastal cities is a main source for microplastics in the ocean. Characteristic of microplastics can improve our understandings of the impacts of human activities on the marine environment. However,there is a lack of such information in China. In this study,microplastic pollution in Xiamen Yundang Wastewater Treatment Plant was studied. We designed an improved sampling device and an experimental method to study the characteristics of microplastics in the influent,effluent and sludge. The results show that the microplastic abundance in the influent,primary and secondary treatment discharge is 1. 703,1. 090 and 0. 324 pieces/L,respectively. The microplastic removal rates in the primary and secondary treatment discharge are 35. 99% and 80. 97% respectively. The concentrations of microplastics in primary and secondary sludge are 2. 14 × 103 and 6. 62 × 103 pieces/kg,respectively. The shape of microplastics are dominated by 43. 89% of fiber and 32. 85% of pellet in the wastewater and 68. 9% of fragment and 34. 78% of pellet in the sludge. The primary colors are white(34. 95%),followed by transparent(22. 74%) in the wastewater. While it is dominated by yellow(39. 13%),black(17. 39%),and white(13. 04%)in the sludge. The chemical composition is primarily composed of 21. 17% of PP and 18. 39% PS in the wastewater

and 34. 78% of PP and 26. 09% of PE in the sludge. It is estimated that ～ 9. 72 × 104 pieces of microplastics are discharged into the Xiamen West Sea each day. Our findings show that waste water treatment plants play an important role in reducing urban microplastic pollutants entering the ocean,but it requires higher microplastic removal efficiency.

Wang, X., et al. (2011). "Increased MAPK and NF-kappaB expression of Langerhans cells is dependent on TLR2 and TLR4, and increased IRF-3 expression is partially dependent on TLR4 following UV exposure." Molecular Medicine Reports **4**(3): 541-546.

Toll-like receptors (TLRs) and epidermal Langerhans cells (LCs) play a crucial role in innate and adaptive immunity. To date, the pattern of TLR expression has not been fully analyzed. The effects of ultraviolet (UV) light on TLR expression and the downstream signaling cascades of human LC have not been examined. In this study, we purified human epidermal LCs using a density gradient centrifugation method and an immunomagnetic microbead method. We found that cultured purified LCs from human skin express mRNAs encoding TLR2, TLR4, TLR5 and TLR7-9. The expression of TLR2 and TLR4 protein was confirmed by Western blot analysis. The results showed for the first time that UV exposure up-regulated the mRNA and protein expression of TLR2 and TLR4 in human LCs. We also found that UV exposure-induced up-regulated MAPK and NF-kappaB/p65 expression was dependent on TLR2 and TLR4, and up-regulated IRF-3 expression was partially dependent on TLR4. In conclusion, UV light up-regulates the expression of TLR2, TLR4 and downstream signaling molecules MAPK, NF-kappaB/p65 and IRF-3 in human LCs. This suggests that UV light has a significant effect on skin immune responses.

Wang, X., et al. (2019). "Sensitive and multiplexed detection of antibiotics using a suspension array platform based on silica-agarose hybrid microbeads." Journal of Hazardous Materials **373**: 115-121.

A multiplex suspension array detection platform of antibiotics has been developed based on silica-agarose hybrid microbeads (SAHMs). Chloramphenicol (CAP), sulfamethoxazole (SMX), metronidazole (MTZ) and amoxicillin (AMX) were employed as model analytes. The antigens (the antibiotics conjugated with BSA) were immobilized on the surface of four different types of SAHMs. Based on an indirect competition immunoassay, the selected antibiotics are detected through the competition of the specific monoclonal antibodies between the multiple antibiotics and the antigens. Due to high resistance to nonspecific protein absorption of SAHMs, the proposed method exhibited wide linear ranges (0.4~72.9 ng/mL for CAP, 2.0~108.5 ng/mL for SMX, 2.6~142.2 ng/mL for MTZ, 1.0~63.3 ng/mL for AMX) and low detection limits of 0.09~0.8 ng/mL. Recoveries for spiked tap water samples were from 82% to 113%, with relative standard deviation lower than 14%, demonstrating the accuracy of the measurements performed with the developed method. This work offered a high-throughput, flexible and accurate tool, which provides a good platform for simultaneous detection of antibiotics.

Wang, X., et al. (2019). "Microplastics impair digestive performance but show little effects on antioxidant activity in mussels under low pH conditions." Environmental Pollution: 113691.

In the marine environment, microplastic contamination and acidification may occur simultaneously, this study evaluated the effects of ocean acidification and microplastics on oxidative stress responses and digestive enzymes in mussels. The thick shell mussels Mytilus coruscus were exposed to four concentrations of polystyrene microspheres (diameter 2 mum, 0, 10, 10⁴ and 10⁶ particles/L) under two pH levels (7.7 and 8.1) for 14 days followed by a 7-day recovery acclimation. Throughout the experiment, we found that microplastics and ocean acidification exerted little oxidative stress to the digestive gland. Only catalase (CAT) and glutathione (GSH) showed a significant increase along with increased microplastics during the experiment, but recovered to the control levels once these stressors were removed. No significant effects of pH and microplastics on glutathione peroxidase (GPx) and superoxide dismutase (SOD) were observed. The responses of digestive enzymes to both stressors were more pronounced than antioxidant enzymes. During the experiment, pepsin (PES), trypsin (TRS), alpha-amylase (AMS) and lipase (LPS) were significantly inhibited under microplastics exposure and this inhibition was aggravated by acidification conditions. Only PES and AMS tended to recover during the recovery period. Lysozyme (LZM) increased significantly under microplastic exposure conditions, but acidification did not exacerbate this effect. Therefore, combined stress of microplastics and ocean acidification slightly impacts oxidative responses but significantly inhibits digestive enzymes in mussels.

Wang, X., et al. (2012). "Diagnostic performance of multiplex cytokine and chemokine assay for tuberculosis." Tuberculosis **92**(6): 513-520.

Simultaneous detection of multiple biomarkers might lead to improved diagnostic performance for Mycobacterium tuberculosis infection. In this study, we screened soluble biomarkers that had significant differences in patients with active tuberculosis and healthy controls and evaluated the diagnostic performance of the multiplex cytokine/chemokine assay. Overall, 178 patients with active pulmonary tuberculosis, 156 healthy individuals and 35 patients with bacterial pneumonia or lung cancer were evaluated. Among the 16 soluble biomarkers screened by the microbead-based multiplex assay, five cytokines/chemokines including IFN-gamma, IP-10, MIG, TNF-alpha and IL-2 that showed most significant differences between active pulmonary tuberculosis patients and healthy controls were selected for further analysis. When analyzed individually, both IP-10 and MIG had sensitivity and specificity comparable to IFN-gamma in detection of active TB. Combined detection of IFN-gamma, IP-10 and MIG had significantly improved sensitivity and specificity as compared with individual cytokine and chemokine detection. The responsive levels of IFN-gamma, IP-10, MIG, TNF-alpha and IL-2 were significantly lower in re-treatment pulmonary tuberculosis patients than in new tuberculosis patients. It is concluded that combined IFN-gamma, IP-10, MIG multiplex detection had better diagnostic performance for tuberculosis than the individual cytokine/chemokine assays. The re-treatment pulmonary tuberculosis patients had poor responses to ESAT-6/CFP-10 peptides stimulation.

Wang, X., et al. (2019). "Microbial Poly-3-Hydroxybutyrate (PHB) as a Feed Additive for Fishes and Piglets." Biotechnology Journal **14**(12): e1900132.

The large-scale use of petrochemical-based plastics is damaging our environment. Discarded plastics are harmful to both marine and land animals, sometimes causing death when ingested. Biodegradable plastics have gained attentions from the public and the academia to reduce environmental burdens. Poly-3-hydroxybutyrate (PHB), the simplest and the best-studied bioplastic member of the polyhydroxyalkanoate (PHA) family synthesized by many bacteria, has been studied as a feed additive for large yellow croaker fish and weaned piglets. The fish grow faster and gain more weight when 1% and 2% PHB is added as a feed additive, accompanied by increased survival rates. Weaned piglets are found to grow normally and showed no significant change in average daily weight gains, average daily feed intakes, feed efficiency, and organ developments when 0.5% PHB is added to the feed. It can therefore be concluded that biodegradable and biocompatible PHB is not harmful as a feed additive for marine large yellow croakers and sensitive weaned piglets. PHB therefore holds great promise as a plastic that combines biodegradability and biocompatibility with good tolerability as a feed supplement for animals.

Wang, X., et al. (2019). "Synergistic effect of biomass and polyurethane waste co-pyrolysis on soot formation at high temperatures." Journal of Environmental Management **239**: 306-315.

Soot is an important toxic pollutant generated during high-temperature incineration of solid waste (i.e., biomass and plastic waste) under air-lean conditions, and has a great impact on flame radiation. The main objective of this work is to study the synergistic effect of biomass and polyurethane co-pyrolysis on soot formation at high temperatures (1100-1250degreeC). The effects of temperature, biomass species, and co-pyrolysis ratio on the yield, morphology, composition and reactivity of soot particles are studied.

Wang, X., et al. (2015). "Intravitreal delivery of human NgR-Fc decoy protein regenerates axons after optic nerve crush and protects ganglion cells in glaucoma models." Investigative Ophthalmology & Visual Science **56**(2): 1357-1366.

PURPOSE: Glaucoma is a major cause of vision loss due to retinal ganglion cell (RGC) degeneration. Therapeutic intervention controls increased IOP, but neuroprotection is unavailable. NogoReceptor1 (NgR1) limits adult central nervous system (CNS) axonal sprouting and regeneration. We examined NgR1 blocking decoy as a potential therapy by defining the pharmacokinetics of intravitreal NgR(310)-Fc, its promotion of RGC axonal regeneration following nerve crush, and its neuroprotective effect in a microbead glaucoma model.

METHODS: Human NgR1(310)-Fc was administered intravitreally, and levels were monitored in rat vitreal humor and retina. Axonal regeneration after optic nerve crush was assessed by cholera toxin beta anterograde labeling. In a microbead model of glaucoma with increased IOP, the number of surviving and actively transporting RGCs was determined after 4 weeks by retrograde tracing with Fluro-Gold (FG) from the superior colliculus.

RESULTS: After intravitreal bolus administration, the terminal half-life of NgR1(310)-Fc between 1 and 7 days was approximately 24 hours. Injection of 5 mug protein once per week after optic nerve crush injury significantly increased RGCs with regenerating axons. Microbeads delivered to the anterior chamber increased pressure, and caused 15% reduction in FG-labeled RGCs of control rats, with a 40% reduction in large diameter RGCs. Intravitreal treatment with NgR1(310)-Fc did not reduce IOP, but maintained large diameter RGC density at control levels.

CONCLUSIONS: Human NgR1(310)-Fc has favorable pharmacokinetics in the vitreal space and rescues large diameter RGC counts from increased IOP. Thus, the NgR1 blocking decoy protein may have efficacy as a disease-modifying therapy for glaucoma.

Wang, X., et al. (2020). "Polystyrene microplastics impaired the feeding and swimming behavior of mysid shrimp Neomysis japonica." Marine Pollution Bulletin **150**: 110660.

Growing evidences revealed the deleterious impacts of microplastics (MPs) on marine organisms. However, the effects of MPs on the movement behavior of marine crustacean is poorly understood. Therefore, this study aims to evaluate the physiological and behavioral responses of mysid shrimp (Neomysis japonica) larvae to polystyrene (PS) and carboxylated polystyrene (PS-COOH). PS-COOH presented a greater physiological toxicity to shrimp larvae compared to PS, causing significant lethal and growth inhibition effect, owing to bioaccumulation of MPs inside stomach. Both two MPs decreased the feeding efficiency of larvae, showing weakened predation competence. Moreover, reduced hunting and/or explorative ability of shrimps caused by MPs was also identified, which was evidenced by an overall decrease in swimming activity, range and frequency after exposure. Our study firstly highlighted that micron-sized polystyrene particles had the negative effects on the movement behavior of mysid shrimp larvae, thus posing potential hazard to population dynamics and

ecological function of marine crustacean.

Wang, X., et al. (2014). "Insulin regulates proangiogenic signaling by downregulating Cited2 in endothelial cells." Diabetes **1)**: A447.

Impaired neovascularization of ischemic tissue in the myocardium and lower limb affects both recovery and survival from complications of diabetes. FoxO transcription factors, which are inhibited by insulin, are known to be potently antiangiogenic. Our aim was to identify genes involved in angiogenesis and regulated by insulin through FoxO in endothelial cells. FoxO1/3/4 knockout mice develop hemangiomas in liver but not in lung. A previous study identified FoxO targets among genes that were changed by FoxO1/3/4 knockout in liver endothelial cells but unchanged in lung endothelial cells, as assayed by gene arrays. We now measured expression of these FoxO target genes by real-time PCR in endothelial cells after adenoviral-mediated expression of wild-type FoxO1 or a constitutively active FoxO1 mutant combined with insulin treatment (10 nM for 4, 8, or 16 hours). Cited2, Ctgf, and Adm mRNA were upregulated by wildtype or mutant FoxO1 and downregulated by insulin in conditions without FoxO1 overexpression or with expression of wildtype, but not mutant, FoxO1. Spry2, Klf6, Bmper and Ccnd1 were regulated by insulin but not by FoxO1, whereas Fbn1 and Sdpr were regulated by FoxO1 but not by insulin. Nine genes were neither regulated by insulin nor by FoxO1. Cited2, one of the genes most robustly regulated by insulin, encodes CBP/p300-interacting transactivator 2 (CITED2) which inhibits transcription of hypoxia-inducible factor-1alpha and other genes. Insulin downregulated Cited2 mRNA by 70% and this effect was abrogated by pretreatment with LY294002 and MK2206 (inhibitors of phosphoinositide 3-kinase and Akt respectively). siRNA-mediated knockdown of CITED2 increased tube formation on Matrigel and sprouting from Cytodex 3 microbeads. We conclude that insulin may promote angiogenesis through downregulation of CITED2 via Akt-dependent inhibition of FoxO1. Enhancing insulin sensitivity of this pathway or directly inhibiting CITED2 may improve neovascularization in patients with type 2 diabetes.

Wang, X., et al. (2014). "Rapid and sensitive suspension array for multiplex detection of organophosphorus pesticides and carbamate pesticides based on silica-hydrogel hybrid microbeads." Journal of Hazardous Materials **273**: 287-292.

A technique for multiplex detection of organophosphorus pesticides and carbamate pesticides has been developed using a suspension array based on silica-hydrogel hybrid microbeads (SHHMs). The main advantage of SHHMs, which consist of both silica and hydrogel materials, is that they not only could be distinguished by their characteristic reflection peak originating from the stop-band of the photonic crystal but also have low non-specific adsorption of proteins. Using fluorescent immunoassay, the LODs for fenitrothion, chlorpyrifos-methyl, fenthion, carbaryl and metolcarb were measured to be 0.02 ng/mL, 0.012 ng/mL, 0.04 ng/mL, 0.05 ng/mL and 0.1 ng/mL, respectively, all of which are much lower than the maximum residue limits, as reported in the European Union pesticides database. All the determination coefficients for these five pesticides were greater than 0.99, demonstrating excellent correlations. The suspension array was specific and had no significant cross-reactivity with other chemicals. The results for the detection of pesticide residues collected from agricultural samples using this method agree well with those from liquid chromatography-tandem mass spectrometry. Our results showed that this simple method is suitable for simultaneous detection of these five pesticides residues in fruits and vegetables.

Wang, X., et al. (2011). "Magnetic protein microbead-aided indirect fluoroimmunoassay for the determination of canine virus specific antibodies." Biosensors & Bioelectronics **26**(7): 3353-3360.

Rabies, canine distemper, and canine parvovirus are common contagious viral diseases of dogs and many other carnivores, and pose a severe threat to the population dynamics of wild carnivores, as well as endangering carnivore conservation. However, clinical diagnosis of these diseases, especially canine distemper and canine parvovirus, is difficult because of the broad spectrum of symptoms that may be confused with other respiratory and enteric diseases of dogs. The most frequently used and proven techniques for diagnosing viral diseases include the conventional enzyme-linked immunosorbent assay (ELISA), rapid fluorescent focus inhibition test (RFFIT), mouse neutralisation test (MNT), and fluorescent antibody virus neutralization (FAVN) test. However, these methods still have some inherent limitations. In this study, a magnetic protein microbead-aided indirect fluoroimmunoassay was developed to detect canine virus specific antibodies, human rabies immunoglobulin, CDV McAbs, and CPV McAbs. In this assay, an avidin-biotin system was employed to combine magnetic microbeads and virus antigens (rabies virus, canine distemper virus, and canine parvovirus). Quantification of the targeted virus antibodies was analyzed through indirect fluoroimmunoassay using the specific antigen-antibody reaction, as well as their corresponding FITC-labeled detection antibodies (mouse anti-human IgG/FITC conjugate or rabbit anti-dog IgG/FITC conjugate). The results indicated that the fluorescence intensity increased when a higher concentration of the targeted analyte was used, but the control had almost no fluorescence, much like the conventional ELISA. For human rabies immunoglobulin, CDV McAbs, and CPV McAbs, the minimum detectable concentrations were 0.2 IU/mL, 0.3 ng/mL, and 0.5 ng/mL, respectively. All of these results indicate that this assay can be employed to determine the presence of canine virus specific antibodies. In addition, the method devised here can be utilized as a general protocol in other bacterial and viral marker analysis.

Wang, X., et al. (2014). "Innovative fluorescent magnetic albumin microbead-assisted cell labeling and intracellular imaging of glioblastoma cells." Biosensors & Bioelectronics **54**: 55-63.

Superparamagnetic nanoparticle-based polymer microbeads utilized as carriers are attractive materials widely applied in the biomedical field. However, the deficiency of toxicity, biocompatibility, and biodegradability for polymer materials often limits the application of these microbeads. In the present study, magnetic albumin microbeads (MAMbs), i.e., human serum albumin-coated gamma-Fe_2O_3 nanoparticles, are synthesized to label human U251 glioblastoma multiforme cells. The effects of MAMbs on the biological behavior of U251 glioblastoma cells, including their proliferation, cell viability, cytoskeletal structure, cell cycle, and apoptosis rate, are investigated. Moreover, fluorescein isothiocyanate (FITC)-MAMbs are fabricated by reaction with fluorescent dye FITC used for intracellular imaging of U251 glioblastoma cells. MAMbs possess undetectable cytotoxicity and excellent biocompatibility with U251 glioblastoma cells, as demonstrated by the biological behavior and morphology of U251 cells exposed to MAMbs. Furthermore, the constructed fluorescent MAMbs allow effective intracellular imaging, as illustrated by fluorescence microscopic analysis. The fabricated fluorescent MAMbs have promising perspectives in biomedical research, especially in cell-targeted labeling and intracellular fluorescence magnetic dual-mode imaging in cancer-targeted diagnosis and therapy.

Wang, Y., et al. (2016). "Contamination and health risk of phthalate esters in soils from a typical waste plastic recycling area." Environmental Chemistry - Huanjing Huaxue **35**(2): 364-372.

Levels and distributions of phthalate esters(PAEs) were investigated in surface soils from a typical waste plastic recycling area in Hebei,China. The results showed that the concentrations

of total PAEs ranged from 0. 517 to 30. 1 [mu]g[middot]g super(-1) with a mean value of 6. 98 [mu]g[middot]g super(-1). Levels of PAEs in the investigated soils were similar to those soils in some e-waste recycling areas and were one to two orders of magnitude higher than those reported in other urban soils from China. Di(2-ethylhexyl)phthalate(DEHP) was the dominant congener(representing 68. 8% of the total PAEs) in the study soils,followed by diisobutyl phthalate(DIBP) and dibutyl phthalate(DBP). Source assessment indicated that the emission from waste plastic recycling was a major contributor to PAEs in the soils.The carcinogenic and non-carcinogenic risks of six congeners,i. e.,dimethyl phthalate,diethyl phthalate,dibutyl phthalate,benzyl butyl phthalate,di(2-ethylhexyl) phthalate and di-n-octylophthalate,classed as priority pollutants by US EPA and European Union, were estimatedthrough the main pathways: ingestion,inhalation and dermal contact. The non-carcinogenic risks to adults and children from exposure to soil DEHP exceeded the acceptable level. Our results show that crude plastic waste processing is a major contributor to PAEs in the soils,which should be of great concern.

Wang, Y., et al. (2003). "Microbial Degradation of the Endocrine-Disrupting Chemicals Phthalic Acid and Dimethyl Phthalate Ester Under Aerobic Conditions." Bulletin of Environmental Contamination & Toxicology **71**(4): 0810-0818.

The article presents information about microbial degradation of the endocrine-disrupting chemicals phthalic acid and dimethyl phthalate ester under aerobic conditions. Phthalates are widely used as additives in plastic manufacturing and to improve mechanical properties of the plastic resin, particularly flexibility. Microbial degradation is believed to be the principal route for complete destruction of phthalate in the environments. Considerable research has been conducted on the molecular biology and organization of degradative genes in selective bacteria over the last decade. However, few studies have been focused on the pathway description of phthalates degradation, and fewer on the degradation ability and processes of bacteria.

Wang, Y., et al. (2019). "The uptake and elimination of polystyrene microplastics by the brine shrimp, Artemia parthenogenetica, and its impact on its feeding behavior and intestinal histology." Chemosphere **234**: 123-131.

Microplastics are a ubiquitous contaminant of marine ecosystems that have received considerable global attention. The effects of microplastic ingestion on some marine biota have been evaluated, but the uptake, elimination, and histopathological impacts of microplastics remain under-investigated especially for zooplankton larvae. Here, we show that 10 micro m polystyrene microspheres can be ingested and egested by Artemia parthenogenetica larvae, which impact their health. The results indicate that A. parthenogenetica larvae have a varying capacity to consume 10 micro m polystyrene microspheres that is dependent on microplastic exposure concentrations, exposure times, and the availability of food. The lowest level of microplastics that was ingested by A. parthenogenetica was 0.15 particles/individual when exposed to 10 particles/mL and 0.05 particles/individual when exposed to 1 particle/mL over 24 h and 14 d, respectively. A. parthenogenetica larvae were able to egest feces with microplastics within 3 h of ingestion. However, ingested microplastics persisted in individuals for up to 14 days. Furthermore, microalgal feeding was significantly reduced by 27.2% in the presence of 10² particles/mL microplastics over 24 h. Histological analyses indicated that a greater abundance of lipid droplets was present among epithelia after 24 h of exposure at a concentration of 10 particles/mL. Moreover, intestinal epithelia were deformed and disorderedly arranged after 14 d of exposure. Overall, these results indicate that marine microplastic pollution could pose a threat to A. parthenogenetica health, especially that of larvae. Consequently, further research is required to evaluate the potential physiological and

histopathological effects of microplastics for other marine invertebrate species.

Wang, Y., et al. (2016). "Digital PCR using micropatterned superporous absorbent array chips." Analyst **141**(12): 3821-3831.

Digital PCR (dPCR) is an emerging technology for genetic analysis and clinical diagnostics. To facilitate the widespread application of dPCR, here we developed a new micropatterned superporous absorbent array chip (muSAAC) which consists of an array of microwells packed with highly porous agarose microbeads. The packed beads construct a hierarchically porous microgel which confers superior water adsorption capacity to enable spontaneous filling of PDMS microwells for fluid compartmentalization without the need of sophisticated microfluidic equipment and operation expertise. Using large lambda-DNA as the model template, we validated the muSAAC for stochastic partitioning and quantitative digital detection of DNA molecules. Furthermore, as a proof-of-concept, we conducted dPCR detection and single-molecule sequencing of a mutation prevalent in blood cancer, the chromosomal translocation t(14;18), demonstrating the feasibility of the muSAAC for analysis of disease-associated mutations. These experiments were carried out using the standard molecular biology techniques and instruments. Because of its low cost, ease of fabrication, and equipment-free liquid partitioning, the muSAAC is readily adaptable to general lab settings, which could significantly facilitate the widespread application of dPCR technology in basic research and clinical practice.

Wang, Y., et al. (2015). "A microfluidic digital single-cell assay for the evaluation of anticancer drugs." Analytical and bioanalytical chemistry **407**(4): 1139-1148.

Issue Title: A different way of looking at vibrational hyperspectral data/Micellar extraction for the analysis of Alzheimer's disease brain proteome/Quantification of polyolefin microplastics in personal-care products/Removal of Triton X-100 by microdialysis Digital single-cell assays hold high potentials for the analysis of cell apoptosis and the evaluation of chemotherapeutic reagents for cancer therapy. In this paper, a microfluidic hydrodynamic trapping system was developed for digital single-cell assays with the capability of monitoring cellular dynamics over time. The microfluidic chip was designed with arrays of bypass structures for trapping individual cells without the need for surface modification, external electric force, or robotic equipment. After optimization of the bypass structure by both numerical simulations and experiments, a single-cell trapping efficiency of 90 % was achieved. We demonstrated the method as a digital single-cell assay for the evaluation of five clinically established chemotherapeutic reagents. As a result, the half maximal inhibitory concentration (IC^sub 50^) values of these compounds could be conveniently determined. We further modeled the gradual decrease of active drugs over time which was often observed in vivo after an injection to investigate cell apoptosis against chemotherapeutic reagents. The developed method provided a valuable means for cell apoptotic analysis and evaluation of anticancer drugs. [Figure not available: see fulltext.]

Wang, Y., et al. (2016). "Contamination and risk of phthalate esters in sediments from a plastic waste recycling area." Research of Environmental Sciences **29**(4): 558-565.

The contamination features and ecotoxicological risks of phthalate esters (PAEs) in sediments from a plastic waste recycling area in Hebei Province were investigated to improve our understanding of the extent of PAEs pollution caused by plastic waste recycling operations. Samples were detected using gas chromatograph-mass spectrometer (GC-MS). The total concentrations of 16 PAEs ranged from 0.527 to 102 micro g/g. With a mean concentration of 18.9 micro g/g, di(2-ethylhexyl) phthalate (DEHP) was the most dominant congener, accounting

for 66.6% of the total PAEs in the sediments. Source assessment indicated that the PAEs in the sediments were mainly derived from the inputs from poorly controlled plastic waste recycling operations. The results showed that the concentrations of DEHP and di-n-butyl phthalate (DBP) exceeded the Environmental Risk Limits (ERLs), and the concentrations of diisobutyl phthalate (DIBP) exceeded the environmental quality standards for sediment of Washington State (0.610 micro g/g). The risk levels from exposure to DBP and DEHP in the sediment were unacceptable for fish and algae, respectively, and therefore they should be paid attention to.

Wang, Y., et al. (2019). "Effects of ingested polystyrene microplastics on brine shrimp, Artemia parthenogenetica." Environmental Pollution **244**: 715-722.

Microplastics are a contaminant of emerging concern which enter the marine environment from a variety of sources. The ingestion and toxic effects of microplastics on marine life, especially for filter feeders, are a cause of concern in view of their ubiquitous nature and their similar size as food sources. To assess the toxic effects of microspheres ingested by brine shrimp larvae, we exposed Artemia parthenogenetica to 10 micro m polystyrene microspheres at different concentrations. These concentrations were approximate to the extrapolated marine aquatic environmentally relevant concentrations. The lowest polystyrene concentrations at which ingestion was visualized in A. parthenogenetica were 12+or-0.57 particles/mL (6.7+or-0.32 micro g/L) and 1.1+or-0.16 particles/mL (0.61+or-0.088 micro g/L), respectively. There were no significant impacts on the survival, growth or development in A. parthenogenetica occurring over the 14-d exposure across a range of polystyrene nominal concentrations (1-1000 particles/mL or 0.55-550 micro g/L). However, abnormal ultrastructures of intestinal epithelial cells were observed upon exposure to polystyrene microspheres, including fewer and disordered microvilli, an increased number of mitochondrion and the appearance of autophagosome. These phenomena could affect nutrition absorption and energy metabolism. Although no major acute or chronic toxicity effects on A. parthenogenetica were observed over 24-h or 14-d exposures, this study provides evidence that the ingestion of polystyrene microplastics at extrapolated environmentally relevant concentrations can be visualized through a microscope to be causing a series of responses in intestinal epithelial cells.

Wang, Y. Q., et al. (2017). "[Prostaglandin E2 Receptor 4 Agonist Promotes Human CD34⁺ Cell Proliferation in vitro by Activating Wnt/beta-Catenin Signaling Pathway]." Zhongguo Shi Yan Xue Ye Xue Za Zhi **25**(3): 656-660.

OBJECTIVE: To investigate the potential signaling pathway that regulates the proliferation of human CD34⁺ cells stimulated by prostaglandin E2 receptor 4 agonist (EP4A) in vitro.

METHODS: Twenty samples of peripheral blood containing stem cells were collected from the G-CSF mobilized healthy donors in our department of hematology. Human CD34⁺ cells were isolated by magnetic activated cell sorting (MACS) microbeads kit. The Cell Counting Kit-8 (CCK8) assay was used to determine the optimal concentration and time of EP4A to promote human CD34⁺ cell proliferation in vitro. Under the optimal condition, quantitative real-time polymerase chain reaction (qRT-PCR) was used to detect mRNA level of beta-catenin, and Western blot was used to assay protein expression of beta-catenin and P-GSK-3beta in human CD34⁺ cells treated with EP4A.

RESULTS: Culturing with 10 micro mol/L EP4A for 72 h, it was found that EP4A promoted human CD34⁺ cell proliferation significantly, and the proliferation rate of human CD34⁺ cells was 1.36 times higher than that of the control(P=0.002). Under the optimal condition, it was also found that EP4A enhanced the beta-catenin expression at both

mRNA and protein levels, and up-regulated phosphorylation of GSK-3beta in human CD34⁺ cells, but these effects could be inhibited by the EP4A antagonist EP4AA.
CONCLUSION: EP4A can enhance human CD34⁺ cell proliferation in vitro by activating Wnt/beta-catenin signaling pathway.

Wang, Z., et al. (2018). "Sorption behaviors of phenanthrene on the microplastics identified in a mariculture farm in Xiangshan Bay, southeastern China." Science of the Total Environment **628-629**: 1617-1626.

Recently, with the accumulation of evidence that microplastic can be ingested by a variety of marine organisms, microplastic sorption behaviors towards organic contaminants (OCs) have become the subject of more studies due to the concerns about the contaminant vector effect. In this study, the priority microplastics identified in a mariculture farm in Xiangshan Bay, China, including polyethylene (PE) and nylon fibers (i.e., derived from new fishing ropes and nets), were examined for their sorption behaviors. The results indicate that both plastic fibers show linear isotherms towards phenanthrene, a common target hydrophobic organic contaminant (HOC), revealing the characteristics of a partitioning mechanism. The sorption capacity of PE fiber was found to be 1-2 orders of magnitude higher (evaluated by Freundlich parameter log K_F) than that of nylon fiber, suggesting the importance of plastic surface functional groups (i.e., with or without hydrophilic groups). By comparing carbon normalized log K_F with literature data, the organic affinity of PE fiber was found to be 1-2 orders of magnitude lower than that of vectors, such as carbonaceous geosorbents (CG), but was 1-2 orders of magnitude higher than that of marine sediments. Small size and rough surface tended to enhance the sorption of plastic fibers of phenanthrene. In addition, phenol (log K_{OW}: 1.46), a low-hydrophobicity compound, showed approximately 3 orders of magnitude lower sorption amounts onto both fibers compared to phenanthrene (log K_{OW}: 4.46), indicating the selectivity of hydrophobicity. The results of this study demonstrate that the high abundance of plastic fibers distributed in mariculture farms could lead to a higher contaminant transfer effect than marine sediments, and their effects on cultured seafood (e.g., crab and fish) need further investigation.

Wang, Z., et al. (2020). "Occurrence and removal of microplastics in an advanced drinking water treatment plant (ADWTP)." Science of the Total Environment **700**: 134520.

Microplastics (MPs) have attracted worldwide attention as the emerging persistent pollutants. Since they have been detected in raw water and the treated water of drinking water treatment plants (DWTPs), there was an urgent need to explore the properties and fates of microplastics in DWTPs. The characteristics of the effluent MPs from each treatment unit in an advanced drinking water treatment plant (ADWTP) were studied, and the relationship between the variations of MPs and the removal performances of treatment processes was also explored. Overall, both the coagulation combined with sedimentation and the granular activated carbon (GAC) filtration performed well in removing microplastics. The former had a removal efficiency of about 40.5-54.5%, mainly for fibres' removal, and the presence of GAC filtration reduced the microplastic abundance by about 56.8-60.9%, mainly for small-sized MPs. It was worthy of attention that a larger amount of polyacrylamide (PAM) was detected in the effluent of the sedimentation compared to raw water, which was caused by the usage of coagulant containing PAM. Specially, the number of 1-5mum MPs in the effluent of ozonation tank was increased by 2.8-16.0%, resulting in a negative removal efficiency in ozonation. The removals of microplastics were depended primarily on their physical properties (size and shape).

Wang, Z., et al. (2019). "Microplastic contamination in freshwater: first observation in Lake Ulansuhai, Yellow River Basin, China." Environmental Chemistry Letters **17**(4): 1821-1830.

Microplastic pollution has been widely studied in the marine environment, but is much less explored in terrestrial waters, notably in China. Therefore, we studied the degree of microplastic pollution in surface waters of Lake Ulansuhai, a major freshwater lake in the Yellow River basin of northern China. Results show microplastic concentrations ranging from 1760 ± 710 to 10,120 ± 4090 n/m3. The microplastic spatial distribution is heterogeneous, with higher levels near the drainage canal entrance of Lake Ulansuhai, and a downward trend from north to south in the lake. The main type of microplastics is colored particles, including fibers as the most abundant. More than 80% of microplastics were smaller than 2 mm. FTIR analysis results show that the main plastics were polyethylene, polystyrene and polybutylene terephthalate. There were also some metallic elements adsorbed on the surface of microplastics, such as Fe, Ca and Zn, detected by energy-dispersive spectrometry. The presence of metallic elements may worsen water pollution.

Wang, Z., et al. (2018). "Poor extraction efficiencies of polystyrene nano- and microplastics from biosolids and soil." PLoS ONE [Electronic Resource] **13**(11): e0208009.

Extraction and quantification of nano- and microplastics from sediments and soils is challenging. Although no standard method has been established so far, flotation is commonly used to separate plastic from mineral material. The objective of this study was to test the efficiency of flotation for the extraction of nano- and microplastics from biosolids and soil. We spiked biosolids and soil samples with polystyrene nano- and microbeads (0.05, 1.0, 2.6, 4.8, and 100 mum diameter). Different extraction methods (w/ and w/o H2O2 digestion) were tested, and plastic beads were separated from mineral particles by flotation in a ZnCl2 solution. Plastic particles were quantified by UV-Vis spectrometry and gravimetrically. While large beads (100 mum) could be quantitatively extracted (~100%) from both biosolids and soils, smaller beads had low extraction efficiencies (ranging from 5 to 80%, with an average of 20%). Except for the 100 mum beads, oxidation with H2O2 negatively impacted the extraction efficiencies. For the soil, extraction with water only, followed by flotation in a ZnCl2 solution, resulted in relatively high extraction efficiencies (>75%) for beads larger than 1 mum, but low efficiencies (<30%) for the 0.05 and 1.0 mum beads. Our results indicate that while flotation generally works to separate plastic nano- and microbeads in a solution, the challenge is to quantitatively extract nano- and microbeads from a biosolids or soil matrix. Samples high in organic matter content require removal of the organic matter, but the common method of H2O2 oxidation leads to poor extraction efficiencies for nano- and microbeads.

Wang, Z., et al. (2017). "SEM/EDS and optical microscopy analyses of microplastics in ocean trawl and fish guts." Science of the Total Environment **603**(604): 616-626.

Microplastic particles from Atlantic and Pacific Ocean trawls, lab-fed fish guts and ocean fish guts have been characterized using optical microscopy and SEM/EDS in terms of size, morphology, and chemistry. We assessed whether these measurements could serve as a rapid screening process for subsequent identification of the likely microplastic candidates by micro-spectroscopy. Optical microscopy enabled morphological classification of the types of particles or fibers present in the sample, as well as the quantification of particle size ranges and fiber lengths. SEM/EDS analysis was used to rule out non-plastic particles and screen the prepared samples for potential microplastic, based on their element signatures and surface characteristics. Chlorinated plastics such as polyvinyl chloride (PVC) could be easily identified with SEM/EDS due to their unique elemental signatures including chlorine, as could mineral species that are falsely identified as plastics by optical microscopy. Particle morphology determined by optical microscopy and SEM suggests the fish ingested particles contained both degradation fragments from larger plastic pieces and also manufactured microplastics. SEM images of microplastic particle surfaces revealed characteristic cracks consistent with environmental exposure, as well as pigment particles consistent with manufactured materials. Most of the microplastic surfaces in the fish guts and ocean trawls were covered with biofilms, radiolarians, and crustaceans. Many of the fish stomachs contained micro-shell pieces which visually resembled microplastics.

Wanger, T. C. and B. R. Scheffers (2011). "Plastic: matching material with usage." Frontiers in Ecology & the Environment **9**(3): 151-152.
The article discusses the study which describes the widespread plastic consumption that contributes to the global plastic pollution crisis. Researchers stress the need to substantially reduce plastic consumption to address the pollution crisis. It also emphasizes the need to support the use of biodegradable materials by developed nations for inexpensive non-plastic alternatives which can be adopted by developing countries.

Wang-Renault, S. F., et al. (2018). "Deregulation of microRNA expression in purified T and B lymphocytes from patients with primary Sjogren's syndrome." Annals of the Rheumatic Diseases **77**(1): 133-140.
OBJECTIVE: MicroRNAs (miRNAs) play an important role in the pathogenesis of autoimmune diseases such as primary Sjogren's syndrome (pSS). This study is the first to investigate miRNA expression patterns in purified T and B lymphocytes from patients with pSS using a high-throughput quantitative PCR (qPCR) approach.
METHODS: Two independent cohorts of both patients with pSS and controls, one for discovery and one for replication, were included in this study. CD4+ T cells and CD19+ B cells were isolated from peripheral blood mononuclear cells by magnetic microbeads and expression of miRNAs was profiled using the Exiqon Human miRNome panel I analysing 372 miRNAs. A selection of differentially expressed miRNAs was replicated in the second cohort using specific qPCR assays.
RESULTS: A major difference in miRNA expression patterns was observed between the lymphocyte populations from patients with pSS and controls. In CD4 T lymphocytes, hsa-let-7d-3p, hsa-miR-155-5 p, hsa-miR-222-3 p, hsa-miR-30c-5p, hsa-miR-146a-5p, hsa-miR-378a-3p and hsa-miR-28-5 p were significantly differentially expressed in both the discovery and the replication cohort. In B lymphocytes, hsa-miR-378a-3p, hsa-miR-222-3 p, hsa-miR-26a-5p, hsa-miR-30b-5p and hsa-miR-19b-3p were significantly differentially expressed. Potential target mRNAs were enriched in disease relevant pathways. Expression of B-cell activating factor (BAFF) mRNA was inversely correlated with the expression of hsa-miR-30b-5p in B lymphocytes from patients with pSS and functional experiments showed increased expression of BAFF after inhibiting hsa-miR-30b-5p.
CONCLUSIONS: This study demonstrates major miRNAs deregulation in T and B cells from patients with pSS in two independent cohorts, which might target genes known to be involved in the pathogenesis of pSS.

Wani, T. A., et al. (2016). "Analytical Application of Flow Immunosensor in Detection of Thyroxine and Triiodothyronine in Serum." Assay & Drug Development Technologies **14**(9): 535-542.
In this study, an immunosensor based on kinetic exclusion analysis (KinExA) was used for thyroxine (T4) and triiodothyronine (T3) estimation. A KinExATM 3200 instrument was used for this analysis, which is an automated flow fluorimeter designed to separate free unbound antibody binding sites in reaction mixtures of antibody, antigen, and antibody-antigen complex.

A T3-BSA- and T4-BSA-coated polymethyl methacrylate (PMMA) bead microcolumn is generated inside the flow cell of the instrument. A sample mixture containing T3 and T4 with their respective monoclonal antibodies and their complexes are drawn past the microbead column. The unbound T3 or T4 monoclonal antibody binding sites are captured by their respective T3 and T4 antigens coated on the PMMA beads as bovine serum albumin conjugates. Fluorescently labeled secondary antibodies bind to the T3 or T4 antigen-antibody complex to generate fluorescence intensity for analysis. The limit of detection for the T3 and T4 assays was found to be 0.06 and 1.9 ng mL⁻¹ with acceptable precision values. The convenience of the automated KinExA format may be valuable in medical diagnostic laboratories.

Wani, T. A., et al. (2016). "New analytical application of antibody-based biosensor in estimation of thyroid-stimulating hormone in serum." Bioanalysis **8**(7): 625-632.

Background: Conventionally, ELISA is used to measure thyroid-stimulating hormone (TSH) for diagnosis of thyroid disease. In this study, an immunosensor-based, kinetic-exclusion analysis (KinExA) was used for TSH estimation. Methodology: A PMMA microbead column coated with TSH antigen is formed inside the flow cell. Samples consisting of mouse anti-TSH monoclonal antibody and TSH antigen complex in solution are passed over the beads and the unbound anti-TSH antibody is captured by the TSH-coated beads, followed by passing fluorescent-labeled antibody over the beads to generate signals for analysis. The limit of detection for the assay was 0.4 mIU l⁻¹ and the precision was acceptable. Conclusion(s): The developed sensor was advantageous due to the automated nature and its convenience, without compromising the sensitivity for estimation of TSH. Copyright © 2016 Future Science Ltd.

Ward, J. E., et al. (2019). "Selective Ingestion and Egestion of Plastic Particles by the Blue Mussel (Mytilus edulis) and Eastern Oyster (Crassostrea virginica): Implications for Using Bivalves as Bioindicators of Microplastic Pollution." Environmental Science & Technology **53**(15): 8776.

Microplastics (MP; 1 μm to 1 mm) of various shapes and compositions are ingested by numerous marine animals. Recently, proposals have been made to adopt bivalve molluscs as bioindicators of MP pollution. To serve as indicators of MP pollution, however, the proposed organisms should ingest, without bias, the majority of plastic particles to which they are exposed. To test this premise, eastern oysters, Crassostrea virginica, and blue mussels, Mytilus edulis, were offered variously sized polystyrene microspheres (diameters 19–1000 μm) and nylon microfibers (lengths 75–1075 × diameter 30 μm), and the proportion of each rejected in pseudofeces and egested in feces was determined. For both species, the proportion of microspheres rejected increased from ca. 10–30% for the smallest spheres to 98% for the largest spheres. A higher proportion of the largest microsphere was rejected compared with the longest microfiber, but similar proportions of microfibers were ingested regardless of length. Differential egestion of MP also occurred. As a result of particle selection, the number and types of MP found in the bivalve gut will depend upon the physical characteristics of the particles. Thus, bivalves will be poor bioindicators of MP pollution in the environment, and it is advised that other marine species be explored.

Wardrop, P., et al. (2016). "Chemical Pollutants Sorbed to Ingested Microbeads from Personal Care Products Accumulate in Fish." Environmental Science & Technology **50**(7): 4037-4044.

The prevalence of microplastics (<5 mm) in natural environments has become a widely recognized global problem. Microplastics have been shown to sorb chemical pollutants from their surrounding environment, thus raising concern as to their role in the movement of these pollutants through the food chain. This experiment investigated whether organic pollutants

sorbed to microbeads (MBs) from personal care products were assimilated by fish following particle ingestion. Rainbow fish (Melanotaenia fluviatilis) were exposed to MBs with sorbed polybrominated diphenyl ethers (PBDEs; BDE-28, -47, -100, -99, -153, -154, -183, 200 ng g-1; BDE-209, 2000 ng g-1) and sampled at 0, 21, 42, and 63 days along with two control treatments (food only and food + clean MBs). Exposed fish had significantly higher ∑8PBDE concentrations than both control treatments after just 21 days, and continued exposure resulted in increased accumulation of the pollutants over the experiment (ca. 115 pg g-1 ww d-1). Lower brominated congeners showed the highest assimilation whereas higher brominated congeners did not appear to transfer, indicating they may be too strongly sorbed to the plastic or unable to be assimilated by the fish due to large molecular size or other factors. Seemingly against this trend, however, BDE-99 did not appear to bioaccumulate in the fish, which may be due to partitioning from the MBs or it being metabolized in vivo. This work provides evidence that MBs from personal care products are capable of transferring sorbed pollutants to fish that ingest them. [ABSTRACT FROM AUTHOR]

Waring, R. H., et al. (2018). "Plastic contamination of the food chain: A threat to human health?" Maturitas **115**: 64-68.
Macro-plastic pollution is found in terrestrial and marine environments and is degraded to micro-particles (MP) and nano-particles (NP) of plastic. These can enter the human food chain either by inhalation or by ingestion, particularly of shellfish and crustaceans. Absorption across the gastrointestinal tract is relatively low, especially for MPs, which appear to have little toxicity. However, NPs are more readily absorbed and may accumulate in the brain, liver and other tissues in aquatic species and other animals. Studies using nanoparticles of other materials suggest that toxicity could potentially affect the central nervous system and the reproductive system, although this would be unlikely unless exposure levels were very high and absorption was increased by physiological factors.

Waris, M. E., et al. (2002). "Two-photon excitation fluorometric measurement of homogeneous microparticle immunoassay for C-reactive protein." Analytical Biochemistry **309**(1): 67-74.
Recent developments in infrared laser technology have enabled the design of a compact instrumentation for two-photon excitation microparticle fluorometry (TPX). The microparticles can be used in immunoassays as the antibody-coated solid phase to capture ah antigen and then detect it with a fluorescently labeled tracer antibody. Unlike most other methods, TPX technology allows low-volume, homogeneous immunoassays with real-time measurements of assay particles in the presence of a moderate excess of fluorescent tracer. In this study, the TPX assay system was used for the reagent characterization and the measurement of C-reactive protein (CRP) in diluted plasma samples, targeting the assay range useful in infectious disease diagnosis. The pentameric structure of the CRP permitted the optimization of an assay with the lowest detectable concentration of 1 mug/L (7.5 pM) by using a single monoclonal antibody both for capture and as the tracer. With a 1:200 predilution of samples, the measurement range of the assay was 1-150mg/L, but an additional 1:10 dilution was required for higher concentrations. The TPX method showed a good correlation with the reference result obtained

in a routine hospital laboratory, demonstrating the feasibility of the technology for immunodiagnostic applications. © 2002 Elsevier Science (USA). All rights reserved.

Warth, B., et al. (2015). "Deoxynivalenol-sulfates: identification and quantification of novel conjugated (masked) mycotoxins in wheat." Analytical and bioanalytical chemistry **407**(4): 1033-1039.

Issue Title: A different way of looking at vibrational hyperspectral data/Micellar extraction for the analysis of Alzheimer's disease brain proteome/Quantification of polyolefin microplastics in personal-care products/Removal of Triton X-100 by microdialysis We report the identification of deoxynivalenol-3-sulfate and deoxynivalenol-15-sulfate as two novel metabolites of the trichothecene mycotoxin deoxynivalenol in wheat. Wheat ears which were either artificially infected with Fusarium graminearum or directly treated with the major Fusarium toxin deoxynivalenol (DON) were sampled 96 h after treatment. Reference standards, which have been chemically synthesized and confirmed by NMR, were used to establish a liquid chromatography-electrospray ionization (LC-ESI)-MS/MS-based "dilute and shoot" method for the detection, unambiguous identification, and quantification of both sulfate conjugates in wheat extracts. Using this approach, detection limits of 0.003 mg/kg for deoxynivalenol-3-sulfate and 0.002 mg/kg for deoxynivalenol-15-sulfate were achieved. Matrix-matched calibration was used for the quantification of DON-sulfates in the investigated samples. In DON-treated samples, DON-3-sulfate was detected in the range of 0.29-1.4 mg/kg fresh weight while DON-15-sulfate concentrations were significantly lower (range 0.015-0.061 mg/kg fresh weight). In Fusarium-infected wheat samples, DON-3-sulfate was the only detected sulfate conjugate (range 0.022-0.059 mg/kg fresh weight). These results clearly demonstrate the potential of wheat to form sulfate conjugates of DON. In order to test whether sulfation is a detoxification reaction in planta, we determined the ability of the sulfated DON derivatives to inhibit in vitro protein synthesis of wheat ribosomes. The results demonstrate that both DON-sulfates can be regarded as detoxification products. DON-15-sulfate was about 44× less inhibitory than the native toxin, and no toxicity was observed for DON-3-sulfate in the tested range. [Figure not available: see fulltext.]

Waschke, J., et al. (2004). "Requirement of Rac activity for maintenance of capillary endothelial barrier properties." American Journal of Physiology **55**(1): 394-H401.

Our previous experiments indicated that GTPases, other than RhoA, are important for the maintenance of endothelial barrier integrity in both intact microvessels of rats and mice and cultured mouse myocardial endothelial (MyEnd) cell monolayers (J Physiol 539: 295-308, 2002). In the present study, we inhibited the endothelial GTPase Rac by Clostridium sordellii lethal toxin (LT) and investigated the relation between the degree of inhibition of Rac by glucosylation and increased endothelial barrier permeability. In rat venular microvessels, LT (200 ng/ml) increased hydraulic conductivity from a control value of 2.5 +/- 0.6 to 100.8 +/- 18.7 x 10-7 cm*s-1*cmH2O-1 after 80 min. In cultured MyEnd cells exposed to LT (200 ng/ml), up to 60% of cellular Rac was glucosylated after 90 min, resulting in depolymerization of F-actin and interruptions of junctional distribution of vascular endothelial cadherin (VE-cadherin) and {beta}-catenin as well as the formation of intercellular gaps. To understand the mechanism by which inhibition of Rac caused disassembly of adherens junctions, we used laser tweezers to quantify VE-cadherin-mediated adhesion. LT and cytochalasin D, an actin depolymerizing agent, both reduced adhesion of VE-cadherin-coated microbeads to the endothelial cell surface, whereas the inhibitor of Rho kinase Y-27632 did not. Stabilization of actin filaments by jasplakinolide completely blocked the effect of cytochalasin D but not of LT on bead adhesion. We conclude that Rac regulates endothelial barrier properties in vivo and in vitro by 1) modulation of actin filament polymerization and 2) acting directly on the tether between VE-cadherin and the cytoskeleton. [PUBLICATION ABSTRACT]

Waschke, J., et al. (2005). "Pemphigus foliaceus IgG causes dissociation of desmoglein 1-containing junctions without blocking desmoglein 1 transinteraction." Journal of Clinical Investigation **115**(11): 3157-3165.

Autoantibodies against the epidermal desmosomal cadherins desmoglein 1 (Dsg1) and Dsg3 have been shown to cause severe to lethal skin blistering clinically defined as pemphigus foliaceus (PF) and pemphigus vulgaris (PV). It is unknown whether antibody-induced dissociation of keratinocytes is caused by direct inhibition of Dsg1 transinteraction or by secondary cellular responses. Here we show in an in vitro system that IgGs purified from PF patient sera caused cellular dissociation of cultured human keratinocytes as well as significant release of Dsg1-coated microbeads attached to Dsg-containing sites on the keratinocyte cellular surface. However, cell dissociation and bead release induced by PF-IgGs was not caused by direct steric hindrance of Dsg1 transinteraction, as demonstrated by single molecule atomic force measurements and by laser trapping of surface-bound Dsg1-coated microbeads. Rather, our experiments strongly indicate that PF-IgG-mediated dissociation events must involve autoantibody-triggered cellular signaling pathways, resulting in destabilization of Dsg1-based adhesive sites and desmosomes.

Waste, S. (2019). "Agilyx, GE to Advance Circular Economy for Plastics." Waste360: N.PAG-N.PAG.

Agilyx Corporation announced a collaboration in artificial intelligence (AI) technology with the General Electric Company (GE) that aims to keep plastic materials from becoming waste. This announcement is the result of a year-long effort to assess GE's advanced modeling technology developed by GE Research and its applicability to the database of chemical conversions of post-use plastics that Agilyx has amassed over the last 15 years. "Together with Agilyx, we can do the same for the plastics industry by integrating Agilyx's deep industry domain knowledge with our AI, machine learning and modeling techniques to bring recycling almost entirely full circle". Watanabe, S., et al. (2014). "Microbead-based ligase detection reaction assay using a molecular beacon probe for the detection of low-abundance point mutations." Analytical Chemistry **86**(1): 900-906.
A microbead-based ligase detection reaction (LDR) assay using a molecular beacon probe was developed for the facile and rapid detection of point mutations present in low copy numbers in a mixed population of wild-type DNA. Biotin-tagged ligation products generated in the LDR were captured on the surface of streptavidin-modified magnetic beads for purification and concentration. The resulting product-tethered microbeads were combined with a molecular beacon probe solution, and the suspension was directly flowed into a capillary. The microbeads were accumulated in a confined space within the capillary using a bar magnet. The packed bead sample was then scanned by a fluorescence scanning imager to detect the presence of any mutations. With the developed methodology, we were able to successfully detect one cancer mutation in a mixture of 400 wild-type templates (t test at 95% confidence level). Furthermore, the post-LDR processing, typically the most laborious and time-consuming step in LDR-based mutation detection assays, could be carried out much more rapidly (approximately 20 min). This was enabled by the simple bead and fluid manipulations involved in the present assay.

Watari, K., et al. (2014). "N-myc downstream regulated gene 1 (NDRG1) as a novel anti-angiogenic and therapeutic target for VEGF/VEGF receptor signaling by vascular endothelial cells." European Journal of Cancer **6)**: 190.
Background: Angiogenesis is essential for the malignant progression of cancer. Therefore, development of a novel type of angiogenesis inhibitor is essential for further improvement of therapeutics against cancer patients. N-myc downstream regulated gene 1 (NDRG1) has been known to play pleiotropic roles in cell proliferation, development, differentiation, and tumorigenesis. We have previously reported that NDRG1 expression levels in cancer cells are closely correlated with tumor angiogenesis and tumor growth in both experimental models and human tumors (Hosoi et al., Cancer Res., 2009; Murakami et al., J Biol Chem., 2013). However, whether tumor angiogenesis could be affected by NDRG1 in host remains unclear. In our present study, we asked whether NDRG1 could specifically modulate tumor angiogenesis, and impaired tumor angiogenesis could be observed by NDRG1 deficiency. Material(s) and Method(s): NDRG1 deficient mice: The NDRG1 deficient mice on C57BL6 background have been

kindly donated to us by Prof. Toshiyuki Miyata (National Cerebral and Cardiovascular Center) (Okuda et al., Mol Cell Biol., 2004). Isolation of mouse endothelial cells: CD31+ endothelial cells were isolated from mouse lung by magnetic sorting using CD31 MicroBeads. Aorta ring assay: 1mm mouse aortic rings were embedded in 3-dimensional growth factor reduced Matrigel, treated with or without FGF-2 (50 ng/mL) or VEGF (25 ng/ml), and incubated at 37degreeC. Vascular length and branching point were measured at day 7. Result(s): In NDRG1 deficient mice as compared to their wild type counterparts, (1) tumor growth and angiogenesis by subcutaneous transplantation of syngeneic cancer cells were markedly suppressed; (2) tumor angiogenesis by cancer cells was suppressed in dorsal air sac assay; (3) exogenous administration of VEGF could not induce angiogenesis in corneas whereas FGF-2 could induce angiogenesis; (4) VEGF-induced angiogenesis was markedly impaired in aorta ring assay; (5) VEGF could not induce cell growth and phosphorylation of Akt and Erk in vascular endothelial cells in vitro; (6) in addition to VEGF, an inflammatory cytokine IL-1b also induced impaired angiogenesis in corneas. Conclusion(s): NDRG1 deficiency in host induced functional impairment of endothelial cells in response to VEGF, affecting impaired tumor angiogenesis, and also inflammatory angiogenesis. Based on our present study, we will discuss whether targeting NDRG1 and its downstream signaling molecules could be useful for further development of novel antiangiogenic drug.

Watermann, B. and B. Eklund (2019). "Can the input of biocides and polymeric substances from antifouling paints into the sea be reduced by the use of non-toxic hard coatings?" Marine Pollution Bulletin **144**: 146-151.

Antifouling coatings are used to protect boat hulls from fouling organisms. The paints are designed to release biocides and by this prevent fouling organisms to attach. Until now the simultaneous release of the bulk plastic material has been over-looked. In this study the amount of antifouling paints on ships and leisure boats in Scandinavian countries and Germany has been compared and a calculation of the release of micro plastics has been performed. The result shows that use of a biocide-free hard coating will completely reduce outlet of biocides and the input of polymers will dramatically be reduced from at the most 5% in comparison to traditional paints where the release rate of plastics is estimated to be 70-85%. The advantage for the boat owners will be large since the hard maintenance work will be reduced, release of micro plastics will be low and thus lead to an improved environment. Copyright © 2019 Elsevier Ltd

Wathsala, R. H. G. R., et al. (2018). "Styrene impairs normal embryo development in the Mediterranean mussel (Mytilus galloprovincialis)." Aquatic Toxicology **201**: 58-65.

This study analysed the effects of styrene, a main monomer in plastic manufacturing and acknowledged to be amongst the most common plastic leachates, on early embryo development of the Mediterranean mussel. Embryotoxicity tests showed that styrene impaired normal embryo development at concentrations (0.01 μg/L–1 mg/L) encompassing the environmental range. Occurrence of normal D-veligers was significantly reduced up to 40% of the total, and larval size was reduced of about 20%. D-veligers grown in the presence of styrene (0.1 and 10 μg/L) showed significant reduction of total Multixenobiotic resistance (MXR) efflux activity that was not apparently related to transcriptional expression of genes encoding P-glycoprotein (ABCB) and Mrp (ABCC), the two main ABC transporters of embryonal MXR system. Indeed, ABCB transcription was not affected by styrene, while ABCC was up-regulated. At these same concentrations, transcriptional profiles of 15 genes underlying key biological functions in embryo development and potential targets of adverse effects of styrene were analysed. Main transcriptional effects were observed for genes involved in shell biogenesis and

lysosomal responses (down-regulation), and in neuroendocrine signaling and immune responses (up-regulation). On the whole, results indicate that styrene may affect mussel early development through dysregulation of gene transcription and suggest the possible conservation of styrene mode of action across bivalve life cycle and between bivalves and humans, as well as through unpredicted impacts on protective systems and on shell biogenesis. Watkins, L., et al. (2019). "The effect of dams on river transport of microplastic pollution." Science of the Total Environment **664**: 834-840.

Dams are known to trap pollutants such as metals and PCBs in the sediment that accumulates within their reservoirs. As more attention is paid to microplastics, an emerging contaminant in waterways worldwide, and how they move along rivers, whether microplastic particles also accumulate behind dams is an important question for informing estimates of global river inputs to oceans. In this study, we measured microplastic concentrations above, below, and within the reservoirs of six dams near Ithaca, NY USA. Samples were processed following the wet peroxide oxidation method and visual counting, followed by Raman Spectroscopy validation. We found that microplastic concentrations in sediment within reservoirs was significantly higher than in sediment above the dams ($p = 0.005$), and in water samples, concentrations within reservoirs was significantly lower ($p = 0.02$). Plastic fibers were the dominant plastic type, but in within-reservoir sediment samples, less abundant plastic types such as plastic fragments were found in higher proportions. These results show that the sediment collecting behind dams is one sink for microplastics in river systems at long timescales, indicating that accounting for dams may be important when modeling global riverine microplastic transport. Watkins, L., et al. (2019). "A case study investigating temporal factors that influence microplastic concentration in streams under different treatment regimes." Environmental Science & Pollution Research **26**(21): 21797-21807.

Microplastics, particles less than 5 mm in size, are an emerging contaminant in waterways worldwide. Most microplastic studies focus on spatial trends in concentration, but in systems as dynamic as rivers, to draw conclusions from existing spatial studies, we must first examine how microplastic concentrations may change with time and flow conditions. In this study, we investigate how microplastic concentrations change over a 24-h period and between seasonally high and low flows. We do this in two streams, controlling for wastewater treatment strategy: one stream in a watershed where waste is treated with septic systems and the other receiving wastewater treatment plant effluent. We hypothesized that a stream with wastewater treatment plant effluent would exhibit higher and more variable microplastic concentrations than a stream in a watershed with septic systems.

Watts, A. J. R., et al. (2014). "Uptake and Retention of Microplastics by the Shore Crab Carcinus maenas." Environmental Science & Technology **48**(15): 8823-8830.

Microplastics, plastics particles <5 mm in length, are a widespread pollutant of the marine environment. Oral ingestion of microplastics has been reported for a wide range of marine

biota, but uptake into the body by other routes has received less attention. Here, we test the hypothesis that the shore crab (Carcinus maenas) can take up microplastics through inspiration across the gills as well as ingestion of pre-exposed food (common mussel Mytilus edulis). We used fluorescently labeled polystyrene microspheres (8-10 μm) to show that ingested microspheres were retained within the body tissues of the crabs for up to 14 days following ingestion and up to 21 days following inspiration across the gill, with uptake significantly higher into the posterior versus anterior gills. Multiphoton imaging suggested that most microspheres were retained in the foregut after dietary exposure due to adherence to the hairlike setae and were found on the external surface of gills following aqueous exposure. Results were used to construct a simple conceptual model of particle flow for the gills and the gut. These results identify ventilation as a route of uptake of microplastics into a common marine nonfilter feeding species. [ABSTRACT FROM AUTHOR]

Watts, A. J. R., et al. (2015). "Ingestion of Plastic Microfibers by the Crab Carcinus maenas and Its Effect on Food Consumption and Energy Balance." Environmental Science & Technology **49**(24): 14597-14604.
Microscopic plastic fragments (<5 mm) are a worldwide conservation issue, polluting both coastal and marine environments. Fibers are the most prominent plastic type reported in the guts of marine organisms, but their effects once ingested are unknown. This study investigated the fate of polypropylene rope microfibers (1-5 mm in length) ingested by the crab Carcinus maenas and the consequences for the crab's energy budget. In chronic 4 week feeding studies, crabs that ingested food containing microfibers (0.3-1.0% plastic by weight) showed reduced food consumption (from 0.33 to 0.03 g d-1) and a significant reduction in energy available for growth (scope for growth) from 0.59 to -0.31 kJ crab d-1 in crabs fed with 1% plastic. The polypropylene microfibers were physically altered by their passage through the foregut and were excreted with a smaller overall size and length and amalgamated into distinctive balls. These results support of the emerging paradigm that a key biological impact of microplastic ingestion is a reduction in energy budgets for the affected marine biota. We also provide novel evidence of the biotransformations that can affect the plastics themselves following ingestion and excretion. [ABSTRACT FROM AUTHOR]

Watts, A. J. R., et al. (2016). "Effect of Microplastic on the Gills of the Shore Crab Carcinus maenas." Environmental Science & Technology **50**(10): 5364-5369.
Microscopic plastic debris (microplastics, <5 mm in diameter) is ubiquitous in the marine environment. Previous work has shown that microplastics may be ingested and inhaled by the shore crab Carcinus maenas, although the biological consequences are unknown. Here, we show that acute aqueous exposure to polystyrene microspheres (8 μm) with different surface coatings

had significant but transient effects on branchial function. Microspheres inhaled into the gill chamber had a small but significant dose-dependent effect on oxygen consumption after 1 h of exposure, returning to normal levels after 16 h. Ion exchange was also affected, with a small but significant decrease in hemolymph sodium ions and an increase in calcium ions after 24 h post-exposure. Tofurther asses the effects on osmoregulation, we challenged crabs with reduced salinity after microplastic exposure. Neither microspheres nor natural sediments altered the crab's response to osmotic stress regardless of plastic concentration added. Carboxylated (COOH) and aminated (NH2) polystyrene microspheres were distributed differently across the gill surface, although neither had a significant adverse impact on gill function. These results illustrate the extent of the physiological effects of microplastics compared to the physiological resilience of shore crabs in maintaining osmoregulatory and respiratory function after acute exposure to both anthropogenic plastics and natural particles. Watzl, A. (1996). "NONWOVENS FROM RECYCLED WASTE." Recycling Textile & Plastic Waste: 89-99.

The article discusses the development of the nonwoven fabric industry under the heading of optimum recyclability in Europe. Recycling defines that both production waste and used materials are returned to the production cycle. It highlights the issues including the avoidance and reduction of waste formation by the industries in the region. It is emphasized that the utilization of technologies is important in processing of the various waste groups. It is also stated that recycling nonwoven products should take a distinction between disposable and durables.

Weagel, E. G., et al. (2015). "Prostate cancer microenvironment modulates macrophage phagocytosis." Cancer Research. Conference: 106th Annual Meeting of the American Association for Cancer Research, AACR **75**(15 SUPPL. 1).

Macrophages play an important role in the body's immune system. There are two main phenotypes of macrophages, M1 and M2. M1 polarized macrophages participate in tumorcidal activity and pro-inflammatory responses. M2 macrophages perform anti-inflammatory responses and promote tissue repair, angiogenesis, and tumor growth. Macrophages within the vicinity of cancer cells may be influenced by the microenvironment and change their gene expression accordingly. Macrophages can express different cytokine profiles depending on their polarization state (M1 or M2). We investigated whether macrophages exposed to cancer cells demonstrate a M2 or M1 phenotype. We stimulated U937 cells with phorbol 12-myristate 13-acetate (PMA) for 24 hours to allow for adhesion and differentiation. We co-cultured PMA-stimulated U937 macrophages with PC3 and DU145 prostate cancer cell lines in a 1:1 ratio with a transpermeable membrane to allow for cell to cell contact and communication, and with PC3 and DU145 conditioned media for 48 hours. We isolated the RNA from the treated macrophages and performed qPCR to assess gene expression levels of the following cytokines: IL-10, a cytokine demonstrating a M2 phenotype was upregulated by 10 and 15 fold for PC3 and DU145 cells respectively and by 3 fold in both cell lines exposed to conditioned media. We also found a trend of downregulation with the cytokines IL-1, IL-12, and TNF - alpha, which also depict a M2 phenotype. We also assessed macrophage function by measuring engulfment by flow cytometry. Treated macrophages were allowed to phagocytose fluorescent microbeads for 1 hour. Flow cytometry analysis revealed that total bead engulfment decreased by up to 80% in macrophages treated with PC3 cells. Moreover, the population of macrophages that engulfed 3+ beads decreased significantly from both the cells and media treatments. Macrophages treated with DU145 cells and spent media also showed a similar trend to macrophages exposed to PC3 cells. The results show that macrophages exposed to PC3 and DU145 cancer cell lines polarized towards an M2 phenotype and could be important in the success of cancer within the microenvironment. Further research will reveal whether this process of a M2 polarization of macrophages is mediated by cytokines and cell vesicles or other factors.

Weagel, E. G., et al. (2016). "Prostate cancer exosomes and their effects on macrophage engulfment and polarization." Cancer Research. Conference: 107th Annual Meeting of the American Association for Cancer Research, AACR **76**(14 Supplement).

The purpose of this study is to explore the effects of prostate cancer-derived exosomes on macrophage engulfment and polarization. Exosomes are small vesicles secreted by virtually all cells, which contain nucleic acids, lipids, proteins, and carbohydrates. Exosomes can be abundantly found in cancer patient secretions (serum, urine, etc.) and contain a high amount of RNA molecules, some of them being miRNA, and parts of the DNA of the cell of origin. One of the functions of exosomes is to mediate cellular communication. This occurs as they are secreted from one cell and then distribute their contents into other cells. Some exosomes specifically target immune cells. The miRNA the exosomes carry can silence genes involved in the activation of these immune cells, leading to immune suppression and tumor growth. Macrophages are often found surrounding the tumor microenvironment, as they are recruited by tumor signals to promote angiogenesis and metastasis. These macrophages, which are often called tumor associated macrophages (TAMs), are exposed to various signals derived from the tumor microenvironment, including exosomes. Previous data generated in our lab suggests that the co-culture of macrophages with PC3 and DU145 cell lines results in a decrease in macrophage phagocytosis and an M2-like polarization state. For this study, we exposed U937 cells to phorbol 12-myristate 13-acetate (PMA) for 24 hours to allow for differentiation. Then, we co-cultured these macrophages with isolated exosomes from spent media from both PC3 and DU145 cell lines at 1, 2, 3, 4, 5, 6, 12, and 24 hours. We then allowed the macrophages to phagocytose fluorescent microbeads for 1 hour. Flow cytometry analysis of these macrophages revealed that the total bead phagocytosis starts decreasing at 3 hours of exosome co-culture compared to control. Interestingly, total bead phagocytosis resumes to normal at 12 and 24 hours of exosome co-culture. Gene expression analysis of these macrophages suggests an M2 phenotype from hours 2-24. These results suggest that prostate cancer-derived exosomes can target macrophages and affect their phagocytosis. Further research is required to elucidate the specific genes these exosomes target.

Weaver, J. and C. Stabler (2012). "Free-radical scavenging cerium oxide nanoparticle hydrogels for cell encapsulation." Journal of Tissue Engineering and Regenerative Medicine **1)**: 276.

Cellular encapsulation is a promising strategy for shielding foreign cells from direct immune attack; however, it fails to prevent inflammation or indirect immune activation, which exposes embedded cells to oxidative stress. Cerium oxide nanoparticles, or nanoceria, are highly unique nanoparticles with the capacity to mimic free-radical scavenging enzymes in a ubiquitous and self-renewing manner. We sought to localize these nanoparticles within a biomaterial. In this study, we incorporated nanoceria within alginate hydrogels and evaluated their catalytic activity as well as their capacity to protect co-encapsulated cells from free radical damage. Nanoceria

was synthesized and evaluated via FTIR, DLS, and superoxide reduction. Nanoceria (0.01-1 mM) retained its catalytic activity within alginate microbeads, where it was found to effectively scavenge superoxide and degrade H<inf>2</inf>O<inf>2</inf> in the surrounding milieu. No cytotoxicity was found at <1.0 mM nanoceria. Nanoceriaalginate microbeads provided statistically significant protection (50% higher viability) of co-encapsulated MIN6 cells from superoxide-mediated cell death. Live/dead imaging qualitatively verified these results. Our data illustrates a novel, self-renewing, ubiquitous free-radical scavenging biomaterial with the demonstrated capacity to protect co-encapsulated cells from free-radical damage. It is envisioned that these materials would be highly beneficial for cell-based implants, particularly pancreatic beta cells.

Webb, S., et al. (2019). "Microplastics in the New Zealand green lipped mussel Perna canaliculus." Marine Pollution Bulletin **149**: 1.

Microplastics are increasingly being recognised as a potential threat to New Zealand's coastal waters, however there is limited data on abundance of microplastics in marine organisms for New Zealand. Microplastic ingestion by the iconic green-lipped mussel Perna canaliculus was assessed. Microplastics were found in Perna canaliculus from 6 out of 9 locations sampled at abundances ranging from 0 to 1.5 particles per mussel and tissue microplastic concentrations ranged from 0 to 0.48 particles g tissue-1 (wet wt). The microplastics ranged in size from 50 to 700 µm with a median diameter of 100 µm. Polyethylene was the most frequently detected polymer with fragments the most common morphotype. These results indicate that microplastics are widespread in New Zealand's coastal waters and further assessment of microplastic contamination of New Zealand coastal environments and biota is warranted.

Weber, A., et al. (2018). "PET microplastics do not negatively affect the survival, development, metabolism and feeding activity of the freshwater invertebrate Gammarus pulex." Environmental Pollution **234**: 181-189.

Over the past decade, microscopic plastic debris, known as microplastics, emerged as a contaminant of concern in marine and freshwater ecosystems. Although regularly detected in aquatic environments, the toxicity of those synthetic particles is not well understood. To address this, we investigated whether the exposure to microplastics adversely affects the amphipod Gammarus pulex, a key freshwater invertebrate. Juvenile (6-9 mm) and adult (12-17 mm) individuals were exposed to irregular, fluorescent polyethylene terephthalate fragments (PET, 10-150 micro m; 0.8-4,000 particles mL⁻¹) for 24 h. Results show that body burden after 24 h depends on the dose and age of G. pulex with juveniles ingesting more microplastics than adults. After chronic exposure over 48 d, microplastics did not significantly affect survival, development (molting), metabolism (glycogen, lipid storage) and feeding activity of G. pulex. This demonstrates that even high concentrations of PET particles did not negatively interfere with the analyzed endpoints. These results contradict previous research on marine crustaceans. Differences may result from variations in the exposure regimes (e.g., duration, particle concentrations), plastic characteristics (e.g., type, size, shape, additives) as well as the species-specific morphological, physiological and behavioral traits. As a detritivorous shredder G. pulex is adapted to feed on non-digestible materials and might, therefore, be less sensitive towards exposure to synthetic particles. Accordingly, we argue that the autecology needs to be taken into account and that research should focus on identifying traits that render species susceptible to microplastic exposure.

Weber, I., et al. (2016). "Ex vivo expansion of T lymphocytes induces substantial alterations in cell size and actin-binding cytoskeletal proteins." Transfusion Medicine and Hemotherapy **43 (Supplement 1)**: 71.

Background: The isolation of immune cells for cellular therapies often involves culture expansion steps, e.g. in the case of selection and amplification of antigen-specific T cell clones or the generation of chimeric antigen receptor-transduced (CAR) T cells. Reports have indicated that during ex vivo expansion, T lymphocytes and other cells can undergo functional impairment, e.g. in migration or antigen recognition which may affect their therapeutic efficacy. The impact of the culture step on actin-binding proteins, which are crucial for these functionalities, is so far not known. Method(s): We analyzed the expression of seven cytoskeletal proteins at the transcriptional and the protein level, including actin modifiers cofilin and profilin, actin branching/bundling partners alpha actinin and filamin A, as well as the linkage proteins between actin and integrin signalling complexes, paxillin, vinculin and talin. Transcription was quantified using qRT-PCR. Protein levels were measured by flow cytometry of permeabilized cells using fluorescence-labelled antibodies titrated to exceed the concentration of the recognized antigens. Cell size was determined by flow cytometry using calibrated microbeads. Result(s): Analysis of cell size during anti-CD3/antiCD28-induced ex vivo expansion of freshly isolated murine CD3+ T lymphocytes in RPMI/10% FCS 30U/ml Interleukin-2 indicated a duplication of the average cell diameter from 7 to 14 mum, and a concomitant increase in cell volume from approximately 179 to 1436 mum3 over the period of 7 days. At the same time, protein levels of all seven actin binding molecules remained constant on a per cell basis, indicating a relative decrease in the intracellular concentrations of these proteins. Moreover, mRNA levels relative to the housekeeping gene GAPDH were reduced 5-7 fold in the case of profilin, cofilin, filamin A and alpha actinin, and approximately 10-50 fold for paxillin, talin and vinculin. Conclusion(s): Ex vivo expansion protocols can induce major increases in size and intracellular volume of T lymphocytes. In parallel, amounts of functionally relevant actin-binding proteins such as profilin, cofilin, alpha actinin, filamin A, paxillin, vinculin and talin did not increase in parallel. Moreover, their transcription was strongly reduced. Our findings indicate that a cell culture step can induce abnormalities in proteins with key functions in the migration and function of T lymphocytes.

Wegner, A., et al. (2012). "Effects of nanopolystyrene on the feeding behavior of the blue mussel (Mytilus edulis L.)." Environmental Toxicology & Chemistry **31**(11): 2490-2497.

As the industrial production of nanoplastic and the degradation of microplastic into smaller particles at sea increase, the potential amount of nanoplastics in the marine environment rises. It has been reported that mussels uptake 100-nm polystyrene (PS) beads; to date, however, the effects of this uptake on the organism are unknown. In the present study, the authors investigated the effects of 30-nm PS on the feeding behavior of the blue mussel (Mytilus edulis) by exposing the organism to different nano PS and different algae (Pavlova lutheri) concentrations. The state of nano PS aggregation in the exposure medium was assessed using dynamic light scattering. In all treatments that contained nano PS, M. edulis produced pseudofeces. The total weight of the feces and pseudofeces increased with increasing nano PS and increasing algae concentration. Furthermore, M. edulis reduced its filtering activity when nano PS was present but still caused a decrease in the apparent nano PS concentration in the water. The presence of nano PS around the foot of M. edulis after the bioassay confirmed that the organism removed nano PS from the water. Chronic effect studies are therefore needed to investigate the effects of nanoplastics in M. edulis and possible consequences for its predators, including humans. Environ. Toxicol. Chem. 2012; 31: 2490-2497. © 2012 SETAC [ABSTRACT FROM AUTHOR]

Wei, T.-T. and Y.-H. Lin (2015). "A WASTE CATALYST FOR A HAZARDOUS CHLORINE - CONTAINING PLASTIC WASTE." Environmental Engineering and Management Journal **14**(9): 2127-2138.

The recycling of plastic waste is important both in the conservation of resources and the environmental protection. A plastic waste (PE/PP/PS/PVC) was pyrolyzed over a series of post-use FCC catalysts using a fluidizing reaction system similar to the FCC process operating isothermally at ambient pressure. Experiments carried out with these catalysts gave good yields of valuable hydrocarbons with differing selectivity in the final products dependent on reaction conditions. A model based on kinetic considerations associated with chemical reactions and catalyst deactivation in the catalytic degradation of plastics has been developed. Greater product selectivity was observed with a hybrid catalyst of MCM-41/Cat-R1 with more than 70.5 wt% olefins products. It is demonstrated that the catalytic degradation of post-consumer chloro-commingled plastics over these recycled catalysts coped with the utility of fluidizing cracking system was shown to be a useful method for the production of potentially valuable hydrocarbons.

Wei, W., et al. (2019). "Revealing the Mechanisms of Polyethylene Microplastics Affecting Anaerobic Digestion of Waste Activated Sludge." Environmental Science & Technology **53**(16): 9604-9613.

Polyethylene (PE) microplastics retained in sewage sludge inevitably enter the anaerobic digestion system. To date, no information has been reported on the mechanisms of PE microplastics affecting anaerobic digestion of waste activated sludge (WAS). This study evaluated the mechanisms using batch and continuous tests. Short exposure to PE microplastics at lower levels (i.e., 10, 30, and 60 particles/g-TS) did not significantly affect the methane production, but higher levels of PE microplastics (i.e., 100 and 200 particles/g TS) significantly (P = 0.006 and 0.0003) decreased methane production by 12.4-27.5%, with a lower methane potential and hydrolysis coefficient. In continuous test over 130 days, feeding WAS with 200 particles PE microplastics/g TS decreased vs destruction by up to 27.3% (P = 2.18 x 10⁻¹⁸) and resulted in a 9.1% (P = 0.002) increase in the volume of digested sludge for disposal. Correspondingly, the microbial community was shifted in the direction against anaerobic digestion. A mechanisms study revealed that the negative effect of PE microplastics was likely attributed to the induction of reactive oxygen species (ROS) rather than the released acetyl tri-n-butyl citrate. The generation of ROS caused a 7.6-15.4% reduction of cell viability, thereby restraining sludge hydrolysis, acidification, and methanogenesis.

Wei, W., et al. (2019). "Polyethylene terephthalate microplastics affect hydrogen production from alkaline anaerobic fermentation of waste activated sludge through altering viability and activity of anaerobic microorganisms." Water Research **163**: 114881.

Alkaline (especially pH 10) anaerobic fermentation of waste activated sludge (WAS) has been reported to be an effective approach for hydrogen production through inhibiting the homoacetogenesis and methanogenesis. However, the potential effect of the widespread microplastics in sludge on the performance of hydrogen production has never been reported. To fill this knowledge gap, the dominant polyethylene terephthalate (PET) microplastics in WAS were selected as the model microplastics to evaluate their influences on hydrogen production during alkaline anaerobic fermentation of WAS as well as the key mechanisms involved. Experimental results demonstrated that hydrogen production from WAS decreased in the presence of PET microplastics (i.e., 10, 30 and 60 particles/g-TS) compared to the control, with the hydrogen yield at 60 particles/g-TS being only 70.7+/-0.9% of the control. Although the hydrogen consumption (i.e., homoacetogenesis and methanogenesis) was restrained under alkaline (pH 10) condition, PET microplastics inhibited hydrolysis, acidogenesis and acetogenesis in alkaline WAS anaerobic fermentation, leading to the inhibitory effect on hydrogen production. This was further confirmed by the microbial analysis, which clearly showed PET microplastics caused the shift of the microbial community toward the direction against hydrolysis-acidification. Mechanism studies revealed that PET microplastics carried on their negative influence mainly through leaching the toxic di-n-butyl phthalate (DBP). The reactive oxygen species (ROS) and live/dead staining tests indicated that the increased ROS was induced by PET microplastics, causing more cells dead, which further resulted in the decreased production of hydrogen.

Weideman, E. A., et al. (2019). "Little evidence that dams in the Orange-Vaal River system trap floating microplastics or microfibres." Marine Pollution Bulletin **149 (no pagination)**(110664).

Rivers can be major sources of plastics into coastal seas, but it is unclear whether dams retain floating plastics, thus reducing the amount reaching the sea. To test if dams trap microplastics, we collected bulk water and neuston net samples from five dams on the Orange-Vaal River system, South Africa. Most manufactured items were microfibres and densities of microplastics were modest (bulk water: 0.21 +/- 0.27 items.L⁻¹; net: 0.04 +/- 0.16 items.m⁻²). There was an interaction between dam and season: dams on the densely populated Vaal River had higher microplastic concentrations during dry than wet conditions, whereas the opposite pattern occurred on the less industrialised Orange River. Overall there was no difference in microplastic concentration at sites above vs below dam walls nor was there a strong correlation between microplastic concentration and distance to the wall. Our results therefore suggest that dams do not trap floating microplastics or microfibres. Copyright © 2019 Elsevier Ltd

Weithmann, N., et al. (2018). "Organic fertilizer as a vehicle for the entry of microplastic into the environment." Science Advances **4**(4): eaap8060.

The contamination of the environment with microplastic, defined as particles smaller than 5 mm, has emerged as a global challenge because it may pose risks to biota and public health. Current research focuses predominantly on aquatic systems, whereas comparatively little is known regarding the sources, pathways, and possible accumulation of plastic particles in terrestrial ecosystems. We investigated the potential of organic fertilizers from biowaste fermentation and composting as an entry path for microplastic particles into the environment. Particles were classified by size and identified by attenuated total reflection-Fourier transform infrared spectroscopy. All fertilizer samples from plants converting biowaste contained plastic particles, but amounts differed significantly with substrate pretreatment, plant, and waste (for example, household versus commerce) type. In contrast, digestates from agricultural energy crop digesters tested for comparison contained only isolated particles, if any. Among the most abundant synthetic polymers observed were those used for common consumer products. Our results indicate that depending on pretreatment, organic fertilizers from biowaste fermentation and composting, as applied in agriculture and gardening worldwide, are a neglected source of microplastic in the environment.

Welden, N. A., et al. (2018). "The effects of trophic transfer and environmental factors on microplastic uptake by plaice, Pleuronectes plastessa, and spider crab, Maja squinado." Environmental Pollution **239**: 351-358.

Microplastic pollution is apparent throughout the marine environment from deep ocean sediments to coastal habitats. Most of this is believed to originate on land, although marine activities, such as fishing and shipping, also contribute to the release and redistribution of microplastic. The relative importance of these maritime plastic sources, the manner by which they are distributed in the environment, and their effect on uptake by marine organisms are yet to be fully quantified. In this study, the relative impact of fishing activities on microplastic uptake by demersal fish and crustaceans was explored. Local fishing intensity, proximity to land and mean water velocity are compared to microplastic uptake in plaice, Pleuronectes platessa, and spider crab, Maja squinado, from the Celtic Sea. Observations were also made of microplastic contamination in ingested sand eels, Ammodytes tobianus, to establish a potential route of trophic transfer. This study is the first to identify microplastic contamination in spider crab and to document trophic transfer in the wild. Individuals were sampled from sites of varied fishing intensity in the Celtic Sea, and their stomach contents examined for the presence of microplastic. Contamination was observed in 50% of P. platessa, 42.4% of M. squinado, and 44.4% of A. tobianus. Locations of highest plastic abundance varied between P. platessa and M. squinado, indicating that different factors influence the uptake of microplastic in these two taxa. No significant link was observed between fishing effort and microplastic abundance; however, proximity to land was linked to increased abundance in M. squinado and Observations of whole prey demonstrate ongoing trophic transfer from A. tobianus to P. platessa. The lack of significant difference in microplastic abundance between predator and prey suggests that microplastic is not retained by P. platessa.

Welden, N. A. and P. R. Cowie (2017). "Degradation of common polymer ropes in a sublittoral marine environment." Marine Pollution Bulletin **118**(1-2): 248-253.

Contamination by microplastic particles and fibres has been observed in sediment and animals sampled from the Firth of Clyde, West Scotland. In addition to microplastics released during clothes washing, a probable source is polymer ropes in abandoned, lost and discarded fishing and recreational sailing gear. The fragmentation of polypropylene, polyethylene, and nylon exposed to benthic conditions at 10 m depth over 12 months was monitored using changes in weight and tensile properties. Water temperature and light levels were continuously monitored. The degree of biofouling was measured using chlorophyll a, the weight of attached macroalgae, and colonising fauna. Results indicate microplastic fibres and particles may be formed in benthic environments despite reduced photodegradation. Polypropylene, Nylon, and polyethylene lost an average of 0.39%, 1.02%, and 0.45% of their mass per month respectively. Microscope images of the rope surface revealed notable surface roughening believed to be caused by abrasion by substrate and the action of fouling organisms. Copyright © 2017 Elsevier Ltd

Welden, N. A. C. and P. R. Cowie (2016). "Environment and gut morphology influence microplastic retention in langoustine, Nephrops norvegicus." Environmental Pollution **214**: 859-865.

Over the past twenty years microplastic pollution has been recorded in all major marine habitats, and is now considered to be of high environmental concern. Correspondingly, the number of reports of microplastic ingestion by marine species is increasing. Despite this, there are still relatively few studies which address the uptake and retention of microplastic in wild populations. Langoustine, Nephrops norvegicus, sampled from the Clyde Sea Area, have previously been seen to contain large aggregations of microplastic fibres. The large proportion

of contaminated individuals and size of the microplastic aggregations observed suggests that Nephrops are at high risk of microplastic ingestion. In this study the levels of ingested microplastic in populations of N. norvegicus from the Clyde Sea Area, North Minch and North Sea are examined. Animals in the near-shore, Clyde Sea population showed both a higher percentage of microplastic containing individuals and much greater weights of microplastic retained in the gut. N. norvegicus revealed that only a small percentage of individuals from the North Sea and Minch contained microplastic, predominantly single strands. An expanded sample from the Clyde Sea Area was examined to identify the factors influencing microplastic retention. This revealed that males, larger individuals, and animals that had recently moulted contained lower levels of microplastic. The presence of identified food items in the gut was not seen to correlate with microplastic loads. Observations of microplastic in the shed stomach lining of recently moulted individuals and the lack of aggregations in wild-caught individuals suggests that ecdysis is the primary route of microplastic loss by N. norvegicus. Therefore the large aggregations observed in wild-caught animals are believed to build up over extended periods as a result of the complex gut structure of N. norvegicus.

Welden, N. A. C. and P. R. Cowie (2016). "Long-term microplastic retention causes reduced body condition in the langoustine, Nephrops norvegicus." Environmental Pollution **218**: 895-900.
Microplastic represents a rising proportion of marine litter and is widely distributed throughout a range of marine habitats. Correspondingly, the number of reports of species containing microplastics increases annually. Nephrops norvegicus in the Firth of Clyde have previously been shown to retain large aggregations of microplastic fibres. The potential for N. norvegicus to retain plastic over an extended time period increases the likelihood of any associated negative impacts to the individual. This study represents the longest observation of the impacts of microplastic retention in invertebrates. We exposed N. norvegicus to plastic over eight months to determine the impacts of extended exposure. Over this period we compared the feeding rate, body mass, and nutritional state of plastic-fed N. norvegicus to that of fed and starved control groups. Following the experimental period, the plastic-fed langoustine contained microplastic aggregations comparable to those of small individuals from the Clyde Sea Area. Comparisons between fed, unfed and plastic-fed individuals indicated a reduction in feeding rate, body mass, and metabolic rate as well as catabolism of stored lipids in plastic contaminated animals. We conclude that N. norvegicus exposed to high levels of environmental microplastic pollution may experience reduced nutrient availability. This can result in reduced population stability and may affect the viability of local fisheries. [ABSTRACT FROM AUTHOR]

Welle, F. and R. Franz (2018). "Microplastic in bottled natural mineral water - literature review and considerations on exposure and risk assessment." Food Additives & Contaminants. Part A, Chemistry, Analysis, Control, Exposure & Risk Assessment **35**(12): 2482-2492.
Microplastics have been ubiquitously found and identified in aquatic and terrestrial environments for several years. Due to their occurrence in the oceans, microplastics were also found and characterised in seafood products and in other foods and beverages such as beer, honey and table salt. Very recently, microplastic particles were also determined in bottled

mineral water. The objective of this publication is to present and discuss a compilation of the currently available literature data on microplastics in bottled mineral water. The related oral exposure of the consumer from substances present in microplastics and from the plastics particles themselves is estimated and toxicological arguments for and considerations on risk assessment from the consumption of bottled mineral water containing microplastics are presented. Exposure estimations based on the reported microplastic amounts found in mineral water and the assumption of total mass transfer of small molecules like additives and oligomers present in the plastic would not raise a safety concern. Available toxicokinetic data suggests that marginal fraction of the ingested low amount of microplastics can be absorbed, if at all, the conclusion is very likely that the reported amounts present in bottled mineral water do not raise a safety concern for the consumer. Considering the use of plastic materials in our daily life, occurrence of microplastics in beverages is likely a minor exposure pathway for plastic particles. Due to recent progress in analytical methods and the public discussion on plastics marine litter, public concern about eating and drinking microplastics with food, and related safety issues was raised. However, a better data basis for exposure estimates and risk assessment would be very helpful to better accommodate consumer concerns. The intention of this paper is to deliver a contribution to this topic taking the bottled mineral water as a case example.

Wellhöner, H. H. and D. M. Neville (1987). "Tetanus toxin binds with high affinity to neuroblastoma x glioma hybrid cells NG 108-15 and impairs their stimulated acetylcholine release." The Journal of biological chemistry **262**(36): 17374-17378.

Differentiated neuroblastoma x glioma hybrid cells NG 108-15 express on their surface specific binding sites for tetanus toxin. 450 sites/cell with a KD of 2 x 10(-11) M were found under "physiological" conditions of pH and salt concentrations. A Hill coefficient of 1.1 indicated noncooperative binding. Specific binding of 125I-toxin to its sites could be prevented either by preincubation of the toxin with a neutralizing monoclonal antibody or by pretreatment of the cells with neuraminidase (Vibrio cholerae). To quantify the action of tetanus toxin on the stimulated release of 14C activity from differentiated cells preincubated with [14C]choline, a new type of perfusion device was designed which could be filled with cells growing in monolayers on Cytodex-3 microbeads. Tetanus toxin inhibited the stimulated 14C release in a time- and dose-dependent manner. A greater than 50% inhibition was found after 2 h of incubation with 10(-12) M toxin. The inhibitory action of tetanus toxin could be prevented with a monoclonal antibody to the toxin or with neuraminidase treatment of the cells. These results suggest that the neuraminidase-sensitive 2 x 10(-11) KD receptors are the productive receptors for tetanus intoxication in differentiated NG 108-15 cells. The possible chemical composition of these receptors is discussed. Differentiated NG 108-15 cells provide a useful model in which picomolar tetanus concentrations produce both measurable saturable binding and inhibition of potassium-evoked, acetylcholine release under physiological conditions of pH and salt concentrations.

Wen, B., et al. (2018). "Single and combined effects of microplastics and cadmium on the cadmium accumulation, antioxidant defence and innate immunity of the discus fish (Symphysodon aequifasciatus)." Environmental Pollution **243**(Part A): 462-471.

Microplastics (MPs) have the potential to interact with the toxicity of other common environmental contaminants, such as heavy metals. Here, we investigated the impacts of polystyrene-MPs (32-40 micro m), cadmium (Cd) and their combination on early juveniles of the discus fish (Symphysodon aequifasciatus) in relation to Cd accumulation, antioxidant defence and innate immunity. Animals were exposed to three concentrations of MPs (0, 50 or 500 micro

g L⁻¹) crossed with two levels of Cd (0 or 50 micro g L⁻¹) for 30 days. Our findings showed that MPs and Cd had no adverse effects on growth and survival. Under exposure to Cd, however, accumulation of Cd in the body of fish decreased with increasing MP concentrations as supported by a reduced metallothionein content. The activities of superoxide dismutase and glutathione peroxidase increased with MPs but decreased with Cd. MPs, Cd or the mixture increased catalase activity, despite an antagonistic interaction between the two stressors. Glutathione levels increased when exposed to high MP concentrations but decreased when co-exposed to Cd. Malondialdehyde content was only influenced by MPs and increased with elevated MPs. MPs or Cd alone did not increase protein carboxyl content but showed a synergistic effect and increased content. MPs or Cd alone showed no effect on lysozyme activity but had a synergistic effect and activated activity. Activities of both acid phosphatase and alkaline phosphatase were enhanced by MPs, Cd or their mixture, although there was an antagonistic interaction between the two stressors. In contrast, MPs, Cd or their mixture decreased complement 3 content, despite an antagonistic interaction between the two stressors. Collectively, this study suggests that exposure to Cd led to reduced Cd accumulation in the presence of MPs. Nevertheless, co-exposure could induce severe oxidative stress and stimulate innate immunity in the juvenile S. aequifasciatus.

Wen, B., et al. (2018). "Microplastics have a more profound impact than elevated temperatures on the predatory performance, digestion and energy metabolism of an Amazonian cichlid." Aquatic Toxicology **195**: 67-76.

Knowledge on the impacts of microplastics (MPs) pollution on freshwater environments and biota remains limited. Meanwhile, freshwater ecosystems have been threatened by elevated temperatures caused by climate change. To date, no information exists on how MPs - especially under elevated temperature conditions - affect predatory performance, digestive processes and metabolic pathways in freshwater organisms. Here, we examined MPs, elevated temperature and their combined effects on juveniles (0+ group) of an Amazonian cichlid, the discus fish (Symphysodon aequifasciatus). For 30 days, fish were exposed to ambient or elevated temperatures (i.e., 28 or 31 degrees C) in the absence or presence of MPs (i.e., 0 or 200 micro g/L). The following metrics were quantified: MPs accumulation; predatory performance; and biomarkers involved in neurotransmission, digestion and energy production. The results showed that survival rate and body length were not affected by MPs, elevated temperatures or their combination. Elevated temperatures resulted in an increase in MP concentrations in fish bodies. Exposure to MPs decreased the post-exposure predatory performance (PEPP) at ambient temperatures but not at elevated temperatures. Elevated temperatures, however, had no effect on the PEPP but antagonistically interacted with MPs, leading to similar predatory performances under present and future conditions. Acetylcholinesterase (AChE) activity was only affected by MPs and decreased in the presence of MPs, indicating adverse effects in nervous and neuromuscular function and, thus, potentially in predatory performance. Trypsin activity was only influenced by MPs and decreased during exposure to MPs. Elevated temperatures or MPs alone increased the amylase activity but interacted antagonistically. Lipase activity was not influenced by either of the two stressors. In contrast, alkaline phosphatase (ALP) activity was affected by MPs or elevated temperatures alone and decreased with both stressors. Such results indicate deficits in the digestive capabilities of early-stage S. aequifasciatus under elevated temperature conditions and especially during exposure to MPs. Electron transport system (ETS) activity was not influenced by either of the two stressors. Both elevated temperatures and MPs alone increased LDH activity; however, the interaction between the two stressors cancelled activity but was still higher than activity in present conditions. Citrate synthase (CS) activity

decreased with elevated temperature but increased during exposure to MPs. Cytochrome c oxidase (COX) activity was only influenced by MPs and increased in the presence of MPs. Thus, S. aequifasciatus juveniles exposed to elevated temperatures and MPs not only relied on anaerobic glycolysis for energy production but also depended on aerobic metabolism in the presence of MPs. Overall, these findings suggested that MPs showed a greater impact than elevated temperatures on the predatory performance, digestion and energy production of S. aequifasciatus. Nevertheless, juvenile survival and growth were minimally impacted, and thus, S. aequifasciatus could cope with near-future temperature increases and MP exposure.

Wen, X., et al. (2018). "Microplastic pollution in surface sediments of urban water areas in Changsha, China: Abundance, composition, surface textures." Marine Pollution Bulletin **136**: 414-423.

Microplastics pollution in the global marine environment has received much recent research attention. However, microplastics contamination of the freshwater environment has not been fully studied, especially with respect to the surface sediments of urban water areas in China. This study investigated surface sediment samples from twelve selected sites in Changsha, China. The average microplastic concentrations in the surface sediments of the urban water areas ranged from 270.17+/-48.23items.kg⁻¹ to 866.59+/-37.96items.kg⁻¹, and the highest concentration of microplastics was found in Yuejin Lake sediments. Most of the collected microplastics were transparent, and most were classified as fragments. Most microplastics (58.31%) were smaller than 1mm across all samples. Raman analysis indicated that polystyrene dominated the sediments samples. This study provided framework for future studies of microplastics pollution in the surface sediment of urban water areas in China.

Werth, A. J., et al. (2019). "Oil adsorption does not structurally or functionally alter whale baleen." Royal Society Open Science **6**(5): 182194.

Mysticete whales filter small prey from seawater using baleen, a unique keratinous oral tissue that grows from the palate, from which it hangs in hundreds of serial plates. Laboratory experiments testing effects of oils on material strength and flexibility, particle capture and tissue architecture of baleen from four mysticete species (bowhead, Balaena mysticetus; North Atlantic right, Eubalaena glacialis; fin, Balaenoptera physalus; humpback, Megaptera novaeangliae) indicate that baleen is hydrophilic and oleophobic, shedding rather than adsorbing oil. Oils of different weights and viscosities were tested, including six petroleum-based oils and two fish or plankton oils of common whale prey. No notable differences were found by oil type or whale species. Baleen did not adsorb oil; oil was readily rinsed from baleen by flowing water, especially from moving fringes. Microscopic examination shows minimal wrinkling or peeling of baleen's cortical keratin layers, probably due to oil repelling infiltrated water. Combined results cast doubt on fears of baleen fouling by oil; filter porosity is not appreciably affected, but oil ingestion risks remain. Particle capture studies suggest potentially greater danger to mysticetes from plastic pollution than oil.

Wesch, C., et al. (2016). "No microplastics in benthic eelpout (Zoarces viviparus): an urgent need for spectroscopic analyses in microplastic detection." Environmental Research **148**: 36-38.

Monitoring the ingestion of microplastics is challenging and suitable detection techniques are insufficiently used. Thus, misidentifying natural for synthetic microfibres cannot be avoided. As part of a framework to monitor the ingestion of microplastics in eelpout, this short report addresses the accurate identification of microfibres. We show that, following visual inspections, putatively synthetic microfibres are indeed of natural origin, as ascertained by spectrometric analyses. Consequently, we call for an inclusion of spectroscopic techniques in standardized microplastic monitoring schemes.

Wesch, C., et al. (2016). "Towards the suitable monitoring of ingestion of microplastics by marine biota: A review." Environmental Pollution **218**: 1200-1208.

Monitoring plastic ingestion in marine biota is a difficult task, especially regarding ubiquitous microplastics (particles of <5 mm). Due to their microscopic size, evidence for microplastic ingestion is often limited to laboratory studies. The following review provides a comparison and assessment of different microplastic ingestion monitoring procedures. Emphasis is given to the most important steps of current monitoring practice: (1) selecting suitable indicator species, (2) sampling and sample processing, (3) analytical procedures and (4) the prevention of secondary contamination of the sample. Moreover, an overview on ingestion records of microplastics by different marine feeding guilds is presented, including filter, suspension and deposit feeders as well as predators and scavengers. Lastly, monitoring processes are addressed critically in terms of their suitability for achieving the aims of an appropriate monitoring programme. Recommendations for future research priorities are presented with a focus on the necessity of standardised and comparable monitoring procedures in microplastic detection. Wesch, C., et al. (2017). "Assuring quality in microplastic monitoring: About the value of clean-air devices as essentials for verified data." Scientific Reports **7**(1): 5424.

Avoiding aerial microfibre contamination of environmental samples is essential for reliable analyses when it comes to the detection of ubiquitous microplastics. Almost all laboratories have contamination problems which are largely unavoidable without investments in clean-air devices. Therefore, our study supplies an approach to assess background microfibre contamination of samples in the laboratory under particle-free air conditions. We tested aerial contamination of samples indoor, in a mobile laboratory, within a laboratory fume hood and on a clean bench with particles filtration during the examining process of a fish. The used clean bench reduced aerial microfibre contamination in our laboratory by 96.5%. This highlights the value of suitable clean-air devices for valid microplastic pollution data. Our results indicate, that pollution levels by microfibres have been overestimated and actual pollution levels may be many times lower. Accordingly, such clean-air devices are recommended for microplastic laboratory applications in future research work to significantly lower error rates.

Wessel, C. C., et al. (2016). "Abundance and characteristics of microplastics in beach sediments: Insights into microplastic accumulation in northern Gulf of Mexico estuaries." Marine Pollution Bulletin **109**(1): 178-183.

Microplastics (plastic debris smaller than 5mm) represent a growing concern worldwide due to increasing amounts of discarded trash. We investigated microplastic debris on sandy shorelines at seven locations in a northern Gulf of Mexico estuary (Mobile Bay, AL) during the summer of 2014. Microplastics were ubiquitous throughout the area studied at concentrations 66-253x larger than reported for the open ocean. The polymers polypropylene and polyethylene were most abundant, with polystyrene, polyester and aliphatic polyamide also present but in lower quantities. There was a gradient in microplastic abundance, with locations more directly exposed to marine currents and tides having higher microplastic abundance and diversity, as well as a higher contribution by denser polymers (e.g. polyester). These results indicate that microplastic accumulation on shorelines in the northern Gulf of Mexico may be a serious concern, and suggest that exposure to inputs from the Gulf is an important determinant of microplastic abundance.

Westall, G. P., et al. (2011). "Detection of class I anti-HLA antibodies by Luminex pre-transplant predicts poor outcomes following lung transplantation." Journal of Heart and Lung Transplantation **1)**: S36.

Purpose: Solid phase assays detect anti-HLA antibodies with high accuracy and sensitivity, however debate continues on how these results should be interpreted in the setting of lung transplantation. Methods and Materials: We performed a retrospective analysis of pretransplant anti-HLA antibody levels detected using a solid-phase HLA microbead assay (Luminex) in 80 patients undergoing lung transplantation at a single centre between 1/1/09 and 1/5/10. All patients underwent prospective T-and B-cell crossmatches (complement-dependent cytotoxicity assays) prior to transplantation. Outcome variables analyzed included acute cellular and antibody-mediated rejection, BOS and survival. Result(s): Pre-transplant class I and class II anti-HLA antibodies were present in 31/80 (38%) and 13/80 (10%) patients, respectively, but did not predict a positive T-or B-cell crossmatch which was weekly positive in 1/80 and 14/80 patients, respectively. HLA class I and II donor-specific antibodies (DSA) were present pre-transplant in 13 and 7 patients, respectively. The presence pre-transplant of class I DSA, irrespective of a negative prospective T-and B-cell crossmatch predicted for a poor outcome (Odds ratio for BOS/death 4.6, p = 0.03). Pre-transplant DSA was not associated with the subsequent development of either acute cellular or antibody-mediated rejection. Only two patients developed clinically significant antibody-mediated rejection. Both developed DSA following transplant having not been present pre-transplant. Conclusion(s): Identifying DSA pre-transplant predicts poor outcomes posttransplant and provides prognostic information beyond that which has been historically provided by a negative prospective crossmatch. Future studies need to focus on defining the level of pre-transplant DSA as measured using solid phase assays that predict for adverse outcomes following lung transplantation.

Westerink, J., et al. (2014). "An oral mixed fat load is followed by a modest anti-inflammatory adipocytokine response in overweight patients with metabolic syndrome." Lipids **49**(3): 247-254.

We investigated the postprandial changes in plasma levels of adipocytokines in overweight patients with metabolic syndrome after an oral fat load. After an oral fat load and during a prolonged fast, blood was drawn at 0, 2, 3, 4 and 8 h for measurement of adiponectin, adipsin, cathepsin S, chemerin, hepatic growth factor, interferon-gamma-inducible protein-10, leptin, macrophage chemoattractant protein-1, macrophage migration inhibitory factor, nerve growth factor, retinol binding protein-4, resistin, serum amyloid A1, tissue inhibitor of metalloproteinase-1 and thrombopoietin using a microbead-based Luminex assay. Area under the curves (AUC) were calculated and compared. Plasma adiponectin levels were higher after an oral fat load compared to fasting at t = 2 h (950 +/- 513 vs. -1,881 +/- 713 ng/ml) while the plasma levels for adipsin (-9 +/- 5 vs. 16 +/- 5 ng/ml), chemerin (-122 +/- 35 vs. 13 +/- 21 ng/ml), SAA-1 (-391 +/- 213 vs. 522 +/- 173 ng/ml) and TPO (-335 +/- 144 vs. 622 +/- 216 ng/ml) were lower after an oral fat load compared to fasting. The baseline corrected AUC for IP-10 was higher after fat load compared to fasting (median -116 pg h/ml; IQR -270 to 10 vs. -21 pg h/ml; IQR -136 to 418 (p = 0.047). In conclusion, in overweight male subjects with the metabolic syndrome, an oral fat load is accompanied with a modest anti-inflammatory response of adipose tissue-derived adipocytokines.

Weston, M. C., et al. (2012). "Maximizing flow velocities in redox-magnetohydrodynamic microfluidics using the transient faradaic current." Analytical Chemistry **84**(21): 9402-9409.

There is a need for a microfluidic pumping technique that is simple to fabricate, yet robust, compatible with a variety of solvents, and which has easily controlled fluid flow.

Redox-magnetohydrodynamics (MHD) offers these advantages. However, the presence of high concentrations of redox species, important for inducing sufficient convection at low magnetic fields for hand-held devices, can limit the use of redox-MHD pumping for analytical applications. A new method for redox-MHD pumping is investigated that takes advantage of the large amplitude of the transient portion of the faradaic current response that occurs upon stepping the potential sufficiently past the standard electrode potential, Edegree, of the pumping redox species at an electrode. This approach increases the velocity of the fluid for a given redox concentration. An electronic switch was implemented between the potentiostat and electrochemical cell to alternately turn on and off different electrodes along the length of the flow path to maximize this transient electronic current and, as a result, the flow speed. Velocities were determined by tracking microbeads in a solution containing electroactive potassium ferrocyanide and potassium ferricyanide, and supporting electrolyte, potassium chloride, in the presence of a magnetic field. Fluid velocities with slight pulsation were obtained with the switch that were 70% faster than the smooth velocities without the switch. This indicates that redox species concentrations can be lowered by a similar amount to achieve a given speed, thereby diminishing interference of the redox species with detection of the analyte in applications of redox-MHD microfluidics for chemical analysis.

Wey, M. Y., et al. (1998). "Operating parameters of autothermal pyrolosis of plastic waste in a fluidized bed." Waste Management and Research **16**(1): 72-82.

In this study, polyethylene was pyrolysed in the fluidized-bed pyrolysis system in a limited oxygen supply. Thus, the heat to pyrolyse the polyethylene was made available by partial incineration of the polyethylene, which can be referred to as autothermal pyrolysis. The fluidized bed was selected as the reactor owing to its high capacity, homogeneity and low tar content. Experimental parameters evaluated included the effect of: (1) the pyrolysis temperatures; (2) the air factors; and (3) the catalyst on the liquid hydrocarbon (gasoline, diesel, fuel oil, residual) formation, and B.T.X. (benzene, toluene, xylene) concentration in gasoline. Moreover, the primary composition in gasoline was analyzed. The results indicated that it is practical to recover oil from plastic waste using the autothermal pyrolysis system.

Wey, M.-Y., et al. (1996). "A study of the autothermal pyrolysis of polyethylene wastes." Journal of the Chinese Institute of Environmental Engineering **6**(4): 349-357.

In this study, plastic waste (HDPE) was pyrolyzed in the fluidized-bed pyrolysis system with a limited oxygen supply. The heat for pyrolysis of mixed wastes was offered by the incineration of partial wastes. Experimental parameters included pyrolysis temperature (For both the main and secondary combustion chambers) and air factor. The effects of pyrolysis temperature and air factor on the production of liquid hydrocarbon (Gasoline, diesel, fuel oil, residue) and gas products were discussed. The B. T. X. concentrations and the H/C ratio in gasoline from the obtained liquid hydrocarbon were also discussed. The results indicated that the operating temperature (The dense bed and the freeboard) was significantly related to the air factor. The introduction of secondary air successfully promoted the secondary reaction. Higher operating temperatures enhanced the formation of lower boiling point oils (Gasoline, diesel). However, lower temperatures had the tendency to form higher molecular-weight hydrocarbons (i.e. fuel oils or heavy oils).

Wey, M.-Y., et al. (1998). "Operating parameters of autothermal pyrolysis of plastic waste in a fluidized bed." WASTE MANAGE. RES. **16**(1): 72-82.

In this study, polyethylene was pyrolyzed in the fluidized-bed pyrolysis system in a limited oxygen supply. Thus, the heat to pyrolyze the polyethylene was made available by partial incineration of the polyethylene, which can be referred to as autothermal pyrolysis. The fluidized bed was selected as the reactor owing to its high capacity, homogeneity and low tar content. Experimental parameters evaluated included the effect of: (1) the pyrolysis temperatures; (2) the air factors; and (3) the catalyst on the liquid hydrocarbon (gasoline, diesel, fuel oil, residual) formation, and B.T.X. (benzene, toluene, xylene) concentration in gasoline. Moreover, the primary composition in gasoline was analyzed. The results indicated that it is practical to recover oil from plastic waste using the autothermal pyrolysis system.

Wezel, A. v., et al. (2016). "Release of primary microplastics from consumer products to wastewater in the Netherlands. (Special Section: Plastic debris in the aquatic environment - mechanisms and implications.)." Environmental Toxicology and Chemistry **35**(7): 1627-1631.

The authors estimate the release of primary microplastics from consumer products - cosmetics and personal care products, cleaning agents, and paint and coatings - via sewage effluent as an expected relevant route to the marine environment. Total estimated concentrations in the 3 scenarios are 0.2 micro g/L, 2.7 micro g/L, and 66 micro g/L in sewage-treatment plant (STP) effluent, respectively. All product categories relevantly contribute. Predicted concentrations are compared with reported actual concentrations in STP effluents.

Whipple, S. D. (2015). "Letter to the Editor regarding "Simultaneous determination of residues in pollen and high-fructose corn syrup from eight neonicotinoid insecticides by liquid chromatography-tandem mass spectrometry"." Analytical and bioanalytical chemistry **407**(4): 1273.

Whitaker, D. R. and G. A. Strasdine (1963). "A multiple-column hydraulic method for fractionation of particles for chromatographic columns." Canadian Journal of Biochemistry **41**(5): 1105-1113.

An apparatus for fractionation of particles is described. Liquid at constant temperature is freed of air bubbles and circulated at constant flow rate through a series of vertical columns of progressively increasing diameters, a settling bottle, and a filter. The particles to be fractionated are either added gradually to the first column by passage of the return flow of liquid through a particle reservoir or are added at the outset to the first column. The flow of liquid distributes the particles between the columns according to particle size and density. Illustrative data are given for fractionation of a cross-linked dextran. a diatomaceous earth, a microbead ion-exchange resin, and a micropowder ion-exchange resin.

White, E. M., et al. (2018). "Ingested Micronizing Plastic Particle Compositions and Size Distributions within Stranded Post-Hatchling Sea Turtles." Environmental Science & Technology **52**(18): 10307.

From July 2015 to November 2016, 96 post-hatchling sea turtles were collected from 118 km of the Atlantic coastline in Florida, USA, including loggerhead, green, and hawksbill sea turtle species. Forty-five of the recovered turtles were rehabilitated and released, but the remaining 52 died and were frozen. At necropsy, the gastrointestinal tracts of most the turtles contained visible plastic, and collected particles of 27 individuals were chemically characterized by Raman microscopy as polyethylene, polypropylene, polyethylene terephthalate, and polystyrene. Mesoparticle plastic fragments 1.0–8.7 mm, microparticle fragments 20–1000 µm, and nanoparticles 5–169 nm were identified in the turtles. Polyethylene and polypropylene were the most common plastics ingested from specimens representing 54.1 and 23.7% of the total observed mesoparticles and 11.7 and 21.0% of the total observed microparticles, respectively. A plastic-to-body mass ratio of 2.07 mg/g was determined for this group. The authors suggest that ingestion of micronizing plastic by post-hatchling sea turtles is likely a substantial risk to survival of these endangered and threatened species. This study also provides some of the first evidence for the formation of nanoscopic plastic particles that we theorize forms in the post-hatchling and juvenile environment and are present post-ingestion.

Whitehouse, S. (2019). "We Can No Longer Ignore Our Oceans." Sea Technology **60**(1): 11-12.
Every day now, it seems we see news headlines spelling out the end of the oceans as we know them. Whether from pollution, warming, acidification, deoxygenation or other troubling consequences of climate change and overuse, the warnings from our oceans are dire. However, their fate is not yet sealed. There is hope. There are steps we can and must take to save our seas. One of our longstanding priorities has been combating the growing marine debris crisis. Each year, nearly 8 million metric tons of plastics enter the oceans from land. Once in the ocean, this plastic breaks down under the sun and waves into tiny particles that can enter the marine food web. Recent research has found these microplastics in a wide range of food and beverages that humans ingest, from seafood to bottled water to table salt.

Whyte, C. (2019). "Banned toxins still threaten dolphins." New Scientist **241**(3213): 8-8.
The article discusses research which indicates that the industrial toxins known as polychlorinated biphenyls (PCBs), which were banned more than 30 years ago, are still threatening dolphins in the Gulf of Trieste region as of 2017, and it mentions how the use of PCBs in the Mediterranean Sea area is impacting bottlenose dolphins. Plastic pollution and PCB contamination in ringed seals are addressed, along with the relationship between water-based shipping and dolphin populations.

Whyte, M., et al. (2010). "Systemic biomarker profiling of metabolic and dysplastic skeletal diseases using multiplex serum protein analyses." Journal of Bone and Mineral Research **1)**: S137.
Understanding the etiology and pathogenesis of dysplastic and metabolic bone diseases has come from both genetic and biochemical investigation. Here, we describe our approach to systemic biomarker profiling using multiplex serum protein analyses to study age- and disease-mediated changes in healthy controls and patients as well as family members with these disorders. The Research Center at Shriners Hospital for Children, St. Louis, Missouri, serves as a national referral center for inpatient diagnosis, treatment, and investigation of pediatric dysplastic, nutritional, and metabolic bone disorders where collection of fasting blood is routine. At Amgen (Thousand Oaks, California), Luminex-based, micro-bead, multiplex kits are used for osteopontin, osteocalcin, ligand of receptor activator NF-kB (RANKL), osteoprotegerin (OPG), fibroblast growth factor 23 (FGF23), matrix metalloproteinases (MMP 1, 3, 7, 8, and 13), and cytokine quantitation. ELISA kits are used for prostaglandin E2 (PGE2), bone-specific alkaline phosphatase (BAP), tartrate-resistant acid phosphatase (TRACP 5B), and collagen formation/degradation markers. Serum levels of sclerostin (SOST) and dickkopf (DKK1) were evaluated by custom ELISAs (developed at Amgen, Inc). All sera were obtained after donors fasted at least 4 hours. To establish reference ranges, we studied 9 healthy children and 18 healthy adults (ages 6-60 yrs). MMPs (1, 3, 7, 8, and 13) correlated positively with age (R² 0.26 - 0.64, p<0.05), whereas osteocalcin, BAP, c-terminal propeptide of collagen type I (CICP), and TRACP 5B correlated negatively (R² 0.23 - 0.71, p<0.05). The patients represented 30 established and 14 unique diagnoses. Affected family members (dominant disorders) and obligate carriers (recessive disorders) were also studied, reflecting a

total of 110 individuals. Our analyses revealed that serum concentrations of FGF23 were significantly increased in x-linked hypophosphatemia (XLH), TRACP 5B in osteopetrosis, and RANKL in juvenile Paget's disease, whereas decreases in BAP were documented for hypophosphatasia, validating our array strategy. Hence, our multiplex serum protein analyses could reveal unique markers for specific bone disorders, and enhance understanding for a wide range of skeletal diseases.

Wichai-utcha, N. and O. Chavalparit (2019). "3Rs Policy and plastic waste management in Thailand." The Journal of Material Cycles and Waste Management **21**(1): 10.

Plastic has become an important and integral part of society throughout the world due to its various applications, such as packaging, agriculture, automobile parts, electronic applications and medical devices. The plastic fabrication process can be modified to form various shapes, colors and specifications according to customer needs. Consequently, the amount of plastic waste is increasing due to the increase in plastic consumption because of the increasing population. Moreover, the problem of marine plastic debris is on the rise globally, including in Thailand, which results from the irresponsibility of mankind. Generally, plastic waste in Thailand can be generated from industrial processes and households. These two waste sources have caused the rise in plastic waste, which has contributed to the problem of waste management in Thailand. Additionally, Thailand is one of the contributors to the leakage of plastic waste into the ocean, which results from inefficient waste management. To reduce the impacts of plastic waste, effective measures have to be applied, such as reducing, reusing and recycling (3Rs) or energy recovery from plastic wastes. To ensure the proper management of solid waste, Thailand has established the National 3R Strategy and the National Master Plan for Waste Management (2016–2021). Furthermore, Thailand also launched a “Plastic Debris Management Plan 2017–2021”, which comprises several approaches, such as promotion and introduction of eco-packaging design and eco-friendly plastic substitution, development of the material flow for plastic containers and packaging inventory, implementation of the 3Rs (reduce–reuse–recycle) strategy for plastic debris management, and the promotion of education for relevant stakeholders in the field of plastics and its alternative materials. In addition, the options to create more effective plastic waste management are to implement legislation or revise the laws to improve the efficiency and reduce the amount of plastic waste, such as imposing plastic bag fees, strengthening the 3Rs measures, and encouraging the implementation of a circular economy in plastic value chains.

Wieczorek, A. M., et al. (2019). "Microplastic Ingestion by Gelatinous Zooplankton May Lower Efficiency of the Biological Pump." Environmental Science and Technology **53**(9): 5387-5395.

The impacts of microplastics on some individual organisms have been well studied but what is less clear is what impacts microplastics have on wider ecosystem processes. Using salps as model organisms, we studied the effect of microplastic ingestion on the downward flux of high-density particulate organic matter in the form of salp faecal pellets. While to date most microplastic studies used virgin microplastics at unrealistic environmental concentrations here we exposed Salpa fusiformis to fractured and UV exposed polyethylene and polystyrene microplastics possessing a biofilm. It was found that when exposed to environmentally relevant concentrations, reported for the Mediterranean and the South Pacific Gyre, only few faecal pellets had microplastics incorporated within them. Under potential future scenarios, however, up to 46% of faecal pellets contained microplastics. Incorporated microplastics significantly altered the size, density and sinking rates of salp faecal pellets (p-value < 0.05 in each instance). Sinking rates decreased by 1.35-fold (95% CI = 1.18, 1.56) for faecal pellets with polyethylene microplastics and 1.47-fold (95% CI = 1.34, 1.61) for polystyrene. These results suggest that today, microplastic ingestion by salps has minimal impact on the biological pump. However, under future microplastic concentrations (or in areas such as convergent zones), microplastics may have the potential to lower the efficiency of the biological pump. Wierckx, N., et al. (2015). "Plastic waste as a novel substrate for industrial biotechnology." Microbial Biotechnology **8**(6): 900-903.

Wierckx, N., et al. (2015). "Plastic waste as substrate for biotechnology." Microbial Biotechnology **8**(6): 900-903.

[...]polyethylene (the most used plastic, ca. 140 million tons per year), is considered to be practically inert and its recycling (other than its downcycling into lumber) is economically unfavourable (Sivan,), thereby creating a phenomenal environmental impact, especially in marine environments (Cozar et al., 2014; 2015). [...]this genus includes some of the most efficient PU degraders known, enabling growth rates on polymeric substrates that rival the rates on many conventional substrates (Howard and Blake,). [...]given the relatively simple and defined composition of plastics compared with biomass, as well as their extreme abundance, it is surprising that this resource has thus far gone mostly unnoticed as a biotechnology feedstock. When successful, plastic-upcycling through biotechnology will increase resource efficiency through the valorization of high-volume waste streams, while also helping to reduce the burden on terrestrial resources that are needed to supply food to the world's human population. [...]through microbial biotechnology, the hereto proposed plastic waste to plastic value workflow will enable new value chains across sectors including materials, chemicals and environmental technologies within the framework of a sustainable knowledge-based bio-economy, with tangible benefits to the environment and society.

Wiewel, B. V. and M. Lamoree (2016). "Geotextile composition, application and ecotoxicology-A review." Journal of Hazardous Materials **317**: 640-655.

Geosynthetics is the umbrella term for thin, flexible material sheets applied in civil and environmental engineering, of which geotextiles form the largest group. Most geotextiles consist of a polymer from the polyolefin, polyester or polyamide family, and additives to improve their stability. The polymer may degrade into microplastic particles over time and under various conditions and can cause adverse effects, as species may ingest these particles or encounter adverse effects due to the interference of the particles with e.g. their photosynthesis system in the case of algae. Leaching of additives may occur from the intact material, as they are often not covalently bound to the polymer backbone, but is greatly enhanced when micro-sized plastic particles have been formed. A total of 42 polymer additives were identified, of which 26 had ecotoxicity information available in terms of a REACH persistence, toxicity and bioaccumulation (PBT) assessment. Of these, 15 were classified as (very) persistent and 2 as toxic. A survey to assess potential toxicity of the remaining 16 substances revealed that no ecotoxicity studies had been performed on 13 of these compounds. For 3 compounds, other toxicity data was found, as well as of several chemical groups known to be used as additives in geotextiles. The current knowledge is thus lacking in two domains: on the one hand, ecotoxicity data is scarce as many substances have not yet been the subject of ecotoxicological studies. On the other hand, in situ toxic effects might be missed by the current approach of single compound toxicity testing. Moreover, environmental occurrence data of the additives are extremely scarce. Wiggin, K. J. and E. B. Holland (2019). "Validation and application of cost and time effective methods for the detection of 3-500mum sized microplastics in the urban marine and estuarine environments surrounding Long Beach, California." Marine Pollution Bulletin **143**: 152-162.

Microplastics (MP) are detected in aquatic environments worldwide, yet detection is often limited to larger sized MP. To address this data gap, the abundance of MP 3-500mum was assessed in the Los Angeles River, the San Gabriel River, and the Long Beach Harbor (CA, USA), three areas with highly urbanized surroundings. Whole surface water samples were taken, subjected to a hydrogen peroxide digestion and MP counts were compared between unstained visual examination and Nile Red staining identification techniques. The largest concentration of MP was found in the Los Angeles River, where 13,622 MP m⁻³ were found using unstained visual examination and 641,292 MP m⁻³ were found utilizing Nile Red staining. The protocol used to detect smaller sized MP is low cost, time efficient, and reproducible. This work highlights the need for more extensive sampling of smaller sized MP globally and universal testing and reporting standards for MP detection.

Wijesekara, H., et al. (2018). "Trace element dynamics of biosolids-derived microbeads." Chemosphere **199**: 331-339.

This study focused on quantifying and characterising microbeads in biosolids (i.e., treated sewage sludge), and in examining interactions of microbeads with trace elements when biosolids are added to soil. Under laboratory conditions, batch experiments were conducted to investigate the adsorption of Cu onto pure and surface modified microbeads suspended in soil. The ecotoxicity of microbead-metal complexes to soil microbial activities was also investigated by monitoring basal respiration and dehydrogenase activity. Concentrations of the microbeads were 352, 146, 324, and 174 particles kg⁻¹ biosolids for <=50, 50-100, 100-250, 250-1000mum size fractions, respectively. The Scanning Electron Microscope (SEM) images illustrated wrinkled and fractured surfaces due to degradation. The adsorption of dissolved organic matter onto microbeads was confirmed through FT-IR microscopy, while using Inductively Coupled Plasma Mass Spectrometer (ICP-MS) the presence of trace metals including Cd (2.34ngg⁻¹), Cu (180.64ngg⁻¹), Ni (12.69ngg⁻¹), Pb (1.17ngg⁻¹), Sb (14.43ngg⁻¹), and Zn (178.03ngg⁻¹) was revealed. Surface modified microbeads were capable of adsorbing Cu compared to the pure microbeads, which may be attributed to the complexation of Cu with dissolved organic matter associated with the microbeads in the matrix. It was further revealed that the biosolids derived microbead-metal complexes decreased soil respiration (up to~26%) and dehydrogenase activity (up to~39%). Hence, microbeads reaching biosolids during wastewater treatment are likely to serve as a vector for trace element contamination, transportation, and toxicity when biosolids are applied to soil.

Wilcox, C., et al. (2020). "Abundance of Floating Plastic Particles Is Increasing in the Western North Atlantic Ocean." Environmental Science & Technology **08**: 08.

Since the start of commercial plastics production in the 1940s, global production has rapidly accelerated, doubling approximately every 11 years. Despite this increase and clear evidence of plastics loss into the oceans, including a substantial standing stock, previous research has not detected a temporal trend in plastic particle concentration in the surface ocean. Using a generalized additive statistical model, we examined the longest data set on floating plastic debris available globally, collected using plankton nets in the western North Atlantic from 1986 to 2015. There was a significant increasing temporal trend in plastic particle concentration that tracked cumulative global plastics production. We estimated an increase of 506,000 tons of floating plastic in the ocean in 2010 alone or 0.2% of global production. Our results suggest that, while loss of plastic particles from the surface ocean undoubtedly occurs, the input exceeds the collective losses.

Wilcox, C., et al. (2016). "Using expert elicitation to estimate the impacts of plastic pollution on marine wildlife." Marine Policy **65**: 107-114.

Marine litter is a growing environmental concern. With the rapid increase in global plastics production and the resulting large volume of litter that enters the marine environment, determining the consequences of this debris on marine fauna and ocean health has now become a critical environmental priority, particularly for threatened and endangered species. However, there are limited data about the impacts of debris on marine species from which to draw conclusions about the population consequences of anthropogenic debris. To address this knowledge gap, information was elicited from experts on the ecological threat (both severity and specificity) of entanglement, ingestion and chemical contamination for three major marine taxa: seabirds, sea turtles and marine mammals. The threat assessment focused on the most common types of litter that are found along the world's coastlines, based on data gathered during three decades of international coastal clean-up efforts. Fishing related gear, balloons and plastic bags were estimated to pose the greatest entanglement risk to marine fauna. In contrast, experts identified a broader suite of items of concern for ingestion, with plastic bags and plastic utensils ranked as the greatest threats. Entanglement and ingestion affected a similar range of taxa, although entanglement was rated as slightly worse because it is more likely to be lethal. Contamination was scored the lowest in terms of impact, affecting a smaller portion of the taxa and being rated as having solely non-lethal impacts. This work points towards a number of opportunities both for policy-based and consumer-driven changes in plastics use that could have demonstrable affects for a range of ecologically important taxa that serve as indicators of marine ecosystem health.

Wilcox, C., et al. (2015). "Threat of plastic pollution to seabirds is global, pervasive, and increasing." Proceedings of the National Academy of Sciences of the United States of America **112**(38): 11899-11904.

Plastic pollution in the ocean is a global concern; concentrations reach 580,000 pieces per km² and production is increasing exponentially. Although a large number of empirical studies provide emerging evidence of impacts to wildlife, there has been little systematic assessment of risk. We performed a spatial risk analysis using predicted debris distributions and ranges for 186 seabird species to model debris exposure. We adjusted the model using published data on plastic ingestion by seabirds. Eighty of 135 (59%) species with studies reported in the literature between 1962 and 2012 had ingested plastic, and, within those studies, on average 29% of individuals had plastic in their gut. Standardizing the data for time and species, we estimate the ingestion rate would reach 90% of individuals if these studies were conducted today. Using these results from the literature, we tuned our risk model and were able to capture 71% of the variation in plastic ingestion based on a model including exposure, time, study method, and body size. We used this tuned model to predict risk across seabird species at the global scale. The highest area of expected impact occurs at the Southern Ocean boundary in the Tasman Sea between Australia and New Zealand, which contrasts with previous work identifying this area as having low anthropogenic pressures and concentrations of marine debris. We predict that plastics ingestion is increasing in seabirds, that it will reach 99% of all species by 2050, and that effective waste management can reduce this threat.

Wildemann, M., et al. (2013). "Fossil fuel derived particulate matter (PM10) induces maturation and aryl hydrocarbon receptor (AhR) signalling in human dendritic cells." Immunology **1)**: 33.

Background and Aims: Inhalation of fossil fuel derived air pollution particles (PM10) is linked with respiratory and systemic inflammatory diseases including asthma. Causative mechanisms are unknown but may relate to immunological effects of the complex mixture of biologically active materials, including endotoxins and aromatic hydrocarbons, associated with PM10. Respiratory dendritic cells (DCs) sample and shape responses to inhaled antigen and particulate matter is present within antigen presenting cells in the airway of individuals exposed to pollution. We therefore hypothesize that exposure of DCs to the complex signals in fossil fuel PM10 enhances their ability to induce inflammatory responses. To begin to test this concept we have examined the effects of PM10 from an urban UK environment on DC activation. Method(s): Monocytes were separated from healthy volunteer peripheral blood mononuclear cells by positive selection with anti-CD14 microbeads and differentiated into DCs in the presence of GM-CSF and IL-4. Cells were exposed for 48 h to: (i) PM10; (ii) baked carbon black (CB) as a particulate control; (iii) E. coli lipopolysaccharide (LPS) as a positive control for DC activation; (iv) FICZ, an agonist of the aryl hydrocarbon receptor (AhR); or (v) medium alone, in the presence or absence of the AhR antagonist CH223191. DC activation markers were measured by flow cytometry, gene expression by qRT-PCR and stimulatory capacity in a mixed leukocyte reaction using naive CD4 T cells. Result(s): PM10, but not CB, induced DC maturation as indicated by dose-dependent upregulation of HLA-DR, CD40, CD86 and CCR7. DC activation by PM10 at 25 mug/ml was broadly equivalent to that induced by 0.01 mug/ml LPS although there was a non-significant trend toward more induction of CCR7 by PM10. In accordance with their mature phenotype, DCs treated with PM10 were more stimulatory for naive T cells at low DC concentrations. Irrespective of stimulation, DCs expressed similar levels of AhR. However, PM10, but not LPS or CB, induced expression of the AhR-regulated gene CYP1A1 although this expression was less than that induced by the classical AhR agonist FICZ. PM10 also induced CYP1B1 and indoleamine 2,3 dioxygenase 1 (ID01) expression and induction of all these AhR regulated genes was inhibited with CH223191, confirming dependence upon AhR signalling. Conclusion(s): Fossil fuel derived PM10 particles induce a complex programme of DC activation that includes both induction of classical maturation and AhR signalling. How these pathways interact to influence DC function and immune regulation in the human airway is under investigation.

Wilflingseder, P. (1977). "[Augmentation mammoplasty (author's transl)]." Langenbecks Archiv fur Chirurgie **345**: 163-172.

Three distinct methods have proved practicable: The dermafat-transposition (DeCholnoky), the skin flap procedures, and the retromammary implants. The motivation of the patient must be carefully balanced against various complications. Frequently a constrictive fibrosis impairs the primary pleasant shape, position, and consistency of the breasts soon or many years after implantation of soft polydimethylsiloxane material, due to phagocytosis and decomposition of plastic particles. Capsulotomy, capsulectomy, or squeezing of the implants can regain approximately the original good appearance, but does not solve the problem of continuous foreign body reaction. The malignancy risks require close follow-up examinations.

Wilkens, J. L., et al. (2020). "Initial Survey of Microplastics in Bottom Sediments from United States Waterways." Bulletin of Environmental Contamination & Toxicology **104**(1): 15-20.

Given the reported extent of microplastics in the aquatic environment, environmentally relevant exposure information for sediments dredged by the US Army Corps of Engineers will lend context to the risks posed by this contaminant during dredging. We measured the occurrence, abundance, and polymer composition of microplastics in sediments collected from nine dredged waterways and two non-dredged reference areas. The number of particles in sediment samples ranged from 162 to 6110 particles/kg dry wt., with a mean of 1636 particles/kg dry wt. Fragments were the most prevalent shape observed among the 11 study sites (100% frequency of occurrence), followed by fibers (81%), spheres (75%), foams (38%) and films (34%). Based on analyses of chemical composition of the particles using Fourier transform infrared spectroscopy, polyethylene:propylene was the most common polymer type observed. Consistent with results presented by other investigators, microplastic concentrations and polymer types in bottom sediments in this study were also aligned with the most widely used plastics worldwide.

Wilkinson, J., et al. (2017). "Occurrence, fate and transformation of emerging contaminants in water: An overarching review of the field." Environmental Pollution **Part 1. 231**: 954-970.

Many of the products and drugs used commonly contain chemical components which may persist through sewage treatment works (STW) and eventually enter the aquatic environment as parent compounds, metabolites, or transformation products. Pharmaceuticals and personal care products (PPCPs) and other emerging contaminants (ECs) have been detected in waters (typically ng/L) as well as more recently bound to sediment and plastic particles (typically ng/g). Despite significant advancement of knowledge since the late 1990s, the fate of these contaminants/transformation products once introduced into the aquatic environment remains relatively unresolved. This review provides a unique focus on the fate of seven major groups of PPCPs/ECs in the aquatic environment, which is frequently not found in similar works which are often compound or topic-specific and limited in background knowledge. Key findings include: a) some replacements for regulation precluded/banned chemicals may be similarly persistent in the environment as those they replace, b) the adsorption of potentially bioactive chemicals to micro- and nanoplastics is a significant topic with risks to aquatic organisms potentially greater than previously thought, and c) micro-/nanoplastics are likely to remain of significant concern for centuries after regulatory limitations on their use become active due to the slow degradation of macro-plastics into smaller components. An interdisciplinary perspective on recent advances in the field is presented here in a unique way which highlights both the principle science and direction of research needed to elucidate the fate and transport patterns of aquatic PPCPs/ECs. Unlike similar reviews, which are often topic-specific, here we aim to present an overarching review of the field with focus on the occurrence, transformation and fate of emerging contaminants. Environmental presence of seven major classes of contaminants (analygesics, antibiotics, antineoplastics, beta-blockers, perfluorinated compounds, personal care products and plasticisers), factors affecting contaminant fate, association with plastic micro-/nanoparticles and photochemical transformation are comprehensively evaluated. Copyright © 2017 Elsevier Ltd

Willems, S. B. J., et al. (2019). "On-Flow Immobilization of Polystyrene Microspheres on beta-Cyclodextrin-Patterned Silica Surfaces through Supramolecular Host-Guest Interactions." Acs Applied Materials & Interfaces **11**(39): 36221-36231.

Species-specific isolation of microsized entities such as microplastics and resistant bacteria from waste streams is becoming a growing environmental challenge. By studying the on-flow immobilization of micron-sized polystyrene particles onto functionalized silica surfaces, we ascertain if supramolecular host-guest chemistry in aqueous solutions can provide an alternative technology for water purification. Polystyrene particles were modified with different degrees of adamantane (guest) molecules, and silica surfaces were patterned with beta-cyclodextrin (beta-CD, host) through microcontact printing (muCP). The latter was exposed to solutions of these particles flowing at different speeds, allowing us to study the effect of flow rate and multivalency on particle binding to the surface. The obtained binding profile was correlated with Comsol simulations. We also observed that particle binding is directly aligned with particle's ability to form host-guest interactions with the beta-CD-patterned surface, as particle binding to the functionalized glass surface increased with higher adamantane load on the polystyrene particle surface. Because of the noncovalent character of these interactions, immobilization is reversible and modified beta-CD surfaces can be recycled, which provides a positive outlook for their incorporation in water purification systems.

Williams, A. (2018). "Centerpiece: Region moves to rein in single-use plastic." EcoAmericas **20**(12): 6.

Early last year the United Nations came as close as a peacekeeping organization can to declaring war. The enemy: ocean plastic. It is past time that we tackle the plastic problem that blights our oceans, Erik Solheim, head of UN Environment, the UN's environmental-protection arm, said at the Feb 23, 2017 launch of the initiative, called the Clean Seas Campaign. Plastic pollution is surfing onto Indonesian beaches, settling onto the ocean floor at the North Pole and rising through the food chain onto our dinner tables. We've stood by too long as the problem has gotten worse. It must stop. As Solheim acknowledged, the campaign was late in coming. Since the early 2000s, countries, nongovernmental organizations and international environmental bodies have called for action to reduce the relentless global production, use and improper disposal-often in waterways leading to the sea-of plastic. The UN estimates that in all, some 13 million tons of plastic enter the world's oceans each year.

Williams, J. L., et al. (2008). "Lairage during transport of eighteen-kilogram pigs has an impact on innate immunity and commensal bacteria diversity in the intestines." Journal of Animal Science **86**(5): 1232-1244.

Long distance transportation may affect the health of pigs; thus, adding a rest stop (lairage) during long journeys may improve their well-being. The objective of this study was to determine whether a mid-journey lairage influenced swine innate immunity and intestinal microbial populations after a 16-h transport. Four replications were conducted, 1 in each of 4 seasons. Eighteen-kilogram pigs were housed in 16 pens (13 to 16 pigs/pen) with 8 pens/treatment. Lairage pigs were transported for 8 h, given a rest with food and water for 8 h, then transported for an additional 8 h. Continuous pigs were continuously transported for 16 h. Jugular blood samples and intestinal tissue and contents were collected from 16 pigs (8/treatment) on d 1, 3, 7, and 14 posttransport. Hematocrit and white blood cell counts were determined and neutrophil cell functions, including phagocytosis/oxidative burst and phagocytosis of latex beads and leukocyte phenotypic cell markers (CD14 and CD18), were analyzed using flow cytometry. Expression of toll-like receptors 2, 4, and 5; IL-8 (a cytokine that is a chemoattractant for neutrophils); CCL20 (a chemokine that is a chemoattractant for dendritic cells); and the antimicrobial peptide PR39 were determined from ileal and jejunal total RNA. Denaturing gradient gel electrophoresis was used to determine shifts in intestinal microbial populations. Total white blood cell and granulocyte counts in continuous pigs were greater ($P<0.01$) on d 1 than in lairage pigs. Phagocytosis of microbeads was greater in continuous ($P<0.05$) than in lairage pigs on d 7. Expression of IL-8 in jejunum was greater ($P<0.05$) for continuous than for lairage pigs on d 1. Expression of CCL20 in the ileum was greater ($P<0.05$) on d 14 for the continuous pigs. Expression of PR39 was greatest ($P<0.05$) in the jejunum of lairage pigs on d 3.

Lairage pigs had a greater ($P<0.05$) variation in microbial populations (lower similarity coefficient) in the jejunum contents on d 1 and 7, in the cecum contents and tissue on d 3, and in the jejunum contents and tissue on d 14. However, continuous pigs had greater ($P<0.05$) variation in the ileal tissues on d 14. This study indicates that adding a lairage to an extended transport alters immune functions, receptor, cytokine and chemokine expression, and gut microbiota compared with pigs transported for 16 h without lairage.

Williams, P. T. and E. Slaney (2007). "Analysis of products from the pyrolysis and liquefaction of single plastics and waste plastic mixtures." Resources, Conservation & Recycling **51**(4): 754-769.

Abstract: Waste plastics in the form of two examples of real world municipal solid waste plastics and a simulated mixture of municipal waste plastics were pyrolysed and liquefied under moderate temperature and pressure in a batch autoclave reactor. In addition, the five main polymers which constitute the majority of plastics occurring in European municipal solid waste comprising, polyethylene, polypropylene, polystyrene, polyethylene terephthalate and polyvinyl chloride were also reacted. The plastics were reacted under both a nitrogen (pyrolysis) and hydrogen pressure (liquefaction) and the yield and composition of products are reported. The hydrocarbon gases produced were mainly methane, ethane, propane and lower concentrations of alkene gases. A mainly oil product was produced with the mixed plastic waste with significant concentrations of aromatic compounds, including single ring aromatic compounds. The composition of the oils and gases suggested that there was significant interaction of the plastics when they were pyrolysed and liquefied as a mixture compared to the results expected from reactions of the single plastics. Williams, S. M., et al. (2018). "Clinical-scale production of cGMP compliant CD3/CD19 cell-depleted NK cells in the evolution of NK cell immunotherapy at a single institution." Transfusion **58**(6): 1458-1467.

BACKGROUND: Allogeneic natural killer (NK) cell adoptive immunotherapy is a growing therapeutic option for patients. Clinical-scale production of NK cells using immunomagnetic selection complies with current good manufacturing practices (cGMPs) and allows for closed-system, automated purification. We report our experience with CD3/CD19 cell-depleted (CD3/CD19_{dep}) NK cell production and compare to previous methods of CD3 cell depletion and CD3 cell depletion/CD56 cell enrichment.

STUDY DESIGN AND METHODS: Nonmobilized mononuclear cells collected by apheresis were incubated with anti-CD3/anti-CD19 microbeads and depleted in an automated cell selection system (CliniMACS, Miltenyi). The NK cell-enriched products were incubated overnight in interleukin (IL)-2 or IL-15, washed, and resuspended prior to lot release testing and infusion.

RESULTS: Since 2010, 94 freshly infusible CD3/CD19_{dep} NK cell products were manufactured in support of eight clinical trials. Sixty-six products were incubated in IL-2 and 28 products in IL-15. Processing resulted in a mean NK cell recovery of 74% and viability of 95.8%; NK cells, T cells, B cells, and monocytes accounted for 47%, 0.2%, 0.08%, and 49% of the final products, respectively. Seven products required dose adjustments to meet lot release. The specification for purity changed throughout the evolution of manufacturing. IL-2 or IL-15 activation enhanced in vitro cytotoxicity compared to preactivated cells. There was no difference in final product composition or cytotoxicity between cytokine cohorts. CONCLUSION: Clinical-scale/cGMP production of NK cells using CD3/CD19 cell-depletion effectively minimized T-cell and B-cell contamination in a single manipulation without compromise to NK-cell recovery. Cytokine activation increased in vitro cytotoxicity compared to column-depleted, preactivated NK cells.

Williams, S. M., et al. (2016). "CD3/CD19-depleted natural killer cell production under good manufacturing practices." Transfusion **56 (Supplement 4)**: 49A.

Background/Case Studies: Allogeneic natural killer (NK) cell adoptive immunotherapy is a growing therapeutic option for patients with malignancy. Clinical-scale production of CD56#sup#+#/sup#CD3 NK cells using immunomagnetic microbead technology complies with good manufacturing practices (GMPs) and allows automated purification in a closed system. High level purification of NK cells using sequential CD3 depletion/CD56 selection results in significant cell loss. We present the largest report of CD3/CD19 depleted NK cells manufactured under GMP conditions for human immunotherapy trials. Study Design/Methods: Mononuclear cells (MNCs) collected by a 15L apheresis from non-mobilized peripheral blood were incubated with anti-CD3 and anti-CD19 ferromagnetic beads and depleted in an automated magnetic column. The NK cell enriched fraction was incubated overnight at 37degreeC and 5% CO#inf#2#/inf# in X-VIVO 15 with 10% human AB serum and IL-2 1000 U/mL or IL-15 10 ng/mL. The cells were washed and resuspended in 5% human serum albumin with samples sent for lot release testing prior to infusion. A chromium release assay tested cytotoxicity. Results/Findings: Since 2010, 94 CD3/CD19 depleted NK cell products were manufactured in support of 8 clinical trials. Processing data is summarized in the Table. Seven products required dose adjustments to meet lot release, including 1 for total nucleated cell (TNC) count >8x10#sup#7#/sup#/kg and 6 for CD3#sup#+#/sup# count >3x10#sup#5#/sup#/ kg. The release specification for purity changed over time from 20% to 30% (CD56#sup#+#/sup#CD3) to a > 3-fold increase in NK cells (CD3/CD19 depleted products vs apheresis MNCs). Products met lot release for viability >70% (7-aminoactinomycin D), CD20#sup#+#/sup# <3%, gram stain 'no organisms seen', and endotoxin <5 EU/kg. Cytokine activation consistently increased cytotoxicity against the K562 cell line over preactivated cells. There was no difference between IL-2 (n=66) or IL-15 (n=28) incubated cells. Conclusion(s): CD3/ CD19 depletion effectively minimizes T cell and B cell contamination in a single manipulation that does not compromise NK cell recovery. Cytokine-activation with IL-2 or IL-15 increases in vitro cytotoxicity compared to preactivated NK cells.

Williams, T. G. J. L., et al. (2010). "A case study of the open-loop recycling of mixed plastic waste for use in a sports-field drainage system." Resources, Conservation and Recycling **55**(2): 118-128.

The management of plastic wastes is important owing to the high levels of embodied fossil fuel energy they contain. Although the environmental benefits of closed-loop recycling of plastics have been established through a number of life cycle studies, the benefits of open-loop recycling of plastics have not been examined for many substituted materials. This paper compares two equivalent sports-field drainage systems, one based on conventional sand and aggregate drainage materials, the other incorporating a novel drainage material produced from mixed plastics waste. The scope is confined to an analysis of primary energy consumption and global warming potential. It was found that the novel drainage system had lower global warming potential and primary energy consumption than the conventional system. These results were robust to sensitivity analyses of electricity mix and transportation distance to installation. © 2010 Elsevier B.V. All rights reserved.

Williamson, C. E., et al. (2019). "The interactive effects of stratospheric ozone depletion, UV radiation, and climate change on aquatic ecosystems." Photochemical & photobiological sciences : Official journal of the European Photochemistry Association and the European Society for Photobiology **18**(3): 717-746.

This assessment summarises the current state of knowledge on the interactive effects of ozone depletion and climate change on aquatic ecosystems, focusing on how these affect exposures to UV radiation in both inland and oceanic waters. The ways in which stratospheric ozone depletion is directly altering climate in the southern hemisphere and the consequent extensive effects on aquatic ecosystems are also addressed. The primary objective is to synthesise novel findings over the past four years in the context of the existing understanding of ecosystem response to UV radiation and the interactive effects of climate change. If it were not for the Montreal Protocol, stratospheric ozone depletion would have led to high levels of exposure to solar UV radiation with much stronger negative effects on all trophic levels in aquatic ecosystems than currently experienced in both inland and oceanic waters. This "world avoided" scenario that has curtailed ozone depletion, means that climate change and other environmental variables will play the primary role in regulating the exposure of aquatic organisms to solar UV radiation. Reductions in the thickness and duration of snow and ice cover are increasing the levels of exposure of aquatic organisms to UV radiation. Climate change was also expected to increase exposure by causing shallow mixed layers, but new data show deepening in some regions and shoaling in others. In contrast, climate-change related increases in heavy precipitation and melting of glaciers and permafrost are increasing the concentration and colour of UV-absorbing dissolved organic matter (DOM) and particulates. This is leading to the "browning" of many inland and coastal waters, with consequent loss of the valuable ecosystem service in which solar UV radiation disinfects surface waters of parasites and pathogens. Many organisms can reduce damage due to exposure to UV radiation through behavioural avoidance, photoprotection, and photoenzymatic repair, but meta-analyses continue to confirm negative effects of UV radiation across all trophic levels. Modeling studies estimating photoinhibition of primary production in parts of the Pacific Ocean have demonstrated that the UV radiation component of sunlight leads to a 20% decrease in estimates of primary productivity. Exposure to UV radiation can also lead to positive effects on some organisms by damaging less UV-tolerant predators, competitors, and pathogens. UV radiation also contributes to the formation of microplastic pollutants and interacts with artificial sunscreens and other pollutants with adverse effects on aquatic ecosystems. Exposure to UV-B radiation can decrease the toxicity of some pollutants such as methyl mercury (due to its role in demethylation) but increase the toxicity of other pollutants such as some pesticides and polycyclic aromatic hydrocarbons. Feeding on microplastics by zooplankton can lead to bioaccumulation in fish. Microplastics are found in up to 20% of fish marketed for human consumption, potentially threatening food security. Depletion of stratospheric ozone has altered climate in the southern hemisphere in ways that have increased oceanic productivity and consequently the growth, survival and reproduction of many sea birds and mammals. In contrast, warmer sea surface temperatures related to these climate shifts are also correlated with declines in both kelp beds in Tasmania and corals in Brazil. This assessment demonstrates that knowledge of the interactive effects of ozone depletion, UV radiation, and climate change factors on aquatic ecosystems has advanced considerably over the past four years and confirms the importance of considering synergies between environmental factors.

Williamson, J. B., et al. (2019). "C-H Functionalization of Commodity Polymers." Angewandte Chemie. International Ed. in English **58**(26): 8654-8668.

Synthetic manipulation of polymer substrates is one of the oldest and most reliable methods to increase the functional diversity of soft materials. Modifying the chemical structure of polymers that are already produced on a commodity scale leverages the current high-volume and low-cost production of commodity plastics for the discovery of modern materials. A myriad of polymer C-H functionalization methods have been developed which enable the modification of material properties on both a laboratory and industrial scale. More recently, driven by advances in C-H activation, photoredox catalysis, and radical chemistry, chemoselective approaches have emerged as a means to impart precise functionality onto commodity polymer substrates. This Review discusses the historical significance of and contemporary advances in the C-H functionalization of commodity polymers. The conceptual approach outlined herein presents exciting new directions for the field, including increasing the value of otherwise pervasive materials, uncovering entirely new material properties, and a viable path to upcycle post-consumer plastic waste.

Willitzki, A., et al. (2012). "New platform technology for comprehensive serological diagnostics of autoimmune diseases." Clinical & Developmental Immunology **2012**: 284740.

Antibody assessment is an essential part in the serological diagnosis of autoimmune diseases. However, different diagnostic strategies have been proposed for the work up of sera in particular from patients with systemic autoimmune rheumatic disease (SARD). In general, screening for SARD-associated antibodies by indirect immunofluorescence (IIF) is followed by confirmatory testing covering different assay techniques. Due to lacking automation, standardization, modern data management, and human bias in IIF screening, this two-stage approach has recently been challenged by multiplex techniques particularly in laboratories with high workload. However, detection of antinuclear antibodies by IIF is still recommended to be the gold standard method for antibody screening in sera from patients with suspected SARD. To address the limitations of IIF and to meet the demand for cost-efficient autoantibody screening, automated IIF methods employing novel pattern recognition algorithms for image analysis have been introduced recently. In this respect, the AKLIDES technology has been the first commercially available platform for automated interpretation of cell-based IIF testing and provides multiplexing by addressable microbead immunoassays for confirmatory testing. This paper gives an overview of recently published studies demonstrating the advantages of this new technology for SARD serology.

The article offers step-by-step instructions for recycling fabric food wraps including copal and pine resin wraps, and beeswax wraps.

Wilson, D. H., et al. (2014). "Simoa HD-1: A fully automated digital immunoassay analyzer capable of single molecule counting, sub-femtomolar sensitivity, and multiplexing." Clinical Chemistry **1)**: S134.

Objective: The aim of this work was to develop the next generation immunoassay analyzer capable of several orders of magnitude greater sensitivity than current best-in-class conventional immunoassay systems. The technology utilizes single molecule array (Simoa) technology to usher in fully automated digital immunoassay and multiplexing capability to the clinical laboratory. Simoa technology isolates individual paramagnetic beads in arrays of femtoliter-sized wells and detects single enzyme-labeled proteins on these beads using sequential fluid flows in microfabricated polymer array assemblies for ultra-sensitive signal measurements. These array assemblies have been incorporated into a low cost disk consumable. The array approach for assay signal quantification allows for rapid digital data acquisition and high throughput, enabling development of a fully automated system for low-cost measurement of clinically relevant biomarkers with high precision and unprecedented sensitivity across a broad dynamic range. Method(s): Detection of single molecules using Simoa has been reported previously. In brief, proteins are captured on antibody-coated paramagnetic microbeads (2.7-mm diameter) and labeled with single enzymes, followed by partitioning single beads into arrays of femtoliter-sized wells and sealing the arrays in the presence of a fluorogenic substrate. We developed a low cost disk consumable that enables standard fluidics handling instrumentation to load and seal assay beads into the arrays using only fluidic flow. Beads with single enzyme label molecules are isolated in single wells in the presence of a substrate, and fluorescent product is allowed to build up within the 40 femtoliter confines of the wells. The fluorescence signal quickly concentrates in such a small volume, allowing detectable signal from a single enzyme label in only 30 seconds. Depending on the analyte concentration, hundreds to many thousands of single molecule signals are counted simultaneously using a fluorescence microscope optical system and image analysis software. Next we integrated this array and imaging module together with a standard fluidics-handling platform that performs sequential cuvette processing of paramagnetic bead-based ELISA reagents. The reagents employ antibody-coated capture beads, biotinylated detector antibodies, and streptavidin-betagalactosidase as the signal enzyme. A standard bead-based immunoassay is performed, and then the beads are transferred to the Simoa module for signal development and digital quantification. Result(s): Prototype single-plex digital immunoassays were developed for PSA, Troponin, IL-6, and Abeta42. A prototype cytokine 6-plex was also developed. LoD's ranged from 0.002 to 0.05 pg/mL. The LoQ of the PSA assay was estimated as 0.037 pg/mL. These sensitivities ranged to over 1000-fold greater than conventional immunoassay. Imprecision for the prototype assays was evaluated over 10 runs across five days in a CLSI format. CVs were generally less than 10%. Spike recovery and linearity met standard criteria for acceptability. The system throughput is 68 tests/ hour, and over 4 logs of dynamic range were demonstrated. The prototype 6-plex gave equivalent precision and sensitivity performance to single-plex versions of the same assay. Conclusion(s): The data indicate we have developed a next generation fully automated immunoassay analyzer capable of orders-of-magnitude greater sensitivity than conventional state-of-the-art immunoassay systems.

Wilson, E. (2019). "Editor's note." New Scientist **244**(3252): 3-3.

An introduction is presented which discusses various reports within the issue, including the science exhibit New Scientist Live 2019, the discovery of Homo naledi fossil at a South African cave by palaeoanthropologist Lee Berger, and the ingestion of microplastics by crabs in Thames river.

Windsor, F. M., et al. (2019). "A catchment-scale perspective of plastic pollution." Global Change Biology **25**(4): 1207-1221.

Plastic pollution is distributed across the globe, but compared with marine environments, there is only rudimentary understanding of the distribution and effects of plastics in other ecosystems. Here, we review the transport and effects of plastics across terrestrial, freshwater and marine environments. We focus on hydrological catchments as well-defined landscape units that provide an integrating scale at which plastic pollution can be investigated and managed. Diverse processes are responsible for the observed ubiquity of plastic pollution, but sources, fluxes and sinks in river catchments are poorly quantified. Early indications are that rivers are hotspots of plastic pollution, supporting some of the highest recorded concentrations. River systems are also likely pivotal conduits for plastic transport among the terrestrial, floodplain, riparian, benthic and transitional ecosystems with which they connect. Although ecological effects of micro- and nanoplastics might arise through a variety of physical and chemical mechanisms, consensus and understanding of their nature, severity and scale are restricted. Furthermore, while individual-level effects are often graphically represented in public media, knowledge of the extent and severity of the impacts of plastic at population, community and ecosystem levels is limited. Given the potential social, ecological and economic consequences, we call for more comprehensive investigations of plastic pollution in ecosystems to guide effective management action and risk assessment. This is reliant on (a) expanding research to quantify sources, sinks, fluxes and fates of plastics in catchments and transitional waters both independently as a major transport routes to marine ecosystems, (b) improving environmentally relevant dose–response relationships for different organisms and effect pathways, (c) scaling up from studies on individual organisms to populations and ecosystems, where individual effects are shown to cause harm and; (d) improving biomonitoring through developing ecologically relevant metrics based on contemporary plastic research. Most research into plastic pollution has focused on marine ecosystems, but these are only the endpoint for plastics of all forms that stem from terrestrial and freshwater environments, particularly rivers. Here, we review the occurrence and transfer of plastic pollution across multiple ecosystems, and advocate the investigation of plastic sources, fluxes and fates in hydrological catchments as well-defined landscape units that provide an integrating scale for understanding and managing ecological effects. [ABSTRACT FROM AUTHOR]

Windsor, F. M., et al. (2019). "Microplastic ingestion by riverine macroinvertebrates." Science of the Total Environment **646**: 68-74.

Although microplastics are a recognised pollutant in marine environments, less attention has been directed towards freshwater ecosystems despite their greater proximity to possible plastic sources. Here, we quantify the presence of microplastic particles (MPs) in river organisms upstream and downstream of five UK Wastewater Treatment Works (WwTWs). MPs were identified in approximately 50% of macroinvertebrate samples collected (Baetidae, Heptageniidae and Hydropsychidae) at concentrations up to 0.14 MP mg tissue⁻¹ and they occurred at all sites. MP abundance was associated with macroinvertebrate biomass and taxonomic family, but MPs occurred independently of feeding guild and biological traits such as habitat affinity and ecological niche. There was no increase in plastic ingestion downstream of WwTW discharges averaged across sites, but MP abundance in macroinvertebrates marginally increased where effluent discharges contributed more to total runoff and declined with increasing river discharge. The ubiquity of microplastics within macroinvertebrates in this case study reveals a potential risk from MPs entering riverine food webs through at least two pathways, involving detritivory and filter-feeding, and we recommend closer attention to freshwater ecosystems in future research. Winkler, A., et al. (2019). "Does mechanical stress cause microplastic release from plastic water

bottles?" Water Research **166**: 115082.

Plastic particle ingestion has become of concern as a possible threat to human health. Previous works have already explored the presence of microplastic (MP) in bottled drinking water as a source of MP intake. Here, we consider the release of MP particles from single-use PET mineral water bottles upon exposure to mechanical stress utilizing SEM plus EDS, which allows the implementation of morphological and elemental analysis of the plastic material surface and quantification of particle concentrations in sample water. The aim of this study was to better evaluate the sources of MP intake from plastic bottles, especially considering the effect of daily use on these bottles such as the abrasion of the plastic material. For that, we analysed MP release of PET bottlenecks and HDPE caps on their surfaces after a series of bottle openings/closings (1 x, 10 x, 100 x). Furthermore, we investigated, if the inner surface of the PET bottles released MPs, counted particle increase of the water and identified MPs in the PET bottled water after exposing the bottles to mechanical stress (squeezing treatment; none, 1min, 10min). The results showed a considerable increase of MP particle occurrence on the surface of PET and HDPE material (bottlenecks and caps) after opening and closing the bottles. After 100 times the effect was impressive, especially on caps. Moreover, great differences exist in cap abrasion between brands which uncovers a discrepancy in plastic behavior of brands. Interestingly, particle concentrations in the bottled mineral water did not significantly increase after exposure to mechanical stress (squeezing treatment). The morphological analysis of the inner wall surface of the bottles supported this observation, as no stress cracks could be detected after the treatment, implying that the bottles itself are not a consistent source of MP particles after this extent of mechanical stress. However, chances of MP ingestion by humans increase with frequent use of the same single-use plastic bottle, though only from the bottleneck-cap system.

Winkler, C. M., et al. (2019). "Visualization of hemodynamics: Fabrication of artificial erythrocytes with encapsulated pivparticles via membrane emulsion technology system." International Journal of Artificia Organs **42 (8)**: 437.

Objectives: Visualization of hemodynamics often represents a simplification of blood as a monophasic fluid. In this study, blood is used as a multiphase fluid. The aim is to fabricate artificial blood to visualize hemodynamics with Particle Image Velocimetry (PIV). More specific, micro beads (ArtErys), which mimic the erythrocytes, are fabricated with a membrane-emulsion-technology system (MET). This system is developed and compared with the results (e.g. ArtEry size) of three other methods: microfluidic, electro-spraying and air flow. Method(s): The ArtErys are made of hydrogels (Agarose 0.3-0.7 wt.%) to match refractive index and biomechanics. For PIV tracking, particles (Sphericalsc, 20 mum) are encapsulated directly into the ArtErys and are not added to the plasma where they might affect the hemodynamics. For the MET system, different oils (e.g. paraffin) are used as disperse phase. The Agarose/PIV mixture is pumped (50 to 100 ml/h) into a constant oil flow (5 to 40 ml/h) through a PTFE membrane (Reichelt Chemietchnik GmbH, pore size 60 mum). The ArtErys are created during this process and transported away by the oil. The MET process is carried out in a heated water bath with a temperature of 55 degreeC. Result(s): The ArtEry size depends mainly on two parameters: the flow rate of the agarose/PIV solution and the flow rate of the oil. A flow rate of 80 ml/h Agarose/PIV solution leads to smallest bead sizes with a mean diameter of 150 mum. High rates lead to merging of the ArtErys, which is reflected in a larger diameter. Furthermore, the bead size depends on the parameter oil flow rate. Here, a rate of 30 ml/h leads to the smallest beads. Discussion(s): The MET method has been successfully implemented to fabricate ArtErys with encapsulated PIV particles. Compared to the other methods, the MET system

fabricates the biggest ArtEry sizes (MET: 150 mum, microfluidic: 15 mum, electro-spraying: 80 mum, air flow: 100 mum).

Winkler, J., et al. (2012). "GMP-grade generation of B-lymphocytes for adoptive immunotherapy in patients after allogeneic stem cell transplantation." Blood. Conference: 54th Annual Meeting of the American Society of Hematology, ASH **120**(21).

Background and objectives: We have recently shown that memory B-lymphocytes from murine CMV immune donor animals adoptively transferred into immunodeficient mice were highly effective in protecting from a viral infection indicating a therapeutic potential of virus specific memory B-cells. These preclinical data provided evidence that a cell-based strategy supporting the humoral immune response might be effective in a clinical setting of post-HSCT immunodeficiency (Klenovsek et al., 2007, Blood 110: 3472-9). As adoptive transfer of B-cells has not been used before in a clinical setting, it is necessary to establish a technology for the generation of GMP-grade B-cell products. Method(s): Starting from the leukapheresis of healthy donors, B-cells were purified by two different separation strategies using GMP-grade microbeads and the CliniMACS^{wedge}TM device. A one-step protocol was used for positive enrichment of B-lymphocytes with anti-CD19 microbeads. In a two-step enrichment protocol, first T-lymphocytes were depleted by anti-CD3 microbeads and the remaining fraction was positively selected by anti-CD19 microbeads. Result(s): The leukapheresis contained a mean of 9.0x10^{wedge}8 CD19-positive B-cells (4.5-12.4 x10^{wedge}8). After the one-step positive purification strategy a mean purity of CD20^{wedge}+ B-lymphocytes of 78.1% with a recovery of 32-41% was obtained. With the two-step T-cell depletion/B-cell enrichment protocol we achieved a mean purity of 96.4 % (93.4-97.8%) with a slightly lower recovery of 14-37%. The absolute B-cell numbers obtained in the product were 1.3 to 4.0 x10^{wedge}8 and 1.7 to 2.6 x10^{wedge}8 for the one-step positive enrichment and the two-step protocol, respectively. Importantly, the absolute number of T-cells was lower in cell products after the two-step protocol (0.1 to 0.9 x10^{wedge}6 T-cells) as compared to the one-step positive CD19-enrichment (1.6 to 3.4 x10^{wedge}6 T-cells). Assuming a patient with 70 kg body weight, the B-cell products obtained after the combined CD3-depletion and CD19-enrichment contained less then 4x10^{wedge}4 T-lymphocytes/kg bodyweight, which is a critical threshold number of T-cells in haploidentical HSCT. The B-cell products showed antibody production after in vitro stimulation in a limiting dilution assay and showed excellent viability after cryopreservation. Conclusion(s): A GMP-grade B-cell product can be obtained with high purity and very low T-cell contamination using the two-step enrichment protocol based on CliniMACS^{wedge}TM technology.

Winters, W. D. (1990). "A new perspective of microbial survival and dissemination in a prospectively contaminated air-fluidized bed model." American Journal of Infection Control **18**(5): 307-315.

A major concern of users of air-fluidized beds has been the possibility that such beds might be a source of microbial contamination. The purpose of this series of prospective, controlled experiments was to measure quantitatively the dissemination and survival of Bacillus subtilis, a species of bacterium that forms desiccation-resistant spores, as it was associated with circulating and clumped microbeads after challenge in an air-fluidized bed operating under decontamination conditions of heating at 48 degrees C and microbead agitation by an air flow of 100% at 110 cu ft/min. Microbead samples collected after B. subtilis challenge from predesignated depths and locations within the air-fluidized bed at 0.25, 1, 2, 4, 24, and 48 hours were assayed for colony-forming units (CFU) of challenge bacteria by end point dilution and streak-plate assays.

Winton, D. J., et al. (2020). "Macroplastic pollution in freshwater environments: Focusing public and policy action." Science of the Total Environment **704**: 135242.

Understanding and managing plastic pollution is an increasingly important environmental priority for policy makers, businesses and scientists. Awareness of the potential damage to the world's oceans has grown but there is less attention given to freshwater ecosystems. Yet, rivers are the dominant source of plastic pollution to the marine environment, as well as a potential sink, accumulating plastic from multiple sources. Actions to reduce the presence of macroplastics in rivers is fundamental to conserving both freshwater and marine environments, but there is limited understanding of potential pollution sources, vectors and storage. Importantly, there are only a handful of studies examining the typologies of freshwater macroplastic pollution, often using different categories and collection methods. This impedes setting priorities for scientific investigation and mitigation measures. The present study identifies the most prevalent macroplastic items in freshwater environments in Europe, with a focus on consumer plastic items, i.e. those that could potentially be reduced by targeted actions by the public, as well as industrial and government intervention. Our analysis addresses the differences between reported macroplastics in freshwater and marine environments as well as those estimated from litter rates. Our results identify a macroplastic "top ten", i.e. those dominant plastic typologies that require a more focused effort to reformulate their use and management, as well as setting a common baseline for a more consistent data gathering and reporting approach.

Wirka, J. (1989). "Plastics Recycling: Missing the Forest for the Plastic Lumber." Resource Recycling **8**(8): 25.

The emphasis to date on plastics recycling has been on eliminating plastics from the waste stream. It is important, however, that plastics recycling reduce the amount of virgin resins necessary for processing this material. The chemical process for converting natural oil and gas into resins, then plastics, has caused serious environmental problems, from toxic air pollution to hazardous waste. Plastic resin producers are among the top emitters of carcinogenic acrylonitril and carbon tetrachloride. The EPA found that five of the six top chemicals whose production results in the most hazardous waste were those used in resin manufacture. The plastics industry must see recycling as a source of alternative feedstock materials to displace use of virgin resins. New technologies must be developed to upgrade secondary resins in order to find high value uses like car parts and other large resin applications. Reducing the amount of plastics in landfills does little if the amount of hydrocarbons and other air pollutants is increased during plastics processing.

Wise, J. K., et al. (2014). "Comparison of Uncultured Marrow Mononuclear Cells and Culture-Expanded Mesenchymal Stem Cells in 3D Collagen-Chitosan Microbeads for Orthopedic Tissue Engineering." Tissue Engineering, Part A: Tissue Engineering **20**(1-2): 210-224.

Stem cell-based therapies have shown promise in enhancing repair of bone and cartilage. Marrow-derived mesenchymal stem cells (MSC) are typically expanded in vitro to increase cell number, but this process is lengthy, costly, and there is a risk of contamination and altered cellular properties. Potential advantages of using fresh uncultured bone marrow mononuclear cells (BMMC) include heterotypic cell and paracrine interactions between MSC and other marrow-derived cells including hematopoietic, endothelial, and other progenitor cells. In the present study, we compared the osteogenic and chondrogenic potential of freshly isolated

BMMC to that of cultured-expanded MSC, when encapsulated in three-dimensional (3D) collagen-chitosan microbeads. The effect of low and high oxygen tension on cell function and differentiation into orthopedic lineages was also examined. Freshly isolated rat BMMC (25106 cells/mL, containing an estimated 5104 MSC/mL) or purified and culture-expanded rat bone marrow-derived MSC (2105 cells/mL) were added to a 65-35wt% collagen-chitosan hydrogel mixture and fabricated into 3D microbeads by emulsification and thermal gelation. Microbeads were cultured in control MSC growth media in either 20% O2 (normoxia) or 5% O2 (hypoxia) for an initial 3 days, and then in control, osteogenic, or chondrogenic media for an additional 21 days. Microbead preparations were evaluated for viability, total DNA content, calcium deposition, and osteocalcin and sulfated glycosaminoglycan expression, and they were examined histologically. Hypoxia enhanced initial progenitor cell survival in fresh BMMC-microbeads, but it did not enhance osteogenic potential. Fresh uncultured BMMC-microbeads showed a similar degree of osteogenesis as culture-expanded MSC-microbeads, even though they initially contained only 1/10th the number of MSC. Chondrogenic differentiation was not strongly supported in any of the microbead formulations. This study demonstrates the microbead-based approach to culturing and delivering cells for tissue regeneration, and suggests that fresh BMMC may be an alternative to using culture-expanded MSC for bone tissue engineering.

Wisniowska, E., et al. (2018). "Efficiency of microplastics removal in selected wastewater treatment plants - preliminary studies." Desalination and Water Treatment **134**: 316-323.

Recently more and more attention is being paid to pollution of the environment by microplastics. The problem is well recognized in marine and surface water in Western Europe. There are also well-documented studies on removal of microplastics during wastewater treatment in Germany, Finland, Denmark, Canada and Norway. So far the problem has not been identified in Eastern European countries, including Poland. Because of this, it is of high importance to evaluate the scale of problem also in these countries. The paper presents the results of preliminary studies on microplastics content in influents, effluents and sewage sludge of selected wastewater treatment plants in southern Poland. It was stated that content of microplastics in influents was in the range from 19.4.10³ to 552.2.10³ particles per 1 m³, in effluents from 28 to 960 particles per 1 m³. Microlitter particles removed from raw wastewater were accumulated in sewage sludge. Total concentration of microplastic particles in the sludge was in the range from 6.7.10³ to 62.6.10³ particles per 1 kg d.m. In liquid phase, finer fractions of microplastics were dominant. In sewage sludge larger particles, especially fibers, were effectively cumulated. About 95%-99% removal efficiency of microplastics from influents was stated. No correlation has been found between the wastewater flow rate and the content of microplastics in influent, these problems require, however, more detailed analysis of microplastics chemical composition and mass.

Witte, B. d., et al. (2014). "Quality assessment of the blue mussel (Mytilus edulis): comparison between commercial and wild types." Marine Pollution Bulletin **85**(1): 146-155.

This study compared species identity, microplastics, chemical and microbial contamination between consumption mussels and wild type mussels, collected at Belgian department stores and Belgian groynes and quaysides, respectively. Species identification based on genetic analysis showed a high number of Mytilus (M.) edulis compared to M. galloprovincialis and M. edulis/galloprovincialis hybrid mussels. The number of total microplastics varied from 2.6 to 5.1 fibres/10 g of mussel. A higher prevalence of orange fibres at quaysides is related to fisheries activities. Chemical contamination of polycyclic aromatic hydrocarbons and polychlorobiphenyls could be related to industrial activities and water turbidity, with maximum concentrations at the quayside of port Zeebrugge. The inverse was noted for Escherichia coli contamination, which was relatively low at Zeebrugge quayside with a total count of 3.9x10² CFU/100 g tissue, due to limited agricultural effluents. Results of this complementary analysis stress the importance of integrated monitoring and quality assessment.

Wittig, B., et al. (1991). "Transcription is associated with Z-DNA formation in metabolically active permeabilized mammalian cell nuclei." Proceedings of the National Academy of Sciences of the United States of America **88**(6): 2259-2263.

Mammalian cells have been encapsulated in agarose microbeads, and from these cells metabolically active permeabilized nuclei were prepared. Previously, we showed that biotin-labeled monoclonal antibodies against Z-DNA can be diffused into the nuclei and, over a specific concentration range, they will bind to Z-DNA within the nucleus in a concentration-independent manner. By using radiolabeled streptavidin, we showed that the amount of Z-DNA antibody bound is related to the torsional strain of the DNA in the nucleus. Relaxation of the DNA results in a decrease of Z-DNA formation, whereas increasing torsional strain through inhibiting topoisomerase I results in increased Z-DNA formation. Here we measure the influence of RNA transcription and DNA replication. Transcription is associated with a substantial increase in the binding of anti-Z-DNA antibodies, paralleling the increased level of RNA synthesized as the level of ribonucleoside triphosphate in the medium is increased. DNA replication yields smaller increases in the binding of Z-DNA antibodies. Stopping RNA transcription with inhibitors results in a large loss of Z-DNA antibody binding, whereas only a small decrease is associated with inhibition of DNA replication.

Witting, M., et al. (2015). "DI-ICR-FT-MS-based high-throughput deep metabotyping: a case study of the Caenorhabditis elegans-Pseudomonas aeruginosa infection model." Analytical and bioanalytical chemistry **407**(4): 1059-1073.

Issue Title: A different way of looking at vibrational hyperspectral data/Micellar extraction for the analysis of Alzheimer's disease brain proteome/Quantification of polyolefin microplastics in personal-care products/Removal of Triton X-100 by microdialysis In metabolomics there is an ever-growing need for faster and more comprehensive analysis methods to cope with the increasing size of biological studies. Direct-infusion ion-cyclotron-resonance Fourier-transform spectrometry (DI-ICR-FT-MS) is used in non-targeted metabolomics to obtain high-resolution snapshots of the metabolic state of a system. We applied this technology to a Caenorhabditis elegans-Pseudomonas aeruginosa infection model and optimized times needed for cultivation and mass-spectrometric analysis. Our results reveal that DI-ICR-FT-MS is a promising tool for high-throughput in-depth non-targeted metabolomics. We performed whole-worm metabolomics and recovered markers of the induced metabolic changes in C. elegans brought about by interaction with pathogens. In this investigation, we reveal complex metabolic phenotypes enabling clustering based upon challenge. Specifically, we observed a marked decrease in amino-acid metabolism with infection by P. aeruginosa and a marked increase in sugar metabolism with infection by Salmonella enterica. We were also able to discriminate between infection with a virulent wild-type Pseudomonas and with an attenuated mutant, making it possible to use this method in larger genetic screens to identify host and pathogen effectors affecting the metabolic phenotype of infection. [Figure not available: see fulltext.]

Wojcik-Fudalewska, D., et al. (2016). "Occurrence of plastic debris in the stomach of the invasive crab

Eriocheir sinensis." Marine Pollution Bulletin **113**(1-2): 306-311.

The Chinese mitten crab is known as a pest causing damage to fishing gears and fish. On the other hand, this highly invasive species is considered a delicacy by Asian migrants and therefore commercially fished and sold in many countries. The ingestion of plastic by the Chinese mitten crab Eriocheir sinensis from the Baltic coastal waters (Poland) and the Tagus Estuary (Portugal) was studied based on stomach content analysis. As many as 13% of the 302 analysed males and females (38.07-89.07 mm carapace width) from both regions, contained microplastic in the form of strands and balls. Most of them were transparent. Ingested plastic particles were identified as fragments of fishing gears. Contamination with plastic may have a negative impact on this species as well as on higher trophic levels feeding on crabs. Copyright © 2016 Elsevier Ltd

Wolcott, A., et al. (2006). "Silica-coated CdTe quantum dots functionalized with thiols for bioconjugation to IgG proteins." Journal of Physical Chemistry. B, Condensed Matter, Materials, Surfaces, Interfaces & Biophysical **110**(11): 5779-5789.

Quantum dots (QDs) have been increasingly used in biolabeling recently as their advantages over molecular fluorophores have become clear. For bioapplications QDs must be water-soluble and buffer stable, making their synthesis challenging and time-consuming. A simple aqueous synthesis of silica-capped, highly fluorescent CdTe quantum dots has been developed. CdTe QDs are advantageous as the emission can be tuned to the near-infrared where tissue absorption is at a minimum, while the silica shell can prevent the leakage of toxic Cd(2+) and provide a surface for easy conjugation to biomolecules such as proteins. The presence of a silica shell of 2-5 nm in thickness has been confirmed by transmission electron microscopy and atomic force microscopy measurements. Photoluminescence studies show that the silica shell results in greatly increased photostability in Tris-borate-ethylenediaminetetraacetate and phosphate-buffered saline buffers. To further improve their biocompatibility, the silica-capped QDs have been functionalized with poly(ethylene glycol) and thiol-terminated biolinkers. Through the use of these linkers, antibody proteins were successfully conjugated as confirmed by agarose gel electrophoresis. Streptavidin-maleimide and biotinylated polystyrene microbeads confirmed the bioactivity and conjugation specificity of the thiolated QDs. These functionalized, silica-capped QDs are ideal labels, easily synthesized, robust, safe, and readily conjugated to biomolecules while maintaining bioactivity. They are potentially useful for a number of applications in biolabeling and imaging.

Wolff, S., et al. (2019). "Determination of the microplastics emission in the effluent of a municipal waste water treatment plant using Raman microspectroscopy." Water Research X **2 (no pagination)**(100014).

Samples from the secondary clarifier effluent of a waste water treatment plant (serving 98500 inhabitants) were analyzed to determine the microplastics (MP) emission. The samples were collected using a stainless steel centrifugal pump and filtered through a 10 mum stainless steel cartridge filter. Microplastics particles (MPPs) and microplastics fibers (MPFs) were recovered by chemical and physical sample purification. To remove natural organic matter, the samples were first subjected to oxidative treatment with H<inf>2</inf>O<inf>2</inf> and NaClO. Inorganic materials were subsequently removed by density separation in ZnCl<inf>2</inf> (rho = 1.9 g/cm³) using a centrifuge. Special centrifuge tubes were developed for this purpose. Sample analysis was performed on a Si filter by Raman micro-spectroscopy. Particles with a diameter (d<inf>p</inf>) >= 10 mum were analyzed. The results were differentiated by dry and wet weather samples. On average, 5900 MPPs m⁻³ were identified in the effluent on wet weather days compared to 3000 MPPs m⁻³ on dry weather days. Most of the MPPs detected were in the 30 mum < d<inf>p</inf> < 100 mum size range. The

MPFs ranged between 100 mum and 1000 mum in length. While most of the MPFs were of PET origin, the MPPs consisted mainly of PET, PP, PE and PS. Copyright © 2018 The Authors

Wollmann, F., et al. (2019). "Microalgae wastewater treatment: Biological and technological approaches." Engineering in Life Sciences **19**(12): 860-871.

Current global environmental issues raise unavoidable challenges for our use of natural resources. Supplying the human population with clean water is becoming a global problem. Numerous organic and inorganic impurities in municipal, industrial, and agricultural waters, ranging from microplastics to high nutrient loads and heavy metals, endanger our nutrition and health. The development of efficient wastewater treatment technologies and circular economic approaches is thus becoming increasingly important. The biomass production of microalgae using industrial wastewater offers the possibility of recycling industrial residues to create new sources of raw materials for energy and material use. This review discusses algae-based wastewater treatment technologies with a special focus on industrial wastewater sources, the potential of non-conventional extremophilic (thermophilic, acidophilic, and psychrophilic) microalgae, and industrial algae-wastewater treatment concepts that have already been put into practice. Wołosiewicz-Głąb, M., et al. (2017). Plastic waste depolymerization as a source of energetic heating oils. Les Ulis, EDP Sciences. **14**.

In the past years there has been an increase in production and consumption of plastics, which are widely used in many areas of life. Waste generated from this material are a challenge for the whole of society, regardless of awareness of sustainable development and its technological progress. Still the method of disposal of plastic waste are focused mainly on their storage and incineration, not using energy contained there. In this paper technology for plastic waste depolymerization with characteristics of fuel oil resulting in the process, as an alternative to traditional energy carriers such as: coal, fine coal or coke used in households will be presented. Oil has a high calorific value and no doubt could replace traditional solutions which use conventional energy sources. Furthermore, the fuel resulting from this process is sulfur-free and chemically pure. The paper presents the installation for plastics waste depolymerization used in selected Polish Institute of Plastics Processing, along with the ability to use the main thermocatalytic transformation product.

Wolpert, V. M. (1994). "Incineration of Municipal Solid Waste Combined with Energy Production-Latest Developments." Renewable Energy **5**(5): 782.

Municipal solid-waste incineration with energy recovery is the preferred method over landfilling for the treatment of solid waste. The development and utilization of the technology depends on the concentration of the urban population and the availability of land for landfilling. The status of municipal solid-waste incineration in the US, Japan, Germany, Sweden, and the UK is described and compared. The use of the technology is growing in all of the nations profiled, especially with the advancement of enhanced air-pollution-control technologies. It is becoming paramount, however, to develop public support for incineration, as waste-to-energy incineration could account for up to 45% of all plastic waste by the year 2000.

Wolraich, M. L. and M. A. Doffing (2004). "Pharmacokinetic considerations in the treatment of attention-deficit hyperactivity disorder with methylphenidate." CNS Drugs **18**(4): 243-250.

Methylphenidate is commonly used for the treatment of attention-deficit hyperactivity disorder

(ADHD). Its efficacy in improving the core symptoms of ADHD, as well as some of the aggressive and oppositional behaviours, is well documented, based on a large volume of research. Methylphenidate has a wide margin of safety and relatively mild adverse effects, most commonly appetite suppression and insomnia. Methylphenidate is a rapidly absorbed medication that, in its d-isomer form, readily penetrates the CNS, particularly the striatum. It appears to function by blocking the reuptake of dopamine. Both the plasma concentrations and behavioural effects of methylphenidate demonstrate a time to maximum of between 1 and 3 hours, with the maximum behavioural effects occurring when the plasma concentrations are increasing. Because of the rapid onset of action, the effects of methylphenidate can be dramatic but usually last only about 4 hours with the immediate-release formulation. The behavioural responses of individuals are also highly variable, so that it is necessary to start treatment at a low dosage and increase up to a maximally effective dosage (usually starting at 10-15 mg/day with increases of 10-15mg at weekly intervals to a maximum dosage of 60 mg/day, irrespective of formulation). Because of the variability in behavioural responses, assessment of plasma concentrations is not clinically useful nor does weight help in deciding an appropriate dosage. The difficulties in administering methylphenidate multiple times a day, particularly during the school day, have been alleviated in the past few years by the development of extended-release preparations with varying behavioural effects lasting 8-12 hours. The 8-hour preparations (Metadate) CD and Ritalin) LA) utilise a microbead technology, while the 12-hour preparation (Concerta) utilises an osmotic pump system. All extended-release formulations effectively control the symptoms of ADHD. While pharmacokinetic differences appear to exist between some of these new formulations, there are currently no clinical data available to demonstrate clinical efficacy differences between them. Won, J. Y. and J. Min (2010). "Highly sensitive Escherichia coli O157:H7 detection in a large volume sample using a conical polymer tube chamber consisting of micro-glass beads." Biosensors & Bioelectronics **26**(1): 112-117.

In this study, we developed a method for the highly sensitive detection of viable pathogenic bacteria in a large volume sample by performing RNA concentration, amplification, and using fluorescently tagged capture probes in a single polymer chamber without transferring RNA samples from one chamber to another. Nucleic acids were extracted from Escherichia coli O157:H7 and loaded into glass micro-beads embedded in a conical polymer tube chamber. Nucleic acids were concentrated in the micro-tube in a low pH buffer (pH 5). The mRNA, which was adsorbed to the glass micro-beads, was amplified by Nucleic Acid Sequence Based Amplification in the same chamber at a relatively high pH (pH 8.9). The products amplified were measured using the hair-loop type detection probe with FAM and DABCYL, which was pre-mixed in the NASBA mater mixture. As a result, high sensitivity (100% for rain water and 60% for river water) with less than 10 viable E. coli O157:H7 in 100ml could be achieved within 4h using the simple method proposed in this study.

Won, J. Y., et al. (2010). "Bacteria adsorption on hydrophilic surfaces for the sensitive detection of pathogenic bacteria using a single tube chamber system." Biosensors and Bioelectronics **26**(4): 1763-1767.

Here, we developed a simple and effective bacterial isolation method that can be directly used for the detection of pathogenic bacteria. This approach only requires a single plastic tube chamber that can performing serial processes such as cell gathering, cell lysis, nucleic acid amplification, and signaling without the need to transfer samples from one chamber to another. A TEOS (tetraethoxysilane) surface was selected for this application because of its superior performance in the amplification process as well as the ability of bacteria to adsorb to its surface, which is necessary for all processes to be performed in single chamber. The optimal aquatic buffer conditions for bacteria adsorption on the hydrophilic surface were determined to be 1% polyethylene glycerol (PEG) and 10mM MgCl2 in 100mM phosphate at pH 4 for the gram negative bacteria, Escherichia coli O157:H7 (E. coli O157:H7) and 10mM Na2SO4 in 100mM phosphate in 100mM phosphate at pH 4 for the gram positive bacteria, Bacillus cereus (B. cereus). When these divalent cation and anion (MgSO4) containing acidic solutions were used, 40% of both bacteria adsorbed onto the hydrophilic surface at a loading rate of 2mL/min after introduction of low concentrations of bacteria. This method was directly employed to detect E. coli O157:H7 in beef using a single plastic tube chamber that was partially filled with nickel micro beads coated with TEOS. In this system, E. coli O157:H7 were lysed by induction heating of the nickel micro beads. The extracted mRNA was readily amplified and detected by adding an isothermal amplification mixture (NASBA, nucleic acid sequence based amplification) containing a hair-loop type reporting probe with FAM and DABCYL. As a result, this highly sensitive sensing tool could detect very low concentrations of E. coli [100 CFU/1g of beef].

Wong, C. S., et al. (1974). "Quantitative tar and plastic waste distributions in the Pacific Ocean." Nature **247**(5435): 30-32.

Quantitative data on tar and plastic waste distributions in the surface waters of the Pacific Ocean are presented. It is shown that tar and plastic wastes are widespread on the surface of the oceans as a result of several factors: likely sources of marine oil transport, augmented by accidential spills, prevailing wind transport and surface circulation.

Wong, J. (2007). Bead based microreactors for sensing applications.

The dissertation research described here focuses on the fabrication and modification of the polymeric beaded sensing elements, one of the many critical components of a Microbead Array Chip-Based Multianalyte Detection System. Detection of biomolecules including proteins and oligonucleotides are based on affinity interactions between carefully selected ligands immobilized on the sensing microspheres. The current work relies on microspheres made of agarose gel shaped into micron sized beads with intrinsic porosity associated to the concentration of agarose in the gel. The beaded material described is considered of a homogeneous nature with limited transport capabilities although superior to homogeneous latex beads. The microbead array system potentially benefits from structural modifications on the sensing elements and includes improvement on the mobile phase mass transport, capture of larger particles, faster assays, and the increase in the multiplexing capabilities. Efforts are also directed to preferentially modify gels made of agarose to facilitate the transition from the existing sensing elements to the new beaded designs made of the same polysaccharide. As a result the chemistry utilized to attach affinity ligands to procure reactive sensing elements remained practically the same. Collectively, these research activities have resulted in a number of novel polymer-based reactive particles that have the potential to service a variety of new sensing applications.

Wong, M. M., et al. (2013). "Sirolimus stimulates vascular stem/progenitor cell migration and differentiation into smooth muscle cells via epidermal growth factor receptor/extracellular signal-regulated kinase/beta-catenin signaling pathway." Arteriosclerosis, Thrombosis, and Vascular Biology **33**(10): 2397-2406.

OBJECTIVE - : Sirolimus-eluting stent therapy has achieved considerable success in overcoming coronary artery restenosis. However, there remain a large number of patients presenting with

restenosis after the treatment, and the source of its persistence remains unclarified. Although recent evidence supports the contribution of vascular stem/progenitor cells in restenosis formation, their functional and molecular responses to sirolimus are largely unknown. APPROACH AND RESULTS - : Using an established technique, vascular progenitor cells were isolated from adventitial tissues of mouse vessel grafts and purified with microbeads specific for stem cell antigen-1. We provide evidence that vascular progenitor cells treated with sirolimus resulted in an induction of their migration in both transwell and wound healing models, clearly mediated by CXCR4 activation. We confirmed the sirolimus-mediated increase of migration from the adventitial into the intima side using an ex vivo decellularized vessel scaffold, where they form neointima-like lesions that expressed high levels of smooth muscle cell (SMC) markers (SM-22alpha and calponin). Subsequent in vitro studies confirmed that sirolimus can induce SMC but not endothelial cell differentiation of progenitor cells. Mechanistically, we showed that sirolimus-induced progenitor-SMC differentiation was mediated via epidermal growth factor receptor and extracellular signal-regulated kinase 1/2 activation that lead to beta-catenin nuclear translocation. The ablation of epidermal growth factor receptor, extracellular signal-regulated kinase 1/2, or beta-catenin attenuated sirolimus-induced SM-22alpha promoter activation and SMC differentiation. CONCLUSIONS - : These findings provide direct evidence of sirolimus-induced progenitor cell migration and differentiation into SMC via CXCR4 and epidermal growth factor receptor/extracellular signal-regulated kinase/beta-catenin signal pathways, thus implicating a novel mechanism of restenosis formation after sirolimus-eluting stent treatment. © 2013 American Heart Association, Inc.

Wong, O. Y. and C. Hilkens (2017). "Tolerogenic dendritic cells regulate T cells via transforming growth factor beta." Rheumatology (United Kingdom) **56 (Supplement 2)**: ii133.

Background: Rheumatoid arthritis (RA) is an autoimmune disease characterized by chronic inflammation and degradation in synovial joints, affecting approximately 1% of the adult population worldwide. Tolerogenic dendritic cells (TolDCs) are a recently developed experimental cellular immunotherapy for RA, currently under clinical trial. Dendritic cells (DCs) are potent antigen presenting cells that activate or tolerize T cells, depending on the maturation state. Mature DCs (MatDCs) activate effector T cells whereas the immature or semimature TolDCs regulate T cells and thereby induce tolerance. The aim of this study was to establish the role of TGF-beta in the mechanism by which TolDCs regulate CD4 T cells from healthy controls and RA patients. Method(s): Peripheral blood mononuclear cells (PBMCs) were isolated from blood samples from healthy donor by centrifugation. Synovial fluid mononuclear cells (SFMCs) were isolated from synovial fluid obtained from RA patients by centrifugation. CD4 T cells were isolated from isolated from PBMC or SFMCs by anti-CD4 magnetic microbeads. DCs were isolated from PBMCs by anti-CD14 magnetic microbeads and cultured into MatDCs or TolDCs. DC phenotype was checked using flow cytometry. Independent assays were conducted with DCs and T cells derived from different donors. TGF-beta inhibitor was added where indicated. Supernatants from the co-cultures were harvested and assayed for IFN-gamma by ELISA. Proliferation of T cells was assessed by thymidine incorporation assays. Allogeneic T cells were primed with DCs in the presence or absence of TGF-beta inhibitor. Primed T cells were washed and restimulated with MatDCs from the original donor. Supernatants were harvested and assessed for IFN-gamma. Proliferation of T cells was assessed. Results were expressed as median of independent events and analysed by Mann- Whitney test. Result(s): TolDCs suppressed inflammatory cytokine IFN-gamma and proliferation of T cells. When TGF-beta was inhibited, suppression of IFN-gamma was reversed. During restimulation of T cells, TolDCprimed T cells remain hyporesponsive and expressed lower levels of IFN-gamma compared to MatDC-primed T

cells. When TGF-beta was inhibited, suppression of IFN-gamma was reversed in healthy T cells but only partially reversed in RA T cells. The results demonstrated that TGF-beta plays a role in the mechanism by which TolDCs regulate T cells from RA patients. The partial reversal of IFN-gamma suppression on TGF-beta inhibition suggests there may be other mechanisms involved in the action of TolDCs. Conclusion(s): TGF-beta is an important cytokine in the tolerogenic function of TolDCs. It is potentially a quality control marker in TolDCs generation.

Wonga, S. L., et al. (2016). "Parametric study on catalytic cracking of LDPE to liquid fuel over ZSM-5 zeolite." Energy Conversion & Management **122**: 428-438.

Pyrolysis or cracking of plastic waste is considered as a potential solution to the environmental problems brought about by plastic waste, with the production of hydrocarbon fuel as a value added benefit. In order to explore the potentials of such process, parametric study have been conducted on the catalytic cracking of LDPE dissolved in benzene in a fixed bed reactor. The five factors studied were temperature (A), catalyst mass (B), feed flow rate (C), carrier gas flow rate (D), as well as concentration of LDPE solution (E), while the responses were LDPE conversion (Y sub(1)) and liquid yield (Y sub(2)). The parametric study showed that four out of five factors (A, B, C and D) have significant effects on Y sub(1) and Y sub(2). The optimum conditions that produced maximum responses for Y sub(1) and Y sub(2) simultaneously are 600 degree C (A), 0.10 g catalyst (B), 1 ml/s LDPE solution (C), 80 ml/min N sub(2) flow (D). The numerical values for Y sub(1) and Y sub(2) were 98.6% and 99.5%, respectively. Analysis on products composition indicated that catalytic cracking of LDPE in fixed bed reaction generally produced high amount of aliphatic branched-chain compounds, together with moderate amount of cyclic compounds. Aromatization of LDPE cracking products is less due to the short retention time of the compounds on the catalysts bed.

Wood, A. (1996). "KEY LESSONS FOR PLASTIC BOTTLE RECYCLING." Recycling Textile & Plastic Waste: 77-86.

The article offers information concerning plastic bottle recycling in Great Britain. It includes the key components of recycling system including legislation, bottle production, product deposit, collecting and sorting, reprocessing and market. It is emphasized that the government, manufacturer, marketer, retailer, citizen, local authority, reprocessor and industries play an important role in plastic bottle recycling. It highlights the industrial legislation for a common strategy and a plan toward recycling in the region.

Wood, C. (2006). "Zero-waste thermal process leaves the UK unmoved." Materials Recycling Week **188**(19): 7-7.

The article reports on several waste management processes developed for environmental protection in Great Britain. Thermal desorption, a waste management process that is capable to convert tyres, sewage sludge, medical waste, and plastics into highly valuable fuel. Non-oxidizing process, a waste management process capable to vaporize volatiles and semi-volatiles with different temperatures. Several companies are proposing new technologies for the environmental management of the country. Furthermore, Tox Free is currently investigating waste management processes that reduces landfill capacity.

Woodall, L. C., et al. (2015). "Using a forensic science approach to minimize environmental contamination and to identify microfibres in marine sediments." Marine Pollution Bulletin **95**(1): 40-46.

There is growing evidence of extensive pollution of the environment by microplastic, with microfibres representing a large proportion of the microplastics seen in marine sediments. Since microfibres are ubiquitous in the environment, present in the laboratory air and water, evaluating microplastic pollution is difficult. Incidental contamination is highly likely unless strict control measures are employed. Here we describe methods developed to minimize the amount of incidental post-sampling contamination when quantifying marine microfibre pollution. We show that our protocol, adapted from the field of forensic fibre examination, reduces fibre abundance by 90% and enables the quick screening of fibre populations. These methods therefore allow an accurate estimate of microplastics polluting marine sediments. In a case study from a series of samples collected on a research vessel, we use these methods to highlight the prevalence of microfibres as marine microplastics.

Woods, M. N., et al. (2018). "Microplastic fiber uptake, ingestion, and egestion rates in the blue mussel (Mytilus edulis)." Marine Pollution Bulletin **137**: 638-645.

Microplastic fibers (MPF) are a ubiquitous marine contaminant, making up to 90% of global microplastic concentrations. Imaging flow cytometry was used to measure uptake and ingestion rates of MPF by blue mussels (Mytilus edulis). Mussels were fed a diet of Rhodomonas salina and MPF concentrations up to 30 MPF mL⁻¹, or 0.374% of available seston. Filtration rates were greatly reduced in mussels exposed to MPF. Uptake of MPF followed a Holling's Type II functional response with 95% of the maximum rate (5227 MPF h⁻ ¹) occurring at 13 MPF mL⁻¹. An average of 39 MPF (SE +/- 15, n = 4) was found in feces (maximum of 70 MPF). Most MPF (71%) were quickly rejected as pseudofeces, with approximately 9% ingested and <1% excreted in feces. Mussels may act as microplastic sinks in Gulf of Maine coastal waters, where MPF concentrations are near the order of magnitude as the experimental treatments herein. Copyright © 2018 Elsevier Ltd

Woodyard, D. (1989). "Upon the slimy sea." Professional Engineering **2**(3): 26-28.

Dumping garbage from ships was being brought under control by the International Maritime Organization's Annex V to the Marpol convention. The disposal of refractory plastic waste had been banned and a minimal distance from shore had been defined for the disposal of food wastes. These regulations had stimulated the design and installation of standard marine incinerators on cargo ships.

Worm, B., et al. (2017). "Plastic as a Persistent Marine Pollutant." Annual Review of Environment & Resources **42**: 1-26.

Synthetic organic polymers-or plastics-did not enter widespread use until the 1950s. By 2015, global production had increased to 322 million metric tons (Mt) year−1, which approaches the total weight of the human population produced in plastic every year. Approximately half is used for packaging and other disposables, 40% of plastic waste is not accounted for in managed landfills or recycling facilities, and 4.8-12.7 Mt year−1 enter the ocean as macroscopic litter and microplastic particles. Here, we argue that such mismanaged plastic waste is similar to other persistent pollutants, such as dichlorodiphenyltrichloroethane (DDT) or polychlorinated biphenyls (PCBs), which once threatened a 'silent spring' on land. Such a scenario seems now possible in the ocean, where plastic cannot be easily removed, accumulates in organisms and sediments, and persists much longer than on land. New evidence indicates a complex toxicology of plastic micro- and nanoparticles on marine life, and transfer up the food chain, including to people. We detail solutions to the current crisis of accumulating plastic pollution, suggesting a Global Convention on Plastic Pollution that incentivizes collaboration between governments, producers, scientists, and citizens. [ABSTRACT FROM AUTHOR]

Wright, S. and I. Mudway (2019). "The ins and outs of microplastics." Annals of Internal Medicine **171**(7): 514-516.

Wright, S. L. and F. J. Kelly (2017). "Plastic and Human Health: A Micro Issue?" Environmental Science & Technology **51**(12): 6634-6647.

Microplastics are a pollutant of environmental concern. Their presence in food destined for human consumption and in air samples has been reported. Thus, microplastic exposure via diet or inhalation could occur, the human health effects of which are unknown. The current review article draws upon cross-disciplinary scientific literature to discuss and evaluate the potential human health impacts of microplastics and outlines urgent areas for future research. Key literature up to September 2016 relating to accumulation, particle toxicity, and chemical and microbial contaminants was critically examined. Although microplastics and human health is an emerging field, complementary existing fields indicate potential particle, chemical and microbial hazards. If inhaled or ingested, microplastics may accumulate and exert localized particle toxicity by inducing or enhancing an immune response. Chemical toxicity could occur due to the localized leaching of component monomers, endogenous additives, and adsorbed environmental pollutants. Chronic exposure is anticipated to be of greater concern due to the accumulative effect that could occur. This is expected to be dose-dependent, and a robust evidence-base of exposure levels is currently lacking. Although there is potential for microplastics to impact human health, assessing current exposure levels and burdens is key. This information will guide future research into the potential mechanisms of toxicity and hence therein possible health effects.

Wright, S. L., et al. (2019). "Raman Spectral Imaging for the Detection of Inhalable Microplastics in Ambient Particulate Matter Samples." Environmental Science & Technology **53**(15): 8947-8956.

Microplastics are ubiquitous contaminants, with preliminary evidence indicating they are a novel component of air pollution. This presents a plausible inhalation exposure pathway, should microplastics occur in the inhalable size range; however, this remains an analytical challenge. Here, we develop a filter-based sampling method compatible with both air quality monitoring and Raman spectral imaging (RSI) for the detection of inhalable-sized microplastics. Clean and particulate matter (PM) contaminated filters of a range of compositions were screened. RSI was validated using a plastic microbead suspension (poly(methyl methacrylate) (5-27 mum), polyethylene (10-27 mum), and polystyrene (4 and 10 mum)). Filters were loaded with the suspension before being analyzed. RSI analysis was conducted using a univariate analysis, fitting unique plastic bands to the spectral data sets, where high spatial intensity indicated the presence of microplastics. Inhalable microplastics were not visibly detectable against quartz or spectroscopically detectable against polytetrafluoroethylene (PTFE)- and alumina-based filters. While microplastics were detectable against cellulose, the PM-contaminated filters (4 and 24 h) burned during analysis. The greatest intensities for microplastics were observed against the silver membrane filter, and inhalable microplastics were still detectable in a 24 h PM sample. These findings will facilitate the acquisition of inhalable microplastic concentrations, which are necessary for understanding microplastic exposure and, ultimately, what their potential role in

PM-associated health effects might be.

Wright, S. L., et al. (2013). "The physical impacts of microplastics on marine organisms: a review." Environmental Pollution **178**: 483-492.

Plastic debris at the micro-, and potentially also the nano-scale, are widespread in the environment. Microplastics have accumulated in oceans and sediments worldwide in recent years, with maximum concentrations reaching 100 000 particles m³. Due to their small size, microplastics may be ingested by low trophic fauna, with uncertain consequences for the health of the organism. This review focuses on marine invertebrates and their susceptibility to the physical impacts of microplastic uptake. Some of the main points discussed are (1) an evaluation of the factors contributing to the bioavailability of microplastics including size and density; (2) an assessment of the relative susceptibility of different feeding guilds; (3) an overview of the factors most likely to influence the physical impacts of microplastics such as accumulation and translocation; and (4) the trophic transfer of microplastics. These findings are important in guiding future marine litter research and management strategies.

Wright, S. L., et al. (2019). "Atmospheric microplastic deposition in an urban environment and an evaluation of transport." Environment International: 105411.

Microplastics are a global environmental issue contaminating aquatic and terrestrial environments. They have been reported in atmospheric deposition, and indoor and outdoor air, raising concern for public health due to the potential for exposure. Moreover, the atmosphere presents a new vehicle for microplastics to enter the wider environment, yet our knowledge of the quantities, characteristics and pathways of airborne microplastics is sparse. Here we show microplastics in atmospheric deposition in a major population centre, central London. Microplastics were found in all samples, with deposition rates ranging from 575 to 1008 microplastics/m²/d. They were found in various shapes, of which fibrous microplastics accounted for the great majority (92%). Across all samples, 15 different petrochemical-based polymers were identified. Bivariate polar plots indicated dependency on wind, with different source areas for fibrous and non-fibrous airborne microplastics. This is the first evidence of airborne microplastics in London and confirms the need to include airborne pathways when consolidating microplastic impacts on the wider environment and human health.

Wroblewski, B. M. (1979). "Wear of high-density polyethylene on bone and cartilage." Journal of Bone & Joint Surgery - British Volume **61-B**(4): 498-500.

Wear of high-density polyethylene on bone and cartilage has resulted in a large volume of plastic particles being shed into the two knees and two hips studied. The giant-cell foreign-body reaction of the synovium may not be sufficient to cope with the amount of debris presented and the destruction of the endosteal bone in one hip, caused by the wear particles and movement of the prosthesis, has made revision impossible. Articulation of high-density polyethylene against bone or cartilage either by design or by the failure of alignment of the component must be avoided.

Wu, B., et al. (2019). "Size-dependent effects of polystyrene microplastics on cytotoxicity and efflux pump inhibition in human Caco-2cells." Chemosphere **221**: 333-341.

Microplastics in the environment may gain entry the human gastrointestinal tract through the food chain. However, information on different adverse effects of microplastics at nanometer or micrometer scales in human intestine cells is limited. This study compared the cytotoxicity and efflux pump inhibition ability of 0.1 mum and 5 mum polystyrene microplastics (PS-MPs) in the human colon adenocarcinoma Caco-2 cells. Both PS-MP sizes exhibited low toxicity on cell viability, oxidative stress, and membrane integrity and fluidity. However, the mitochondrial membrane potential was disrupted by both sizes of PS-MPs, and the 5 mum PS-MPs induced higher effects than 0.1 mum PS-MPs. Furthermore, 0.1 mum (>=20 mug/mL) or 5 mum (>=80 mug/mL) PS-MPs inhibited plasma membrane ATP-binding cassette (ABC) transporter activity and increased arsenic (one substrate of ABC transporter) toxicity. The 0.1 mum PS-MPs might act as substrates of ABC transporter to reduce the transport capacity of other substrates. However, high concentrations of 5 mum PS-MPs might reduce ABC transporter activity through induction of mitochondrial depolarization and potential depletion of ATP. This study provides basic information on the toxicity of 0.1 mum and 5 mum PS-MPs in human intestine cells, which are useful for assessing the risk of PS-MPs in humans. Copyright © 2019 Elsevier Ltd

Wu, D., et al. (2010). "Immunoassay on free-standing electrospun membranes." Acs Applied Materials & Interfaces **2**(1): 252-258.

For the purpose of immunoassay, electrospun membranes can be thought as the threadlike self-assembling of nano/microbeads. Nonwoven membranes of electrospun poly(epsilon-caprolactone) (PCL) fibers display excellent tenacity, flexibility and suitable surface energy. These PCL membranes exhibit easy handling in air, fast spreading, and wetting in aqueous solution, and rapid adsorption of protein molecules by hydrophobic interaction. After a fold-and-press process, the membrane porosity was reduced from approximately 75% to less than 10%, whereas the thickness increased from 5.3 to 280 microm. The resulting fluorescence signal from adsorbed protein increased>120x. With anti-HSA and HSA-FITC as an immunoassay model, a linear detection range from 500 ng/mL down to 1 ng/mL is obtained, with a detection of limit (LOD) of approximately 0.08 ng/mL. By comparison, conventional nitrocellulose and a 24.3 microm PCL fiber electrospun membrane displayed a much higher LOD of approximately 100 ng/mL. Immunoassay on free-standing electrospun membrane successfully combines the low-cost and simplicity of conventional membrane immunoassay, with the fast reaction speed and high sensitivity characteristic of magnetic nano/microbeads bioassays.

Wu, D., et al. (2019). "Molecular characterisation of cytochrome P450 enzymes in waterflea (Daphnia pulex) and their expression regulation by polystyrene nanoplastics." Aquatic Toxicology **217**: 105350.

Cytochrome P450 (CYP) enzymes are one of the largest protein families, and they metabolise a wide range of lipophilic organic endogenous and exogenous compounds. Many cytochrome P450 genes have been cloned and characterised, and they are frequently used as biomarkers in environmental toxicology studies because of their sensitivity and inducibility. In the present study, the full-length cDNAs of DpCYP370B and DpCYP4 were cloned from Daphnia pulex for the first time. The sequence of DpCYP370B consisted of an ORF of 1515 bp that encoded a 504 amino acid polypeptide, while the sequence of DpCYP4 comprised an ORF of 1527 bp that encoded a 508 amino acid polypeptide. Homologous alignments revealed the presence of a conserved cysteine haeme-iron ligand signature, FxxGxxxCxG, located in the C-terminal portion. Both the proteins contained a sequence for a transmembrane region that was deduced to be located in the endoplasmic reticulum. Subsequently, the expression levels of DpCYP370B and DpCYP4, as well as those of CYP4AN1, CYP4C33, and CYP4C34, were investigated using quantitative real-time PCR after exposure to five polystyrene nanoplastic concentrations: 0 (control), 0.1, 0.5, 1, and 2 mg/L for 21 days. Except for DpCYP4, the highest mRNA expression was observed at 0.5 mg/L nanoplastics; next, the expression of three of the enzymes (DpCYP370B, CYP4AN1, CYP4C34,) decreased to that of the control level at 1 and 2 mg/L doses

of nanoplastics. The expression of DpCYP4 did not significantly change compared with that of the control group. These results indicated that CYP genes might play an important role in protecting D. pulex against nanoplastic pollutants.

Wu, F., et al. (2020). "Variation in microplastics composition at small spatial and temporal scales in a tidal flat of the Yangtze Estuary, China." Science of the Total Environment **699 (no pagination)**(134252).

Microplastics are small, degrade slowly, and easily persist in the water column because they are close to neutrally buoyant. Understanding the distribution of microplastics is fundamental to evaluating the ecological risks that they cause and to identifying ways to control microplastics pollution. Most of the existing research on the distribution of microplastics in the coastal zone has focused on large spatial and temporal scales. To build on past work, we investigated variation in microplastics in a tidal flat of the Yangtze Estuary on small spatial (sediment depth, mudflat vs. vegetation zone) and temporal (fortnightly and semidiurnal) scales. Microplastics were more abundant in surface (0-2 cm) sediments during neap versus spring tide cycles, likely indicating increased deposition during periods with calm waters and increased suspension when water was more turbulent, but did not vary at greater depths in the sediment. Individual microplastics particles were also larger during neap versus spring tide periods. In contrast to the variation between spring and neap tide periods, we found no variation in the abundance of microplastics on the semidiurnal scale. Microplastics were also more abundant in the transect in the vegetation than at slightly lower elevations in the adjacent mudflat. Across all samples, the abundance of microplastics was negatively correlated with the strength of hydrological processes such as submergence time and flow velocity. Our results showed that sampling of microplastics in the intertidal environment needs to consider variation among spring and neap tide cycles, and also among different intertidal habitats that may differ only slightly in elevation. We encourage coupling sampling with direct measures of hydrological processes so that variation in microplastics abundance and size can be rigorously linked to hydrological processes. Wu, F., et al. (2020). "Accumulation of microplastics in typical commercial aquatic species: A case study at a productive aquaculture site in China." Science of the Total Environment **708**: 135432.

The widespread occurrence of microplastics in the marine environment has drawn global attention because microplastics may impact the populations of marine organisms. As such, aquaculture industry may suffer from microplastic pollution, especially when plastic products are widely used for aquaculture. Here, we assessed the abundance and characteristics (type, size and composition) of microplastics in sediment and typical commercial species (fish, bivalves and shrimps) in an aquaculture site at Xiangshan Bay, which has been operated intensively for decades. Satellite remote sensing images revealed that aquaculture activities were associated with microplastic pollution in sediment, where the microplastics (51-88 items/kg dry weight) were mostly fibres (>94%) and between 500 and 2000 micro m. Cellulose was the predominant polymer (60-88% of microplastic composition), followed by polypropylene. Microplastics accumulated in all the commercial species (0.95-2.1 items per individual), where shrimp (Parapenaeopsis hardwickii) had lower potential for microplastic accumulation than the other species. The predominance of fibres and cellulose in the commercial species implies their limited ability to recognize the type and composition of microplastics during ingestion. Given the limited accumulation of microplastics in these typical commercial species even at a productive aquaculture site, we suggest that microplastics may not increase the health risk of consuming seafood and their impacts on commercial species may be less deleterious than previously thought.

Wu, G., et al. (2013). "Triboelectrostatic separation for granular plastic waste recycling: a review." Waste Management **33**(3): 585-597.

The world's plastic consumption has increased incredibly in recent decades, generating more and more plastic waste, which makes it a great public concern. Recycling is the best treatment for plastic waste since it cannot only reduce the waste but also reduce the consumption of oil for producing new virgin plastic. Mechanical recycling is recommended for plastic waste to avoid the loss of its virgin value. As a mechanical separation technology, triboelectrostatic separation utilizes the difference between surface properties of different materials to get them oppositely charged, deflected in the electric field and separately collected. It has advantages such as high efficiency, low cost, no concern of water disposal or secondary pollution and a relatively wide processing range of particle size especially suitable for the granular plastic waste. The process of triboelectrostatic separation for plastic waste is reviewed in this paper. Different devices have been developed and proven to be effective for separation of plastic waste. The influence factors are also discussed. It can be concluded that the triboelectrostatic separation of plastic waste is a promising technology. However, more research is required before it can be widely applied in industry.

Wu, J., et al. (2019). "Effect of salinity and humic acid on the aggregation and toxicity of polystyrene nanoplastics with different functional groups and charges." Environmental Pollution **245**: 836-843.

Studies regarding the effect of environmental factors on the environmental behaviour and potential toxicity of nanoplastics (NPs) are limited but important. In this study, four polystyrene NPs with different functional groups and charges (PS, PS-COOH, n-PSNH₂, p-PSNH₂) were selected to investigate the effect of humic acid (HA) and salinity on their aggregation behaviour and toxicity. The results showed that salinity significantly accelerated the aggregation of the four NPs, while HA mainly exerted a stabilizing effect on the three negatively charged NPs. In contrast, the positively charged p-PSNH₂ aggregated significantly at first but remained stable as HA concentration further increased. The joint effect mainly depended on their concentration ratio. The aggregation phenomena can be explained by the Derjaguin - Landau - Verwey - Overbeek (DLVO) theory. Also, the acute toxicity of NPs on Daphnia magna was affected by the surface charge of NPs, and the positively charged p-PSNH₂ showed the lowest toxicity among the selected NPs. Furthermore, the presence of HA effectively alleviated the toxicity of PS and p-PSNH₂, as the survival rates increased from 15% to 45%-95% and 100% respectively. Our results demonstrate that the surface properties of NPs significantly influence their aggregation and toxicity.

Wu, J. S., et al. (1999). "Preparation and in-vitro evaluation of a biodegradable carrier system for inducing spawning in fish." Chinese Pharmaceutical Journal **51**(2): 171-179.

Repeated injections of hormone drugs to fish reared in captivity during the spawning season is a routine procedure for local fishermen in Taiwan. To prevent stress resulting from multiple administrations, we developed a delivery system using poly(D,L-lactide-co-glycolide) (PLGA) as a carrier. Two drugs, human chorionic gonadotropin (HCG) and leutenizing hormone-releasing hormone Analog-2 (LHRH-A2), which are commonly used by fishermen, were loaded into polymeric microbeads. The microbeads released more than 20% of the loaded drug in an initial burst. However, drug readsorbed to the carrier and 100% release was not achieved in the in vitro studies. For induction of spawning, burst release accompanied by subsequent slow release is a potential single injection administration system.

Wu, M., et al. (2019). "A composite obtained from waste automotive plastics and sugarcane skin flour: Mechanical properties and thermo-chemical analysis." Powder Technology **347**: 27-34.

In this study, wood plastic composites (WPC) were made using waste automobile bumpers (WAB) and sugarcane skin flour (SSF) as matrix and fibres, respectively. A novel KH550/TCA201 composite coupling agent was applied to modify the composites. Then, the composites were analysed by FTIR, TG-MS, GC-MS and SEM-EDS after being pyrolyzed in a thermogravimetric analyser and a tubular fixed bed. The results show that the mechanical strength of the composite modified by the KH550/TCA201 composite coupling agent is higher than that of the composite modified by a single coupling agent. When KH550/TCA201 is 2% with KH550:TCA201 = 1:1, the tensile, flexural and impact strength of the WPC composites reaches a maximum. In the pyrolysis of WPC, a large amount of alkanes, olefins, aromatics and a small amount of CO<inf>2</inf> were produced from 380 degreeC to 500 degreeC. During the WPC pyrolysis process, the release of HF and HBr is higher than that of WAB, whereas the release of HCl is less than that of WAB. In the pyrolysis oil, the main fluoride production occurs at 400-600 degreeC and reaches a maximum at 500 degreeC. Meanwhile, in the fast pyrolysis oil, the content of organic fluoride is 6 times higher compared with the slow pyrolysis oil. For the solid residue, the content of F, Cl, Br and other pollutants increased with an increase in temperature. Specifically, the chlorine content was higher at slow pyrolysis than at fast pyrolysis. Therefore, from a controllable and environmental standpoint, slow pyrolysis should be adopted in order to increase the content of the contaminated halogen elements in the solid residue. Wu, N., et al. (2019). "Co-effects of biofouling and inorganic matters increased the density of environmental microplastics in the sediments of Bohai Bay coast." Science of the Total Environment: 134431.

Size, shape and color are the basic parameters of environmental microplastic (MPs). However, the density of microplastics which is an important parameter to influence the fate of MPs in the environment has not been measured. Meanwhile, the MPs characteristics from coastal sediments of Bohai Bay remain unclear. In this study, the concentrations, distribution and composition (shapes and sizes) of MPs were investigated. The average concentration of MPs in the coastal sediments of Bohai Bay was 192.3 +/- 138.9 items/kg dw, which was at a moderate pollution level. The MPs with fiber shape (54.5%), small size (52.0%) and low density (PE and PP) were dominant. In addition, flotation experiment showed that most of PE and PP had the higher density compared with seawater. Digestion experiments suggested that the density change of MPs was caused by the co-contribution of biofouling and inorganic minerals. The density increasing rates of PE and PP were 7.4%-12.6% and 12.1%-17.5%, respectively. Finally, we also estimated that the total number of MPs in the sediments of Bohai Sea was 534 trillion, which were significantly higher than that in global ocean surface, suggesting that the coastal sediments could be the sink of MPs.

Wu, N., et al. (2019). "Occurrence and distribution of microplastics in the surface water and sediment of two typical estuaries in Bohai Bay, China." Environmental Science. Processes & Impacts **21**(7): 1143-1152.

Estuaries are considered to be seriously polluted by microplastics. As the most important water body in North China, the pollution level of microplastics in two typical estuaries (Haihe Estuary (HHE) and Yondingxinhe Estuary (YDXE)) of Bohai Bay is not well understood. The occurrence and distribution of microplastics in the surface water and sediment of HHE and YDXE were investigated. The mean concentration of microplastics in surface-water samples was 1485.7 +/-

819.9 items per m3 for HHE and 788.0 +/- 464.2 items per m3 for YDXE, respectively, whereas the concentration of microplastics in sediment was 216.1 +/- 92.1 items per kg dw for HHE and 85.0 +/- 40.1 items per kg dw for YDXE, respectively. The concentration of microplastics in surface-water and sediment-samples of HHE was higher than that of YDXE, though YDXE is a typical sewage-received river. Anthropogenic activities and the river input were the main sources of microplastic pollution in estuarine areas. Sewage rivers could be point sources of microplastic pollution on a small scale. The small size (particle diameter < 1 mm) of microplastics was a dominant feature, the most abundant shape was fiber and colored microplastics were found widely in YDXE and HHE. We provided detailed information on microplastic pollution to support their control and management in HHE and YDXE.

Wu, P., et al. (2019). "Adsorption mechanisms of five bisphenol analogues on PVC microplastics." Science of the Total Environment **Part 1. 650**: 671-678.

Polyvinyl chloride (PVC) plastics are easily embrittled and decomposed to microplastics in an aquatic environment. The plasticizers such as bisphenol A (BPA), bisphenol S (BPS) and their analogues might be released and adsorbed by the PVC microplastics causing consequential pollution to the ecosystem. Herein, a systematic study was performed to determine the adsorption mechanisms of five bisphenol analogues (BPA, BPS, BPF, BPB and BPAF) on PVC microplastics. The maximum adsorption efficiency reached 0.19 +/- 0.02 mg.g⁻¹ (BPA), 0.15 +/- 0.01 mg.g⁻¹ (BPS), 0.16 +/- 0.01 mg.g⁻¹ (BPF), 0.22 +/- 0.01 mg.g⁻¹ (BPB), and 0.24 +/- 0.02 mg.g⁻¹ (BPAF) at PVC dosage of 1.5 g.L⁻¹. The kinetics study shows that the adsorption processes can be divided into three stages including external mass transport, intraparticle diffusion and dynamic equilibrium. The isotherm modeling shows a better fit of the adsorption results to the Freundlich isotherm compared to the Langmuir model. The thermodynamic study indicates the adsorption of all bisphenols as exothermic processes. Furthermore, the adsorption mechanisms of bisphenols were explicated intensively, with respect to hydrophobic interactions, electrostatic forces, and noncovalent bonds. A positive effect of hydrophobic interactions was identified for bisphenols adsorption on PVC microplastics, but an obvious inhibition by electrostatic repulsions was revealed for BPF due to its ionization in the neutral solution. In addition, noncovalent bonds (hydrogen and halogen bonds) may promote the adsorption of bisphenols on PVC microplastics. Finally, the desorption and competitive adsorption of five bisphenol analogues on the microplastics were provided together with a perspective for future works. Copyright © 2018

Wu, P., et al. (2019). "Environmental occurrences, fate, and impacts of microplastics." Ecotoxicology and Environmental Safety **184 (no pagination)**(109612).

Microplastics (MPs) are small plastic pieces with size less than 5 mm that have entered and polluted the environment. While many investigations including several critical reviews on MPs in the environment have been conducted, most of them are focused on their occurrences in marine environment. Current understanding on the occurrences, behaviors, and impacts of MPs in the terrestrial environment is far from complete. A systematic review of the literature was thus conducted to promote the research on MPs in the environment. This work is designed to provide a comprehensive overview that summarizes current knowledge and research findings on environmental occurrences, fate and transport, and impacts of MPs. In addition to discussing the occurrences, characteristics, and sources of MPs in the ocean, freshwater, sediments, soils, and atmosphere, the review also summarizes both the experimental and modeling data of the environmental fate and transport of MPs. Research findings on the toxic effects, bioaccumulation, and bioavailability of MPs in the environment are also covered in this critical review. Future perspectives are discussed as well. Wu, P., et al. (2019). "Spatial-temporal distribution of microplastics in surface water and sediments of Maozhou River within Guangdong-Hong Kong-Macao Greater Bay Area." Science of the Total Environment: 135187.

Concerns over the negative impacts of microplastics on human health have led to growing attention on the occurrence of microplastics in aquatic environment. Recent studies have extended their focus from marine to inland waters, especially on the spatial-temporal distribution of the microplastics in urban rivers. In this study, Maozhou River, the largest river in Shenzhen, a tributary of the Pearl River, was selected as a representative inland waterway of Guangdong-Hong Kong-Macao Greater Bay Area. The spatial-temporal investigation was performed on microplastics in the surface water and sediments of 17 sites along the mainstream of the Maozhou River.

Wu, S., et al. (2016). "Multiplexed detection of lung cancer biomarkers based on quantum dots and microbeads." Talanta **156-157**: 48-54.

We have developed a multiplexed fluoroimmunoassay of three lung cancer biomarkers based on multicolor quantum dots (QDs) as detection elements and micro-magnetic beads as immune carriers. QDs have the ability to simplify multiplexed analysis. In our method, the fluorescent signals derived from three cross-talk-free QD conjugated probes with emission maxima at 525, 585 and 625nm could be analyzed to determine the concentrations of the target proteins. With this system, fragments of cytokeratin 19 (CYRFA 21-1), carcinoembryonic antigen (CEA), and neuron-specific enolase (NSE), were simultaneously detected in a single sample with a low detection limit down to the 1.0ng/mL level (364pg/mL for CYRFA 21-1, 38pg/mL for CEA, 370pg/mL for NSE in a single detection). Additional advantages of the presented method include ease of operation, low cost, and a very low sample volume (20micro L).

Wu, S., et al. (2019). "Effects of polystyrene microbeads on cytotoxicity and transcriptomic profiles in human Caco-2 cells." Environmental Toxicology **03**: 03.

Microplastics (MPs) pollution is a global paradigm that raises concern in relation to environment and human health. In order to investigate the molecular toxicity mechanisms of MPs, transcriptomic analyses were performed on in vitro Caco-2 cell model. After observing that polystyrene microplastics (PS-MPs) decreased cell viability in a dose-dependent manner, the responsible genes and involved pathways that might make contribution to PS-MBs-induced toxicity to Caco-2 cells were identified with Illumina RNA seq. A total of 442 genes including, 210 up-regulated ones and 232 down-regulated ones, showed differential expression after treatment by PS-MPs with a concentration of 12.5 mg L⁻¹ or 50.0 mg L⁻¹ for 24 hours. Gene Ontology (GO) annotation enriched unigenes can be grouped into three separated clusters: cellular component (CC), biological process (BP), and molecular function (MF). The dominate pathways related to NF-kappaB, MAPK signaling, cytokine-cytokine receptor interaction, and toll-like receptor were strongly influenced by PS-MBs. These pathways are involved in modulating cell inflammatory and proliferation. The qPCR were applied to investigate the transcriptional level of five proliferation related genes (Ras, ERK, MER, CDK4, Cyclin D1) and four inflammation related genes (TRPV1, iNOS, IL-1beta, IL-8), and the results were consistent with RNA-seq data. This study has provided new insight into the understanding of the toxicity effects of PS-MBs-induced intestinal inflammatory diseases.

Wu, T. Y., et al. (2016). "A novel sensitive pathogen detection system based on Microbead Quantum Dot System." Biosensors & Bioelectronics **78**: 37-44.

A fast and accurate detection system for pathogens can provide immediate measurements for the identification of infectious agents. Therefore, the Microbead Quantum-dots Detection System (MQDS) was developed to identify and measure target DNAs of pathogenic microorganisms and eliminated the need of PCR amplifications. This nanomaterial-based technique can detect different microorganisms by flow cytometry measurements. In MQDS, pathogen specific DNA probes were designed to form a hairpin structure and conjugated on microbeads. In the presence of the complementary target DNA sequence, the probes will compete for binding with the reporter probes but will not interfere with the binding between the probe and internal control DNA. To monitor the binding process by flow cytometry, both the reporter probes and internal control probes were conjugated with Quantum dots that fluoresce at different emission wavelengths using the click reaction. When MQDS was used to detect the pathogens in environmental samples, a high correlation coefficient (R=0.994) for Legionella spp., with a detection limit of 0.1 ng of the extracted DNAs and 10 CFU/test, can be achieved. Thus, this newly developed technique can also be applied to detect other pathogens, particularly viruses and other genetic diseases.

Wu, W., et al. (2019). "AIEgens Barcodes Combined with AIEgens Nanobeads for High-sensitivity Multiplexed Detection." Theranostics **9**(24): 7210-7221.

Suspension arrays based on optical encoded microspheres have attracted great attention for multiplexed detection in gene analysis, protein profiling, early disease diagnosis, treatment monitoring and so on. However, the fluorescence stability of barcodes and detection sensitivity require further improvement to meet the increasing demands of "precision diagnosis". Methods: This work reports a novel suspension array platform based on extremely stable AIEgens (AIE33 and AIE NIR800) microbeads as barcodes and AIEgens (1,1,2,3,4,5-Hexaphenyl-1H-silole, HPS) nanobeads as fluorescent signal reporter coupled with flow cytometry for multiplexed detection. Results: Due to the excellent fluorescent signal amplification effect of the HPS nanobeads, our multiplex assay showed enhanced detection sensitivity, compared to multiplex assay using QDs nanobeads (up to 3-fold improvement) and commercial organic dye of phycoerythrin (up to 5-fold improvement) as the fluorescent signal reporters. Conclusion: Furthermore, validating experiments showed similar detection performance to the clinical gold-standard method of ImmunoCAP for allergen detection in patient serum samples, demonstrating the suspension array platform based on AIEgens microbeads with excellent fluorescence stability and AIEgens nanobeads with strong signal amplification ability is promising for high-sensitivity multiplexed bioassay applications.

Wu, W., et al. (2017). "Microplastics pollution and reduction strategies." Frontiers of Environmental Science and Engineering **11**(1).

Microplastic particles smaller than 5 mm in size are of increasing concern, especially in aquatic environments, such as the ocean. Primary source is microbeads (<1 mm) used in cosmetics and cleaning agents and fiber fragments from washing of clothes, and secondary source such as broken down plastic litter and debris. These particles are mostly made from polyethylene (PE), polypropylene (PP), polystyrene (PS), polyethylene terephthalate (PET) and polyesters. They are ingested by diverse marine fauna, including zooplanktons, mussel, oyster, shrimp, fish etc. and can enter human food chains via several pathways. Strategy for control of microplastics pollution should primarily focus on source reduction and subsequently on the development of cost-effective clean up and remediation technologies. Recent research results on biodegradation of plastics have revealed a potential for microbial biodegradation and bioremediation of plastic pollutants, such as PE, PS and PET under appropriate conditions.

Wu, X., et al. (2019). "Transport of polystyrene nanoplastics in natural soils: Effect of soil properties, ionic strength and cation type." Science of the Total Environment **707**: 136065.

Nanoplastics as emerging pollutants have caused growing concerns and posed potential threats to the environment. Nonetheless, only few studies investigated transport behaviors of nanoplastics in natural soils. In this study, column experiments were conducted to investigate the effect of soil properties, ionic strength and cation type on the transport of polystyrene nanoplastics (PSNPs) in a desert soil (DS), a black soil (BS) and a red soil (RS). The effluent recovery of PSNPs in three soils followed the order of DS (0%-96.8%) > BS (0%-87.5%) > RS (0%). The retention of PSNPs was positively correlated with Fe/Al oxides contents (DS: Fe-2.69%, Al-12.6%; BS: Fe-4.04%, Al-15.9%; RS: Fe-6.57%, Al-26.9%), whereas negatively correlated with soil pH (DS: 9.75; BS: 6.57; RS: 4.97). Soil minerals and pH were thus identified as the crucial soil properties determining transport of PSNPs, due to their coupled effects on surface charges to affect electrostatic interactions between soils and PSNPs. In addition, increasing solution ionic strength strongly inhibited the transport of PSNPs in the DS (0%-96.8%) and BS (0%-87.5%). Ca²⁺ (IS: 1-5 mM) was more pronounced in enhancing PSNP retention than Na⁺ (IS: 1-20 mM). Our findings highlight that the transport and fate of PSNPs in natural soils are highly sensitive to soil physicochemical properties, ionic strength and cation type, and reveal that nanoplastics have strong mobility ability in soils with high pH and low Fe/Al oxides contents, which may pose potential risks to the soil and groundwater environment.

Wu, X., et al. (2019). "Selective enrichment of bacterial pathogens by microplastic biofilm." Water Research **165**: 114979.

Microplastics have been found to be ubiquitous in freshwater ecosystems, providing a novel substrate for biofilm formation. Here, we incubated biofilm on microplastics and two natural substrates (rock and leaf) under a controlled environment to investigate the differences of microbial community structure, antibiotic resistance gene (ARG) profiles, and ARG microbial hosts between biofilms on three types of substrates.

Wu, X., et al. (2013). "Regulation of differentiation in trabecular bone-derived mesenchymal stem cells by T cell activation and inflammation." Oncology Reports **30**(5): 2211-2219.

Mesenchymal stem cells (MSCs) are multipotent stem cells with the ability to migrate to sites of inflammation and injury, where they participate in tissue regeneration and repair. The present study aimed to investigate the effects of T cell activation and inflammation on the differentiation of MSCs. Human trabecular bone-derived MSCs were isolated from patients undergoing total hip replacement, and T cells were isolated and purified from peripheral blood mononuclear cells (PBMCs) using CD3 MicroBeads. MSCs were co-cultured with activated T cells to mimic the inflammatory microenvironment. MTS assay was used to detect cell proliferation.qRT-PCR, western blotting, histology and immunohistochemical staining were used to detect the adipo-/osteo-specific gene expression and the relative signaling pathway. The MTS results showed that higher concentrations of T cells significantly increased the proliferation of MSCs. Expression of the inflammatory gene IL-6 was upregulated, while expression of IL-10 and INFgamma was downregulated in MSCs exposed to activated T cells. The results also showed that PHA-activated T cells significantly upregulated the expression of PPARgamma and FABP4 (adipo-specific genes) in MSCs, but no difference was noted in the expression of RUNX2,

osteocalcin and ALP (osteo-specific genes) at the protein level. T cell treatment and inflammation inhibited the protein expression of TGF-beta1 and the phosphorylation of Smad3, resulting in the weakening of the TGF-beta/Smad pathway and enhancing the adipogenic differentiation of MSCs. The results indicated that PHA-activated T cells and inflammation could promote adipogenesis without affecting the late stage of osteogenesis of MSCs, by increasing the expression of key adipogenic genes through TGF-beta/Smad3 signaling.

Wu, X., et al. (2013). "Enhancement of human regulatory gammadelta t cells in vitro induced by granulocyte colony-stimulating factor." Blood. Conference: 55th Annual Meeting of the American Society of Hematology, ASH **122**(21).

Background and Objective Graft versus host disease (GVHD) is the main complications following allogeneic hematopoietic stem cell transplantation (allo-HSCT). Regulatory gammadelta T cells (gammadelta Tregs), which express Foxp3 and primarily belong to CD27+CD25high phenotype, are a novel subset of cells with immunosuppressive function and have the potential application prospect in GVHD therapy. Peripheral blood mononuclear cells (PBMCs) could be induced to generate gammadelta Tregs in vitro by stimulating with anti-TCR gammadelta and transforming growth factor-beta (TGF-beta). Our previous studies demonstrated that granulocyte colony-stimulating factor (G-CSF) had immunomodulatory effect on T cells; G-CSF mobilization influenced the distribution and clonality of TRGV and TRDV repertoire (T cell receptors of gammadelta T cells) significant positive correlation was observed between the invariable clonality of TRDV1 gene repertoire after G-CSF mobilization and low incidence of GVHD in recipients. To further characterize the immunoregulatory functions of G-CSF, this study explored the possibility of gammadelta Tregs induced by G-CSF in vitro. Methods PBMCs of healthy donors were cultured in vitro by stimulating with anti-TCR gammadelta and different cytokines for 9-12 days. The culture system was grouped based on the difference of added cytokines, including: (1) TGF-beta (2) G-CSF (3) TGF-beta+G-CSF (4) blank group. The induced cells were used as effector cells in the carboxylfluorescein diacetate succinimidyl ester (CFSE) assays and cell immunophenotyping was analyzed by flow cytometry. Autologous CD4+T cells were purified by microbeads, labeled with CFSE, used as responder cells finally co-cultured with effector cells. After 5 days incubation, cells were harvested and analyzed for flow cytometry by gating on the CFSE-labeled cells. The expression levels of Foxp3 and CD25 genes were detected by real-time polymerase chain reaction. Results After 9 days' culture in vitro, the proportion of Foxp3+ gammadelta T cells was 7.87% in the blank group, which was significantly lower than that in the TGF-beta, G-CSF and TGF-beta + G-CSF group (62.3%, 52.9% and 63.5%) (P<0.001). The proportions of CD25+gammadelta T and CD27+gammadelta T cells were 3.9% and 3.5% in the blank group, which were also significantly lower than that in the TGF-beta, G-CSF and TGF-beta + G-CSF group (CD25+gammadelta T cells: 43.5%, 43.4% and 44.4%; CD27+gammadelta T cells: 41.5%, 41.9% and 44.0%, respectively) (P<0.001, P<0.001). The effector cells induced by anti-TCR gammadelta with TGF-beta, G-CSF and TGF-beta + G-CSF all manifested a more significant suppressive effect on responder cells than cells induced only by anti-TCR gammadelta. However, there was no significant difference in the effect of cell proliferation suppression in the TGF-beta, G-CSF and TGF-beta + G-CSF groups. The expression level of Foxp3 gene was 0.384% in the blank group, which was significantly lower than that in the TGF-beta, G-CSF and TGF-beta + G-CSF group (0.623%, 0.639% and 0.843%, respectively) (P<0.001). The expression level of Foxp3 in TGF-beta+ G-CSF group was significantly higher than that in the TGF-beta and G-CSF group (P=0.001, P=0.007). The expression level of CD25 gene was similar among the four groups (P=0.457). Conclusions The generation of gammadelta Tregs could be enhance in vitro induced by G-CSF. This may be one of the reasons that G-CSF play an immunoregulatory role on

decreased GVHD onset during allo-HSCT.

Wu, Y., et al. (2006). "Diazo coupling method for covalent attachment of proteins to solid substrates." Bioconjugate Chemistry **17**(2): 359-365.

We describe a process for covalently linking proteins to glass microscope slides and microbeads in a manner that optimizes the reactivity of the immobilized proteins and that is suitable for high-throughput microarray and flow cytometry analysis. The method involves the diazo coupling of proteins onto activated self-assembled monolayers formed from p-aminophenyl trimethoxysilane. Proteins immobilized by this method maintained bioactivity and produced enhanced levels of protein-protein interaction, low background fluorescence, and high selectivity. The binding of immobilized proteins to their specific binding partner was analyzed quantitatively and successfully correlated with solution concentrations. Diazotized surfaces bound more efficiently to proteins containing a hexahistidine tag than those without a his-tag. Moreover, significantly higher reactivity of the immobilized his-tagged proteins was observed on diazotized surfaces than on amine-terminated surfaces. Results suggest that his-tagged proteins are immobilized by reaction of the his-tag with the diazotized surface, thus offering the possibility for preferential orientation of covalently bound proteins. © 2006 American Chemical Society.

Wu, Y., et al. (2019). "Effect of microplastics exposure on the photosynthesis system of freshwater algae." Journal of Hazardous Materials **374**: 219-227.

Microplastics are widely distributed in freshwater environments. At present, most of the studies on the toxicity of microplastics are concentrated on aquatic feeding animals, but relatively few have addressed freshwater algae. This study investigated the effect of microplastics (polypropylene (PP) and polyvinyl chloride (PVC)) exposure on the photosynthetic system of freshwater algae over the logarithmic growth period. The results showed that both PVC and PP had a negative effect on chlorophyll a concentrations of Chlorella (C.) pyrenoidosa and Microcystis (M.) flos-aquae; among them, when the concentration of PVC exceeded 250 mg/L, compared with the control group, the chlorophyll a content of C. pyrenoidosa was reduced by 55.23%. For photosynthetic activity, higher concentrations of PVC and PP can induce lower values of F_v/F_m, F_v/F₀, and F_v'/F_m', suggesting a larger impact in algae. However, algae were able to adjust, with increased values of F_v/F_m, F_v/F₀, and F_v'/F_m'. This dose-negative effect phenomenon also exists in the study of the rapid light-response curves. In addition, comparing the two microplastics, we could see that PVC greatly inhibits the photosynthesis system of freshwater algae. Our study confirmed that microplastics can affect algae growth under certain concentrations, which provides evidence for understanding the risks of microplastics.

Wu, Y., et al. (2018). "Generation of Size-controlled Poly (ethylene Glycol) Diacrylate Droplets via Semi-3-Dimensional Flow Focusing Microfluidic Devices." Journal of Visualized Experiments **137**(07): 03.

Uniform and size-controllable poly (ethylene glycol) diacrylate (PEGDA) droplets could be produced via the flow focusing process in a microfluidic device. This paper proposes a semi-three-dimensional (semi-3D) flow-focusing microfluidic chip for droplet formation. The polydimethylsiloxane (PDMS) chip was fabricated using the multi-layer soft lithography method. Hexadecane containing surfactant was used as the continuous phase, and PEGDA with the ultraviolet (UV) photo-initiator was the dispersed phase. Surfactants allowed the local surface tension to drop and formed a more cusped tip which promoted breaking into tiny micro-droplets. As the pressure of dispersed phase was constant, the size of droplets became smaller with increasing continuous phase pressure before dispersed phase flow was broken off. As a result, droplets with size variation from 1 micro m to 80 micro m in diameter could be selectively achieved by changing the pressure ratio in two inlet channels, and the average coefficient of variation was estimated to be below 7%. Furthermore, droplets could turn into micro-beads by UV exposure for photo-polymerization. Conjugating biomolecules on such micro-beads surface have many potential applications in the fields of biology and chemistry.

Wu, Y., et al. (2019). "On-chip cell mechanophenotyping using phase modulated surface acoustic wave." Biomicrofluidics **13**(2): 024107.

A surface acoustic wave (SAW) microfluidic chip was designed to measure the compressibility of cells and to differentiate cell mechanophenotypes. Polystyrene microbeads and poly(methylmethacrylate) (PMMA) microbeads were first tested in order to calibrate and validate the acoustic field. We observed the prefocused microbeads being pushed into the new pressure node upon phase shift. The captured trajectory matched well with the equation describing acoustic radiation force. The compressibility of polystyrene microbeads and that of PMMA microbeads was calculated, respectively, by fitting the trajectory from the experiment and that simulated by the equation across a range of compressibility values. Following, A549 human alveolar basal epithelial cells (A549 cells), human airway smooth muscle (HASM) cells, and MCF-7 breast cancer cells were tested using the same procedure. The compressibility of each cell from the three cell types was measured also by fitting trajectories between the experiment and that from the equation; the size was measured by image analysis. A549 cells were more compressible than HASM and MCF-7 cells; HASM cells could be further distinguished from MCF-7 cells by cell size. In addition, MCF-7 cells were treated by colchicine and 2-methoxyestradiol to disrupt the cell microtubules and were found to be more compressible. Computer simulation was also carried out to investigate the effect of cell compressibility and cell size due to acoustic radiation force to examine the sensitivity of the measurement. The SAW microfluidic method is capable of differentiating cell types or cells under different conditions based on the cell compressibility and the cell size.

Wu, Y., et al. (2008). "Phenylboronic acid immunoaffinity reactor coupled with flow injection chemiluminescence for determination of alpha-fetoprotein." Analytica Chimica Acta **630**(2): 186-193.

A reusable and sensitive immunoassay based on phenylboronic acid immunoaffinity reactor in combination with flow injection chemiluminescence (CL) for determination of glycoprotein was described. The reactor was fabricated by immobilizing 3-aminophenylboronic acid (APBA) on glass microbeads with gamma-glycidoxypropyltrimethoxysilane (GPMS) as linkage. The alpha-fetoprotein (AFP) could be easily immobilized on the APBA coated beads through sugar-boronic interaction. After an off-line incubation, the mixture of the analyte AFP with horseradish peroxidase-labeled AFP antibody (HRP-anti-AFP) was injected into the reactor. This led the trapping of free HRP-anti-AFP by the surface coated AFP on glass beads. The trapped HRP-anti-AFP was detected by chemiluminescence due to its sensitizing effect on the reaction of luminol and hydrogen peroxide. Under optimal conditions, the chemiluminescent signal was proportional to AFP concentration in the range of 10-10 0 ng m L(-1). The whole assay process including regeneration of the reactor could be completed within 31 min. The proposed system showed acceptable detection and fabrication reproducibility, and the results obtained with the present method were in acceptable agreement with those from parallel single-analyte test of practical clinical sera. The described method enabled a low-cost, time saving and was potential to detect the serum AFP level in clinical diagnosis.

Wu, Y. J., et al. (2017). "Effects of immunoglobulin D on expression of IgD receptor and protein tyrosine kinase signaling in human CD4⁺ T cells." Chinese Journal of Pharmacology and Toxicology **31 (10)**: 977.

OBJECTIVE: To observe whether human CD4⁺ T cells could be activated by immunoglobulin D (IgD) via IgD receptor(lgDR)-Lck. METHOD(S): Human CD4⁺T cells were purified from peripheral blood mononuclear cells (PBMCs) with microbeads. The viability of T cells were detected by CCK-8. The binding affinity and expression of IgDR on T cells were detected by flow cytometry. The protein expression of IgDR, Lck and P-Lck were analyzed by western blot. RESULT(S): IgD could concentrationdependent bind to IgDR on CD4⁺T cells. The expression of IgDR was increased in response to treatment with IgD in a time-dependent and concentration-dependent manner. Stimulating by IgD resulted in enhanced phosphorylation of Lck compared with that in the medium control sample. The expression of Lck was not changed. As inhibitor of PTK, Herbimycin A or A770041, which combined with IgD could significantly inhibit phosphorylation of Lck(Tyr³⁹⁴). The proliferation promoting effect of IgD was blocked by Herbimycin A or A770041. IgD could stimulate CD4⁺ T cell activation and proliferation through upregulating activating tyrosine residue of Lck (Tyr³⁹⁴) phosphorylation. CONCLUSION(S): These results demonstrate that IgD exaggerates CD4⁺T cell activities, which may be through promoting Lck phosphorylation.

Wu, Y. J., et al. (2018). "CP-25 Attenuates the Activation of CD4⁺ T Cells Stimulated with Immunoglobulin D in Human." Frontiers in Pharmacology **9**: 4.

Researchers have shown that the level of immunoglobulin D (IgD) is often elevated in patients with autoimmune diseases. The possible roles of IgD on the function of human T cell activation are still unclear. Paeoniflorin-6'-O-benzene sulfonate (code: CP-25), the chemistry structural modifications of paeoniflorin, was a novel drug of anti-inflammation and immunomodulation. The aims of this study were to determine if human CD4⁺ T cells could be activated by IgD via the IgD receptor (IgDR)-Lck pathway and whether the novel compound CP-25 could affect the activation of T cells by regulating Lck. Human CD4⁺ T cells were purified from peripheral blood mononuclear cells using microbeads. T cell viability and proliferation were detected by Cell Counting Kit-8 and CFSE Cell Proliferation Kit. Cytokines secreted by T cells were assessed with the Quantibody Human Inflammation Array. The binding affinity and expression of IgDR on T cells were detected by flow cytometry, and protein expression of IgDR, Lck, and P-Lck were analyzed by western blot. IgD was shown to bind to IgDR on CD4⁺ T cells in a concentration-dependent manner and stimulate the activation and proliferation of these cells by enhancing phosphorylation of the activating tyrosine residue of Lck (Tyr³⁹⁴). CP-25 inhibited the IgD-stimulated activation and proliferation of CD4⁺ T cells, as well as the production of inflammatory cytokines; it was thus suggested that this process might be related to the downregulation of Lck (Tyr³⁹⁴) phosphorylation. These results demonstrate that IgD amplifies the activation of CD4⁺ T cells, which could be mediated by Lck phosphorylation. Further, CP-25, via its ability to modulate Lck, is a novel potential therapeutic agent for the treatment of human autoimmune diseases.

Wu, Y.-j., et al. (2017). "Effects of immunoglobulin D on expression of IgD receptor and protein tyrosine kinase signaling in human CD4+ T cells." Zhongguo Yaolixue yu Dulixue Zazhi = Chinese Journal of Pharmacology and Toxicology **31**(10): 977.

OBJECTIVE To observe whether human CD4 + T cells could be activated by immuno-globulin D (IgD) via IgD receptor(IgDR)-Lck. METHODS Human CD4+ T cells were purified from peripheral blood mononuclear cells (PBMCs) with microbeads. The viability of T cells were detected by CCK-8. The binding affinity and expression of IgDR on T cells were detected by flow cytometry. The protein expression of IgDR, Lck and P-Lck were analyzed by western blot. RESULTS IgD could concentration-dependent bind to IgDR on CD4+ T cells. The expression of IgDR was increased in response to treatment with IgD in a time- dependent and concentration- dependent manner. Stimulating by IgD resulted in enhanced phosphorylation of Lck compared with that in the medium control sample. The expression of Lck was not changed. As inhibitor of PTK, Herbimycin A or A770041, which combined with IgD could significantly inhibit phosphorylation of Lck(Tyr394). The proliferation promoting effect of IgD was blocked by Herbimycin A or A770041. IgD could stimulate CD4+ T cell activation and proliferation through upreg?ulating activating tyrosine residue of Lck (Tyr394) phosphorylation. CONCLUSION These results demon?strate that IgD exaggerates CD4+T cell activities, which may be through promoting Lck phosphorylation.

Wu, Z. and H. Nakanishi (2013). "Differential pathways for the interleukin-1beta production activated by chromogranin A and Abeta in microglia." Molecular Neurodegeneration **1)**: S29.

Background Although chromogranin A (CGA) is frequently present in Alzheimer's disease (AD) senile plaques associated with microglial activation, little is known about basic difference between CGA and fibrillar Abeta as neuroinflammatory factors. Here we have thus compared the interleukin-1beta (IL-1beta) production pathways by CGA and fibrillar Abeta in microglia. Materials and methods MG6 microglia and primary cultured microglia were used in this study. Microglia isolated from young and aged mouse brains by magnetic cell sorting using CD11b-conjugated microbeads were also used. Processings of pro-caspase-1 and pro-IL-1beta were analysed by immunoblottings. Secretion of IL-1beta was measured by ELISA.The frontal cortex of human brains from AD and no clinical evidence of dementia were used for immunohistochemical analyses. Results In cultured microglia, production of IL-1beta was induced by CGA, but not by fibrillar Abeta. CGA activated both nuclear factor-kB (NFkB) and pro-caspase-1, whereas fibrillar Abeta activated pro-caspase-1 only. For the activation of pro-caspase-1, both CGA and fibrillar Abeta needed the enzymatic activity of cathepsin B (CatB), but only fibrillar Abeta required cytosolic leakage of CatB and the NLRP3 inflammasome activation [1,2]. In contrast, fibrillar Abeta induced the IL-1beta secretion from microglia isolated from the aged mouse brain. In AD brain, highly activated microglia, which showed intense immunoreactivity for CatB and IL-1beta, surrounded CGA-positive plaques more frequently than Abeta- positive plaques. Conclusions These observations indicate differential pathways for the microglial IL-1beta production by CGA and fibrillar Abeta, which may aid in better understanding of pathological significance of neuroinflammation in AD.

Wylie, D., et al. (2012). "Novel nanotechnologies for multiple spatially and temporally resolved live single cell membrane sampling and analysis." Free Radical Biology and Medicine **1)**: S127-S128.

Studying biology at the single cell level is of profound importance as the very concept of cellular heterogeneity within supposed 'identical cell populations' is the basis for how many diseases develop, especially cancer. No cancer or disease is ever diagnosed at the first cancer or diseased cell level but having a platform that can analyse and compare components of a diseased cell's proteome relative to that of a normal cell within the same cell population would be a huge step in that direction. Using a system where optical traps are generated holographically with a spatial light modulator (SLM), we can accurately control multiple mono-disperse lipidcoated microbeads (or Smart Droplet Microtools, SDMs) within a microfluidic cell culture environment.

We are able to spatially and temporally resolve sampling of various membrane associated fluorescently tagged proteins from multiple individual adherent viable cells and cell lines in a microfluidic culture environment and can sample repeatedly, if necessary, both before and after the addition of various biological and chemical reagents. This technology has the potential for subsequent downstream processing of the SDMs and their cargo for quantitative analysis and for delivering stimuli and other reagents to the cells.

Wylot, B., et al. (2013). "Hematopoetic stem/progenitor cellderived microglia-like cells with potential to support regeneration in the central nervous system." GLIA **1)**: S204.

In response to the central nervous system (CNS) injury, hematopoetic cells migrate to the lesion where they can potentially contribute to tissue regeneration. Following CNS injury, these cells can secrete a plethora of immunomodulating cytokines and/or pro-regenerative growth factors as well as phagocyte proinflammatory tissue debris. Nevertheless, the role of primitive hematopoetic stem/progenitor cells (HSPC) - derived from bone marrow - to support CNS regeneration has not been studied in detail. Therefore, the aim of the present study was to examine characteristics of HSPC in vitro as well as to test proregenerative potential of these cells to support CNS repair in vivo. Highly pure population of primitive hematopoetic stem/progenitor cells was isolated from the bone marrow and the CNS with fluorescence activated cell sorting (FACS). The number of HSPC in the CNS lesion was significantly increased compared to intact CNS tissue. Sorted-bone marrow HSPC were co-cultured with primary astrocytes to examine their phenotype according to the presence of specific antigens and gene expression as well as to test their phagocytosis potential. In the presence of astrocytes, bone marrow-derived HSPC differentiated in vitro into microglia-like cells expressing specific myeloid/microglia markers and showing high ability to ingest fluorescent microbeads. The in vivo potential of HPSC for supporting regeneration was examined by their transplantation into the CNS lesion. Results of our study demonstrated that primitive hematopoetic stem/progenitor cells are the source of microglia-like cells which can support regeneration in the central nervous system.

Wyssusek, K. H., et al. (2019). "Operating room greening initiatives - the old, the new, and the way forward: A narrative review." Waste Management and Research **37**(1): 3-19.

Healthcare waste is a rampant issue in Australian hospitals. The operating room (OR) contributes disproportionately to total hospital waste. There has been considerable research in the literature concentrating on strategies to improve OR and hospital waste accumulation, in an attempt to provide guidance and direction on how to reduce the healthcare ecological footprint. We reviewed the literature for leading greening initiatives currently utilised in the OR in Australia and internationally. This narrative literature review focuses on the trend of OR greening initiatives over the last 25 years, comparing different innovative approaches, the successes and setbacks, and the financial implications of initiatives. A variety of measures that hospital management, surgeons, anaesthetists, nurses and other healthcare personnel can take to reduce the ecological footprint of their healthcare facility are outlined. Greening initiatives include reducing, recycling, reusing, rethinking and researching, as well as novel technology and smarter architectural design. We also evaluated the barriers to improving waste management, which include lack of leadership, misconceptions among staff, and an overall resistance to change. In conclusion, in a world where greenhouse gas emissions cause unprecedented climate change and landfill space is finite, it is incumbent upon hospitals to help reduce the environmental impact of their facility. Reducing pollution and greenhouse gas emissions would moderate the incidence of human disease, save money for the healthcare system and society as a whole, and contribute to a safer and healthier world we all would like to live in. Xanthos, D. and T. R. Walker (2017). "International policies to reduce plastic marine pollution from single-use plastics (plastic bags and microbeads): A review." Marine Pollution Bulletin **118**(1-2): 17-26.

Marine plastic pollution has been a growing concern for decades. Single-use plastics (plastic bags and microbeads) are a significant source of this pollution. Although research outlining environmental, social, and economic impacts of marine plastic pollution is growing, few studies have examined policy and legislative tools to reduce plastic pollution, particularly single-use plastics (plastic bags and microbeads). This paper reviews current international market-based strategies and policies to reduce plastic bags and microbeads. While policies to reduce microbeads began in 2014, interventions for plastic bags began much earlier in 1991. However, few studies have documented or measured the effectiveness of these reduction strategies. Recommendations to further reduce single-use plastic marine pollution include: (i) research to evaluate effectiveness of bans and levies to ensure policies are having positive impacts on marine environments; and (ii) education and outreach to reduce consumption of plastic bags and microbeads at source.

Xia, B., et al. (2019). "Polystyrene microplastics increase uptake, elimination and cytotoxicity of decabromodiphenyl ether (BDE-209) in the marine scallop Chlamys farreri." Environmental Pollution: 113657.

Microplastics are a growing problem in marine environments due to their ubiquitous occurrence and affinity for chemical pollutants. However, the influence of microplastics on the uptake, depuration and toxicity of decabromodiphenyl ether (BDE-209) in marine organisms is unclear. We exposed the marine scallop Chlamys farreri to polystyrene microplastics (PS; 125 mug/L) combined with BDE-209 (10 and 100 mug/L) to determine their toxicokinetics, cellular toxicity and histopathological effects. The results showed that PS acted as both a carrier and a scavenger for the bioaccumulation of BDE-209. Importantly, the carrier role of PS was greater than scavenger one. PS increased the negative effect of BDE-209 (100 mug/L) on hemocyte phagocytosis, and ultrastructural changes in gills and digestive gland of scallops due to their carrier role for the bioaccumulation of BDE-209. However, PS did not increase the DNA damage of BDE-209 on the hemocytes. These findings are evidence of microplastics transferring adsorbed pollutants to marine organisms, and increasing their toxicity.

Xia, H., et al. (2017). "Analysis of marker gene transcripts and 35 cytokines in adipose tissue mesenchymal stem cells spanning 15 consecutive passages." Molecular Biology of the Cell. Conference **28**(26).

Mesenchymal stem cells (MSC) are multipotent stem cells, typically isolated from bone marrow, adipose tissue, and umbilical cord. But they have also been isolated from other fetal and adult tissues. MSC can differentiate into many different cell types, among them adipocytes, chondrocytes, and osteoblasts. The therapeutic potential of MSC has been assessed for a number of conditions, including conditions characterized by inflammation. MSC have been found to promote tissue regeneration and modulate immune responses involving inflammation. Thus, the cytokine secretion profile of MSC is important in these cells' ability to modulate inflammation. However, with increasing in vitro passages, MSC progressively lose their potency. To ascertain the changes in their cytokine secretion profile during in vitro propagation, we grew adipose tissue MSC for 17 successive passages, and for each passage quantified 35 secreted cytokines by the Luminex microbeads multiplex assays. The results show that the cytokine concentrations in the culture media increased, with various cytokines peaking around passages

8-11. Then the levels decreased, in some cases precipitously. The variations in cytokine levels from passage to passage ranged from relatively small to dramatic. For example, eotaxin concentration at passage 10 was nearly 30-fold greater than that at passage 6, and it was below detection limit at passage 17. The hepatocyte growth factor (HGF) and interleukin 1 receptor antagonist (IL-1RA) exhibited a different profile; both had early passage peak levels and then gradual drop. EGF, MIG, IL-3, and IL-15 could not be detected at any passage. We also assessed the expression profile of the main MSC marker genes and several negative marker genes. The expression of the positive markers CD29, CD44, and CD73 expressions did not have appreciable changes across the span of passages, CD 90 expression generally increased with passage number, and CD166 had significantly higher levels at passages 4 and 5, but much lower at other passages. The most remarkable of the negative markers was CD34; its level at passage 15 was nearly 100-fold greater than its lowest levels at some earlier passages.

Xia, M., et al. (2018). "The adsorption of Cs⁺ from wastewater using lithium-modified montmorillonite caged in calcium alginate beads." Chemosphere **203**: 271-280.

The increasing nuclear energy consumption has posed serious environmental concerns (e.g. nuclear leakage), and the removal of radionuclides such as cesium becomes an urgent issue to be solved currently. In this research, a novel non-toxic adsorbent lithium-modified montmorillonite clay encapsulated in calcium alginate microbeads (MCA/Li) was fabricated by using ion-exchange method and then used successfully in the remediation of cesium-contaminated wastewater. Analyses of scanning electron microscopy, X-ray diffraction, Fourier transform infrared spectroscopy, and X-ray photoelectron spectroscopy were used to characterize the physicochemical properties of adsorbent MCA/Li, such as internal crystal structure, constituent elements, and functional groups. The effects of concentration ratios (sodium alginate/montmorillonite), solution pH, contacting time and initial Cs⁺ concentration on the adsorption behavior were carefully investigated via batch adsorption experiments. The adsorbent MCA/Li exhibited higher selectivity and removal efficiency towards Cs⁺ with the maximum adsorption capacity of 100.25mg/g. In the kinetics study, the pseudo-first-order fitted the cesium adsorption data of MCA/Li better than the pseudo-second-order. The adsorption mechanism studies revealed the process followed the Langmuir isotherm model, which suggested that Cs⁺ adsorption onto MCA/Li is a monolayer homogeneous adsorption process. The research findings indicated this novel adsorbent MCA/Li demonstrated great potential in radioactive wastewater treatment due to its convenience in synthesis, high adsorption capacity, and low cost.

Xiang, Q., et al. (2019). "Adsorbed Sulfamethoxazole Exacerbates the Effects of Polystyrene (∼2 μm) on Gut Microbiota and the Antibiotic Resistome of a Soil Collembolan." Environmental Science & Technology **53**(21): 12823.

Microplastics pollution in the environment is now receiving worldwide attention; however, the effects of copollution of antibiotics and microplastics on the gut microbiome of globally distributed and functionally important nontarget soil animals remain poorly understood. We studied a model collembolan (Folsomia candida) and found that the ingestion of microplastics (polystyrene, 2–2.9 μm) substantially altered the gut microbiome, antibiotic resistance gene (ARG) profile, and the isotopic fractionation in the soil collembolan tissue. Importantly, collembolans exposed to polystyrene microplastics loaded with sulfamethoxazole (MA) presented a distinctive gut microbiome, ARG profile, and isotopic fractionation compared to those exposed to polystyrene alone (MH). We observed that the abundance of ARGs and mobile genetic elements (MGEs) in the MA-treated collembolan guts was significantly higher than in the

MH and the control treatments. There were also strong interactions between the gut microbiome and ARGs in the collembolan guts. We further found that bacterial β-diversity correlated significantly with the δ13C and δ15N values in collembolan body tissues. Together, our results indicate that changes in isotopic fractionation and ARG profiles in the collembolan were induced by the changes in gut microbiota and suggest that microplastics from diverse sources may have profound influences on soil fauna and soil food webs.

Xiao, D., et al. (2019). "Development of agricultural waste/recycled plastic/waste oil bio-composite wallpaper based on two-phase dye and liquefaction filling technology." Environmental Science & Pollution Research **12**: 12.

In this paper, a complete biomass composite processing system based on agricultural waste powders, recycled plastics, and waste oil is proposed. The wood-colored wallpaper, the green wallpaper, and the blue wallpaper are produced by this processing system. These wallpapers are new products with low cost, high added value, and environmental friendliness. These wallpapers have also been systematically tested. Based on the analysis of test results, a 3D model of material formation mechanism, liquefaction filling technology, and hybrid network model construction technology are obtained. The experiment found the reasonable RLDPE and RLLDPE ratio (1:0.26), the reasonable ratio of biomass to specialty solvents (1:1.5), the reasonable dose of the solid dye (3%), and the reasonable concentration of dye solutions. Wood-colored bio-composite wallpaper products have a smooth surface, wood color (DELTAE = 36.7), natural aroma, and good comprehensive mechanical properties (tensile strength 9.255 MPa; elongation at break 20.998%; Young's modulus 2229.475 MPa). The processing system and wallpaper products in this article not only promote the plastic recycling economy and sustainable agricultural development but also provide new channels for the development of waste oil reuse and new ideas for the development of high value-added biocomposite materials.

Xiao, J., et al. (2008). "[An effective method for T-cell and B-cell simultaneous depletion in vitro from mobilized peripheral blood stem/progenitor cell graft for haploidentical transplantation]." Zhongguo Shi Yan Xue Ye Xue Za Zhi **16**(5): 1126-1129.

Depletion of T and B cells from the graft is prerequisite for haploidentical transplantation to decrease the risk of GVHD and EBV-associated lymphoproliferative disease. This study was aimed to investigate the performance of T-cell and B-cell simultaneous depletion from mobilized peripheral blood stem cells (PBSCs) for the first time in China, using anti-CD3 and anti-CD19 antibodies conjugated to magnetic microbeads by the CliniMACS device. The depletion efficiency of T-cell and B-cells was analyzed by flow cytometry; the function of the stem cells after depletion was evaluated using colony assays. The results indicated that the mononuclear cell count prior to T- and B-cell depletion was 4.88 x 10(10). After depletion, the percentage of T cells was 0.02% with a log (10) depletion of 4.4. The percentage of B cells was less than 0.01% with a log (10) depletion of at least 3.3. The product contained not only CD34(+) stem cells, but also NK cells, monocytes and granulocytes. After T- and B-cell depletion the purity of CD34(+) cells was 0.98%, the number of CD34 cells was 1.84 x 10(8) and their recovery rate was 69.7%. The number of NK cells was 2.54 x 10(9) and the recovery rate of NK cells was 71.7%. In vitro colony assays showed no negative impact on function of the hematopoietic stem cells. In conclusion, the CliniMACS system can be used to efficiently deplete T and B cells from PBSCs simultaneously, without adverse effect on biological function of hematopoietic stem cells. This study provides technical platform for haploidentical hematopoietic stem cell transplantation.

Xiao, X., et al. (2018). "Bisphenol AP is anti-estrogenic and may cause adverse effects at low doses relevant to human exposure." Environmental Pollution **242**: 1625-1632.

A recent increase in the use of bisphenol A (BPA) alternatives to manufacture plastics has led to safety concerns. Here, we evaluated the estrogenic and anti-estrogenic activities of bisphenol AP (BPAP), a poorly studied BPA alternative, using in vitro , in vivo and in silico tools. BPAP exhibited weak estrogenicity but strong anti-estrogenicity (IC 50 = 2.35 μM) in a GeneBLAzer™ β-lactamase reporter gene assay. BPAP, when administered alone or in combination with E 2 (50 μg kg−1 bw d−1) for 3 d, significantly decreased the uterine weights of post-weaning CD-1 mice at doses of 10 mg kg−1 bw d−1 and higher. When administered alone to prepubertal CD-1 mice for 10 d, BPAP significantly decreased the uterine weights at doses of 80 μg kg−1 bw d−1 and higher. Toxicogenomic analysis showed that BPAP regulated an opposite patterns of gene expression than that of E 2 in mouse uteri. In a glucose tolerance test using male mice, BPAP was found to disrupt the blood glucose homeostasis at low doses relevant to human exposure (1 and 100 μg kg−1 bw d−1). Our results suggest that BPAP should be of great concern which might affect the sexual development in immature feminine and disrupt the blood glucose homeostasis at very low doses. Graphical abstract Image Highlights • BPAP shows weak estrogenicity but strong antiestrogenicity in vitro. • BPAP shows antiuterotrophic effect in mice at doses of 80 μg kg−1 bw/day and higher. • BPAP disrupts glycemic homeostasis in mice at doses relevant to human exposure. • BPAP induces opposite patterns of gene regulation than that of E 2 in mouse uteri. BPAP exhibits strong anti-estrogenicity. It can decrease the uterine weights by regulating estrogen-response genes and disrupt the blood glucose homeostasis in mice at very low doses. Xiao, Y., et al. (2019). "Preparation of magnetic nanomaterials and application in sensor detection." Journal of Food Safety and Quality **10**(20): 6893-6901.

Driven by the external magnetic field, the magnetic nanomaterials can quickly adsorb the target materials and separate them from the substrate. Based on this, magnetic nanomaterials have been widely used in adsorption and separation, environmental management, food safety and other aspects, and will have a greater application prospect. This paper introduced the research progress in preparation, enrichment and separation of magnetic nanomaterials and sensor detection. The preparation method of magnetic nanomaterials included solid, liquid and gas combination method. The adsorption and separation of organic pollutants (such as microplastics) and inorganic metal ions (such as chromium ions, lead ions) by magnetic nanomaterials were introduced. The applications of magnetic nanomaterials in electrochemical sensors, biosensors and optical sensors also were introduced.

Xie, B., et al. (1994). "Urea and lactate determined in 1-microL whole-blood samples with a miniaturized thermal biosensor." Clinical Chemistry **40**(12): 2282-2287.

A miniaturized flow-injected thermal biosensor was developed for the determination of urea and L-lactate in undiluted blood in 1-microL samples. The sensor employed a small enzyme column constructed of stainless steel tubing and microbead thermistors. Urease and lactate oxidase/catalase were separately immobilized onto controlled-pore glass beads, which, in turn, were charged into the enzyme column. With a flow rate of 70 microL/min, linear analytical ranges from 0.2 to at least 50 mmol/L and 0.2 to 14 mmol/L were obtained for urea and lactate, respectively. The relative standard deviations (CVs) for measurements of analyte in buffer were 0.91% for urea and 1.84% for lactate. For urea in whole blood, the CV for 50 determinations was 4.1%. Contrived samples containing various concentrations of urea and L-lactate in whole blood were determined with this sensor and with a spectrophotometric method. Comparisons of the results gave correlation coefficients of 0.989 and 0.984 for 30 blood urea and 30 blood lactate assays in concentrations ranging from 4 to 20.9 mmol/L and from 1.7 to 12.7 mmol/L, respectively.

Xie, M. W., et al. (2013). "Erratum: Marrow-derived stromal cell delivery on fibrin microbeads can correct radiation-induced wound-healing deficits (Journal of Investigative Dermatology (2013) 133 (553-561) DOI: 10.1038/jid.2012.326)." Journal of Investigative Dermatology **133**(3): 859.

Xie, X., et al. (2020). "Exposure to polystyrene microplastics causes reproductive toxicity through oxidative stress and activation of the p38 MAPK signaling pathway." Ecotoxicology & Environmental Safety **190**: 110133.

Microplastics (MP) are receiving increased attention as a harmful environmental pollutant, however information on the reproduction toxicity of MP in terrestrial animals, especially mammals, is limited. In this experiment, we investigated the impact of polystyrene microplastics (micro-PS) on the reproductive system of male mice. Healthy Balb/c mice were exposed to saline or to different doses of micro-PS for 6 weeks. The results showed that micro-PS exposure resulted in a significant decrease in the number and motility of sperm, and a significant increase in sperm deformity rate. We also detected a decrease in the activity of the sperm metabolism-related enzymes, succinate dehydrogenase (SDH) and lactate dehydrogenase (LDH), and a decrease in the serum testosterone content in the micro-PS exposure group. We found that micro-PS exposure caused oxidative stress and activated JNK and p38 MAPK. In addition, we found that when N-acetylcysteine (NAC) scavenges ROS, and when the p38 MAPK-specific inhibitor SB203580 inhibits p38MAPK, the micro-PS-induced sperm damage is alleviated and testosterone secretion improves. In conclusion, our findings suggest that micro-PS induces reproductive toxicity in mice through oxidative stress and activation of the p38 MAPK signaling pathways.

Xin, X., et al. (2010). "Primary cell culture of meningothelial cells-a new model to study the arachnoid in glaucomatous optic neuropathy." Graefe's Archive for Clinical and Experimental Ophthalmology **248**(9): 1273-1278.

Background: In a previous report, we found that the occurrence and amount of meningothelial cell nests in the subarachnoid space are significantly increased in glaucomatous optic nerves compared to normals. In order to allow research into the role of meningothelial cells during diseases of the optic nerve, an in vitro model is necessary. For this purpose, we developed a culture method for porcine meningothelial cells from the arachnoid layer covering the optic nerve. Method(s): Meningothelial cells were scraped from the arachnoid layer of porcine optic nerves and cultured for 2-3 weeks until the cells formed a monolayer. To eliminate contaminating fibroblasts from the culture, cells were negatively selected using magnetic anti-fibroblast beads after the first passage. Cells were detached using 0.05% Trypsin-EDTA, incubated with anti-fibroblast beads, separated using a magnetic column and the flow-through was collected. The purified primary meningothelial cells were characterized by electron microscopy and immunocytochemistry using anti-glial fibrillary acidic protein (GFAP) and anti-keratan sulfate antibodies. Result(s): Primary cells grew out after dissection and formed a

monolayer within 2-3 weeks, which was composed of two morphologically different cell types, flattened cells with round nuclei and fibroblast-like cells with long processes. The fibroblast-like cells in the culture could be labelled and selected using anti-fibroblast microbeads. The second cell type did not bind to the anti-fibroblast beads, and upon immunocytochemistry showed a marked expression of both GFAP and keratan sulphate. In addition, examination of these cells by electron microscopy revealed morphological characteristics of meningothelial cells, including hemidesmosomes and cytoplasmatic filaments. Conclusion(s): The technique described in this paper for the primary culture of meningothelial cells from the subarachnoid space of the optic nerve and using magnetic beads for the removal of fibroblasts is effective in obtaining a highly enriched meningothelial cell culture. © 2010 Springer-Verlag.

Xiong, X., et al. (2018). "Microplastics in the intestinal tracts of East Asian finless porpoises (Neophocaena asiaeorientalis sunameri) from Yellow Sea and Bohai Sea of China." Marine Pollution Bulletin **136**: 55-60.

The direct evidences for the ingestion of microplastics by cetaceans, especially the cetaceans in Asian marine areas are limited. In this study, residue of microplastics in the intestinal tracts of East Asian finless porpoises (Neophocaena asiaeorientalis sunameri) was investigated. Microplastics were detected in all specimens, with mean abundance of 19.1+or-7.2 items/individual. With respect to microplastics properties, fibers, blue items, and polypropylene were predominant in shapes, colors, and plastic materials, respectively. Trophic transfer and unintentional ingestion might be the potential pathways for microplastics ingested by finless porpoise. The specific intestinal structure might account for the predominance of fibers and the accumulation of microplastics at the beginning portion of intestines. This study indicates that cetaceans in Chinese marine areas also suffer from microplastics pollution. Further studies on the fate and ecological effects of microplastics should be conducted to reveal their potential risks to cetaceans.

Xiong, Z., et al. (2010). "Microparticles from stored RBC units show inflammatory chemokine binding that is altered by platelets." American Journal of Respiratory and Critical Care Medicine. Conference: American Thoracic Society International Conference, ATS **181**(1 MeetingAbstracts).

Rationale: Transfusion of stored red cells is an independent predictor for the development of and mortality from acute respiratory distress syndrome (ARDS) in patients at risk for ARDS. While storage results in reduced structural integrity of red cells leading to spheroechinocyte formation and release of microparticles, the functional aspects of red cell microparticle formation, particularly as it relates to inflammation, have not been well-studied. We hypothesized that red cell microparticles released during storage express the transmembrane chemokine binding protein Duffy antigen and show inflammatory chemokine binding. Method(s): Microparticles were isolated from Adsol stored, leukoreduced red cell unit bags using ultracentrifugation technique modified from published methods. Microparticles were defined by flow cytometry by surface glycophorin A expression and size ~70-700 nm relative to fluorescent microbeads employed for relative quantification. Red cell units were assayed for Duffy antigen status using standard Blood Bank methods. Duffy expression on microparticles and red cells were confirmed by flow cytometry using murine anti-human Duffy monoclonal antibody. Microparticles were tested for 125I-CXCL1/GRO-a binding in the presence of increasing concentrations of cold CXCL1 to determine the equilibrium dissociation constant, or Kd, of chemokine for microparticle binding sites. Result(s): Glycophorin A+ microparticles from red cell units on storage day 29 (14,473 + 11,412) were significantly higher than from units obtained on storage day 13 (369 + 97) (p=0.03). Duffy surface expression on microparticles was

detectable by flow cytometry, and microparticles showed specific, saturable 125I-CXCL1 chemokine binding. CXCL1 binding affinity remained relatively constant on intact, purified red cells with storage (3.8 + 1.3 nM, 7370 + 3901 binding sites/cell surface), whereas microparticle Duffy showed wide variation in Kd (0.6-44 nM; 20,700-58,000 binding sites/cell surface). Addition of platelets into the microparticle-chemokine mixture reduced microparticle chemokine binding (2933 + 343 vs 1186 + 85 cpm, p<0.04). Conclusion(s): Red cell microparticles express Duffy antigen with functional alterations in chemokine binding activity as compared to the intact stored red cell. Furthermore, microparticle-chemokine binding is altered by the presence of platelets. We speculate that red cell microparticle formation increases with storage duration, and microparticle Duffy regulates inflammatory chemokine bioavailability in the microvasculature through altered chemokine binding and release through interaction with platelets.

Xiu, F. R., et al. (2020). "A novel safety treatment strategy of DEHP-rich flexible polyvinyl chloride waste through low-temperature critical aqueous ammonia treatment." Science of the Total Environment **708 (no pagination)**(134532).

Flexible polyvinyl chloride (f-PVC) contains high content of plasticizers and chlorine. Improper treatment of waste f-PVC can easily lead to resource wasting and bring environmental risks. In this work, a novel strategy for resource recycling and dechlorination of waste f-PVC containing high content of di-(2-ethylhexyl) phthalate (DEHP) was developed by using low-temperature critical aqueous ammonia (LCA) process. The LCA treatment of waste DEHP-rich f-PVC (WDP) was performed at the temperature range of 200-400 degreeC with the ammonia concentration of 1%-5%. The results indicated that the LCA temperature had a significant effect on the chemical composition of decomposition products. High concentration of 2-ethyl-1-hexanol (86.12%), which is an important chemical feedstock and is derived from the decomposition of DEHP, could be obtained from WDP by the LCA process at 250 degreeC, and the concentration of 2-ethyl-1-hexanol decreased markedly with increasing the temperature. Benzaldehyde and acetophenone were generated when the temperature increased to 300 degreeC, and their concentrations increased with the rise of temperature. The increase of the ammonia concentration and the temperature could enhance the dechlorination efficiency of WDP. The dechlorination could reach 98.7% at 300 degreeC. This result showed that the LCA process was a promising and high-efficiency strategy for the sustainable management of WDP. Copyright © 2019 Elsevier B.V.

Xu, B., et al. (2001). "Functional comparison of the single-layer agarose microbeads and the developed three-layer agarose microbeads as the bioartificial pancreas: an in vitro study." Cell Transplantation **10**(4-5): 403-408.

In this study, the insulin secretory characteristics of the microencapsulated hamster islets were studied during long-term culture. The hamster islets were encapsulated as single-layer agarose microbeads or three-layer agarose microbeads with agarose and agarose containing poly(styrene sulfonic acid) (PSSa), respectively. The influence of PSSa on the function of the rat islets microencapsulted in three-layer microbeads was primarily monitored. The aim of this study was to examine the influence of the PSSa on the in vitro function of the islets encapsulated in the agarose/PSSa microbeads compared with single-layer agarose microbeads during long-term culture. The microbeads were cultured for 30 days in medium of Eagle's MEM at 37 degrees C in 5% CO2 and 95% air. The basal insulin secretion into the culture medium was measured daily during the first 12 days and two times per week until 30 days. The microbeads were subjected to static incubation test on the 10th, 20th, and 30th day during culture. The

basal insulin secretion level of the agarose/PSSa microbeads was significantly higher than that of single-layer agarose microbeads. The static incubation tests revealed a similar pattern of insulin secretion from both microbeads when they were exposed to high glucose challenge. In the static incubation test, both could significantly increase insulin release to more than 6.61 times (stimulation index) in response to high glucose stimulation and could significantly decrease when glucose concentration returned from high glucose to low glucose on the 10th, 20th, and 30th day of culture. This study demonstrated that the hamster islets enclosed in agarose/PSSa hydrogel not only continuously secreted basal amounts of insulin, but also maintained their response to high glucose stimulation similar to the agarose microbeads. The above results together with those of our previous in vivo study suggest that the three-layer microbeads (agarose/PSSa) are well suitable for xenotransplantation of islets for the clinical application.

Xu, B., et al. (2018). "Microplastics play a minor role in tetracycline sorption in the presence of dissolved organic matter." Environmental Pollution **240**: 87-94.

Microplastics have a great potential to sorb organic pollutants from the adjacent environment. In this study, the sorption of tetracycline, a polar and ionizable antibiotic, on three types of microplastics (polyethylene (PE), polypropylene (PP) and polystyrene (PS)) were investigated in batch sorption experiments. The sorption isotherms were well fitted by the Langmuir model, indicating that not only hydrophobic interactions but also other interactions (e.g. electrostatic interactions) played important roles in the sorption process. PS had the maximum sorption capacity, following the order PS > PP > PE, which can be attributed to polar interactions and π-π interactions. The sorption of tetracycline on microplastics was significantly influenced by pH, with sorption capacity increasing gradually, peaking at pH 6.0 and then decreasing, likely due to the influence of tetracycline speciation with the change of pH. Fulvic acid was selected as representative dissolved organic matter (DOM) to examine the effect on sorption. The increasing concentration of fulvic acid inhibited the sorption of tetracycline on three microplastics, decreasing them by more than 90% at the fulvic acid concentration of 20 mg/L, which implied a greater affinity of tetracycline to fulvic acid than to microplastics. Increasing salinity from 0.05 to 3.5% had negligible effects on the sorption of tetracycline on the three microplastics. Our results highlight the importance of pH and DOM on the sorption of tetracycline on microplastics, and suggest the relatively minor role of microplastics in the fate and transport of tetracycline in the aquatic environment in the presence of DOM. [ABSTRACT FROM AUTHOR]

Xu, B., et al. (2018). "The sorption kinetics and isotherms of sulfamethoxazole with polyethylene microplastics." Marine Pollution Bulletin **131**(Pt A): 191-196.

Microplastics and sulfamethoxazole coexist ubiquitously in the marine environment, and microplastics tend to sorb organic pollutants from the surrounding environment. Here, the sorption kinetics and isotherms of sulfamethoxazole on polyethylene (PE) microplastics closely fitted a pseudo-second-order model (R²=0.98) and linear model (R²=0.99), respectively, indicating that the sorption process was partition-dominant interaction. The main binding mechanism was possibly the van der Waals interaction for hydrophilic sulfamethoxazole onto hydrophobic PE microplastics. The effects of pH, dissolved organic matter and salinity on sorption behavior were also studied. The sorption behavior of sulfamethoxazole on PE microplastics was not significantly influenced by pH and salinity, probably because the electrostatic repulsion played a minor role. In addition, the negligible effect of dissolved organic matter was attributed to the greater affinity of sulfamethoxazole to PE microplastics than to dissolved organic matter. Our results demonstrated that PE microplastics may serve as a carrier for sulfamethoxazole in the aquatic environment.

Xu, B., et al. (2019). "Microplastics in the soil environment: Occurrence, risks, interactions and fate-A review." Critical Reviews in Environmental Science and Technology.

The issue of microplastic pollution emerged from the marine environment, but the terrestrial environment is estimated to receive annually 4-23 times more plastic wastes. Microplastic pollution in the soil environment has thus begun to elicit great concern. This review summarizes the observed effects of microplastic pollution on soil ecosystems as well as sorption and transport behaviors of microplastics in such environments. Microplastic pollution has been detected in various soils including agricultural/farmland, greenhouse, home garden, coastal, industrial, and floodplain soils. Microplastics affect soil physical and chemical properties, microbial and enzyme activities, and plant growth, and also pose adverse ecotoxicological effects to soil fauna. These effects depend on the concentration, size, and shape of microplastics, as well as soil texture. Microplastics are known to sorb organic and inorganic pollutants, possibly affecting the distribution of these substances in soil. Existing evidence demonstrates the negligible effect of microplastics on bioaccumulation of contaminants in soil fauna. The horizontal and vertical transport of microplastics can be facilitated by soil fauna. Pollutants associated with microplastics may disperse further following the transport of microplastics in soil. This review also highlights perspectives for future research on microplastics in soil. Xu, H., et al. (2017). "B cell-activating factor regulates the survival of B lymphocytes infected with human cytomegalovirus." Immunology Letters **187**: 1-6.

BACKGROUND: Previous studies have suggested that B lymphocytes can be polyclonally activated by human cytomegalovirus (HCMV), and individuals infected by HCMV exhibit characteristic features of an autoimmunity disease. B cell-activating factor (BAFF) plays important roles in the survival and differentiation of B cells; however, few studies have examined the potential role of BAFF on B cells infected by HCMV.

METHODS: HCMV virus strain (HCMV AD-169) was concentrated by normal methods and used to infect microbead-purified tonsil CD19+ B cells. Cells and supernatants were collected at the 1st, 3rd, 5th, and 7th day of co-culture, respectively. Cellular phenotypes, including expression of BAFF and its cognate receptors (BAFF-R, TACI, and BCMA) were detected by flow cytometry (FCM); cells apoptosis rates were also examined by FCM; and IgG titers in supernatants was detected by ELISA. In parallel, neutralizing anti-BAFF-R antibody was applied to observe the effect of BAFF/BAFF-R signaling on apoptosis and the IgG secretion ability of B cells stimulated by HCMV.

RESULTS: LogTCID₅₀ of 3rd and 4th generation of HCMV was -3.54 and -3.28, respectively. FCM results showed that the purity of CD19⁺ B cells was >98%. BAFF-R was highly expressed and upregulated on HCMV-infected B cells (93.5%-99.3%), compared with B cells prior to HCMV infection and uninfected group; while BAFF-R expression gradually decreased with time and to the lowest level at 5th day (81%) in the control medium-only group. In contrast, expression of TACI and BCMA gradually increased during culture in both HCMV-infected and medium-only control B cells. Furthermore, the apoptosis rate of HCMV-infected and medium-only control B cells did not vary significantly during culture, but IgG secretion ability of HCMV-infected B cells significantly increased over time while no changes were observed with the medium-only control. Importantly, the apoptosis rate of B cells significantly increased when BAFF/BAFF-R signal was blocked prior to HCMV infection (P<0.05), although no significant changes of IgG levels were observed (P>0.05).

CONCLUSIONS: BAFF-R was consistently expressed on B cells infected by HCMV. Enhancement of BAFF/BAFF-R signaling decreased the apoptosis rate and extended the survival of B cells.

Xu, J., et al. (2019). "Micro-rheological and micro-heterogeneity properties of soluble glutinous rice starch (SGRS) solutions studied by diffusing wave spectroscopy (DWS)." Journal of Food Measurement and Characterization **13**(4): 2822-2827.

As a natural biopolymer, soluble glutinous rice starch (SGRS) is widely used in the food industry; and has better binding characteristics than dextrin. The micro-structural heterogeneity and micro-rheology of SGRS solutions were investigated by the novel technique diffusion wave spectroscopy (DWS). By comparing the mean-square displacement (MSD) of the microbeads imbedded in six concentrations of SGRS solutions, we found that the solutions exhibited nearly homogeneous behavior at <=0.5%, but the material displayed a clear degree of heterogeneity at >1%. Micro-rheology investigation revealed that SGRS solutions showed nearly perfect viscous behavior at <=0.5%, but the property changed into viscoelastic one at >1%. The magnitude of high-frequency viscoelastic moduli for the 3-5% SGRS solutions can be characterized by , G*, infinity omega ^{3/4}, which is the semi-flexible polymer behavior. However, the magnitude of high-frequency viscoelastic moduli (, G*,) for the 7-10% SGRS solutions is proportional to omega ^{1/2}, which is the flexible polymer behavior. All micro-structural heterogeneity and micro-rheological property shifts occurred in relatively small concentration ranges.

Xu, L., et al. (2011). "Effects of increasing dietary concentrations of corn naturally contaminated with deoxynivalenol on broiler and turkey poult performance and response to lipopolysaccharide." Poultry Science **90**(12): 2766-2774.

In this study, 2 experiments determined the effects of increasing dietary concentrations of deoxynivalenol (DON) on performance, intestinal morphology, and measures of innate immunity in broilers and turkeys. For experiment 1, the 3-wk study used 5 concentrations of DON (up to 18 or 10 mg of DON/kg of feed in broilers or turkeys, respectively) from naturally contaminated corn. The BW gains were cubically or quadratically affected by the increasing dietary concentrations of DON for broilers and turkeys, respectively; however, feed consumption was not affected. For experiment 2, the birds were subsequently injected or not injected with lipopolysaccharide (LPS) 24 h before tissue and blood sample collection. Dietary DON had no effect on intestinal crypt depth, but linearly increased the mid-ileal villus height in broilers (P=0.04). An interaction was observed between the LPS challenge and the dietary DON with regards to heterophil to lymphocyte ratio (P<0.05) in broilers, but not in turkeys. The cecal tonsil cell phagocytosis of microbeads was not affected by the dietary concentration of DON either with or without the subsequent LPS challenge for both broilers and turkeys. Conversely, the phagocytic capacity of cecal tonsil cells to engulf killed Staphylococcus aureus was significantly reduced (over 2.5-fold) when broilers were fed the highest concentration of dietary DON (non-LPS-challenged; P<0.05). However, diets containing DON showed no effects on broilers when they were challenged with LPS. Antibody-dependent phagocytosis (S. aureus) was not affected in turkeys fed DON. Overall, corn naturally contaminated with up to 18 or 10 mg/kg of DON (broiler or turkey, respectively) reduced bird BW gain at 21 d of age, reduced

antibody-dependent phagocytosis of previously killed S. aureus by cecal tonsil cells in non-LPS-challenged broilers, and greatly decreased heterophil to lymphocyte ratios in LPS-challenged broilers.

Xu, M., et al. (2019). "Internalization and toxicity: A preliminary study of effects of nanoplastic particles on human lung epithelial cell." Science of the Total Environment **694**: 133794.

As a kind of newly emerging pollutant, nanoplastics are easily to be ingested by organisms, and cause severe damage to biological functions because of their small size, high specific surface area, and strong biological penetration. Recently, there are increasing reports of numerous airborne microplastics, including polystyrene (PS), being detected in atmospheric samples, which implies a potential risk to the human respiratory system. In this work, we evaluated the effects of polystyrene nanoparticles of two different sizes (PS-NP25: 25nm diameter and PS-NP70: 70nm diameter) on the human alveolar epithelial A549 cell line including internalization, cell viability, cell cycle, apoptosis, and associated gene transcription and protein expression.

Xu, P., et al. (2019). "Sorption of polybrominated diphenyl ethers by microplastics." Marine Pollution Bulletin **145**: 260-269.

The sorption of polybrominated diphenyl ethers (PBDEs) onto polyethylene (PE), polypropylene (PP), polystyrene (PS), and polyamide (PA) microplastics was analyzed using different kinetic and isotherm models, and under various environmental conditions, including temperature, pH, salinity and dissolved organic matter (DOM). The sorption capacity was in the order of PS>PA>PP>PE, due to the different crystallinity, specific surface area, and surface structure. PS demonstrated the equilibrium sorption capacity, namely, 6.41ng/g BDE-47, 12.83ng/g BDE-99, and 14.42ng/g BDE-153. The second-order kinetic model described the sorption kinetics of PBDEs, and surface sorption was the main mechanism. The sorption of PBDEs by microplastics was a multilayer and physical process. Low temperatures reduced BDE-47 sorption on microplastics, and sorption was a spontaneous and endothermic process. The sorption of BDE-47 was not significantly influenced by pH and salinity. However, DOM exerted a negative effect on the sorption of BDE-47.

Xu, P., et al. (2018). "Microplastic risk assessment in surface waters: A case study in the Changjiang Estuary, China." Marine Pollution Bulletin **133**: 647-654.

The rapid development of plastic industry has resulted in a series of environmental problems caused by microplastics originating from larger plastics. Microplastic pollution risk in surface waters of the Changjiang Estuary was explored based on risk assessment models. The average microplastic concentration was 23.1+/-18.2 n/100L. Shape, size, color and composition types of microplastics were examined. The risk assessment models were developed using data on both the concentration and chemical hazard of microplastic polymers. Assessment results indicated that polyvinyl chloride exhibited a critical concern for microplastic risk. Areas around aquaculture farms were regarded as "hotspots" of microplastic pollution due to the accumulation of microplastics and the presence of hazardous microplastic. This risk assessment of microplastics bridged gaps in understanding between field research and policy-making for surface waters. This research provides baseline data for assessing the environmental risk of microplastics in this growing area of research.

Xu, P., et al. (2019). "Spatial-temporal distribution and pollution load of microplastics in the Changjiang Estuary." Zhongguo Huanjing Kexue = China Environmental Science **39**(5).

There has been a recent focus on microplastics(5 mm) because of their presence in different environmental media. The spatial and temporal distribution of microplastics in the surface sediments of the Changjiang Estuary were investigated in March and July 2017. Sampling was conducted at 17 stations covering the north passage and south passage of the Changjiang Estuary, East China Sea and Hangzhou bay. Among these sampling stations, the highest concentration of microplastics was(39.33±14.34)particles/kg(DW) in the Hangzhou bay in summer. There was no significant difference in spatial distribution of microplastics. The amount of precipitation was highly related with the abundance of microplastics, which showd higher concentrations in summer than in spring. The size, color, shape and composition of microplastics were classified. Attenuated total reflectance-Fourier transform infrared spectrometry showed that there were several types of microplastics existing in sediments, including polyethylene,polypropylene, polyvinyl chloride, polyamide, and polystyrene, among them, polyethylene was the main type. The method of pollution load index was used to assess the degree of microplastic pollution. Overall, the Changjiang Estuary-Hangzhou bay and its adjacent areas were less polluted by microplastics.

Xu, S., et al. (2020). "Microplastics in aquatic environments: Occurrence, accumulation, and biological effects." Science of the Total Environment **703**: 134699.

Microplastics, whether originating directly from industrial and household products or from the degradation of larger plastics, are currently of intense global concern. These particles are present in aquatic environments in high concentrations and may adversely affect aquatic organisms. An additional concern is the ability of microplastics to adsorb inorganic and organic pollutants and subsequently liberate them into marine and freshwater systems. In this review, we report on the occurrence and abundance of microplastics in the global aquatic environment. We then consider the accumulation (uptake, distribution, and elimination) of microplastics in aquatic organisms and the important factors that lead to bioaccumulation. The effects of microplastics on aquatic organisms of different trophic levels are also discussed. Several studies have shown that the size, shape, and surface physicochemical characteristics of microplastics are essential determinants of their biological effects. Finally, we examine the combined effects of microplastics and other pollutants, including persistent organic pollutants and heavy metals. Our review concludes by suggesting future lines of research based on the remaining knowledge gaps in microplastic research.

Xu, W., et al. (2018). "Isolation, identification, and degradation characteristics of a DMP-degrading strain." Journal of Agro Environment Science **37**(8): 1724-1732.

To isolate a dimethyl phthalate (DMP)-degrading strain, the soil that had been exposed to long-term plastic pollution was collected and used. The DMP-degrading strain was screened out using selective media method, and identified by morphological, physiological, and biochemical analyses, as well as 16S rDNA sequence analysis. Moreover, the degradation characteristics were studied. The results showed that the DMP-degraded strain was classified as Paracoccus sp., named as QD15-1 and belongs to Gram-negative bacterium. The substrate utilization tests showed that the QD15-1 strain could utilize phthalic acid esters (PAEs) pollutants, such as DMP, dibutyl phthalate (DBP), diethyl phthalate (DEP) and diethylhexyl phthalate (DEHP). When DMP was the only carbon source, the optimized conditions of the QD15-1 strain were as follows: pH, 8; temperature, 30 degrees C. The degradation kinetics of QD15-1 were studied in varied initial DMP concentrations under optimal conditions; the results indicated that degradation of DMP conforms to the pseudo-first order kinetic equation, and the half life of DMP was shortened as the initial concentration was increasing up. Importantly, PCR analysis showed the QD15-1 strain to contain PAE-degrading genes, such as the phthalate dioxygenase gene (PAphtAb), and 3, 4-dihydroxy-3, 4-dihydrophthalate dehydrogenase (PAphtB). Liquid mass spectrometry showed that the intermediate metabolites in the minimal medium included o-benzene dicarboxylic acid monoester and phthalic acid. The DMP degradation pathway in the gram-negative strain Paracoccus sp. QD15-1 was speculated to operate as follows: DMP was degraded into o-benzene dicarboxylic acid monoester, decomposed into phthalic acid, and was then further degraded by the above-mentioned genes. These results indicate that QD15-1 is a high-efficiency DMP-degrading strain, and it is expected that the strain QD15-1 could be used to clear DMP pollution in future.

Xu, X., et al. (2018). "Research progress on the transference and pollution characteristics of microplastics in wastewater treatment plants." China Environmental Science **38**(11): 4393-4400.

Due to the widespread use and persistent contamination of synthetic polymers, microplastic (<5 mm) has been got more and more attention in recent years as a new type of pollutants. The discharge of sewage was one of the main sources of microplastic in freshwater and marine environment, so the sewage treatment plants also became an important path for microplastic to enter into fresh water and marine environment. The source of microplastic was investigated systematically, the research progress in the transport and pollution characteristics of microplastic in wastewater treatment plants was reviewed, and the differences of microplastic pollution in wastewater treatment plants at home and abroad in recent years were compared. It would provide reference for the research and supervision of microplastic pollution in domestic sewage treatment plants and look forward to the future development and improvement direction of wastewater treatment process.

Xu, X., et al. (2019). "Microplastics in the wastewater treatment plants (WWTPs): Occurrence and removal." Chemosphere **235**: 1089-1096.

WWTPs may be one of the important ways for MPs to enter surface water. In the present study, the influent and effluent from eleven WWTPs in Changzhou were collected and analyzed. At the same time, the abundance, size, color, and shape of MPs in influent and effluent were investigated. The average abundance of MPs in the influent and effluent were 196.00 +/- 11.89 n/L and 9.04 +/- 1.12 n/L respectively, and the MPs removal efficiency of eleven WWTPs was almost over 90% in which it could be up to 97.15%. MPs were divided into four particle size based on abundance changes, and the size of MPs with the highest abundant was mainly concentrated at 0.1-0.5 mm. Among these MPs, fibers were the main shape in wastewater, followed by fragments, flakes, spheres and films. The colors of MPs in wastewater were various and 14 types of plastics were detected from wastewater using attenuated total reflection Fourier transform infrared spectroscopy (ATR-FTIR). Moreover, Rayon and PET were the dominant polymer types in eleven WWTPs. The research results provided basic data for the research and supervision of MPs pollution in WWTPs. Xu, X., et al. (2020). "Detection of Treponema denticola in Chronic Periodontitis by Quantitative Real-Time Polymerase Chain Reaction." Journal of Nanoscience & Nanotechnology **20**(3): 1463-1469.

Chronic periodontitis constitutes a significant public health issue, particularly in China. Treponema denticola is one of the bacterial species critically involved in the development of this disease. Therefore, an effort was made in this study to design a technique for isolation of DNA from gingival fluid and detection of T. denticola genes by PCR methodology. For this purpose, samples were collected from 30 patients with severe periodontitis and 20 patients with mild periodontitis. A group of 50 healthy individuals served as a control. Following the isolation of

DNA from the gingival fluid by magnetic microbeads, the material was analyzed for the presence of 16S rRNA by conventional and quantitative real-time PCR protocols. This newly developed methodology identified the presence of T. denticola in all samples from periodontitis patients. Quantitative analysis of copy numbers demonstrated that the bacterial count was highest in the severe periodontitis group and intermediate in the mild periodontitis group. The smallest number of bacteria were present in healthy controls. Besides being rapid, accurate and specific, the proposed method eliminates the need for anaerobic bacterial cultures, making it applicable in a typical clinical setting.

Xu, X., et al. (2019). "Marine microplastic-associated bacterial community succession in response to geography, exposure time, and plastic type in China's coastal seawaters." Marine Pollution Bulletin **145**: 278-286.

Microplastics have emerged as new pollutants in oceans. Nevertheless, information of the long-term variations in the composition of plastic-associated microbial communities in coastal waters remains limited. This study applied high-throughput sequencing to investigate the successional stages of microbial communities attached to polypropylene and polyvinyl chloride microplastics exposed for one year in the coastal seawater of China. The composition of plastisphere microbial communities varied remarkably across geographical locations and exposure times. The dominant bacteria in the plastisphere were affiliated with the Alphaproteobacteria class, particularly Rhodobacteraceae, followed by the Gammaproteobacteria class. Scanning electron microscopy analysis revealed that the microplastics showed signs of degradation. Microbial communities showed adaptations to plastisphere including more diverse microbial community and greater "xenobiotics biodegradation and metabolism" in metabolic pathway analysis. The findings elucidate the long-term changes in the community composition of microorganisms that colonize microplastics and expand the understanding of plastisphere microbial communities present in the marine environment.

Xu, X. Y., et al. (2017). "Microplastic ingestion reduces energy intake in the clam Atactodea striata." Marine Pollution Bulletin **124**(2): 798-802.

The effects of microplastic concentrations (10 items l⁻¹ and 1000 items l⁻¹) on the physiological responses of Atactodea striata (clearance rate, absorption efficiency, respiration rate) were investigated. The fates of ingested microplastics and the efficiency of depuration in removing ingested microplastics were also studied. A. striata ingested microplastics and the clearance rate was reduced at high concentration of microplastics. Since the respiration rate and absorption efficiency remained unchanged in exposed A. striata, reduction in the clearance rate would reduce the energy intake. Ingestion and retention of microplastics in the body were further limited by the production of pseudofaeces and faeces, and depuration in clean water, resulting in a very small amount of microplastics stored in the body of the clam.

Xue, J. and K. Kannan (2019). "Mass flows and removal of eight bisphenol analogs, bisphenol A diglycidyl ether and its derivatives in two wastewater treatment plants in New York State, USA." Science of the Total Environment **648**: 442-449.

Despite high production and usage of bisphenols including bisphenol A (BPA) as well as bisphenol A diglycidyl ether and its derivatives (BADGEs), little is known about the occurrence and fate of these substances in wastewater treatment plants (WWTPs) in the U.S. In this study, we investigated the occurrence, removal, mass flows, and fate of eight bisphenol analogues and six BADGEs based on the concentrations measured in influent, primary effluent, final effluent, and sludge from two WWTPs (WWTP<inf>A</inf> and WWTP<inf>B</inf>) in the Albany area of New York State, USA. BPA, bisphenol F, bisphenol S, and BADGE.2H<inf>2</inf>O were the predominant compounds found in influents of both WWTPs, at respective geometric mean (GM) concentrations of 90.0, 90.2, 31.2, and 6.48 ng/L in WWTP<inf>A</inf>, and 53.3, <MLOQ, 27.6, 2.25 ng/L in WWTP<inf>B</inf>. Incomplete removal of these compounds was observed in both WWTPs with the highest removal rate (52%) was found for BPA after the secondary treatment in WWTP<inf>A</inf>. The fraction of BPA sorbed to suspended particulate matter (SPM) was 6.83%. Mean daily mass loadings of total bisphenols and BADGEs ranged from 9.2 [(BADGEs) in WWTP<inf>B</inf>] to 226 mg/d/1000 inhabitants [(BPs) in WWTP<inf>A</inf>]. The environmental emission rates of total bisphenols and BADGEs through effluent discharges from WWTPs ranged from 13.7 [(BADGEs) in WWTP<inf>B</inf>] to 246 mg/d/1000 inhabitants [(BPs) in WWTP<inf>A</inf>]. Overall, bisphenols and BADGEs were not removed completely by activated sludge treatment. Furthermore, formation of bisphenols from the degradation of microplastics or other precursors such as alkylated bisphenols, in WWTPs is suggested. Copyright © 2018 Elsevier B.V.

Xue, Y., et al. (2010). Physics-based multistage fatigue model for fatigue in notched structures. TMS 2010 - 139th Annual Meeting and Exhibition, February 14, 2010 - February 18, 2010, Seattle, WA, United states, Minerals, Metals and Materials Society.

A physically motivated mechanistic MultiStage Fatigue (MSF) model was developed for variable loading and multiaxial loading cases for notched structures. The MSF model depicts the effects of microstructural features on fatigue damage evolution stages, i.e., incubation, small crack growth, and long crack growth, allowing the assessment of variations in fatigue behaviors associated with the random microstructural features and stochastic interference between fatigue damage and those microstructural features. Therefore, the MSF model is an example of a necessary fatigue model for a structural health prognosis system. In this paper, special functions/effects in notched structures related to prognosis-specific requirements for airframe structures were evaluated and added into the MSF model. The notch-root behavior was presented as a function of not only the local plasticity accumulation but also the damage at the microscale associated with cyclic loads. Meanwhile, overload effects to the microplasticity in the vicinity of intermetallic particles were incorporated into the incubation model. Thus, the variable loads associated with generic flight spectrum were reorganized based on the transient material behavior at notch root. Finally, the MSF model was validated to predict damage and fatigue life of a wrought aerospace-graded Al alloy in experiments under various spectrums and notch root stress concentrations.

Yabanli, M., et al. (2019). "Microplastic pollution at the intersection of the Aegean and Mediterranean Seas: A study of the Datca Peninsula (Turkey)." Marine Pollution Bulletin **145**: 47-55.

This study aims to reveal microplastic pollution. It is the first to be conducted in the South Aegean Region and one of the limited numbers of such studies in Turkey. To this aim, in September 2018 microplastic particles (MP's) pollution was evaluated on the sandy beaches along the coastline of the Datca Peninsula (Southern Aegean coast of Turkey) located at the intersection of the Aegean and Mediterranean Seas. MP's were analyzed using standard operating procedure along with some experimental techniques. Prior to the identification process, microplastics ranging from 1 to 5mm were exposed to an experimental pre-treatment and efficient polymer scanning. The results showed that fragments (72%) were the dominant category from all the beaches exposed to dominant winds and surface currents and that MP contamination in the Datca Peninsula was higher than that reported in the literature from similar locations around the world (1154.4+/-700.3 particles kg⁻¹ dw). More specifically the highest contamination was found in Aktur Beach (2073.3+/-648.6 particles kg⁻¹ dw) which could be considered as a hotspot for the whole region in terms of MP pollution. As a result of the study, as sampling stations are remote from major cities and industrial zones, maritime activities increase during summer season and tar has been observed on particles during analyses, it can be asserted that the pollution may be caused by marine resources.

Yada, D., et al. "Plastic waste as an effective stormwater best management practice. (Geotechnical Special Publication No.211)." Geo-frontiers 2011 **Dallas**: Texas, March 13-16, 2011; 2011.

This study focused on the manufacture, hydraulic and mechanical properties of a porous plastic-based cementitious (P-PBC) material. P-PBC, produced from plastic waste, soil and aggregates, will offer an effective technique for reducing stormwater runoff, improving water quality and providing a structural pavement suitable for pedestrian and vehicular loadings. It will also help divert a large amount of plastic from landfills and incinerators thus playing a crucial role in the recycling efforts currently underway. P-PBC specimens with different plastic to soil/aggregate ratios were prepared and then tested for hydraulic conductivity (k) and indirect tensile strength (ITS). Results showed that k and ITS values of specimens were within the expected values found in the literature for porous pavements. It was also found that the k values decreased with the increase of percentage of plastic waste. ITS, on the other hand, increased with the amount of plastic waste. The study findings indicated that P-PBC could be an effective Stormwater Best Management Practice with significant positive economic and ecological implications.

Yamada, K., et al. (1999). "Constituents of Organic Pollutants in Leachates from Different Types of

Landfill Sites and Their Fate in the Treatment Processes." Mizu Kankyo Gakkaishi/Journal of Japan Society on Water Environment **22**(1): 40-45.

Constituents of oraganic pollutants in leachates from different types of landfill sites were measured by gas chromatograph - mass spectrometry (GC/MS). The leachates contained various volatile and semi-volatile compounds, some of which were regarded as endocrine disrupting chemicals. The leachate from a site filled with more plastic waste contained more micropollutants such as plastic additives than the leachte from a site filled mainly with incinerator ash waste. These micropollutants were decreased in their concentrations along the treatment processes of the leachates. Leachates from least controlled sites where only non hazardous industrial wastes can be dumped legally also contained micropollutants. The changes in the concentration along with the age of the sites were explained by water - octanol partitioning coefficient.

Yamaguchi, T., et al. (2014). "Correlation between human tear cytokine levels and cellular corneal changes in patients with bacterial keratitis by in vivo confocal microscopy." Investigative Ophthalmology & Visual Science **55**(11): 7457-7466.

PURPOSE: We investigated bilateral tear cytokine levels in patients with unilateral bacterial keratitis (BK) as associated with in vivo confocal microscopic (IVCM) alterations in corneal nerves and dendritiform immune cells (DCs).

METHODS: A total of 54 (13 BK, 13 contralateral, 28 healthy controls) tear samples was collected prospectively and analyzed by multiplex microbeads assay. The IVCM of the central cornea was performed on the same day, and assessed for corneal nerve and DC alterations.

RESULTS: Interleukin-1beta, IL-6, and IL-8 were significantly elevated only in affected eyes (66.6 +/- 26.8, 7174 +/- 2430, and 810 +/- 315 rhog/mL, respectively; P = 0.04, P < 0.001, and P < 0.001, respectively), compared to healthy controls (13.0 +/- 4.0, 171.8 +/- 32.1, and 56.5 +/- 33.8 rhog/mL). Levels of chemokine ligand 2 (CCL-2), IL-10, and IL-17a were elevated only in contralateral eyes (813 +/- 478, 86.7 +/- 38.3, and 3350 +/- 881 rhog/mL, respectively; P = 0.02, P = 0.01, and P = 0.04, respectively), compared to controls (73.7 +/- 25.3, 17.5 +/- 4.9, and 1350 +/- 337 rhog/mL). Triggering receptor expressed on myeloid cells (TREM)-1 was significantly elevated in affected (551 +/- 231 rhog/mL, P = 0.02) and contralateral unaffected (545 +/- 298 rhog/mL, P = 0.03) eyes compared to controls (31.3 +/- 12.4 rhog/mL). The density of DCs was significantly increased in affected (226.9 +/- 37.3 cells/mm(2), P < 0.001) and unaffected (122.3 +/- 23.7 cells/mm(2), P < 0.001) eyes compared to controls (22.7 +/- 5.9 cells/mm(2)). Sub-basal nerve density significantly decreased in affected (3337 +/- 1615 mum/mm(2), P < 0.001) and contralateral (13,230 +/- 1635 mum/mm(2), P < 0.001) eyes compared to controls (21,200 +/- 545 mum/mm(2)). Levels of IL-1beta, IL-6, and IL-8 were significantly correlated with DC density (R = 0.40, R = 0.55, and R = 0.31, all P < 0.02) and nerve density (R = -0.30, R = -0.53, and R = -0.39, all P < 0.01).

CONCLUSIONS: Proinflammatory tear cytokines are elevated bilaterally in patients with unilateral BK, and are correlated strongly with alterations in DCs and nerve density as detected by IVCM.

Yamamoto, N., et al. (2011). "Cytotoxicity evaluation of reactive metabolites using rat liver homogenate microsome-encapsulated alginate gel microbeads." Journal of Bioscience and Bioengineering **111**(4): 454-458.

We present an improved cytotoxicity test for reactive metabolites, in which the S9 microsomal fraction of rat liver homogenate is encapsulated in alginate gel microbeads to avoid cytotoxic effects of S9-self-generated toxicants, microsomal lipid peroxides. The S9-encapsulated gel microbeads were prepared by a coaxial two-fluid nozzle and surfaces of the microbeads were

coated with poly-L-lysine (PLL). Although the initial metabolic rate of the S9-encapsulated gel microbeads was about 20% slower than that of bare S9, the microbeads prevented the leakage of microsomal lipid peroxides thanks to the dense alginate and PLL polymer networks. In fact, the half maximal effective concentration of the indirect mutagen cyclophosphamide on NIH3T3 cells in the presence of the S9-encapsulated gel microbeads was about 5 times higher than that in the presence of bare S9. Use of the S9-encapsulated gel microbeads enabled the more accurate evaluation of the cytotoxicity of the reactive metabolites without the S9-based cytotoxicity.

Yamamoto, T., et al. (2005). High efficiency heat and material recovery of plastic waste including polyvinyl chloride by using sumitomo metals' waste gasification and smelting system, World Scientific Publishing Co., Inc., 27 Warren Street Suite 401-402 Hackensack NJ 07601 USA, [URL:http://www.worldscinet.com/index.html].

Ordinary waste treatment systems have problems caused by low heat and material recovery, such as the emission of dioxin and heavy metals. To promote heat and material recovery, a new type of waste gasification and smelting system, using iron-making and steel-making technologies based on high-temperature metallurgy, has been developed for much kind of wastes. This system can steadily gasify and smelt municipal waste and industrial waste such as plastic waste including polyvinyl chloride, automobile shredder residue, soil and so on. As a result of steady operation in the high temperature reduction atmosphere, dioxin-free high calorie purified gas and heavy metal-free high quality slag were produced. Three commercial plants which have capacities of 132tons/day (2 units of 66tons/day) based on municipal waste in Tosu, Japan and 100tons/day (1 units of 100tons/day) based on industrial waste in Yamaguchi and industrial waste in Yamaguchi and Kashima, Japan have been operating at full capacity.

Yamamoto, T. and A. Yasuhara (1999). "Quantities of bisphenol a leached from plastic waste samples." Chemosphere **38**(11): 2569-2576.

To quantify the leaching of bisphenol A into water, various samples of plastic waste were cut into small pieces, soaked in water for two weeks at room temperature in the dark, and the concentration of bisphenol A in the water determined by gas chromatography/mass spectrometry (GC/MS). The amount of bisphenol A leached from the plastic wastes ranged from undetectable to 139 micrograms/g. The detection limit was 2 ng/g when 100 g of plastic waste was used. Polyvinyl chloride products yielded the highest concentrations because bisphenol A is used in its manufacture as a stabilizer.

Yamana, H., et al. (2014). "Down-regulated expression of monocyte/macrophage major histocompatibility complex receptors in human and mouse monocytes by expression of their ligands." Clinical & Experimental Immunology **178**(1): 118-128.

Mouse monocyte/macrophage major histocompatibility complex (MHC) receptor 1 (MMR1; or MMR2) specific for H-2D(d) (or H-2K(d)) molecules is expressed on monocytes from non-H-2D(d) (or non-H-2K(d)), but not those from H-2D(d) (or H-2K(d)), inbred mice. The MMR1 and/or MMR2 is essential for the rejection of H-2D(d) - and/or H-2K(d) -transgenic mouse skin onto C57BL/6 (H-2D(b) K(b)) mice. Recently, we found that human leucocyte antigen (HLA)-B44 was the sole ligand of human MMR1 using microbeads that had been conjugated with 80 types of HLA class I molecules covering 94.2% (or 99.4%) and 92.4% (or 96.2%) of HLA-A and B molecules of Native Americans (or Japanese), respectively. In the present study, we also explored the ligand specificity of human MMR2 using microbeads. Microbeads coated with HLA-A32, HLA-B13 or HLA-B62 antigens bound specifically to human embryonic kidney (HEK)293T or EL-4 cells expressing human MMR2 and to the solubilized MMR2-green fluorescent protein (GFP) fusion protein; and MMR2(+) monocytes from a volunteer bound HLA-B62 molecules with a Kd of 8.7 x 10(-9) M, implying a three times down-regulation of MMR2 expression by the ligand expression. H-2K(d) (or H-2D(d)) transgene into C57BL/6 mice down-regulated not only MMR2 (or MMR1) but also MMR1 (or MMR2) expression, leading to further down-regulation of MMR expression. In fact, monocytes from two (i.e. MMR1(+) /MMR2(+) and MMR1(-) /MMR2(-)) volunteers bound seven to nine types of microbeads among 80, indicating <= 10 types of MMR expression on monocytes. The physiological role of constitutive MMRs on monocytes possibly towards allogeneic (e.g. fetal) cells in the blood appears to be distinct from that of inducible MMRs on macrophages toward allografts in tissue.

Yamaoka, K., et al. (2009). "Inhibition of Jak3-Stat6 pathway leading to an anti-inflammatory process in rheumatoid arthritis." Arthritis and Rheumatism **10)**: 147.

Purpose: Janus kinase 3 (Jak3) is a tyrosine kinase necessary for lymphocyte differentiation and proliferation, causing severe combined immunodeficiency. Because of its necessity for lymphocyte function, it is also known to be expressed at the inflammation site such as synovium from rheumatoid arthritis (RA) patients. Recently, a transcription factor Stat6, which is activated by Jak3 was reported to be specifically expressed on dendritic cells in the synovium from RA patient. Recent clinical trials of a Jak inhibitor CP-690,550 for RA has been conducted showing dramatic effects. Herein we have analyzed the function of dendritic cells (DCs) from Jak3 and Stat6 deficient mice to elucidate the involvement of Jak3-Stat6 in inflammatory process. Objective(s): To elucidate the role of Jak3-Stat6 in dendritic cell function and inflammatory process. Method(s): Jak3 and Stat6 deficient mouse was used to obtain splenic DCs or bone marrow derived DCs. Mouse bone marrow and purified human monocyte was cultured with GM-CSF and IL-4 or GM-CSF only to derive DC in vitro. Human monocyte and bone marrow derived DCs was positively purified with CD14 or CD11c microbeads respectively. Jak3 and Stat6 expression was analyzed by western blotting and cytokine concentration was measured by enzyme-linked immunosorbent assay (ELISA) or cytokine beads array. Result(s): Jak3 and Stat6 deficient mice showed normal DC development in vivo and in vitro. Further evaluation with DC cell surface marker and antigen uptake was comparable with wild-type mice. Surprisingly, both Jak3 and Stat6 deficient DCs showed increased IL-10 production in response to toll-like receptor ligand stimulation while other inflammatory cytokine (TNF-a, IL-6) was at comparable level with wild type DCs. We further evaluated the cytokine profile with different genetic background and found that overproduction of IL-10 by Stat6-/- DCs was a consistent phenomenon. Conclusion(s): We have evaluated DCs from Jak3 deficient and Stat6 deficient mice and found normal development with high production of IL-10 which was not affected by genetic background of the mice. Recently, a Jak inhibitor possessing high potency to Jak3 has been shown to have anti-rheumatic activity. It has shown potent anti-inflammatory effect with minimum side effect on haematopoietic cells leading to a question on its mechanism of action. Our results suggests that Jak3-Stat6 not only plays an important role in lymphocyte function but also has essential roles in regulating DC function and its inhibition leads to suppression of RA by enhancing IL-10 production by DC.

Yamashita, S., et al. (2019). Water flow measurement for swimmers using artificial food-grade roe as tracer particles. ACM International Conference Proceeding Series.

Water flow is strongly related to swimming speed; thus, technologies for measuring the three-dimensional movement of water are highly desired in the water sports industry. However, existing fluid measurement methods are not suitable for use with humans because they

introduce tiny plastic particles (known as tracer particles) that contain fluorescent ink, which is used to visualize water flow. A laser then irradiates the environment to make the particles brighter than the surroundings to track their movement with cameras. This method has potential adverse effects to humans, such as accidental swallowing of the particles and laser burns to the skin and eyes. In this research, we propose a human-friendly water flow measuring technology using tracer particles made of food-grade materials and a harmless light source. To visualize tracer particles, we give the particles an optical property, which makes them sufficiently brighter than the surroundings when placed between circularly polarized plates. We tested the proposed setup for water flow measurement in an actual swimming environment with swimmers. We observed that tracer particles moved in accordance with the water flow caused by a swimming stroke. © 2019 Association for Computing Machinery.

Yan, B., et al. (2017). "Development of a novel flow cytometric immunobead array to quantify VWF: Ag and VWF: GPIbR and its application in acute myocardial infarction." European Journal of Haematology **99**(3): 207-215.

OBJECTIVES: Both von Willebrand disease (VWD) and acute myocardial infarction (AMI) involve quantitative and qualitative changes in von Willebrand factor (VWF). Our objective was to develop a rapid and precise flow cytometric immunobead array (FCIA) to quantify VWF antigen (VWF:Ag) and ristocetin-triggered platelet glycoprotein Ib binding (VWF:GPIbR) and apply it in a clinical setting.

METHODS: Microbeads, coated with monoclonal antibodies for SZ29 or SZ151 IgG, were incubated with diluted plasma. VWF-binding microbeads were detected with FITC-conjugated sheep-anti-human VWF IgG by flow cytometry. Plasma VWF:Ag and VWF:GPIbR levels in normal controls (CTL; n=105), patients with VWD (n=21), and patients with AMI (n=146) were tested by FCIA and ELISA in parallel. ADAMTS13 activity and VWF multimer analyses were also implemented.

RESULTS: Our novel FCIA showed a strong correlation with the ELISA results (VWF:Ag, r=.855; VWF:GPIbR, r=.813). The intra-assay coefficient variations (CVs) of VWF:Ag-FCIA and VWF:GPIbR-FCIA were 9.2% and 7.7%, respectively, and the interassay CVs were 12.6% and 13.5%, respectively. Plasma VWF:Ag and VWF:GPIbR levels were significantly higher in patients with AMI than in CTL (P<.0001), whereas the ratios of ADAMTS13/VWF:Ag and ADAMTS13/VWF:GPIbR were significantly lower (P<.0001). Levels of plasma ultra-large VWF (UL-VWF) were dramatically increased in patients with AMI.

CONCLUSIONS: The novel VWF:Ag and VWF:GPIbR-FCIA assays were found to be simpler, more specific, and more accurate than the classical ELISA method. In addition, elevated VWF:GPIbR and UL-VWF may contribute to the pathogenesis of AMI.

Yan, M., et al. (2019). "Microplastic abundance, distribution and composition in the Pearl River along Guangzhou city and Pearl River estuary, China." Chemosphere **217**: 879-886.

Like many urban rivers, the Pearl River in China is contaminated with microplastics. Compared with marine environments, microplastic pollution in freshwater is less understood, especially in urban rivers. In the present study, the abundance and distribution of microplastics in water from the Pearl River was investigated, including the estuary and the urban section along Guangzhou. The average abundance of microplastics was 19,860 items/m³ and 8902 items/m³ in the urban section and estuary, respectively. Wastewater effluents from cities might be a main source of microplastics in the Pearl River, and the urban tributaries might act as retention systems for microplastics. Among these microplastics, over 80% of them were less than 0.5mm. The main shapes of microplastics were film, fragment, and fiber, mostly blue or transparent. Moreover, the most common polymer types of these microplastics were polyamide (26.2%) and cellophane (23.1%). This study reveals the contamination and characteristics of microplastics in the Pearl River, and provides important data for further research on microplastics in freshwater ecosystems.

Yan, Y., et al. (2018). "Determination of 8 benzotriazole ultraviolet absorbers in food contact grade plastic resin by ultra high performance liquid chromatography." Journal of Food Safety and Quality **9**(2): 434-440.

Objective: To establish a method to determine 8 kinds of ultraviolet absorbers (UV-0, UV-9, UV-71, UV-329, UV-326, UV-327, UV-234, UV-360) in food plastic packaging resin using reflow extraction followed by ultra high performance liquid chromatography (UPLC).

Yan, Z., et al. (2020). "An efficient method for extracting microplastics from feces of different species." Journal of Hazardous Materials **384**: 121489.

Concerns have been raised regarding the ingestion of microplastics (MPs) by numerous organisms including humans. However, no efficient and standardized methods are available for extracting MPs from feces. In this study, we introduce a novel approach with high digestion efficiency that involves using Fenton's reagent and nitric acid to remove feces solids. Firstly, Fenton's reagent was used to degrade small solids and decompose large solids into small pieces. Secondly, nitric acid was used to digest the remaining solids and filters. Furthermore, absolute ethyl alcohol was used to remove the mineral residues wrapped on the plastic surfaces and disperse MPs. By using this method, 97.78 % MPs can be recovered from human and chicken feces, and no significant changes were observed in the physical and Raman spectral properties of different polymer types of MPs. This method has also been verified by extracting MPs from field feces. Overall, the proposed method can efficiently digest feces solids and extract MPs with higher recovery rate, less intermediate steps and less damage, which can serve as an economical and feasible method for the detection of MPs in the feces of different species.

Yang, C., et al. (2019). "Anomalous dispersion of bioinspired flower-like microparticles for oil/water separation." Nanotechnology **31**(9): 095712.

Hydrophobic particles have been suffering from aggregation in aqueous media, which limits their applications in oil/water separation. Surfactants have been used to increase the dispersity of the hydrophobic particles in water, but this approach compromises particles' hydrophobicity and oil absorption capabilities. Recently, hierarchical microparticles decorated with nanospikes were found to exhibit long-term anomalous dispersion in liquid medium without adding any surfactants. However, whether this anomalous dispersion phenomenon was applicable to 2D nano-petals decorated microparticles still remains unknown. Here, we developed a ZnO-based flower-like microparticles (FLMPs) whose surfaces were attached with 2D nano-petals, and we examined their anomalous dispersity. Our results showed that both hydrophilic and hydrophobic FLMPs could achieve anomalous dispersity either in water or organic solvents, likely due to reduced interparticle collision by the 2D nano-petals. In addition, the functional hydrophobic FLMPs also possessed a large surface area and superhydrophobic surfaces to efficiently absorb oil spills on water and oil emulsion suspended in water. In contrast, the hydrophobic microbeads (MBs) without nano-petals structure seriously aggregated in water and exhibited reduced oil absorption abilities. Our work demonstrated the new finding of 2D nano-pedal structure-mediated anomalous dispersity, and provided a new method for effective oil/water separation using superhydrophobic particles without surfactants.

Yang, C. J., et al. (2008). "High-Throughput Single Copy DNA Amplification and Cell Analysis in Engineered Nanoliter Droplets." Analytical Chemistry (Washington) **80**(10): 3522-3529.

A high-throughput single copy genetic amplification (SCGA) process is developed that utilizes a microfabricated droplet generator (mu DG) to rapidly encapsulate individual DNA molecules or cells together with primer functionalized microbeads in uniform PCR mix droplets. The nanoliter volume droplets uniquely enable quantitative high-yield amplification of DNA targets suitable for long-range sequencing and genetic analysis. A hybrid glass- polydimethylsiloxane (PDMS) microdevice assembly is used to integrate a micropump into the mu DG that provides uniform droplet size, controlled generation frequency, and effective bead incorporation. After bulk PCR amplification, the droplets are lysed and the beads are recovered and rapidly analyzed via flow cytometry. DNA targets ranging in size from 380 to 1139 bp at single molecule concentrations are quantitatively amplified using SCGA. Long-range sequencing results from beads each carrying similar to 100 amol of a 624 bp product demonstrate that these amplicons are competent for achieving attomole-scale Sanger sequencing from a single bead and for advancing pyrosequencing read-lengths. Successful single cell analysis of the glyceraldehyde 3 phosphate dehydrogenase (GAPDH) gene in human lymphocyte cells and of the gyr B gene in bacterial Escherichia coli K12 cells establishes that SCGA will also be valuable for performing high-throughput genetic analysis on single cells.

Yang, D., et al. (2015). "Microplastic Pollution in Table Salts from China." Environmental Science & Technology **49**(22): 13622-13627.

Microplastics have been found in seas all over the world. We hypothesize that sea salts might contain microplastics, because they are directly supplied by seawater. To test our hypothesis, we collected 15 brands of sea salts, lake salts, and rock/well salts from supermarkets throughout China. The microplastics content was 550-681 particles/kg in sea salts, 43-364 particles/kg in lake salts, and 7-204 particles/kg in rock/well salts. In sea salts, fragments and fibers were the prevalent types of particles compared with pellets and sheets. Microplastics measuring less than 200 mum represented the majority of the particles, accounting for 55% of the total microplastics, and the most common microplastics were polyethylene terephthalate, followed by polyethylene and cellophane in sea salts. The abundance of microplastics in sea salts was significantly higher than that in lake salts and rock/well salts. This result indicates that sea products, such as sea salts, are contaminated by microplastics. To the best of our knowledge, this is the first report on microplastic pollution in abiotic sea products.

Yang, D. K., et al. (2014). "Selection of aptamers for fluorescent detection of alpha-methylacyl-CoA racemase by single-bead SELEX." Biosensors & Bioelectronics **62**: 106-112.

This paper first reports DNA aptamers and a fluorescent enzyme-linked aptamer assay (ELAA) targeting alpha-methylacyl-CoA racemase (AMACR), an emerging prostate cancer biomarker. The aptamers were in vitro selected using a new single-bead SELEX approach, which was rapid and consumed only ca. 45 ng AMACR. Before SELEX, silane chemistry was used to prepare epoxide-functionalized glass microbeads (EGBs, 500 mum in size and manipulated by tweezers) for AMACR coating. Recombinant AMACR was also prepared. During SELEX, the ligand evolution was assured by a differential real-time quantitative PCR assay. After SELEX, the aptamers were identified by the alignment analysis and 2nd structure prediction from the selected, cloned sequences. The circular dichroism (CD) analysis revealed that the aptamers formed stable B-form, stem-loop conformations. The fluorescent ELAA method confirmed the nM-level affinity and high specificity of the aptamers against AMACR. Finally, an aptamer-based fluorescent AMACR assay was demonstrated. The assay featured a wide dynamic range (from 10(-1) to 10(3)

nM of AMACR), a low detection limit of 0.44 nM (19.5 ng/mL), and high AMACR specificity and is promising for clinical AMACR diagnostics.

Yang, H., et al. (2014). "Magnetic prussian blue/graphene oxide nanocomposites caged in calcium alginate microbeads for elimination of cesium ions from water and soil." Chemical Engineering Journal **246**: 10-19.

To remove cesium ions in water and soil, magnetic prussian blue/graphene oxide (PB/Fe₃O₄/GO) nanocomposites encapsulated in calcium alginate microbeads (PFGM) were designed and fabricated. The protocol was processed with environment-friendly and low-cost precursors at ambient temperature and pressure. The adsorbents presented high selectivity to Cs⁺ and could extract it even in trace amounts. Sorption of 80% Cs⁺ to the new adsorbent were fulfilled in less than 2 h, and maximum adsorption capacities were 43.52 mg/g. Cesium ions were absorbed primarily by both of chemisorption (K⁺/H⁺-exchange) and physisorption (ion trapping). The saturation adsorption and adsorption kinetics fitted well with the Langmuir isotherm and the pseudo-second-order kinetic model. Both the temperature and pH value would affect the sorption performance, meanwhile, the microbeads were stable in natural water, seawater, and pH value of solutions ranging from 4 to 10 without collapse of microbeads and leaching of prussian blue. Most importantly, these microbeads could be separated effectively from aqueous solution (or soil suspensions) by an external magnetic field, which was convenient for large-scale treatment of cesium-contaminated water (or soil).

Yang, H., et al. (2020). "Toxicity comparison of nano-sized and micron-sized microplastics to Goldfish Carassius auratus Larvae." Journal of Hazardous Materials **388**: 122058.

Plastic pollution is one of the most serious environmental issues worldwide. The negative influence of plastics on aquatic organisms has increasingly concerned, especially the influence of microplastic (MPs). In the present study, the toxicology of nano-sized MPs (nMPs) and micron-sized MPs (mMPs) were comparatively studied. Goldfish larvae were exposed to 10, 100 and 1000 mug/L nMPs and mMPs for 1, 3 and 7 days. The enrichment of MPs, body length, heart rate, motor ability, microscopic and ultrastructure of intestine, liver, gill and muscle tissue, as well as the oxidative stress were analyzed.

Yang, H. J., et al. (2016). "Antifungal activity of nano and micro charcoal particle polymers against Paecilomyces variotii, Trichoderma virens and Chaetomium globosum." New Biotechnology **33**(1): 55-60.

This study investigates the antifungal activity of a polymer integrated with nano-porous charcoal particles against Paecilomyces variotii, Chaetomium globosum, Trichoderma virens, which are all filamentous fungi. The charcoal polymers were prepared by combining charcoal powders with plastic resin under a vacuum to form charcoal particle protrusions on the polymer surface. The mycelial growth of P. variotii and T. virens exhibited a reduction of 10 and 30%, respectively, after the conidia were pre-treated with charcoal polymers, and in particular, no mycelial growth was found in C. globosum during 5 days of culture. The adsorption of Ca²⁺ into charcoal was suggested to inhibit growth due to the reduction in the flux of calcium ions (Ca²⁺) into the hyphae. In 5h, about 15mM of Ca²⁺ were removed from CaCl<inf>2</inf> solution with 0.2g/mL of polymers, and the nano-sized pores of the charcoals on the polymer were responsible for the Ca²⁺ adsorption. Yang, J., et al. (2019). "Effects of different soil environmental factors on tetracycline adsorption of microplastics." Nong Ye Huan Jing Ke Xue Xue Bao = Journal of Agro-Environment Science(11): 2503.

To investigate the effect of different soil environmental factors on the adsorption of antibiotics on microplastics, this study used three microplastics, i.e., polyethylene（PE）, polystyrene（PS）, and polyamide（PA）, with tetracycline（TC）as the target antibiotic, in a batch equilibrium experiment to study the mechanism of TC adsorption on microplastics and the influence of different soil environmental factors on its adsorption behavior. The results showed that the TC adsorption capacities of the microplastics were in the order PE>PS>PA,and these microplastics were suitable for fitting using Langmuir's equation. The maximum adsorption capacities were 0.154, 0.086, and0.075 mg·g–1, respectively. The TC adsorption capacity for PE reached the maximum value under neutral pH conditions; for PS, it was the largest under acidic conditions, and it decreased with an increase in pH; and for PA, pH had little effect on TC adsorption capacity. Different concentrations of Ca2+ and Mg2+ hinder the absorption of TC by microplastics, and the cation concentration was inversely proportional to the adsorption capacity. The presence of fulvic acid inhibited the adsorption of TC on PE; however, the presence of low concentration fulvic acid(<1 mg·L–1)promoted the adsorption of TC on PA and PS. In conclusion, the experiments showed that the adsorption of TC on different microplastics was significantly different; furthermore, different soil environmental factors considerably affected the adsorption behavior of TC on microplastics, which lays the foundation for further investigation of the adsorption behavior of microplastics in soil.

Yang, J., et al. (2019). "Effects of soil environmental factors and UV aging on Cu²⁺ adsorption on microplastics." Environmental Science & Pollution Research **26**(22): 23027-23036.

Microplastics (MPs) in natural environments have attracted lots of attention. Although the quantity of MPs present in terrene is much higher than that in aquatic environment, few studies have investigated the chemical behavior of MPs in terrestrial environment. This study investigate the Cu²⁺ (as a model heavy metal) adsorption capacity of six kinds of MPs (polyamide-6 (PA), polyethylene (PE), polystyrene (PS), polyethylene terephthalate (PET), polyvinyl chloride (PVC), polymethyl methacrylate (PMMA)) in batch adsorption experiments and the effects of different soil environmental factors, including pH and the presence of cations and low-molecular-weight organic acids (LMWOAs), as well as ultraviolet (UV) aging. The Cu²⁺ adsorption capacities of PA and PMMA were higher than those of other MPs and their maximum equilibrium adsorption capacities (estimated by the Langmuir adsorption equation) were 323.6 mug/g +/- 38.2 and 41.03 +/- 1.78 mug/g, respectively. The Cu²⁺ adsorption on MPs was affected by pH, and the greatest amount of Cu²⁺ adsorbed on PA and PMMA was observed at pH = 6 and pH = 7, respectively. The presence of Ca²⁺ or Mg²⁺ inhibited Cu²⁺ adsorption by MPs, due to competition for the adsorption sites. Moreover, Cu²⁺ adsorption by MPs was affected by various types of LMWOAs. The Cu²⁺ adsorption on PA was significantly reduced by citric acid, followed by oxalic acid, and oxalic acid was particularly evident for Cu²⁺ adsorption on PMMA. UV aging (200 h) had different effect on Cu²⁺ adsorption on MPs and it depends on the change of carbonyl index.

Yang, J., et al. (2016). "Integrated microfluidic aptasensor for mass spectrometric detection of vasopressin in human plasma ultrafiltrate." Analytical Methods **8**(26): 5190-5196.

We present a microfluidic aptamer-based biosensor for detection of low-molecular-weight biomarkers in patient samples. Using a microfluidic device that integrates aptamer-based specific analyte extraction, isocratic elution, and detection by matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectrometry, we demonstrate rapid, sensitive and label-free detection of arginine vasopressin (AVP) in human plasma ultrafiltrate. AVP molecules in complex matrices are specifically captured by an aptamer that is immobilized on microbeads via affinity binding in a microchamber. After the removal of unbound, contaminating molecules through washing, aptamer-AVP complexes are thermally disrupted via on-chip temperature control. Released AVP molecules are eluted with purified water and transferred to a separate microchamber, and deposited onto a single spot on a MALDI plate via repeated, piezoelectrically actuated ejection, which enriches AVP molecules over the spot area. This integrated on-chip sample processing enables the quantitative detection of low-abundance AVP by MALDI-TOF mass spectrometry in a rapid and label-free manner. Our experimental results show the detection of AVP in human plasma ultrafiltrate as low as physiologically relevant picomolar concentrations via aptamer-based selective preconcentration, demonstrating the potential of our approach as a rapid (~1 h), sensitive clinical AVP assay. © The Royal Society of Chemistry 2016.

Yang, L., et al. (2019). "Removal of microplastics in municipal sewage from China's largest water reclamation plant." Water Research **155**: 175-181.

Municipal sewage treatment plants (STPs) are an important point source of microplastics in domestic waterways. In the present study, effluents from the largest water reclamation plant in China were sampled throughout the treatment process and microplastics were extracted and identified to evaluate their removal. As expected, microplastics were detected in the influent (12.03 +/- 1.29 items/L). Following treatment, concentrations of microplastics were reduced by greater than 95% and 0.59 +/- 0.22 items/L of microplastics were detected in reclaimed waters. Among detected microplastics, 18 types of polymers of ten colors were identified. Polyethylene terephthalate (PET), polystyrene (PS) and polypropylene (PP) accounted for greater than 70% of detected microplastics. Furthermore, microfibers were the dominant shape detected with an average size of 1110.72 +/- 862.95 mum. However, microparticles accounted for only 14.08% of total microplastics with an average size of 681.46 +/- 528.73 mum. Results of the present study suggest that current treatment technologies employed at the chosen STP are efficient to remove the majority of microplastics, however consideration of STPs as a point source of microplastics is important due to the large volumes of effluents being released into the aquatic environment on a consistent basis. Copyright © 2019 Elsevier Ltd

Yang, L., et al. (2019). "Microfiber release from different fabrics during washing." Environmental Pollution **249**: 136-143.

Microfiber is a subgroup of microplastics and accounts for a large proportion of microplastics in aquatic environment, especially in municipal effluents. The purpose of the present study was to quantify microfiber shedding from three most populate synthetic textile fabrics: polyester, polyamide, and acetate fabrics. The results showed that more microfibers were released after washing with a pulsator laundry machine than a platen laundry machine. The greatest number of microfibers was released from acetate fabric, which was up to 74,816 ± 10,656 microfibers/m2 per wash, although microfibers were shed from all materials. Moreover, an increasing trend was found in the number of microfibers shedding from synthetic fabrics with the washing temperature increasing, and greater microfiber release occurred when washing fabrics with detergent rather than with water alone. The lint filter bag equipped with the pulsator laundry machine retained the longer microfibers (>1000 μm), but not the shorter microfibers (<500 μm) instead of releasing into the drainage system. Our data suggested that microfibers released during washing of synthetic fabrics may be an important source of microfibers in aquatic environment due to the increasing production and use of synthetic fabrics

globally. Thus, more efficient filtering bags or other technologies in household washing machines should be developed to prevent and reduce the release of microfibers from domestic washing. Image 1 • The releasing of microfibers from three kinds of synthetic fabrics were evaluated. • More microfibers were released after washing with pulsator laundry machine. • The greatest number of microfibers were released from the acetate fabric. • The temperature and detergent promoted the releasing of microfibers. • The lint filter bag retained parts of microfibers with long size (>1000 μm). [ABSTRACT FROM AUTHOR]

Yang, L. H., et al. (2015). "A "turn-on" fluorescent microbead sensor for detecting nitric oxide." International Journal of Nanomedicine **10**: 115-123.

Nitric oxide (NO) is a messenger molecule involved in numerous physical and pathological processes in biological systems. Therefore, the development of a highly sensitive material able to detect NO in vivo is a key step in treating cardiovascular and a number of types of cancer-related diseases, as well as neurological dysfunction. Here we describe the development of a fluorescent probe using microbeads to enhance the fluorescence signal. Microbeads are infused with the fluorophore, dansyl-piperazine (Ds-pip), and quenched when the fluorophore is coordinated with a rhodium (Rh)-complex, ie, Rh2(AcO(-))4(Ds-pip). In contrast, they are able to fluoresce when the transition-metal complex is replaced by NO. To confirm the "on/off" mechanism for detecting NO, we investigated the structural molecular properties using the Fritz Haber Institute ab initio molecular simulations (FHI-AIMS) package. According to the binding energy calculation, NO molecules bind more strongly and rapidly with the Rh-core of the Rh-complex than with Ds-pip. This suggests that NO can bond strongly with the Rh-core and replace Ds-pip, even though Ds-pip is already near the Rh-core. However, the recovery process takes longer than the quenching process because the recovery process needs to overcome the energy barrier for formation of the transition state complex, ie, NO-(AcO(-))4-(Ds-pip). Further, we confirm that the Rh-complex with the Ds-pip structure has too small an energy gap to give off visible light from the highest unoccupied molecular orbital/lowest unoccupied molecular orbital energy level.

Yang, S., et al. (2011). "Novel double labeled mixed lymphocyte in vitro assay to predict the dominant graft in 2 unit UCB transplantation." Blood. Conference: 53rd Annual Meeting of the American Society of Hematology, ASH **118**(21).

Introduction: Umbilical cord blood cells (UCB) from allogeneic donors have been established as an alternative source for HSC transplantation in patients who lack suitably HLA matched bone marrow or peripheral blood stem cells from adult donors. Transplantation using 2 unit UCB has been shown to compensate the low engraftment and slow hematopoietic recovery resulting from 1 unit UCB transplantation in full stature adult patients. At present, there are no unit specific factors that reliably predicts for the "winning unit" in 2 unit UCB transplantation, e.g. cell viability, number of infused total nucleated cells, CD34+ or CD3+ cells, sex mismatch, ABO blood group, and degree of HLA mismatch. In vivo mouse models suggest that CD34 negative subsets play an important role. Among CD34 negative subsets, CD8 T subset accounts for approximately 34.0+/-23.3% of T lymphocytes from UCB. In bone marrow transplantation CD8 T cells have been found to facilitate donor hematopoietic cell engraftment. Moreover, it has been reported that 1 dominant unit coincides with a specific CD8 T cell response against the non-engrafted unit which was not observed from CD4 or NK cells. Method(s): In this study, we used volunteer donated UCB research units (kindly provided by P. Rubinstein, MD, New York Blood Center). Mononuclear cells (MNC) were purified by Ficoll gradient centrifugation, and CD3 T cells were isolated with CD3 MicroBeads (Miltenyi Biotec; autoMACS). The purified CD3 (confirmed by FACS >95% purity) cells were labeled with CFSE and DDAO-SE. After labeling, the cells from two different donors were mixed in 96-well U-bottom plates for continued culture in 37 degreeC 5% CO<inf>2</inf>. The expansion from each labeled donor cells was evaluated using flow cytometry; the dead cells were gated out using propidium iodide, and the data was analyzed using FlowJo software. For proper T cells activation, we also compared different activation conditions using i.) anti-CD3/CD28 Beads, ii.) anti-CD3 antibody plus anti-CD28 antibody, and iii.) cytokine IL-2. The schematic illustration of methods is shown in Figure 1. [Image Presented] Results and discussion: We noted that T cells from UCB are primarily at naive stage as determined by CD45RA (93.8 +/-7.11%) and CCR7 (84.9 +/-12.0%) expression. We also determined the optimal activation condition using a modified mixed lymphocyte reaction from 2 UCB units. Four days after incubation, the proliferation from 2 units labeled with CFSE and DDAO-SE could be reproducibly distinguished using FL1 channel for CFSE and FL4 channel for DDAO-SE (Figure 1). The optimal concentration for labeling using CFSE (1 mM) and DDAO (1 muM or 3 mM) was determined by titration. To avoid cell toxicity resulting from CFSE and DDAO-SE labeling, as well as self-crossing from each donor using two dyes, we examined additional mixed lymphocyte analyses in which each donor was labeled with CFSE or DDAO-SE respectively and vice versa. As shown in Figure 1, we found consistently that the predicated dominant unit accounted for the majority of culture (73.2% stained with DDAO; 63.5% stained with CFSE) after 4 days co-culture. The dominance was not correlated with cell proliferation indicated by the proliferation index (1.12 for dominant and 1.48 for another unit). After confirmation of this in vitro assay, further studies were conducted to evaluate the IFN-gamma

release of 2 UCB units in this optimized mixed lymphocyte assay in the condition using cytokine IL-2. Interestingly, we could only detect IFN-gamma by intracellular staining in one unit when co-culture was set-up using CD3 T cells from each unit; the expression of IFN-gamma was not detected when we used CD3 T cells from 1 unit. The correlation between dominance and the expression of IFN-gamma is currently under investigation. Conclusion(s): UCB Transplantation is an important alternative for patients lacking bone marrow or peripheral blood stem cell donors. With the establishment of this novel modified mixed lymphocyte in vitro assay for prediction of the "winning" immune dominant unit, routine analyses can be performed to guide unit selection. Further interventions can be exploited to preferentially treat the expected dominant unit with glycosylation, cytokines, prostaglandins, or C3a compliments to further enhance hematopoietic stem cells trafficking and engraftment to the marrow.

Yang, S., et al. (2016). "Environmental fate and health risks of phthalate acid esters in soils: a review." Zhongguo Shengtai Nongye Xuebao / Chinese Journal of Eco Agriculture **24**(6): 695-703.

Phthalic acid esters (PAEs) are classified as environmental hormone organic compounds, commonly contained in plastic, resin and rubber, accounting for 20%-60%, as plasticizers with potentially hazardous impacts on the environment and human health. In soils, the main anthropogenic sources of PAEs are agricultural chemicals, sewage water irrigation and atmospheric precipitation. PAEs can abundantly accumulate in the soil and be transported to different environmental systems via a series of environmental, geochemical processes such as volatilization, leaching, adsorption, biodegradation, plant uptake and food chain. This article combined the results of domestic and international studies to summarize the state of soil PAEs pollution in China. Anthropogenic activities and land use changes were the main factors responsible for seasonal and spatial distributions of PAEs. The contents of PAEs in soils in most regions of China reached dozens milligram per kilogram, which obviously exceeded the standards for the US and the European countries. Di-n-butyl phthalate (DnBP) and di (2-ethylhexyl) phthalate (DEHP) were the dominant PAEs in soils, similar to those observed in other countries. Also the environmental behavior of PAEs in soil-gas interface (volatilization and atmospheric precipitation), soil-plant system (phytoremediation and plant uptake) and soil-water interface (sediment adsorption and desorption) were analyzed to determine the causes of soil PAEs transfer between air, water, sediments and plants. There were significant differences in the characteristics of PAEs absorption, accumulation, distribution and transformation among the different interfaces. Because of the widespread application of PAEs and its occurrence in most common daily chemicals, humans are exposed to PAEs through foods contaminated during crop growth in soil or during packaging. Humans are also at risk through exposure to air (for breathing or absorption by skin), causing severely ecological and health risks in many regions of China. It was recommended that future soil PAEs research should focus on regional soil pollution and environmental behavior, PAEs transmission and evolution regularity in space and time, medium migration mechanisms, risk reduction and remediation measure research. There was need to use knowledge about the environmental fate and health risks of PAEs in soils to improve the regulation of organic pollution transformation in soils. This knowledge was also necessary for providing theoretical basis for the protection of ecological environments and soil health.

Yang, S., et al. (2018). "Alpha 1-antitrypsin inhibits microglia activation and facilitates the survival of iPSC grafts in hypertension mouse model." Cellular Immunology **328**: 49-57.

This study was conducted to investigate the use of Alpha 1-antitrypsin (AAT) to inhibit microglia activation in chronic hypertension model and provide a permissive environment for stem cell transplantation. Chronic ocular hypertension of C57BL/6 mice using magnetic microbead injection was induced 3weeks prior to iPSCs transplantation. The ocular hypertension model was assessed histologically and intraocular pressure was measured. Survival of grafted cells and microglia activation were examined by flow cytometry and immunofluorescence in AAT and PBS treated hosts. Retinal cytokines expression was also detected by real-time PCR. Chronic ocular hypertension resulted in persistent microglia activation and stem cell grafts loss. AAT treatment significantly inhibited microglia activation and facilitated the survival of transplant iPSCs 4w post transplantation compared to PBS treatment. AAT holds tremendous potential for the clinical application to control neuroinflammation factor in glaucoma and improve the stem cell replacement therapy of retinal neurodegenerative disease.

Yang, X., et al. (2018). "Influence of microplastic addition on glyphosate decay and soil microbial activities in Chinese loess soil." Environmental Pollution **242**(Pt A): 338-347.

The intensive use of pesticide and plastic mulches has considerably enhanced crop growth and yield. Pesticide residues and plastic debris, however, have caused serious environmental problems. This study investigated the effects of the commonly used herbicide glyphosate and micrometre-sized plastic debris, referred as microplastics, on glyphosate decay and soil microbial activities in Chinese loess soil by a microcosm experiment over 30 days incubation.

Yang, X., et al. (2019). "Biogenic transport of glyphosate in the presence of LDPE microplastics: a mesocosm experiment." Environmental Pollution **245**: 829-835.

The accumulation of plastic debris and herbicide residues has become a huge challenge and poses many potential risks to environmental health and soil quality. In the present study, we investigated the transport of glyphosate and its main metabolite, aminomethylphosphonic acid (AMPA) via earthworms in the presence of different concentrations of light density polyethylene microplastics in the litter layer during a 14-day mesocosm experiment. The results showed earthworm gallery weight was negatively affected by the combination of glyphosate and microplastics. Glyphosate and AMPA concentrated in the first centimetre of the top soil layer and the downward transport of glyphosate and AMPA was only detected in the earthworm burrows, ranging from 0.04 to 4.25 micro g g⁻¹ for glyphosate and from 0.01 (less than limit of detection) to 0.76 micro g g⁻¹ for AMPA. The transport rate of glyphosate (including AMPA) from the litter layer into earthworm burrows ranged from 6.6+or-4.6% to 18.3+or-2.4%, depending on synergetic effects of microplastics and glyphosate application. The findings imply that earthworm activities strongly influence pollutant movement into the soil, which potentially affects soil ecosystems. Further studies focused on the fate of pollutants in the microenvironment of earthworm burrows are needed.

Yang, X., et al. (2009). "[Analysis of Differentially Expressed Proteins in Self-Paired Sera of Advanced Non-small Cell Lung Cancer Patients Responsive to Gefinitib.]." Chinese Journal of Lung Cancer **12**(7): 765-769.

BACKGROUND: All the advanced NSCLC patients that received EGFR-TKI therapy will eventually relapse after a period of efficacy. The aim of this study is to investigate the serum biomarkers as potential predictive factors for the efficacy of epidermal growth factor receptor (EGFR) tyrosine kinase inhibitor (TKI) targeted therapy in advanced non-small cell lung cancer.

METHODS: Twenty self-paired serum samples were collected from 9 advanced NSCLC patients that evaluated as disease control (SD or PR) after gefinitib therapy, at the time points of before and after gefinitib treatment but 2 weeks before being evaluated as disease progress. All samples were pre-separated by WCX microbeads, and then detected on the MALDI-TOF-MS platform of

Bruker Autoflex. ClinProTools (Version: 2.1) was used to analyze the differentially expressed proteins.

RESULTS: There were 7 protein peaks (m/z), 3 242.09, 8 690.36, 2 952.64, 3 224.04, 1 450.51, 1 887.8 and 3 935.73 found statistically differentially expressed between the self-paired samples. Three proteins (3 242.09, 2 952.64 and 3 224.04) were down-regulated and four proteins (8 690.36, 1 450.51, 1 887.8 and 3 935.73) up-regulated in gefinitib treated sera.

CONCLUSIONS: The data here suggest that several specific protein peaks might indicate gefinitib resistance, yet the identities of these proteins and the mechanisms underlying the responsiveness to gefinitib treatment need further investigation.

Yang, Y., et al. (2020). "Lipid metabolic response to polystyrene particles in nematode Caenorhabditis elegans." Environmental Pollution **256**: 113439.

Nanoplastics can be used in various fields, such as personal care products. Nevertheless, the effect of nanoplastic exposure on metabolism and its association with stress response remain largely unclear. Using Caenorhabditis elegans as an animal model, we determined the effect of nanopolystyrene exposure on lipid metabolism and its association with the response to nanopolystyrene. Exposure (from L1-larave to adult day-3) to 100nm nanopolystyrene (>=1mug/L) induced severe lipid accumulation and increase in expressions of mdt-15 and sbp-1 encoding two lipid metabolic sensors. Meanwhile, we found that SBP-1 acted downstream of intestinal MDT-15 during the control of response to nanopolystyrene. Intestinal transcriptional factor SBP-1 activated two downstream targets, fatty acyl CoA desaturase FAT-6 and heat-shock protein HSP-4 (a marker of endoplasmic reticulum unfolded protein response (ER UPR)) to regulate nanopolystyrene toxicity. Both MDT-15 and SBP-1 were involved in the activation of ER-UPR in nanopolystyrene exposed nematodes. Moreover, SBP-1 regulated the innate immune response by activating FAT-6 in nanopolystyrene exposed nematodes. In the intestine, function of MDT-15 and SBP-1 in regulating nanopolystyrene toxicity was under the control of upstream signaling cascade (PMK-1-SKN-1) in p38 MAPK signaling pathway. Therefore, our data raised an important molecular basis for potential protective function of lipid metabolic response in nanopolystyrene exposed nematodes.

Yang, Y., et al. (2020). "Biodegradation and mineralization of polystyrene by plastic-eating superworms Zophobas atratus." Science of the Total Environment **708**: 135233.

Polystyrene (PS) is one of the major plastic debris accumulated in environment. Previously, we reported that mealworm (Tenebrio molitor) was capable of degrading and mineralizing Styrofoam (PS foam). This finding arouses our curiosity to explore whether more other insect species have the same capability as mealworms. Here, an insect larva, superworm (Zophobas atratus), was newly proven to be capable of eating, degrading and mineralizing PS. Superworms could live with Styrofoam as sole diet as well as those fed with a normal diet (bran) over a 28-day period. The average consumption rate of Styrofoam for each superworm was estimated at 0.58 mg/d that was 4 times more than that of mealworm. Analyses of frass, using gel permeation chromatography (GPC), solid-state ¹³C cross-polarization/magic angle spinning nuclear magnetic resonance (CP/MAS NMR) spectroscopy, and thermogravimetric interfaced with Fourier transform infrared (TG-FTIR) spectroscopy, demonstrated that the depolymerization of long-chain PS molecules and the formation of low molecular-weight products occurred in the larval gut. A respirometry test showed that up to 36.7% of the ingested Styrofoam carbon was converted into CO₂ during a 16-day test period. The PS-degrading capability of superworm was inhibited by the antibiotic suppression of gut microbiota, indicating that gut microbiota contributed to PS degradation. This new finding

extends the PS-degrading insects beyond the species within the Tenebrio genus and indicates that the gut microbiota of superworm would be a novel bioresource for pursuit of plastic-degrading enzymes.

Yang, Y. C., et al. (2011). "Selective and absolute quantification of endogenous hypochlorous acid with quantum-dot conjugated microbeads." Analytical Chemistry **83**(21): 8267-8272.

Endogenous hypochlorous acid (HOCl) secreted by leukocytes plays a critical role in both the immune defense of mammalians and the pathogenesis of various diseases intimately related to inflammation. We report the first selective and absolute quantification of endogenous HOCl produced by leukocytes in vitro and in vivo with a novel quantum dot-based sensor. An activated human neutrophil secreted 6.5 +/- 0.9 x 10(8) HOCl molecules into its phagosome, and kinetic measurement for the secretions showed that the extracellular generation of HOCl was temporally retarded, but the quantity eventually attained a level comparable with its intraphagosomal counterpart with a delay of about 1.5 h. The quantity of HOCl secreted from the hepatic leukocytes of rats with or without stimulation of lipopolysaccharide was also determined. These results indicate a possibility to extend our approach to not only clinical settings for quantitative assessment of the bactericidal capability of isolated leukocytes of patients but also fundamental biomedical research that requires critical evaluation of the inflammatory response of animals.

Yang, Y. F., et al. (2019). "Toxicity-based toxicokinetic/toxicodynamic assessment for bioaccumulation of polystyrene microplastics in mice." Journal of Hazardous Materials **366**: 703-713.

While a large body of literature has shown that microplastics (MPs) are highly likely to be accumulated in marine organisms and terrestrial animals, information about toxicity of MPs in mammal from a mechanistic point of view is more limited. Our paper fills this knowledge gap by assessing polystyrene (PS)-MPs-mice system based on toxicity-based toxicokinetic/toxicodynamic (TBTK/TD) modeling to quantify organ-bioaccumulation and biomarker responses appraised with published dataset. The key TBTK-parameters for mice liver, kidney, and gut posed by 5 or 20 mum PS-MPs could be obtained. We found that gut had the highest bioaccumulation factor (BCF) of ~8 exposed to 5 mum PS-MPs with a mean residence time of ~17 days. We showed that threshold concentrations of 5 and 20 mum PS-MPs among the most sensitive biomarkers were 8 +/- 5 (mean +/- SE) and 0.71 +/- 0.14 mug g⁻¹ bw, respectively, implicating that particle size was likely to affect TK/TD behavior in mice. The mice-based TK parameters and threshold criteria greatly assist in designing robust researches to evaluate MP consumption by humans. We establish a TBTK/TD framework for mechanistically assessing potential from mice size-specific MPs exposure that would offer a tool-kit for extrapolating to humans from health risk assessment perspective.

Yang, Z., et al. (2014). "Photonic crystal-encoded suspension array and its application in screening malignant tumors. [Chinese]." Chinese Journal of Clinical Oncology **41**(1): 42-45.

Multiple tumor makers are needed to improve the diagnostic rate of the simultaneously detection of malignant tumors through screening. Therefore, multiplex detection technology is urgently required to improve the screening efficiency. Suspension arrays are multiplex detection method based on gene microarrays. It consists of encoded microbeads, probes, targets, and report molecules are applied to analyze targets quantitatively. The microbead encoding strategy is a hotspot in suspension array research. The photonic crystal encoding mentioned in this review is a type of optical encoding that is very stable and easily decoded. Photonic suspension arrays have broad prospects in the screening and diagnosis of malignant tumors through long-term studies. This review summarizes the basic principle, classification, and characteristics of photonic suspension arrays and their application in the screening of malignant tumors.

Yang, Z. X., et al. (2013). "Handy, rapid and multiplex detection of tumor markers based on encoded silica-hydrogel hybrid beads array chip." Biosensors & Bioelectronics **48**: 153-157.

Malignant tumor has become the leading cause of death worldwide; however, multiplex detection technology could provide great assistance in large-scale population screening of diseases which could effectively reduce the mortality of malignant tumors. Here a microbeads array chip, which could be a perfect alternative method for the early screening, was developed. Silica-hydrogel hybrid bead (SHHB) with photonic encoding, which consists of both silica and hydrogel materials, was manufactured as the carrier of microbeads array for the first time. The SHHB has the advantages of the beads made of silica or hydrogel, but does not have their limitations. Reaction conditions of SHHBs array were optimized and then the fluorescent concentration curves of two widely-used tumor markers, human alpha fetoprotein and carcinoembryonic antigen, were constructed. The accuracy of SHHBs array has been proven according to the comparison between the results obtained by detecting 50 clinical samples with SHHBs array and chemiluminescence immunoassay. A cassette like chip device has also been developed to standardize operational processes and benefit automization in the next work. Hence it is concluded that SHHBs array chip is a handy, rapid and multiplex immunoassay technology, which could imply its practical application in clinical immunoassay in the near future.

Yao, L., et al. (2019). "Freshwater microplastics pollution: Detecting and visualizing emerging trends based on Citespace II." Chemosphere **245**: 125627.

Microplastic particles with less than 5 mm in diameter has been detected in human feces and freshwater systems. Microplastics could cause serious physical and chemical harm to humans and organisms. Some previous studies on microplastics mainly concentrate on the marine environment, but few have focused on freshwater microplastics. Therefore, Citespace II is used to systematically analyze the related literature in order to comprehensively understand the research state of freshwater microplastics. The results show that there is still a large gap between research on freshwater and marine microplastics. Studies on freshwater microplastics have mainly been undertaken in developed countries such as the United States and Germany, while fewer studies have been conducted in the developing countries which face the most serious plastic pollution. Most studies focus on the rivers and lakes, but other freshwater sources with microplastic pollution, such as groundwater and reservoirs, have received less attention. This study also explored the possible opportunities and challenges that may be faced in freshwater research in order to introduce specific policies and measures to mitigate this emerging pollutant.

Yao, L. S., et al. (2007). "Culture of neural stem cells in alginate microbeads. [Chinese]." Chinese Journal of Biomedical Engineering **26**(1): 126-133.

Neural Stem Cells (NSCs) with the capacity of self-renewal and differentiation into neurons and glial cells have obtained more and more worldwide attention. The finding, research and application of NSCs will play an important role in the nerve disease treatment and nerve injury repair. The shortage of the source and the amount of NSCs, however, is the main obstacle for its clinic application. Large-scale three-dimensional culture of NSCs in vitro provides a feasible answer for this problem. But the shear stress in bioreactors would cause serious cell damage especially for the shear sensitive cells like NSCs. To avoid the shear stress, encapsulation of NSCs

and then cultivation in bioreactors is thus worth of investigating. Therefore, we explored the method of culturing NSCs in Calcium-Alginate Microbeads (Ca-Alg MBs). To provide the optimum growth conditions for NSCs in Ca-Alg MBs, the gelation parameters, such as diameter, reactant concentration, and gelation time were determined firstly to form the proper bead structure for cell growth. The diffusion experiment was performed to get the diffusion data for different Ca-Alg MBs and a diffusive mathematical model was set up to find the diffusion coefficient (D) of glucose in Ca-Alg MBs by fitting the experimental data. Base on the orthogonal test, the optimum gelation conditions for preparing microbeads with a proper diffusivity were determined. And the gelation parameters were 2mm in bead diameter, 1.5% sodium alginate, 3.5%CaCl<inf>2</inf>, and the gelation time of 10 min. The culture of encapsulated NSCs with different cell density was then conducted. The results showed that the culture effect with the encapsulation density of 0.08 x 10⁶ cells . mL⁻¹ was the best among the testing samples. The recovered NSCs were stained by immunofluorescence and the majority of the expanded NSCs in Ca-Alg MBs were nestin-positive. The experimental results demonstrated that mouse hippocampus-derived NSCs could survive and be expanded in Calcium-alginate Microbeads.

Yao, M., et al. (2017). "Microencapsulation of Lactobacillus salivarious Li01 for enhanced storage viability and targeted microbiome delivery." FASEB Journal. Conference: Experimental Biology **31**(1 Supplement 1).

Probiotics, used in food products, dietary supplements and pharmaceutical products have been considered to provide health-promoting effects in humans. In order to be efficacious, probiotics need to be viable at sufficient abundance in the intestine. However, many functional foods containing probiotics suffer from a large loss of bacterial viability during shelf storage and gastrointestinal transit after ingestion. In this study, probiotic Lactobacillus salivarious Li01 was incorporated into alginate or alginate-gelatin microbeads. Their morphology was characterized by SEM. Probiotic viability was determined under aerobic conditions, heat treatment and simulated gastrointestinal conditions. The results showed that microbeads were roughly round and almost all the bacterial cells were encapsulated in the microbeads. Encapsulation significantly enhanced the viability of the probiotic during aerobic storage. Moreover, the microbeads maintained their structures during simulated gastric digestion before they dissolved during simulated digestion in the small intestine. Most importantly, the alginate-gelatin microbeads protected encapsulated bacteria during simulated gastrointestinal digestion and effectively enhanced their survival rate in comparison with alginate microbeads and non-encapsulated bacteria. In conclusion, the alginate-gelatin microbeads showed a great potential to facilitate the delivery of probiotics such as lactobacillus salivarious Li01 in various products.

Yasmin, M., et al. (2014). "Multi-drug resistant Mycobacterium tuberculosis complex genetic diversity and clues on recent transmission in Punjab, Pakistan." Infection, Genetics & Evolution **27**: 6-14.

Multi-Drug Resistant Tuberculosis (MDR-TB), i.e. bacilli resistant to rifampicin (RIF) and isoniazid (INH), is a major Public Health concern in Pakistan according to WHO estimates (3.5% and 32% of new and retreated cases, respectively). Previous Pakistanis reports identified a correlation between being MDR and belonging to Beijing or EAI lineages in one study, and belonging to "H4"-Ural Euro-American sublineage in another study. In addition, MDR-TB transmission was suspected in Karachi. We tested MDR characteristics on a Punjab sample of 278 clinical isolates (without selection for Multi-Drug Resistance) including new and retreated cases collected from 2008 to 2012. All samples were characterized by a new, microbead-based method named

"TB-SPRINT" (molecular diagnostic including spoligotype identification, and genetic resistance determinants to first-line anti-TB drugs RIF and INH). Isolates from 2011 to 2012 (n=100) were further analyzed using 24-loci MIRU-VNTR. We detected 8.7% MDR isolates (CI95%=[5.0; 12.5]), mainly among CAS lineage that predominates in this central-East region of Pakistan. Out of 20 MDR-TB cases, 12 different TB-SPRINT profiles were identified, limiting the suspicion of MDR-TB transmission. 24 MIRU-VNTR confirmed the unrelatedness of isolates with different TB-SPRINT profiles and discriminated 3 isolates with identical TB-SPRINT profiles. In conclusion, our study did not confirm any of the correlations between Multi-Drug Resistance and lineage or sublineage in Punjab, Pakistan. MDR-TB isolates were diverse indicating that transmission is not pervasive. TB-SPRINT proved useful as a first step for detecting MDR-TB likely transmission events, before more extensive genotyping such as 15 or 24 MIRU-VNTR and thorough epidemiological investigation.

Yasuda, K., et al. (1989). "Basic research on the emission of polycyclic aromatic hydrocarbons caused by waste incineration." Journal of the Air and Waste Management Association **39**(12): 1557-1561.

The emission of polycyclic aromatic hydrocarbons (PAH) caused by municipal waste incineration varies according to waste composition and operating parameters such as furnace temperature and excess air. However, to obtain a sample sufficient to measure the emission of PAH at trace levels, it is necessary to operate the incinerator for many hours. Since during these lengthy periods it has not always been possible to maintain stable conditions, it is very difficult to determine the relationship between the emission and waste composition. In our basic research, therefore, we used municipal waste with an artificially regulated composition for our combustion experiments, and by using an experimental incinerator we examined the emission behavior of PAH with respect to changes in waste composition and combustion conditions. The following facts were revealed by the results: · The PAH found in the flue gas were predominantly the more volatile compounds. · When municipal waste was incinerated at over 850°C, the concentration of PAH in the flue gas increased rapidly as the proportion of plastics in the waste increased from 0 to 24 percent. · The elimination of plastics from municipal waste by separate collection and the improvement of combustion conditions can effectively diminish the emission of PAH. The emission of polycyclic aromatic hydrocarbons (PAH) caused by municipal waste incineration varies according to waste composition and operating parameters such as furnace temperature and excess air. In our basic research, therefore, we used municipal waste with an artificially regulated composition for our combustion experiments, and by using an experimental incinerator we examined the emission behavior of PAH with respect to changes in waste composition and combustion conditions. The PAH found in the flue gas were predominantly the more volatile compounds. When municipal waste was incinerated at over 850°C, the concentration of PAH in the flue gas increased rapidly as the proportion of plastics in the waste increased from 0 to 24 percent. The elimination of plastics from municipal waste by separate collection and the improvement of combustion conditions can effectively diminish the emission of PAH.

Yasuda, S., et al. (2017). "Twisting microfluidics in a planetary centrifuge." Soft Matter **13**(11): 2141-2147.

This paper reports a twisting microfluidic method utilising a centrifuge-based fluid extruding system in a planetary centrifuge which simultaneously generates an orbital rotation and an axial spin. In this method, fluid extrusion from a micro-scale capillary to an 'open-space' solution or air enables release of the fluid from the capillary-based microchannel, which physically means that there is a release of fluids from a confined low-Reynolds-number environment to an open

non-low-Reynolds-number environment. As a result, the extruded fluids are separated from the axial spin of the capillary, and the difference in the angular rates of the axial spin between the capillary and the extruded fluids produces the 'twisting' of the fluid. In this study, we achieve control of the twist of highly viscous fluids, and we construct a simple physical model for the fluid twist. In addition, we demonstrate the formation of twisted hydrogel microstructures (stripe-patterned microbeads and multi-helical microfibres) with control over the stripe pattern and the helical pitch length. We believe that this method will enable the generation of more sophisticated microstructures which cannot easily be formed by usual channel-based microfluidic devices. This method can also provide advanced control of microfluids, as in the case of rapid mixing of highly viscous fluids. This method can contribute to a wide range of applications in materials science, biophysics, biomedical science, and microengineering in the future.

Yazdani Foshtomi, M., et al. (2019). "Composition and abundance of microplastics in surface sediments and their interaction with sedimentary heavy metals, PAHs and TPH (total petroleum hydrocarbons)." Marine Pollution Bulletin **149 (no pagination)**(110655).

The composition and abundance of microplastics (MPs) and concentrations of heavy metals, PAHs and TPH in surface sediments as well as their relationship with the number of MPs in three contrasting sediment types were investigated in Bandar Abbas, Iran. Total number of MPs ranged from 3542 to 33561 items per m² in different stations. The collected MPs displayed a variety of shapes and colors. White filaments were the most dominant MP item in the Khor-e-Yekshabeh and Suru stations while blue fragments were dominant items in the Gorsozan. Concentrations of heavy metals, PAHs and TPH also varied among stations. There were significant correlations between the total number of MPs, sediment grain size and ten measured heavy metals ($P < 0.05$). In contrast, no significant correlations were detected with PAHs (except for Benzo (a) ant) and TPH concentrations ($P > 0.05$). MPs in sediment as vectors for heavy metals and some PAHs can ingest by benthic animals, resulting in their bioaccumulation in marine food web. Copyright © 2019 Elsevier Ltd

Ye, L.-j. and N.-x. Wu (2019). "Progress on detection of microplastics and their effects on ecosystem." Huan Jing Yu Zhi Ye Yi Xue = Journal of Environmental & Occupational Medicine **36**(12): 1161.

Microplastics are a sort of plastic pieces with a size less than 5 mm and large specific surface area, and can absorb pollutants in the environment. A large number of studies have shown that microplastics are widely distributed in the environment and may have a variety of adverse health effects on organisms. The evidence for human health effects, however, is insufficient yet. Thus, this review introduced the distribution of microplastics in the environment and human diet, the extraction and detection methods of microplastics, and various ways of affecting organisms, aiming to provide a theoretical basis for developing relevant standards and studying the toxicity of microplastics.

Ye, S. and A. L. Andrady (1991). "Fouling of Floating Plastic Debris under Biscayne Bay Exposure Conditions." Marine Pollution Bulletin MPNBAZ, Vol. 22, No. 12, p 608-613, December 1991. 6 fig, 2 tab, 22 ref.

Incidence of plastic waste in the marine environment is a relatively recent phenomenon directly attributable to the industry-wide use of plastic fishing gear in commercial fishing and the continuing popularity of plastic packaging material. Six plastic/rubber materials commonly encountered in marine debris and beach litter were studied under Biscayne Bay (Florida) exposure conditions to determine the effect of fouling on buoyancy. Fouling of plastic materials

was generally preceded by the formation of a transparent slimy biofilm on the surface. Within weeks of exposure to seawater under restricted floating conditions, nearly all sample surfaces developed algal fouling communities. The foulant colonies were predominantly green algae and biofilm for the first 7 weeks of exposure, hydroid colonies during 9-11 weeks of exposure, and encrusting bryozoa and tunicates during 13-19 weeks of exposure. In spite of the variability in specific surface area, most samples were fouled sufficiently to sink in seawater by about the seventh week of exposure. Rapid defouling of the submerged fouled samples was observed. The results suggest that free-floating plastics at sea may, under certain conditions, undergo fouling-induced sinking followed by resurfacing as floating debris. (MacKeen-PTT) 35 045968000

Yee, M. S. L., et al. (2014). "Potent antifouling silver-polymer nanocomposite microspheres using ion-exchange resin as templating matrix." Colloids and Surfaces A: Physicochemical and Engineering Aspects **457**(1): 382-391.

Biofouling of marine surfaces is a significant and complex problem especially in the shipping industry. This study seeks to develop a silver-polymer nanocomposite (Ag-PNC) system by synthesizing highly dispersed silver nanoparticles with narrow size distributions using Dowex protonated copolymer ion exchange resins as a templating matrix. Ag ions were introduced into the copolymer microbeads through an ion exchange process with silver nitrate, followed by chemical reduction using sodium borohydride to form metallic Ag on the surface of the microbead structure. Scanning electron microscopy (SEM) imaging revealed the uniform distribution of Ag nanoparticles with diameters between 20 and 60. nm on the surface of the microbeads, while UV-visible (UV-VIS) analysis showed the characteristic surface plasmon resonance for Ag nanoparticles ranging from 406 to 422. nm. Thermal stability of the nanocomposites was enhanced with the incorporation of Ag nanoparticles, with significant degradation occurring at 460. degreeC compared to 300. degreeC for the copolymer microbead, while the glass transition temperature of the Ag-PNCs increased from 130. degreeC to 323. degreeC. Significant inhibition of biofilm formation by Halomonas pacifica, a common marine bacteria responsible for initial marine fouling process, was observed, following treatment with Ag-PNC. Biocompatibility testing with human lung fibroblast and human keratinocytes show no significant toxicity to human cells. Toxicity testing of the Ag-PNC material with non-target marine microalgae Dunaliela tertiolecta and Isochrysis sp. also displayed no significant morphological changes, with cytostatic growth inhibition. These results strongly suggest that Ag-Dowex nanocomposites possess great potential to be an alternative to other antifouling agents due to their affordable, accessible and high yield production method. © 2014 Elsevier B.V.

Yellanki, S. K. and N. K. Nerella (2010). "Stomach-specific drug delivery of riboflavin using floating alginate beads." International Journal of Pharmacy and Pharmaceutical Sciences **2**(SUPPL. 2): 160-163.

A multiple-unit-type oral floating dosage form (FDF) of Riboflavin was developed to prolong gastric residence time, and increase drug bioavailability. The floating bead formulations were prepared by dispersing Riboflavin together with calcium carbonate into a mixture of sodium alginate and hydroxypropyl methylcellulose solution and then dripping the dispersion into an acidified solution of 1% (w/v) calcium chloride. The formulations were optimized for different weight ratios of gas-forming agent and sodium alginate. Prepared microbeads were evaluated for Particle size, Scanning electron microscopy, In-Vitro buoyancy study, Drug entrapment efficiency and In-Vitro drug release. The beads containing higher amounts of calcium carbonate demonstrated instantaneous, complete, and excellent floating ability. All the formulations remained buoyant and controlled release for up to 10 hrs. The mechanism of drug release was found to follow Higuchi matrix order release. Results indicate that FDF performed significantly better than the simple tablet dosage form.

Yeo, B. G., et al. (2017). "Polycyclic Aromatic Hydrocarbons (PAHs) and Hopanes in Plastic Resin Pellets as Markers of Oil Pollution via International Pellet Watch Monitoring." Archives of Environmental Contamination and Toxicology **73**(2): 196-206.

Oil pollution in the marine environment is an unavoidable problem due to chronic input from local sources, particularly in urban areas and oil spills. Oil pollution not only causes immediate physical damages to surrounding wildlife but also some components, including higher molecular weight PAHs, can persist in the environment for many years and pose insidious threats to the ecosystem. Long-term and nontargeted monitoring of oil pollution is important. This paper examines the ability of International Pellet Watch (IPW) for initial identification and monitoring of oil pollution by analysing PAHs and hopanes in plastic pellet samples collected globally by volunteers. PAH concentrations with the sum of 28 parent and methyl PAHs vary geographically, ranging from 0.035 to 24.4 micro g/g-pellet, in line with the presence or absence of local oil pollution sources, such as oil refineries or oil spill sites. This suggests that PAHs can be used to monitor petroleum pollution in IPW. A colour-coded categorization for PAH concentrations within IPW monitoring also is established to facilitate data presentation and understanding. PAH concentrations are generally higher in Western Europe, especially around the North Sea shorelines, moderate in East Asia and North America, and lower in South East Asia, Oceania, South America, and Africa. Hopane concentrations, with a smaller spatial variation (1.7-101 micro g/g-pellet), showed no spatial pattern. This result and the poor correlation between hopanes and PAHs suggest that hopane concentrations alone are unsuited to identify petroleum pollution. However, hopane compositions can be used for fingerprinting sources of oil pollution. Thus, both PAHs and hopanes in IPW allow for low cost, remote monitoring of global oil pollution. Yeo, B. G., et al. (2015). "POPs monitoring in Australia and New Zealand using plastic resin pellets, and International Pellet Watch as a tool for education and raising public awareness on plastic debris and POPs." Marine Pollution Bulletin **101**(1): 137-145.

Persistent organic pollutants (i.e. PCBs, DDTs, and HCHs) were analyzed along Australia and New Zealand North Island coastlines. PCB concentrations were high in urban areas (107-294 ng/g-pellet), with Sydney Harbour the most polluted. Hepta-chlorinated PCB was abundant, with ~. 30% in urban areas suggesting legacy pollution. DDT concentrations showed similar pattern except in rural agricultural sites, Taupo Bay and Ahipara, New Zealand (23 and 47 ng/g-pellet). p,p'-DDE predominance at these 2 sites suggested historical input; they also had high HCH concentrations (17 and 29 ng/g-pellet). The role of International Pellet Watch (IPW) in science communication was studied through feedbacks from IPW volunteers, case studies and examples. IPW data were categorized into understandable terms and tailored reports based on volunteers' backgrounds complemented with pollution maps. The effectiveness of IPW science communication has led to its use in awareness and education activities focusing on both POPs and plastic debris issues. Copyright © 2015 Elsevier Ltd.

Yeo, B. G., et al. (2019). "PCBs and PBDEs in microplastic particles and zooplankton in open water in the Pacific Ocean and around the coast of Japan." Marine Pollution Bulletin **(no pagination)**(110806).

PCBs and PBDEs in microplastics and zooplankton collected in surface water at 27 locations in the Pacific Ocean and around the coast of Japan were investigated. Both PCBs and PBDEs were observed in buoyant microplastics, even in smaller particles of 0.315-1 mm. Concentrations of

SIGMA13 PCBs were 0.04-124 ng/g, and were higher in urban bay areas such as Tokyo Bay. Sporadic moderate to high concentrations of PBDEs were observed in both urban-offshore and rural-offshore locations, consisting mostly of higher-brominated congeners. From the latter, BDE 209 ranged from not detected to 2158 ng/g. The microplastic-to-zooplankton abundance ratio threshold was 0.6 for PCBs and 0.08 for PBDEs, above which exposure would be greater from microplastics than from zooplankton. Yi, X., et al. (2019). "Combined effect of polystyrene plastics and triphenyltin chloride on the green algae Chlorella pyrenoidosa." Environmental Science & Pollution Research **26**(15): 15011-15018.

The combined effect of polystyrene (PS) particles and triphenyltin chloride (TPTCl) to the green algae Chlorella pyrenoidosa was studied. The 96 h IC₅₀ of TPTCl to the green algae C. pyrenoidosa was 30.64 mug/L. The toxicity of PS particles to C. pyrenoidosa was size-dependent, with the 96 h IC₅₀ at 9.10 mg/L for 0.55 mum PS but no toxicity observed for 5.0 mum PS. The exposure to 0.55 mum PS led to damage on structure of algal cells, which could in turn cause inhibition on photosynthesis and population growth of the green algae. TPTCl concentrations in test medium were lowered by 15-19% at presence of 0.55 mum PS particles, indicating a reduced bioavailability of TPTCl. In spite of this reduced bioavailability, the presence of PS increased the toxicity of TPTCl, which might be attributed to facilitated uptake of TPTCl by the green algae after the damage of cell structure. The overall results of the present study provided important information on the effect of PS on the bioavailability and toxicity of TPTCl to phytoplankton species.

Yi, X., et al. (2019). "The effect of polystyrene plastics on the toxicity of triphenyltin to the marine diatom <i>Skeletonema costatum</i>—influence of plastic particle size." Environmental science and pollution research international **26**(25): 25445-25451.

The effect of polystyrene (PS) particles on the toxicity of triphenyltin (TPT) to the marine diatom Skeletonema costatum was investigated. The 0.1-μm PS particles attached to the cell walls of S. costatum but did not cause adverse effects on the growth of the diatom. The adsorption of TPT to PS particles was negligible in seawater systems, but the presence of 0.1-μm PS significantly reduced the bioavailable concentrations of TPT in f/2-Si medium, indicating a potential three-way interaction between TPT, PS particles, and components of f/2-Si medium. The adsorption of TPT to PS of smaller size (i.e., 0.1 μm) was stronger than that of PS of larger size (i.e., 5 μm), which was probably attributed to larger surface areas of smaller PS particles. The presence of PS could reduce the toxicity of TPT. IC50 values of TPT increased from 0.56 to 0.85 and 0.71 μg/L at the presence of 20 mg/L 0.1-μm PS and 5-μm PS, respectively. The overall results of this study profiled the combined toxic effects of PS and TPT on marine phytoplankton species and highlighted the difference in adsorption of organic pollutants by microplastics in different ambient mediums.

Yifeng, L., et al. (2016). "Uptake and Accumulation of Polystyrene Microplastics in Zebrafish (Danio rerio) and Toxic Effects in Liver." Environmental Science & Technology **50**(7): 4054-4060.

Microplastics have become emerging contaminants, causing widespread concern about their potential toxic effects. In this study, the uptake and tissue accumulation of polystyrene microplastics (PS-MPs) in zebrafish were detected, and the toxic effects in liver were investigated. The results showed that after 7 days of exposure, 5 μm diameter MPs accumulated in fish gills, liver, and gut, while 20 μm diameter MPs accumulated only in fish gills and gut. Histopathological analysis showed that both 5 μm and 70 nm PS-MPs caused inflammation and lipid accumulation in fish liver. PS-MPs also induced significantly increased activities of

superoxide dismutase and catalase, indicating that oxidative stress was induced after treatment with MPs. In addition, metabolomic analysis suggested that exposure to MPs induced alterations of metabolic profiles in fish liver and disturbed the lipid and energy metabolism. These findings provide new insights into the toxic effects of MPs on fish. [ABSTRACT FROM AUTHOR]

Yilmaz, F., et al. (2013). "Bioinspired surface modification of poly(2-hydroxyethyl methacrylate) based microbeads via oxidative polymerization of dopamine." Colloids & Surfaces B: Biointerfaces **109**: 176-182.

Surface modification of support materials is crucial for improving their selectivities and biocompatibilities in bioaffinity applications. However, conventional modification techniques including chemical or physical conjugations mostly suffer from limitations of their multistep and complicated procedures, surface denaturations, batch-to-batch inconsistencies, and insufficient surface conjugations. In this study, we demonstrate a simple yet effective bioinspired approach for the surface modification of poly(2-hydroxyethyl methacrylate) [PHEMA] based bioaffinity adsorbents through oxidative polymerization of dopamine. The magnetic (mPHEMA) and non-magnetic (PHEMA) polymeric microbeads were fabricated by suspension polymerization technique. Surface modification of obtained microbeads was then carried out by using dopamine molecules under alkaline conditions. The polydopamine (PDOPA) coated microbeads were further employed as a bioaffinity absorbent targeted for immunoglobulin G (IgG) molecules. The effects of pH, temperature, protein concentration and ionic strength on the IgG adsorption process have been investigated. We found that PDOPA coated microbeads display dramatically higher IgG adsorption capacities when compared with their un-modified forms. Adsorption capacities also increased with increasing temperature. Monolayer Langmuir adsorption model can be thought more applicable for these adsorbent systems.

Yilmaz, V., et al. (2012). "Cytokine levels in peripheral cell culture without B cell in myasthenia gravis patients." Journal of Neuroimmunology **253 (1-2)**: 167.

Objective: In acquired myasthenia gravis (MG), the differential antibody production in disease subgroups is regulated by T cells and by related cytokine activity. In this study, T cell activity mediated by cy-tokine secretion is compared in patients with autoantibodies (Abs) to acetylcholine receptor (AP), to muscle-specific kinase (MP) and without detectable antibodies (SN) in an in vitro cell culture with specific and non-specific T cell stimulation. Method(s): The study group of 59 MG patients (18 AP, 19 MP and 22 SN) with generalized disease (W/M: 42/17) were included. Fifty-six % of the patients were on immunosuppressives. In addition, 10 healthy controls (HC) (W/M: 6/4) were evaluated. Peripheral blood mononuclear cells without B cells were stimulated with t-AChR, recombinant-MuSK or anti-CD3 antibody. IFN-gamma, IL-10, IL-2, IL-13, IL-17A and IL-21 were measured in supernatants using a microbead array system (Milliplex). Results were compared with non-parametric tests. Result(s): Spontaneous IFN-gamma, IL-13 and IL-2 secretion was lower in the MG group than HC (p=0.004, 0.004 and 0.028). However, when the patients with or without treatment were compared, a suppression of only IFN-gamma was shown in steroid-treated patients (p=0.02) whereas lower IL-13 and IL-2 were not related to ongoing treatment. Spontaneous IL-10 production was not depressed in the

MG group. In all groups, in vitro antigen specific stimulation with AChR or MuSK did not alter the cytokines compared to non-stimulated cells, whereas anti-CD3 stimulation induced effective secretion of all measured cy-tokines except IL-2. When all cytokines were compared, anti-CD3 stimulated lower levels of IL-10, IL-13, IL-17A, IL-2, IL-21 in MG compared to HC (p=0.019, 0.022, 0.021, 0.002, 0.027), also in patients not-on-treatment (p=0.02, 0.05, 0.03 and 0.04). CD3 stimulation was also less effective for IFN-gamma in MG patients without treatment compared to HC (p=0.01). The differences were also evident in all subgroup comparisons. Conclusion(s): In MG, even in patients not on treatment, disease specific (AChR and MuSK) stimulations induced no cytokine secretion and non-specific (CD3) T cell stimulation induced only lower levels of cy-tokines in vitro. The decrease of cytokine induction in immunosup-pressive naive patients emphasizes the disease related changes in the immune response of MG patients on T cell cytokine activity.

Yin, L., et al. (2018). "Polystyrene microplastics alter the behavior, energy reserve and nutritional composition of marine jacopever (Sebastes schlegelii)." Journal of Hazardous Materials **360**: 97-105.

Uptake and toxicity of microplastics on marine organisms have been reported elsewhere. However, there is limited knowledge regarding the ecological effects of microplastics on marine organisms. In this study, we investigated the effects of polystyrene microplastics (1 × 106 microspheres per L) on the behavior, energy reserve and nutritional composition of juvenile jacopever (Sebastes schlegelii). Compared to the controls, fish treated by microplastics showed lower sensitivity toward the added food in the tank, and increased foraging time, indicating that microplastics significantly weakened feeding activity of the fish. Interestingly, the microplastics treated-fish obviously reduced swimming speed and range of movement, demonstrating that polystyrene microplastics could have negative effect on hunting behavior. Furthermore, polystyrene microplastics accumulated in the gills and intestine, causing significant histopathological changes in the gallbladder and liver. Moreover, the energy reserve and nutritional quality of fish were influenced by microplastics as evidenced by lower growth, protein and lipid contents. Our results highlighted the potential negative effects of microplastics on marine ecological function and food safety.

Yin, L., et al. (2019). "Microplastic Pollution in Surface Water of Urban Lakes in Changsha, China." International Journal of Environmental Research & Public Health [Electronic Resource] **16**(9): 12.

As emerging pollutants, microplastics have attracted the attention of scholars from all over the world. However, there is a lack of research on freshwater areas, even in densely populated urban areas. This study investigated eight urban lakes in Changsha, China. It was found that microplastic concentrations ranged from 2425 +/- 247.5 items/m³ to 7050 +/- 1060.66 items/m³ in the surface water of research areas and the maximum concentration was found in Yuejin Lake, a tourist spot in the center of the city. Anthropogenic factors are an important reason for microplastic abundance in urban lakes. The major shape of microplastics was linear and most of the microplastics were transparent. More than 89.5% of the microplastics had a size of less than 2 mm. Polypropylene was the dominant type in the studied waters. This study can provide a valuable reference for a better understanding of microplastic pollution in urban areas of China.

Yin, L., et al. (2019). "Impacts of polystyrene microplastics on the behavior and metabolism in a marine demersal teleost, black rockfish (Sebastes schlegelii)." Journal of Hazardous Materials **380**: 120861.

After nano- (0.5 mum) or micro- (15 mum) polystyrene (PS) microplastics exposure, the behavior, metabolism and energy reserve in marine demersal fish (Sebastes schlegelii) were

evaluated. The behavior of fish was accurately recorded by video behavior tracking technology.

Ying, D., et al. (2018). "Development and evaluation of a rapid point-of-care test for detecting the hepatitis E virus antigen." Clinical Biochemistry **55**: 89-92.

BACKGROUND: Hepatitis E virus (HEV)-caused acute viral hepatitis is a major threat to public health worldwide. Recently, an enzyme linked immunosorbent assay (ELISA) kit detecting the HEV antigen was reported to have good concordance with the HEV RNA load and showed good clinical performance. But the ELISA kits can barely satisfy the needs of community clinics. In this study, a fluorescent microbead-based immunoassay (FMIA) for detecting the HEV antigen was developed and evaluated.

METHODS: A mouse anti-HEV monoclonal antibody (mAb) conjugated with fluorescent microbeads was used as capturing antibody and another mouse mAb was used as detection antibody. Overall, 150 serum samples were collected from HEV-infected patients (n=50) and non-HEV cases (n=100) to evaluate the performance of the FMIA.

RESULTS: The FMIA results showed a strong linear correlation with the viral RNA load. The diagnostic sensitivity and specificity of the HEV antigen FMIA were 92.0% (46/50) and 100.0% (100/100), respectively, and the test was consistent (kappa=0.937, p=0.627) with the commercial HEV antigen ELISA. The FMIA also showed good consistency with the PCR results (kappa=0.939, p=0.134).

CONCLUSIONS: As a rapid point-of-care (POC) test, a FMIA that is developed with acceptable performance is suitable for acute hepatitis E diagnosis, especially in developing countries and regions, because of its reduced time and simplified operation.

Yodkaew, R., et al. (2007). "Sound absorption of an interior ceiling material from chaff." Proceedings of the 44th Kasetsart University Annual Conference, Kasetsart.

Chaff is an abundant agricultural waste. Unique to chaff is its low moisture content, porous texture in nanoscale and light weight. These characteristics are suitable for local and national material industry. The objectives of this research were to develop chaff intergrated panels for sound absorption. Several chaff panels were made into 50 cm x 50 cm boards with 1 cm thick. The panels were made by mixing chaffs with plastic resin glue, latex glue and natural rubber. The panels were then tested for sound absorption. A comparison with ceiling boards and sound absorption materials in the market, i.e, gymsum board, acoustic board and fibreglass insulator board, was made. Results show that the ceiling board made from chaff with the mixing ratio of 5:1 (chaff:plastic resin glue) is able to absorb sound better than gymsum board and is able to absorb sound nearly as effectively as the fibreglass insulator board.

Yonkos, L. T., et al. (2014). "Microplastics in four estuarine rivers in the Chesapeake Bay, U.S.A." Environmental Science & Technology **48**(24): 14195-14202.

Once believed to degrade into simple compounds, increasing evidence suggests plastics entering the environment are mechanically, photochemically, and/or biologically degraded to the extent that they become imperceptible to the naked eye yet are not significantly reduced in total mass. Thus, more and smaller plastics particles, termed microplastics, reside in the environment and are now a contaminant category of concern. The current study tested the hypotheses that microplastics concentration would be higher in proximity to urban sources, and vary temporally in response to weather phenomena such as storm events. Triplicate surface water samples were collected approximately monthly between July and December 2011 from four estuarine tributaries within the Chesapeake Bay, U.S.A. using a manta net to capture appropriately sized microplastics (operationally defined as 0.3-5.0 mm). Selected sites have watersheds with broadly divergent land use characteristics (e.g., proportion urban/suburban, agricultural and/or forested) and wide ranging population densities. Microplastics were found in all but one of 60 samples, with concentrations ranging over 3 orders of magnitude (<1.0 to >560 g/km(2)). Concentrations demonstrated statistically significant positive correlations with population density and proportion of urban/suburban development within watersheds. The greatest microplastics concentrations also occurred at three of four sites shortly after major rain events.

Yoo, H. J., et al. (2018). "Short-Length DNA Adsorption on Graphene Oxide-Coated Microbeads for DNA Target Separation from Clinical Samples." Journal of Nanoscience & Nanotechnology **18**(9): 6364-6368.
Nucleic acid preparation (concentration and purification of various nucleic acid targets) from biological samples is essential for personalized and precision medicine. The adsorption of short-length DNA on graphene oxide (GO) layers was investigated and compared with that on silica surfaces. GO was efficiently coated on glass beads to be used more easily and spatially. Surface of the GO bead was confirmed by field-emission scanning electron microscopy. GO-coated beads were packed and the adsorption conditions of short-length DNA were optimized under various pH and flow rate conditions. The amount of adsorbed DNA was confirmed by real-time polymerase chain reaction and visualized using fluorescence microscopy.

Yoo, J. H., et al. (2014). "Microfluidic based biosensing for Escherichia coli detection by embedding antimicrobial peptide-labeled beads." Sensors and Actuators B: Chemical **191**: 211-218.
Due to their ability of effective binding to multiple target microbes, the antimicrobial peptides (AMPs) have recently received lots of attention as an alternative to antibodies for detecting bacteria. We developed a new biosensing method to detect Escherichia coli (E. coli) by implementing a microfluidic chip designed with a weir inside the channel, in which AMP-labeled microbeads were embedded. We characterized the detection rate of the stained E. coli within a certain period of time to examine the detection effectiveness of our device. As the flow rate of the bacterial suspension increases, the detection time to reach the saturation level decreases to less than 30min, suggesting rapid detection, while the detection efficiency is maintained at a similar level. Except with very low concentrations of E. coli (<103 cells/mL), both the detection time and the efficiency do not depend on the E. coli concentration. Our method has the potential to be developed as a novel biosensing platform for rapid and accurate detection of pathogens.

Yoo, J. H., et al. (2012). "The detection of p53 gene via fluorescence quenching of quantum dot in microfluidic chip." Journal of Nanoscience & Nanotechnology **12**(5): 4109-4114.
Recently, quantum dot (QD) has been used widely in the field of bio assay including cell imaging, biomarker, and fluorescence resonance energy transfer (FRET) sensor. The DNA assay without labeling process has several advantages including low cost, short time, and simplicity. Microbeads of agarose, glass, and polystyrene have been used as a solid support in microfluidic devices to trace molecules. The main advantages of microfluidics include high throughput, short analysis time, small sample volume, and high sensitivity. PDMS based microfluidic chips were prepared for the detection of p53 gene by using QD-DNA conjugate. The microfluidic chip has a weir in the channel to trap microbeads to which QD-DNA probes bind. Carboxylated CdSe/ZnS QDs (wavelength of emission: 605 nm) could bind to microbeads of polystyrene/divinyl benzene via EDC/NHS crosslinking reaction. The target gene and DNA intercalating dye (TOTO-3) were loaded into the micro-channel. Fluorescence quenching from QDs by intercalating dye was observed after hybridization of DNA at the weir in the channel of microfluidic chip. The fluorescence quenching from QDs by TOTO-3 was dependent on the concentration of target

gene. This experiment shows the possibility of rapid detection of DNA via bead-QD complex on microfluidic chip.

Yoo, J. J., et al. (2014). "Electrochemical detection of insulating beads at subattomolar concentration via magnetic enrichment in a microfluidic device." Analytical Chemistry **86**(9): 4302-4307.

We report electrochemical detection of collisions between individual magnetic microbeads, present at subattomolar concentrations, and electrode surfaces. This limit of detection is 4 orders of magnitude lower than has been reported previously, and it is enabled by using a magnetic field to preconcentrate the microbeads prior to detection in a microfluidic electrochemical cell. Importantly, the frequency of collisions between the microbeads and the electrode is not compromised by the low concentration of microbeads. These findings represent an unusual case of detecting individual electrochemical events at very low analyte concentration. In addition to experiments supporting these claims, finite-element simulations provide additional insights into the nature of the interactions between flowing microbeads and their influence on electrochemical processes.

Yoon, J., et al. (2016). "Fabrication of type I collagen microcarrier using a microfluidic 3D T-junction device and its application for the quantitative analysis of cell-ECM interactions." Biofabrication **8**(3): 035014.

We presented a new quantitative analysis for cell and extracellular matrix (ECM) interactions, using cell-coated ECM hydrogel microbeads (hydrobeads) made of type I collagen. The hydrobeads can carry cells as three-dimensional spheroidal forms with an ECM inside, facilitating a direct interaction between the cells and ECM. The cells on hydrobeads do not have a hypoxic core, which opens the possibility for using as a cell microcarrier for bottom-up tissue reconstitution. This technique can utilize various types of cells, even MDA-MB-231 cells, which have weak cell-cell interactions and do not form spheroids in conventional spheroid culture methods. Morphological indices of the cell-coated hydrobead visually present cell-ECM interactions in a quantitative manner.

Yordanova, D., et al. (2013). "Plastic waste: definition, types, properties and alternatives for utilisation and disposal." Journal of Balkan Ecology **16**(4): 341-346.

The growing consumption of plastic goods inevitably leads to an increase of the amounts of generated plastic waste. The only possible solution for dealing with this problem is utilisation of plastic waste for material or energy recovery, which is in compliance with the main principles of sustainable development. This paper deals with the diverse properties of various types of plastic (polyethylene terephthalate (PET), high density polyethylene (HDPE), low density polyethylene (LDPE), polyvinylchloride (PVC), polypropylene (PP), polystyrene (PS), polyurethane (PUR), expanded polyurethane, epoxy resins, phenolates), the use of hazardous substances in the production of plastics (new persistent organic pollutants (POPs), such as tetrabromodiphenyl ether, pentabromodiphenyl ether, hexabromodiphenyl ether and heptabromodiphenyl ether) and difficulties related to the organization of separate collection of waste from all sectors which complicate the selection of a process for plastic waste recovery.

Yoshida, K. (2017). "Development of Functional Thin Polymer Films Using a Layer-by-Layer Deposition Technique." Yakugaku Zasshi - Journal of the Pharmaceutical Society of Japan **137**(10): 1215-1221.

Functional thin films containing insulin were prepared using layer-by-layer (LbL) deposition of insulin and negatively- or positively-charged polymers on the surface of solid substrates. LbL films composed of insulin and negatively-charged polymers such as poly(acrylic acid) (PAA),

poly(vinylsulfate) (PVS), and dextran sulfate (DS) were prepared through electrostatic affinity between the materials. The insulin/PAA, insulin/PVS, and insulin/DS films were stable in acidic solutions, whereas they decomposed under physiological conditions as a result of a change in the net electric charge of insulin from positive to negative. Interestingly, the insulin-containing LbL films were stable even in the presence of a digestive-enzyme (pepcin) at pH 1.4 (stomach pH). In contrast, LbL films consisting of insulin and positively-charged polymers such as poly(allylamine hydrochloride) (PAH) decomposed in acidic solutions due to the positive charges of insulin generated in acidic media. The insulin-containing LbL films can be prepared not only on the surface of flat substrates, such as quartz slides, but also on the surface of microparticles, such as poly(lactic acid) (PLA) microbeads. Thus, insulin-containing LbL film-coated PLA microbeads can be handled as a powder. In addition, insulin-containing microcapsules were prepared by coating LbL films on the surface of insulin-doped calcium carbonate (CaCO₃) microparticles, followed by dissolution of the CaCO₃ core. The release of insulin from the microcapsules was accelerated at pH 7.4, whereas it was suppressed in acidic solutions. These results suggest the potential use of insulin-containing microcapsules in the development of oral formulations of insulin.

Yoshimoto, K., et al. (2018). "Possible involvement of BAFF and matrixmetalloproteinase-9 in the activation of monocytes of patients with primary sjogren's syndrome." Annals of the Rheumatic Diseases **77 (Supplement 2)**: 882.

Background: B cell activating factor belonging to TNF family (BAFF) is well known as a factor which regulates proliferation, differentiation and survival of B cells, and plays a pivotal role in the pathogenesis of primary Sjogren's syndrome (pSS). In our previous study, we found that BAFF significantly enhanced IL-6 production by pSS monocytes and the amount of IL-6 produced by BAFF-stimulated monocytes was positively and significantly correlated with the expression level of a BAFF receptor (BR3). These data collectively suggest that the BAFF signalling through BR3 is involved in activation of monocytes to promote production of inflammatory cytokines, such as IL-6. Matrix metalloproteinase-9 (MMP-9) is well known as one of the enzymes involved in degradation of extracellular matrix (ECM) and mainly produced by activated T cells and monocytes. It has been reported that the concentration of MMP-9 in saliva was significantly higher in pSS patients as compared to healthy controls (HC). Therefore, it is conceivable that MMP-9 is involved in the pathogenesis of pSS through degradation of ECM of salivary glands, which consequently results in decrease in saliva, one of the clinical manifestations of pSS. Objective(s): To explored the relationship between BAFF and MMP-9 in the pathogenesis of pSS. Method(s): Peripheral monocytes from pSS patients (n=37) and HC (n=19) were prepared by using CD14 +microbeads and cultured in vitro in the presence or absence of recombinant human soluble BAFF (rhsBAFF) for 96 hours. The amounts of IL-6 and MMP-9 in the culture supernatants were measured by ELISA. Signal transduction pathways were investigated by exposing rhsBAFF-stimulated pSS monocytes to several inhibitors against NF-kappaB (BAY11-7082 and BAY11- 7085) and PI3 kinase (LY294002). FACS analysis of whole blood samples was performed to investigate the expression levels of BR3 and MMP-9 in monocytes. The expression level of MMP-9 was also analysed by quantitative RT-PCR (qPCR). Serum levels of BAFF and MMP-9 were measured by an electrochemiluminescence assay. Result(s): Serum levels of BAFF and MMP-9 in pSS patients were significantly higher than those of HC, and the levels showed positive and significant correlation. FACS analysis of whole blood samples demonstrated that MMP-9 was mainly expressed in monocytes and that the expression level was significantly higher in pSS than in HC. ELISA and qPCR revealed that stimulation of pSS moncytes with rhsBAFF drastically enhanced the expression of MMP-9 as compared to normal monocytes.

Remarkably, the amount of MMP-9 produced by the cells was positively and significantly correlated with the expression level of BR3 in pSS monocytes, suggesting that BAFF-signalling is involved in the production of MMP- 9 by the cells. Moreover, the elevated production of MMP-9 was significantly suppressed by specific inhibitors against NF-kappaB and PI3 kinase in a dose dependent manner. Conclusion(s): The present study suggests that BAFF stimulates monocytes through BR3 to promote MMP9 production and may contribute to ECM degradation. Our study also suggests that NF-kappaB and PI3 kinase are involved in the pathway.

Yoshizawa, A., et al. (2010). "The impact of donor specific antibody on liver allograft survival after living donor liver transplantation." Transplantation **1)**: 376.

Introduction: The relevance of a positive crossmatch test against the donor to the outcome of liver transplantation remains unclear. We have reported that survival rate of the crossmatch-positive recipients was significantly lower than that of crossmatch-negative recipients after living donor liver transplantation (LDLT); 1 year survival rates of crossmatch positive and negative recipients were 56.0% and 82.1%, respectively (p=0.014).(Ashihara et al. Transplantation 2007;83:506-9, Kaido et al. Liver Transplantation 2009;15:1420-5) Recently, donor specific antibody (DSA) can be determined and quantified by single antigen beads method. In this study, we retrospectively analyzed the relationship between pre-transplant quantity of DSA and clinical outcomes in crossmatch-positive LDLT. Method(s): 870 recipients underwent LDLT between Jan 2000 and March 2008. A lymphocyte crossmatch test was preoperatively performed, using direct complement-dependent cytotoxicity. To characterize DSA, the preserved sera from recipients with positive crossmatch at transplantation were examined using micro-beads coated with single Class I HLA antigen and a Liminex analyzer. To study of contribution of antibody-mediated rejection (AMR), C4d was detected by immunohistochemical staining in paraffin-bedded specimens obtained by liver biopsy. Biopsies in which only vascular endothelium was stained were evaluated as endothelial-positive and biopsies in which both vascular endothelium and stroma were stained were evaluated as stromal-positive. Biopsies showing any stromal or endothelial staining of C4d were recorded as positive. Any C4d staining on elastic fibers within arteries and stroma was regarded as a nonspecific finding without clinical significance. (Sakashita, et al. Modern Pathology 2007; 20: 676-84) Result: The crossmatch test was positive in 25 of 870 recipients. Twenty-five crossmatch-positive recipients were 3 males and 22 females. Median age of them was 33.5 years old (range 0 - 68). Original diseases of them were as follows: 8 biliary atresia, 6 primary biliary cirrhosis, 3 viral liver cirrhosis, and other diseases. Five donors were unrelated spouses, and 20 donors were related; 8 mothers, 3 fathers, 2 sisters, 4 daughters, and 3 sons. Nine crossmatch-positive recipients died during perioperative period. The fluorescence intensity (FI) of Luminex single was divided to high FI (FI of greater than 10,000), low FI (FI of lower than 10,000), and negative. The numbers of the recipients with high FI, low FI, and negative were 11, 3, and 8, respectively, and 3 patients were not tested because of preserved blood sample shortage. Eight of 11 patients with high IF periooperatively died; 5 patients died because of sepsis after repeated steroid pulse therapy, and 3 patients also perioperatively died due to uncontrolled infection. C4d was positive in liver biopsy specimen from 5 high-IF recipients. All of 3 patients with low IF survived, but showed chronic cholangitis or steatohepatitis accompanied by positive C4d within 3 months after transplantation. On the other hand, 7 of 8 crossmatch-positive recipients with negative DSA survived. Conclusion(s): HLA Class I DSA with FI greater than 10,000 had great negative impacts on patient survival secondary to AMR in crossmatch-possitive patients. Detection of DSA added on crossmatch test is a more prominent predictor for AMR after liver transplantation.

You, Y., et al. (2013). "Neurotrophic factors impart functional protection to the retina against ocular hypertension." Clinical and Experimental Ophthalmology **1)**: 127.

Purpose: TrkB signalling plays a critical role in the maintenance of retinal integrity. TrkB dimerization and autophosphorylation lead to activation of prosurvival cell signalling pathways that can afford neuroprotection to retinal ganglion cells (RGCs). We investigated functional changes in the retinas of mice with impaired TrkB downstream signalling in response to exposure to increased intraocular pressure, and determined whether augmenting the TrkB signalling using a specific agonist 7,8- dihydroxyflavone (7,8-DHF), can prevent this functional loss in experimental glaucoma. Method(s): A unilateral chronic ocular hypertensive model was established by weekly microbead injections into the anterior chamber of adult B6.129S4-Bdnftm1Jae/J heterozygous mice with wildtype as control. 7,8-DHF was administered weekly to another set of mice with unilaterally increased IOP for 8 weeks. Electroretinogram (ERG) and scotopic threshold response (STR) measurements were performed to assess retinal function. Result(s): Exposure to increased intraocular pressure leads to a decline in the inner retinal function (STR amplitudes) in both wildtype ($p < 0.04$) and heterozygous ($p < 0.004$) mice. Heterozygous mice were however more susceptible to the decline in the inner retinal function compared to their wildtype counterparts ($p < 0.04$). Administration of 7,8-DHF prevented the loss of STR amplitudes to a greater extent in heterozygous mice ($p < 0.001$). Scotopic ERG recordings were not significantly altered in any of the cases. Conclusion(s): This study demonstrates that the TrkB signalling plays an important role in protecting retinal ganglion cell function in glaucoma and that the detrimental effects of TrkB downstream deficiency can be compensated by exogenous administration of 7,8-DHF - a TrkB agonist.

Young, B. R., et al. (1978). "The motility and chemotactic response of Phytophthora cinnamomi zoospores in 'ideal' soils." Phytophthora Newsletter **6**: 59-60.

Passage of zoospores at 2.5 cm/min through 21-cm columns of microbeads caused little loss of motility even with beads providing pore neck sizes slightly less than the overall zoospore dimension, or when passed at 50 cm/min (70 times autonomous swimming speed) through a range of bead sizes. Where pore neck size allowed unimpeded movement along helical pathways, chemotaxis to 5 mM ethanol in Pfeffer tubes was considerably greater at low flow speeds than at flow speeds of zero.

Young, L. (2019). "Highlights from the Resource Recycling Conference." Waste360: N.PAG-N.PAG.

Shailesh Gothal of the brokerage firm Gemini Corporation noted the importance of the Indian export market in the wake of National Sword, and he believes it will remain a strong growth market for recovered paper export, in part due to the difficulties in increasing domestic collection in India. Domestic mills are demanding 1 to 2 percent contamination rates, and the export markets are all trending to 0.5 percent. That said, the blended price per ton at his MRF has gone from $140 in 2010 to $30 now, while paper quality standards have risen by four times, and the facilities are experiencing higher processing costs, in part from labor challenges. [Extracted from the article]

Young, M. and N. J. Adams (2010). "Plastic debris and seabird presence in the Hauraki Gulf, New Zealand." New Zealand Journal of Marine and Freshwater Research **44**(3): 167-175.

The potential threat of plastic pollution to seabirds within the Hauraki Gulf was assessed by determining its abundance and distribution at two different spatial scales and assessing the community of resident seabirds during July to September 2008. Samples of floating plastics within the gulf were taken during 66 trawls from the surface of the water in three regions within the inner gulf and Waitamata harbour. Within each of these regions, samples were taken in and outside of visually identified natural slick lines that are surface manifestations of small-scale convergence zones. During each trawl, the identity and abundance of seabirds were assessed. Plastic debris was recorded in all three regions sampled with the greatest abundance being recorded in the harbour. Plastics and debris were also significantly more concentrated within natural slick lines. Both user and industrial plastics were identified and consisted of colours and lengths likely to be mistaken as food items for small to medium seabirds. Surface or near-surface feeding seabirds in the gulf most likely mistakenly to consume plastics were fluttering shearwaters, Cape pigeons and Buller's shearwaters. However, these birds were most abundant in the area of the gulf where abundance of plastic pollution was lowest. The Hauraki Gulf is considered significantly less polluted by plastic debris than other severely polluted areas cited in literature.

Yu, C., et al. (2009). "Dynamics of CD4⁺CD25⁺ regulatory T cells of mice infected with Schistosoma japonicum and reversal of function." Zhongguo Bingyuan Shengwuxue Zazhi / Journal of Pathogen Biology **4**(10): 754-757.

Objective: To investigate the dynamics of CD4⁺CD25⁺ regulatory T cells of mice infected with Schistosoma japonicum and ascertain factors that could reverse the inhibition of CD4⁺ CD25⁺ regulatory T cells.

Yu, F., et al. (2019). "Adsorption behavior of organic pollutants and metals on micro/nanoplastics in the aquatic environment." Science of the Total Environment **694**: 133643.

Plastic debris becomes currently a ubiquitous environmental pollutant and is susceptible to contamination by many other pollutants, including aqueous metals and organic matter. This review summarizes the effects of environmental factors on the properties and sorption behavior of microplastics, presents a further discussion on the fate of microplastics adsorption on contaminants, and critically discusses the mechanism of sorption behaviors between micro/nanoplastics and normal contaminants. Previous references indicated that the hydrophobicity and particle sizes of microplastics were the dominant influence factors for virgin plastic debris adsorption, whereas for aged microplastics, hydrogen bonding, hydrophilicity and increasing specific surface ratio affected the adsorption behavior. The effects of pH and salinity always influence the sorption conditions by changing the charge state of microplastics and contaminants and causing competing adsorption. In addition, the existence of microplastics affects biotoxicity, increases the dissolved organic matter in the environment, and influences carbon cycling. The knowledge is fundamental to the assessment of potential risks posed by microplastics to organisms from human beings to the entire environment.

Yu, G., et al. (2018). "An agricultural waste based composite to replace or reduce the use of plastics." International Journal of Environmental Science and Development **9**(7): 167-172.

BioPlastics such as PLA has a few drawbacks among them incompatible with existing recycling stream and hence classified as "unrecyclable" in many countries; not truly biodegradable in natural conditions since it requires high temperature to decompose (>58 degrees C); high impact to the environment for it's high carbon footage production process; and competing to our food production for taking the corps as it's feedstock. FPC^{TM} presented in this paper resolves all the above difficulties by using agricultural waste which contains fiber as it's main ingredient, mixed with proprietary Compatiblizer^{TM} which is converted starch without adding any man-made chemicals, so FPC^{TM} is inherently biodegradable and compostable, yet FPC^{TM} can be mixed with almost any plastics in any percentage, making it exhibits no harm to the existing recycling system, such characteristics also make FPC^{TM} to be an excellent binder to create new material from various recycled plastics including ocean plastic waste and textile waste. Products using 100% FPC^{TM} are not only biodegradable & compostable, but also a truly circular bioeconomy fashion without competing with our food source, while significantly reduce air pollution because the agricultural waste would otherwise be burned off; and in the meantime create high value since the processing of biomass is not targeted to obtained low-value calories through burning, but the replacement of petro-chemical products without causing long-term burden to our land and ocean.

Yu, H. W., et al. (2012). "Multiplex competitive microbead-based flow cytometric immunoassay using quantum dot fluorescent labels." Analytica Chimica Acta **750**: 191-198.

In answer to the ever-increasing need to perform the simultaneous analysis of environmental hazards, microcarrier-based multiplex technologies show great promise. Further integration with biofunctionalized quantum dots (QDs) creates new opportunities to extend the capabilities of multicolor flow cytometry with their unique fluorescence properties. Here, we have developed a competitive microbead-based flow cytometric immunoassay using QDs fluorescent labels for simultaneous detection of two analytes, bringing the benefits of sensitive, rapid and easy-of-manipulation analytical tool for environmental contaminants. As model target compounds, the cyanobacterial toxin microcystin-LR and the polycyclic aromatic hydrocarbon compound benzo[a]pyrene were selected. The assay was carried out in two steps: the competitive immunological reaction of multiple targets using their exclusive sensing elements of QD/antibody detection probes and antigen-coated microsphere, and the subsequent flow cytometric analysis. The fluorescence of the QD-encoded microsphere was thus found to be inversely proportional to target analyte concentration. Under optimized conditions, the proposed assay performed well within 30 min for the identification and quantitative analysis of the two environmental contaminants. For microcystin-LR and benzo[a]pyrene, dose-response curves with IC(50) values of 5 mug L(-1) and 1.1 mug L(-1) and dynamic ranges of 0.52-30 mug L(-1) and 0.13-10 mug L(-1) were obtained, respectively. Recovery was 92.6-106.5% for 5 types of water samples like bottled water, tap water, surface water and seawater using only filtration as sample pretreatment.

Yu, J. Production of green bioplastics from agri-food chain residues and co-products. (Woodhead Publishing in Food Science, Technology and Nutrition). Cambridge, Woodhead Publishing Ltd.

The environmental benefits are elucidated of polyhydroxyalkanoates (PHAs), natural thermoplastics synthesised by microbial species on renewable carbon sources, which may substantially reduce plastic pollution, greenhouse gas emissions and fossil energy consumption by replacing their petrochemical counterparts. Agri-food chain co-products are potential feedstocks for PHA bioplastics with technology innovations in pretreatment, microbial fermentation, and polymer recovery and purification. Pre-treatment is to convert special co-products into fermentative substrates and precursors for microbial biosynthesis of polyesters with desired molecular size, chemical composition and material properties. High volumetric productivity is a technical and economical indicator of PHA fermentation technology and can be achieved by using high cell density culture on highly concentrated feedstocks. Technical limitations may result in low to moderate productivities in large bioreactors with feedstocks of low carbon content. PHA recovery and purification is an essential and costly step in the process, which has moderated progress in technical innovation compared with PHA biosynthesis and material science. Problems are analyzed for potential breakthrough in polymer recovery and purification. In the near future, microbial production of PHA bioplastics could be integrated into advanced biorefineries to make fuels, chemicals and materials from renewable biomass including agri-food chain co-products in a cost-effective way.

Yu, J., et al. (2010). "The use of human mesenchymal stem cells encapsulated in RGD modified alginate microspheres in the repair of myocardial infarction in the rat." Biomaterials **31**(27): 7012-7020.

The combination of scaffold material and cell transplantation therapy has been extensively investigated in cardiac tissue engineering. However, many polymers are difficult to administer or lack the structural integrity to restore LV function. Additionally, polymers need to be biological friendly, favorably influence the microenvironment and increase stem cell retention and survival. This study determined whether human mesenchymal stem cells (hMSCs) encapsulated in RGD modified alginate microspheres are capable of facilitating myocardial repair. The in vitro study of hMSCs demonstrated that the RGD modified alginate can improve cell attachment, growth and increase angiogenic growth factor expression. Alginate microbeads and hMSCs encapsulated in microbeads successfully maintained LV shape and prevented negative LV remodeling after an MI. Cell survival was significantly increased in the encapsulated hMSC group compared with PBS control or cells alone. Microspheres, hMSCs, and hMSCs in microspheres groups reduced infarct area and enhanced arteriole formation. In summary, surface modification and microencapsulation techniques can be combined with cell transplantation leading to the maintenance of LV geometry, preservation of LV function, increase of angiogenesis and improvement of cell survival.

Yu, J., et al. (2019). "Characterization of microplastics in environment by thermal gravimetric analysis coupled with Fourier transform infrared spectroscopy." Marine Pollution Bulletin **145**: 153-160.

As a global pollutant, microplastics have attracted attention from the public and researchers. However, the lack of standard and time-saving methods for analysis has become one of the bottlenecks in microplastics research. Here, we demonstrate TGA coupled to FTIR to identify and quantify certain microplastics in environment. Samples were pyrolyzed in TGA and the pyrolysis gases were analyzed by FTIR. Combining TGA and FTIR data adds discriminatory power as temperature profiles and absorption spectra differ among several common plastics. To quantify on a mass basis, we calibrated on characteristic IR peaks at temperatures of maximum weight loss for individual polymers. The method can distinguish PVC, PS and was validated by spiking samples with known quantities of microplastics. The result of field sample experiments showed that TGA-FTIR can be used to identify and quantify PVC and PS in bivalves, seawater and soil. And the method may be applicable to environmental samples.

Yu, K. (2014). Copper ion adsorption by chitosan gel nanoparticles and calcium-alginate gel beads for water purification applications.

Water purification is emerging as a critical need as resources become increasingly limited. Chitosan and alginate are both low-cost natural carbohydrate materials used for the removal of heavy metal ions from aqueous solutions. The objective of this research is to enhance

understanding of the process and mechanisms of copper ion adsorption by these biopolymer gel particles at multiple size scales, with the aim of guiding the next generation of biosorbent design for water purification applications. First, the equilibrium adsorption capability of copper ions from copper sulfate solution onto chitosan gel nanoparticles, calcium-alginate gel microbeads, chitosan/alginate combination particles and large alginate gel beads at fixed pH was studied. Results show that the adsorption behavior of chitosan and alginate in the low concentration region follows the Langmuir isotherm. Chitosan gel nanoparticles exhibit a minor increase in adsorption capacity compared to other forms of chitosan. Alginate has significantly higher capacity than chitosan, which can be attributed to a comparatively higher density of adsorption sites. Combination particles consisting of alginate microbeads coated with chitosan nanoparticles possess an intermediate maximum adsorption capacity, corresponding to the weight ratio of the alginate and chitosan. Also, adsorption kinetics of copper ions onto calcium-alginate gel microbeads, chitosan/alginate combination particles and large alginate gel beads were investigated. It was observed that the adsorption kinetics of large alginate gel beads was much faster than that of alginate microbeads and combination particles. The adsorption of copper ions on to combination particles was slightly faster than on to plain alginate microbeads. A pseudo-second order kinetic model successfully predicted the adsorption behavior over the whole range of studies, indicating that chemisorption is the rate controlling step and the chemisorption reaction is second order. Moreover, the adsorption behavior of fixed-bed columns packed with large alginate gel beads was studied by varying the column size and volumetric flow rate. The column had shorter active life at a higher flow rate, or at a smaller size. The Thomas model, Adams-Bohart model and Yoon-Nelson model successfully fit experimental data, allowing prediction of the breakthrough time.

Yu, K., et al. (2013). "Copper ion adsorption by chitosan nanoparticles and alginate microparticles for water purification applications." Colloids and Surfaces A: Physicochemical and Engineering Aspects **425**: 31-41.

Chitosan and alginate are natural carbohydrate materials used to remove heavy metal ions from aqueous solutions. In this research, chitosan gel nanoparticles were formed by ionic cross-linking with sodium tripolyphosphate and characterized by zetasizing and TEM. The equilibrium adsorption capability of chitosan nanoparticles and calcium-alginate gel microbeads for Cu²⁺ from copper sulfate solutions at fixed pH has been explored. Results show that the adsorption behavior of chitosan and alginate in the low concentration region follows the Langmuir isotherm. Approximately linearly increasing adsorption behavior was observed at higher solution concentrations. Chitosan gel nanoparticles exhibit a minor increase in adsorption capacity compared to other forms of chitosan. Alginate has significantly higher capacity than chitosan, which can be attributed to a comparatively higher density of adsorption sites. Combination particles consisting of alginate microbeads coated with chitosan nanoparticles possess an intermediate maximum adsorption capacity, corresponding to the weight ratio of the alginate and chitosan. © 2013 Elsevier B.V..

Yu, M., et al. (2019). "Leaching of microplastics by preferential flow in earthworm (Lumbricus terrestris) burrows." Environmental chemistry (Online) **16**(1): 31-40.

Abstract. In the current study, we examine how the activities of earthworms (Lumbricus terrestris) affect microplastic (MP) distribution and concentration in soil, with a focus on low density polyethylene (LDPE). We also want to determine if MPs can be flushed out with water. We used a laboratory sandy soil column (polyvinyl chloride tube) experimental set-up and tested five different treatments: (1) treatment with just soil (control) to check if the saturated

conductivity (Ksat) could be impacted by MP, (2) treatment with MP, (3) treatment with MP and litter, (4) treatment with earthworms and litter as a second control for treatment 5 and (5) treatment with MPs, earthworms and litter. Each treatment consisted of eight replicates. For the treatments with MP, the concentration of MP added at the start of the experiment was 7 % by weight (3.97 g, polyethylene, 50 % 1 mm–250 µm, 30 % 250 µm–150 µm and 20 % <150 µm) based on 52.78 g of dry litter from Populus nigra. In the treatments using earthworms, two adult earthworms, with an initial average weight of (7.14 ± 0.26) g, were placed in each column. Results showed that LDPE particles could be introduced into the soil by the earthworms. MP particles were detected in each soil sample and within different soil layers for the earthworm treatments. Earthworms showed a tendency to transport the smaller MP particles and that the amount of MPs in size class <250 µm increased in soil samples with increasing soil depth in comparison to the other size classes. After leaching, MPs were only detected in the leachate from the treatments with the earthworms, and the MP had similar size distributions as the soil samples in the 40–50 cm layer of the treatment with MP, earthworms and litter. The results of this study clearly show that biogenic activities can mobilise MP transport from the surface into the soil and even be leached into drainage. It is highly likely that biogenic activities constitute a potential pathway for MPs to be transported into soil and groundwater.

Yu, P., et al. (2018). "Accumulation of polystyrene microplastics in juvenile Eriocheir sinensis and oxidative stress effects in the liver." Aquatic Toxicology **200**: 28-36.

As a widespread and ubiquitous pollutant of marine ecosystems, microplastic has the potential to become an emerging global threat for aquatic organisms. The present study aims to elucidate the effects of microplastics on the growth, accumulation and oxidative stress response in the liver of Eriocheir sinensis. Fluorescent microplastic particles (diameter=0.5 micro m) accumulated in the gill, liver and gut tissues of E. sinensis were investigated when crabs were exposed to a concentration of 40000 micro g/L for 7 days. A 21 day toxicity test suggested that the rate of weight gain, specific growth rate, and hepatosomatic index of E. sinensis decreased with increasing microplastic concentration (0 micro g/L, 40 micro g/L, 400 micro g/L, 4000 micro g/L and 40000 micro g/L). The activities of AChE and GPT in crabs exposed to microplastics were lower than those in control group. GOT activity increased significantly after exposure to a low concentration of microplastics and then decreased continuously with increasing microplastic concentrations. The activities of superoxide dismutase (SOD), aspartate transaminase (GOT), glutathione (GSH), and glutathione peroxidase (GPx) increased in specimens exposed to low concentrations of microplastics (40 and 400 micro g/L) compared to the control and decreased in organisms exposed to high concentrations (4000 and 40000 micro g/L). In contrast, the activities of acetylcholinesterase, catalase (CAT), and alanine aminotransferase were significantly lower in the organisms exposed to microplastics compared to control animals. Upon exposure to increasing microplastic concentrations, the expression of genes encoding the antioxidants SOD, CAT, GPx and glutathione S-transferase in the liver decreased after first increasing. Exposure to microplastics increased the expression of the gene encoding p38 in the MAPK signaling pathway and significantly decreased the expressions of genes encoding ERK, AKT, and MEK. The results of this study demonstrate that microplastics can accumulate in the tissues of E. sinensis and negatively affect growth. In addition, exposure to microplastics causes damage and induces oxidative stress in the hepatopancreas of E. sinensis. The findings provide basic biological data for environmental and human risk assessments of microplastics of high concern.

Yu, P. H., et al. (1998). "Conversion of food industrial wastes into bioplastics." Applied Biochemistry and

Biotechnology **70-72**(1): 603-614.

The usage of plastics in packaging and disposable products, and the generation of plastic waste, have been increasing drastically. Broader usage of biodegradable plastics in packaging and disposable products as a solution to environmental problems would heavily depend on further reduction of costs and the discovery of novel biodegradable plastics with improved properties. In the authors' laboratories, various carbohydrates in the growth media, including sucrose, lactic acid, butyric acid, valeric acid, and various combinations of butyric and valeric acids, were utilized as the carbon (c) sources for the production of bioplastics byAlcaligenes eutrophus. As the first step in pursuit of eventual usage of industrial food wastewater as nutrients for microorganisms to synthesize bioplastics, the authors investigated the usage of malt wastes from a beer brewery plant as the C sources for the production of bioplastics by microorganisms. Specific polymer production yield by A. Latus DSM 1124 increased to 70% polymer/cell (g/g) and 32g/L cell dry wt, using malt wastes as the C source. The results of these experiments indicated that, with the use of different types of food wastes as the C source, different polyhydroxyal-kanoate copolymers could be produced with distinct polymer properties.[PUBLICATION ABSTRACT]

Yu, S., et al. (2019). "Aggregation kinetics of different surface-modified polystyrene nanoparticles in monovalent and divalent electrolytes." Environmental Pollution **255**(Pt 2): 113302.

The intentional production and degradation of plastic debris may result in the formation of nanoplastics. Currently, the scarce information on the environmental behaviors of nanoplastics hinders accurate assessment of their potential risks. Herein, the aggregation kinetics of different surface-modified polystyrene nanoparticles in monovalent and divalent electrolytes was investigated to shed some light on the fate of nanoplastics in the aquatic environment. Three monodisperse nanoparticles including unmodified nanoparticles (PS-Bare), carboxylated nanoparticles (PS-COOH) and amino modified nanoparticles (PS-NH₂), as well as one polydisperse nanoparticles that formed by laser ablation of polystyrene films (PS-Laser) were used as models to understand the effects of surface groups and morphology.

Yu, X., et al. (2016). "Occurrence of microplastics in the beach sand of the Chinese inner sea: The Bohai Sea." Environmental Pollution **214**: 722-730.

The occurrence of microplastics in the beach sand of the Bohai Sea was investigated for the first time. The Bohai Sea is the largest Chinese inner sea and its coastal region is one of the most densely urbanized and industrialized zones of China. Samples from three costal sites (i.e., Bijianshan, Xingcheng and Dongdaihe) were collected, quantified and identified for microplastic analysis. Effects of sample depth and tourism activity were investigated. Surface samples (2 cm) contained higher microplastic concentrations than deep samples (20 cm). Samples from the bathing beach exhibited higher microplastic concentrations than the non-bathing beach, suggesting the direct contribution of microplastics from tourism activity. Of eight types of microplastics that were found, PEVA (polyethylene vinyl acetate), LDPE (light density polyethylene) and PS (polystyrene) were the largest in abundances. Moreover, the non-plastic items from samples were analyzed and results revealed that the majority abundance of the observed non-plastics were viscose cellulose fibers. Further studies are required to evaluate the environmental hazards of microplastics, especially as they may "act as a contaminant transporter" to the Bohai Sea ecosystem. Yu, Y., et al. (2015). "Biodegradation and Mineralization of Polystyrene by Plastic-Eating Mealworms: Part 1. Chemical and Physical Characterization and Isotopic Tests." Environmental Science & Technology

49(20): 12080-12086.

Polystyrene (PS) is generally considered to be durable and resistant to biodegradation. Mealworms (the larvae of Tenebrio molitor Linnaeus) from different sources chew and eat Styrofoam, a common PS product. The Styrofoam was efficiently degraded in the larval gut within a retention time of less than 24 h. Fed with Styrofoam as the sole diet, the larvae lived as well as those fed with a normal diet (bran) over a period of 1 month. The analysis of fecula egested from Styrofoam-feeding larvae, using gel permeation chromatography (GPC), solid-state 13C cross-polarization/magic angle spinning nuclear magnetic resonance (CP/MAS NMR) spectroscopy, and thermogravimetric Fourier transform infrared (TG-FTIR) spectroscopy, substantiated that cleavage/depolymerization of long-chain PS molecules and the formation of depolymerized metabolites occurred in the larval gut. Within a 16 day test period, 47.7% of the ingested Styrofoam carbon was converted into CO_2 and the residue (ca. 49.2%) was egested as fecula with a limited fraction incorporated into biomass (ca. 0.5%). Tests with α 13C- or β 13C-labeled PS confirmed that the 13C-labeled PS was mineralized to $^{13}CO_2$ and incorporated into lipids. The discovery of the rapid biodegradation of PS in the larval gut reveals a new fate for plastic waste in the environment. [ABSTRACT FROM AUTHOR]

Yu, Y., et al. (2018). "Advancement and Challenges of Microplastic Pollution in the Aquatic Environment: a Review." Water, Air & Soil Pollution **229**(5): 1-1.

As a new persistent environmental pollutant, microplastic pollution has attracted great interest recently. Microplastic particles are distributed widely throughout the world’s freshwaters, oceans, and seas, including the water column and sediments reaching as far as the deep sea. However, the practical considerations and protocols for microplastic pollution have, to the best of our knowledge, not been reviewed properly with regard to assessing their distribution, biotoxicity, sampling, and identification in the aquatic environment. In this review, the implications of microplastic pollution, including its wide distribution, biotoxicity threats, sampling, and identification challenges in the <ext-link>aquatic environment</ext-link>, were discussed and evaluated. The challenges and perspective of the related research are also presented to identify knowledge gaps and to prioritize future research needs.In this review, the implications of microplastic pollution, including its wide distribution, biotoxicity threats, sampling, and identification challenges in the aquatic environment, were discussed and evaluated. Yu, Y. L., et al. (2012). "Development of a miniature analytical system in a lab-on-valve for determination of trace copper by bead injection spectroscopy." Talanta **88**: 352-357.

A miniature analytical system based on a lab-on-valve platform is developed for trace metal analysis by bead injection spectroscopy. A multipurpose flow cell integrated into a lab-on-valve is furnished with two pieces of fiber optics to communicate with light source and charge coupled device (CCD) spectrometer, respectively, in order to monitor real-time absorbance of the samples. Micro-beads loaded with chromogenic reagent are packed into the multipurpose flow cell to form a renewable microcolumn for solid phase extraction by bead injection. When the sample solution flows through the microcolumn, the target analyte will be captured on the surface of beads and detected directly by the CCD spectrometer without elution. The beads are automatically discarded from the multipurpose flow cell after each analytical cycle. This analytical system was employed to determine trace copper by loading of a chromogenic reagent 2-carboxy-2'-hydroxy-5'-sulfoformazylbenzene (zincon) on the beads of an anion exchanger (Sephadex QAE A-25). With a sample volume of 2.5mL, a detection limit of 3mugL(-1) and a linear range of 10-100mugL(-1) were obtained for copper, along with a RSD value of 2.5% (at the 50mugL(-1) level). The accuracy and practical applicability of the proposed system were validated by analysing certified reference materials, i.e., GBW10010, GBW09101, GBW08608, and further demonstrated by spiking recovery of copper in a water sample.

Yu, Z., et al. (2019). "Development and Validation of an Efficient Method for Processing Microplastics in Biota Samples." Environmental Toxicology & Chemistry **38**(7): 1400-1408.

The impacts of microplastics on aquatic ecosystems and biota are gaining attention globally. Although microplastics have been widely detected in biota, there currently are few standardized detection and identification methods. The present study developed a novel one-step digestion method which was evaluated with mussel and fish samples. This method employed nitric acid and hydrogen peroxide (HNO₃ :H₂ O₂ = 4:1 by volume) as digestion reagents, which completely digested biota samples <5 g weight within 30 min at 50 degreeC. A density separation step was subsequently used to remove organic residues as necessary. The efficiency and suitability of this method were tested by spiking microplastics of 7 different types and of various sizes (1000, 900, 675, 300, 250, and 150 mum) into mussel and gastrointestinal tracts of fish. The recoveries of microplastics ranged from 90 to 100%. No significant changes in weight, surface area, and particle size (t test, $p > 0.05$) were observed for all tested polymers. Fourier transform infrared spectral analyses demonstrated that the method did not degrade any of the polymers except for polyethylene terephthalate. The method was demonstrated with mussel and fish samples collected from the Pearl River delta, south China, and was able to recover microplastics effectively. Overall, the present method is time-saving and easy to operate, with low procedural cross-contamination. The properties of microplastics recovered by the present method remained largely intact, greatly benefiting subsequent qualitative and quantitative analyses. Yuan, C., et al. (2018). "Synthesis of Monodisperse Plasmonic Magnetic Microbeads and Their Application in Ultrasensitive Detection of Biomolecules." Analytical Chemistry **90**(13): 8178-8187.

Plasmon-enhanced fluorescence (PEF)-based analytical technology has recently demonstrated its ability in detecting biomarkers with ultrahigh sensitivity. However, the scope of the PEF-based technology has been hindered by its reliance on flat substrates with relatively low binding kinetics and the limited multiplex detection ability. Herein, we reported a simple yet robust method for the fabrication of plasmonic magnetic microbeads (PMMBs)-based suspension array technology (SAT) with fluorescence enhancement of about 60-fold, improving the detection limit of biomarkers by 2-orders of magnitude toward 100 fM. We also

demonstrated the performance of this method for the detection of anti-acidic ribosomal phosphoprotein 0 (anti-P0) autoantibody in sera from systemic lupus erythematosus (SLE) patients. Owing to the high sensitivity and efficient magnet-based sample collection, our method can be employed for detection of ultrasmall volumes of samples (e.g., 2 muL), promising for point-of-care detection. Furthermore, a size-encoded PMMBs-based multiplexed suspension array for simultaneous detection of multiple biomarkers is realized, illustrating the great potential of this technology in high-throughput disease diagnosis applications.

Yuan, W., et al. (2019). "New Perspective on the Nanoplastics Disrupting the Reproduction of an Endangered Fern in Artificial Freshwater." Environmental Science & Technology **53**(21): 12715-12724.

The potential risks of micro/nanoplastics on the ecological environment, particularly aquatic fauna, have been realized in recent years. However, information about its potential effects on aquatic plants is scarce. In this study, a four-week exposure experiment was conducted to investigate the effects of varying polystyrene nanoplastics concentration (PS-NPs, 0-100 mug/mL) on the early development of an endangered aquatic plant, Ceratopteris pteridoides. Fluorescent observations demonstrated that PS-NPs were adsorbed and accumulated on the spore surface of C. pteridoides rapidly and massively with increasing exposure concentration and time. The adsorption and accumulation of PS-NPs on the spore surface posed a negative effect on spore imbibition, causing 2.3-22.4% reduction in final spore size. Spore germination and gametophyte sex differentiation were both negatively affected by PS-NP exposure, resulting in 10.4-88.0% inhibition in germination ratio and 2.9-53.4% reduction in hermaphroditic gametophyte ratio. Additionally, PS-NPs were observed to penetrate into the roots of gametophytes. Higher concentration of PS-NPs (100 mug/mL) can even induce pathological changes on gametophytes, although with a low incidence (4.9%). The results above indicated that exposure to PS-NPs caused a series of disruptions from the spore imbibition to germination and gametophyte stages, and are likely to pose an eco-physiological risk on the reproductive success of endangered ferns.

Yuen, L. H., et al. (2014). "Pattern-based detection of toxic metals in surface water with DNA polyfluorophores." Angewandte Chemie. International Ed. in English **53**(21): 5361-5365.

Heavy metal contamination of water can be toxic to humans and wildlife; thus the development of methods to detect this contamination is of high importance. Here we describe the design and application of DNA-based fluorescent chemosensors on microbeads to differentiate eight toxic metal ions in water. We developed and synthesized four fluorescent 2'-deoxyribosides of metal-binding ligands. A tetramer-length oligodeoxy-fluoroside (ODF) library of 6561 members was constructed and screened for sequences responsive to metal ions, of which seven sequences were selected. Statistical analysis of the response patterns showed successful differentiation of the analytes at concentrations as low as 100 nM. Sensors were able to classify water samples from 13 varied sites and quantify metal contamination in unknown specimens. The results demonstrate the practical potential of bead-based ODF chemosensors to analyze heavy metal contamination in water samples by a simple and inexpensive optical method.

Yukioka, S., et al. (2018). "ADSORPTION CHARACTERISTICS OF MICROPOLLUTANTS ON MICROPLASTICS BY FOCUSING ON THEIR DIAMETERS IN WATER ENVIRONMENT." Doboku Gakkai Ronbunshu. G, Kankyo = Journal of Japan Society of Civil Engineers. Ser. G, Environmental Research **74**(7).

Recently, a new exposure pathway of micropollutants via Microplastics (MPs) to aquatic organisms have been a great concern. Main objective of this study was to understand adsorption characteristics of perfluoroalkyl acids (PFAAs), polycyclic aromatic hydrocarbons

(PAHs) and their halogenated compounds (X-PAHs) in water environment by focusing on the diameters of MPs. Adsorption bach experiments with standard substances of MPs were conducted. Field surveys were conducted in Lake Biwa and Osaka bay from Oct. to Nov. 2017 in order to analyze 15 PFAAs, 16 PAHs, 11 X-PAHs on adsorbed MPs in surface water. It was shown that MPs in water environment with smaller diameter tended to adsorb more PFAAs, PAHs, X-PAHs. It was assumed that micropollutants were adsorbed more to MPs than to suspended solids when their diameters were in the range of several tens of µm. In addition, it was suspected that more PFAAs and PAHs were adsorbed to MPs when surface areas of MPs were increased by the effect of physical and/or chemical reactions in the water environment.

Yukioka, S., et al. (2020). "Occurrence and characteristics of microplastics in surface road dust in Kusatsu (Japan), Da Nang (Vietnam), and Kathmandu (Nepal)." Environmental Pollution **256**: 113447.

Microplastics (MPs, plastics<5mm) are a growing concern in ecosystems, being found in the soil and water environment. One of the primary sources of MPs has been suspected to be road dust in urban areas as it can flow into waters with runoff. To understand the occurrence of MPs (100mum-5mm) in surface road dust of three cities (Kusatsu, Shiga, Japan; Da Nang, Vietnam; and Kathmandu, Nepal), we collected surface road dust samples. The samples were pretreated (organic matter decomposition and gravity separation), and all MP candidates were individually observed by microscope for color, shape, and size; and analyzed their polymer types using fourier transform infrared spectrometry. The abundances of MPs 100mum to 5mm in size were 2.0+/-1.6 pieces/m² (13 polymer types) in Kusatsu, 19.7+/-13.7 pieces/m² in Da Nang (14 types), and 12.5+/-10.1 pieces/m² in Kathmandu (15 types). We classified the MPs into two groups; containers/packaging-MPs and rubber-MPs. Among all MPs, the containers/packaging-MPs accounted for 55+/-5% of the polymer types composition. In contrast, the rubber-MPs accounted for 16+/-6% of all MPs which were higher than those previously published for environmental water and sediment samples. The containers/packaging-MPs were fragments of various colors while most of the rubber-MPs were fragments or granules in black. The number-size distributions of MPs showed that the mode of formation explains the differences between their polymer types (tearing for containers/packaging-MPs and abrasion for rubber-MPs). In Da Nang and Kathmandu, the abundance of containers/packaging-MPs and rubber-MPs were correlated so that those MPs might be micronized from the originated materials in the sources with the similar composition (e.g. dump points). It was indicated that the characteristics of MPs pollution in surface road dust might be different depending on waste management practices.

Yuksel, A. (2016). "The evaluation and assessment of the kind and amount of solid waste produced in a hospital kitchen." Revista Espanola de Nutricion Humana y Dietetica **20 (Supplement 1)**: 547.

Introduction: The environment is the most important source in meeting the nutritional needs of people's basic needs. Solid waste is one of the most important causes of environmental pollution. Today, incerasing of the population and the development of technology leads to increase the production of not only types of package materials but also the waste per capita. Method(s): In the hospital, the waste that may ocur at the end of the food and meal production was calculated according to records of the menu items. On those days produced waste was collected and seperated according to their types (glass, paper-cardboard, composites, metals, organic, plastic, porcelain, wood). Then all the seperated waste groups were weighted and recorded. Result(s): The total weight of all types of solid waste were obtained according and 7238.5kg total solid waste produced was found. 1106.2kg of this waste (15.3%) were plastics, 272.0kg (3.8%) were metal, 1132.8kg (15.6%) were paper and board, and 3013.8kg (41.6%) were

organic waste. The amount of plastic waste collected from produced solid waste were 323.8kg (7.3%), the amount of metal waste were 205.4kg (4.6%) and 318.5kg of waste were paper and cardboard (7.2%), respectively. During the study period in the kitchen 3317.3kg, of recycle package waste were produced and 967.7kg (29.2%) were found to be collected. 21.0% of the collected organic waste were found to be used in composting. It is evaluated that, the 148.9kg of total waste were organic which is able to eat, can be reduced by appropriate revisions in the recipts. Conclusions, discussion and/or practical application: It is important to plan how to reduce the amount of waste before production and collect the waste effectively will be beneficial to solve the waste problem. COMPETING INTERESTS: The authors of this document can confirm there is no conflict of interests.

Yun, K. S., et al. (2009). "Chapter 5: Microfluidic Chips Designed for Measuring Biomolecules Through a Microbead-Based Quantum Dot Fluorescence Assay." Methods in Molecular Biology **544**: 53-67.

This chapter introduces the demonstration of specific antibody detection by using a microbead-based assay with quantum dot (QD) fluorescence on a polydimethylsiloxane (PDMS) microfluidic chip. The microfluidic chip is designed to isolate a single microbead where the binding reaction of antibodies occurs on the surface. The microfluidic chip is fabricated on a glass substrate using a transparent sili-cone elastomer, PDMS, for easy access of monitoring and flexible gate operations to capture the single microbead. For antibody detection, a sequence of functionalized assays has been performed in the fabricated chip, including the capturing of microbeads, antibody injection into a microchamber, quantum dot injection, and fluorescence detection. Various concentrations of human IgG antibodies have been introduced to bind to a single microbead captured and isolated inside a designated microchamber in a small volume of 75 pL. Fluorescence detection is monitored using a CCD camera after the second binding with the QDs conjugated with anti-human IgG. In this experiment, a human IgG antibody concentration below 0.1 kg/mL has been successfully detected.

Yung, C. W., et al. (2009). "Micromagnetic-microfluidic blood cleansing device." Lab on a Chip **9**(9): 1171-1177.

Sepsis is a lethal disease caused by a systemic microbial infection that spreads via the bloodstream to overwhelm the body's defenses. Current therapeutic approaches are often suboptimal, in part, because they do not fully eliminate the pathogen, and hence the source of deadly toxins. Here we describe an extracorporeal blood cleansing device to selectively remove pathogens from contaminated blood and thereby enhance the patient's response to antibiotic therapy. Immunomagnetic microbeads were modified to create magnetic opsonins that were used to cleanse flowing human whole blood of Candida albicans fungi, a leading cause of sepsis-related deaths. The micromagnetic-microfluidic blood cleansing device generates magnetic field gradients across vertically stacked channels to enable continuous and high throughput separation of fungi from flowing whole blood. A multiplexed version of the device containing four parallel channels achieved over 80% clearance of fungi from contaminated blood at a flow rate of 20 mL/h in a single pass, a rate 1000 times faster than a previously described prototype micromagnetic-microfluidic cell separation system. These results provide the first proof-of-principle that a multiplexed micromagnetic-microfluidic separation system can be used to cleanse pathogens from flowing human blood at a rate and separation efficiency that is relevant for clinical applications.

Yura, H., et al. (2008). "Selection of hematopoietic stem cells with a combination of galactose-bound vinyl polymer and soybean agglutinin, a galactose-specific lectin." Transfusion **48**(3): 561-566.

BACKGROUND: Selection of hematopoietic stem cells can be used to prevent graft-versus-host disease (GVHD) after allograft transplantation. The purpose of the study was to examine a novel cell separation system comprising a galactose-bound vinyl polymer (Gal-VP) and soybean agglutinin (SBA), a galactose-specific lectin.

STUDY DESIGN AND METHODS: A vinyl polymer (VP) containing alpha-1,6- and beta-1,4-linked galactose terminals was used to facilitate cell separation. A VP containing an alpha-1,4-linked glucose terminal (alpha-1,4-Glu-VP) was also synthesized as a control for alpha-1,6- and beta-1,4-Gal-VP. Peripheral blood samples were collected from healthy volunteers and umbilical cord blood cells were collected after normal labor.

RESULTS: The sugar-VP was adsorbed on the surface of various materials. In the presence of SBA, T lymphocytes bound to beta-1,4-Gal-VP-coated microbeads, but not to alpha-1,4-Glu-VP-coated microbeads. When peripheral or cord blood cells were cultured on alpha-1,6-Gal-VP-coated plates, most red blood cells, lymphocytes, granulocytes, and monocytes adhered to the plate in the presence of 300 mg per mL SBA, whereas few CD34+ cells attached, even with 800 mg per mL SBA.

CONCLUSION: SBA binds selectively to blood cells by recognizing cell-surface sugars, which are dependent on the extent of cellular differentiation. Therefore, the combination of alpha-1,6-Gal-VP and SBA might be useful for separation of blood cells according to their stage of differentiation and lineage.

Yurtsever, M. (2019). "Glitters as a Source of Primary Microplastics: An Approach to Environmental Responsibility and Ethics." Journal of Agricultural and Environmental Ethics **32**(3): 459-478.

This paper is about “glitters”, one of the sources of primary microplastics, which, in turn, are deemed an emerging source of pollutants affecting the environment. Today, most glitters available on the market are essentially microplastics, as they are made of polyesters and are of a size smaller than 5 mm. The tiny, shiny, decorative and colorful glitters are used in a wide range of products including but not limited to make-up or craft materials, clothing, shoes, bags, ornaments, and various objects. The marketing of micron-sized plastic materials, the environmental risks of which are no longer disputable, as disposable products clearly merits attention. People without substantial knowledge or awareness about microplastics pollution and sources thereof have been consuming these glitter products without giving it a second thought. Given their tasteless, odourless, invisible, durable, and last but certainly not least, ubiquitous characteristics, small microplastics nowadays came to pose a substantial threat for the environment and the biota, as a sneaky and persistent contaminant. Microplastic pollution is a completely anthropogenic one. In this context, the consumers should assume a careful and sensible attitude, and question all their consumption habits. On the other hand, the responsibilities of the manufacturers and regulators are also substantial. For, in the lack of any regulation or sanctions in the context of laws and legislation concerning a global problem, and in a context of scarce awareness on part of the society, the people would continue to buy and consume plastic products like glitters without really thinking about them, for as long as they are supplied to the market.

Yurtsever, M. and U. Yurtsever (2019). "Use of a convolutional neural network for the classification of microbeads in urban wastewater." Chemosphere **216**: 271-280.

Scientists are on the lookout for a practical model that can serve as a standard for sorting out, identifying, and characterizing microplastics which are common occurrences in water sources and wastewaters. The microbeads (MBs) used in cosmetics and discharged into the sewer systems after use cause substantial microplastics pollution in the receiving waters. Today, the use of plastic microbeads in cosmetics is banned. The existing use cases are to be discontinued within a few years. Yet, there are no restrictions regarding the use of microbeads in a number of industries, cleaning products, pharmaceuticals and medical practices. In this context, the determination and classification of MBs which had so far been discharged to water sources and which continue to be discharged, represent crucial problems. In this work, we examined a new approach for the classification of MBs based on microscopic images. For classification purposes, Convolutional Neural Network (CNN) -a Deep Learning algorithm- was employed, whereas GoogLeNet architecture served as the model. The network is built from scratch, and trained then after tested on a total of 42928 images containing MBs in 5 distinct cleansers. The study performed with the CNN which achieved a classification performance of 89% for MBs in wastewater.

Yusof Shuaib, I., et al. (2017). "Isolation and characterisation of microplastic abundance in Lates calcarifer from Setiu Wetlands, Malaysia." Malaysian Journal of Analytical Sciences **21**(5): 1054-1064.

The presence of microplastics (<1 mm) in wild and cage-cultured Asian sea bass (Lates calcarifer) was successfully studied. Fish samples were collected from Setiu Wetlands in October 2016. Microplastics were isolated from fish samples using the alkaline solution method (10 M of NaOH solution). Microplastics were sorted visually according to their shapes and colours after being observed under dissecting microscope. A total of 4,498 pieces of microplastics were identified and threadlike shape was the most abundant microplastic particles found during this study. The identification of functional groups in the composition of microplastics was achieved using Fourier transform infrared (FTIR) spectroscopy. Microplastics, with the presence of strong peaks at upsilon =3342 cm⁻¹ (N-H str), 1510 cm⁻¹ (N-H bend) and upsilon =1706 cm⁻¹ (C=O str) are associated with the materials consist of polyamide. Additionally, peaks related to the polyvinyl alcohol groups are recorded at upsilon =3321-4323 cm⁻¹ (O-H str), 1706 cm⁻¹ (C=O str), 1219 cm⁻¹ (O-H wag) and upsilon =1028-1128 cm⁻¹ (C-O str). The abundance levels of microplastics ingested by wild and cage-cultured fishes are statistically significantly different, p<0.05.

Zada, L., et al. (2018). "Fast microplastics identification with stimulated Raman scattering microscopy." Journal of Raman Spectroscopy **49**(7): 1136-1144.

The abundance of plastic products in modern society has resulted in a proliferation of small plastic particles called “microplastics” in the global environment. Currently, spectroscopic techniques such as Fourier-transform infrared and spontaneous (i.e., conventional) Raman spectroscopy are widely employed for the identification of the plastic microparticles, but these are rather time consuming. Stimulated Raman scattering (SRS) microscopy, based on the coherent interaction of 2 different laser beams with vibrational levels in the molecules of the sample, would enable much faster detection and identification of microplastics. Here, we present for the first time an SRS-based method for identifying 5 different high production-volume polymer types in microplastics extracted from environmental or consumer product samples. The particles from the extracts were collected on a flat alumina filter, and 6 SRS images were acquired at specifically chosen wavenumbers. Next, we decomposed these spectral data into specific images for the 5 polymers selected for calibration. We tested the approach on an artificial mixture of plastic particles and determined the signal-to-noise and level of cross talk for the 5 polymer types. As a proof of principle, we identified polyethylene terephthalate particles extracted from a commercial personal care product, demonstrating also the thousand-fold higher speed of mapping with SRS compared with conventional Raman. Furthermore, after density separation of a Rhine estuary sediment sample, we scanned 1 cm2 of the filter surface in less than 5 hr and detected and identified 88 microplastics, which corresponds to 12,000 particles per kilogram dry weight. We conclude that SRS can be an efficient method for monitoring microplastics in the environment and potentially many other matrices of interest.

Zafar, U., et al. (2013). "Fungal communities associated with the biodegradation of polyester polyurethane buried under compost at different temperatures." Applied & Environmental Microbiology **79**(23): 7313-7324.

Plastics play an essential role in the modern world due to their low cost and durability. However, accumulation of plastic waste in the environment causes wide-scale pollution with long-lasting effects, making plastic waste management expensive and problematic. Polyurethanes (PUs) are heteropolymers that made up ca. 7% of the total plastic production in Europe in 2011. Polyester PUs in particular have been extensively reported as susceptible to microbial biodegradation in the environment, particularly by fungi. In this study, we investigated the impact of composting on PUs, as composting is a microbially rich process that is increasingly being used for the processing of green waste and food waste as an economically viable alternative to landfill disposal. PU coupons were incubated for 12 weeks in fresh compost at 25degreeC, 45degreeC, and 50degreeC to emulate the thermophilic and maturation stages of the composting process. Incubation at all temperatures caused significant physical deterioration of the polyester PU coupons and was associated with extensive fungal colonization. Terminal restriction fragment length polymorphism (TRFLP) analysis and pyrosequencing of the fungal communities on the PU surface and in the surrounding compost revealed that the population on the surface of PU was different from the surrounding compost community, suggesting enrichment and selection. The most dominant fungi identified from the surfaces of PU coupons by pyrosequencing was Fusarium solani at 25degreeC, while at both 45degreeC and 50degreeC, Candida ethanolica was the dominant species. The results of this preliminary study suggest that the composting process has the potential to biodegrade PU waste if optimized further in the future.

Zakharian, A. R., et al. (2006). "Single-beam trapping of micro-beads in polarized light: Numerical simulations." Optics Express **14**(8): 3660-3676.

Using numerical solutions of Maxwell's equations in conjunction with the Lorentz law of force, we compute the electromagnetic force distribution in and around a dielectric micro-sphere trapped by a focused laser beam. Dependence of the optical trap's stiffness on the polarization state of the incident beam is analyzed for particles suspended in air or immersed in water, under conditions similar to those realized in practical optical tweezers. A comparison of the simulation results with available experimental data reveals the merit of one physical model relative to two competing models; the three models arise from different interpretations of the same physical picture.

Zam, W., et al. (2013). "Formulation and In-vitro release of pomegranate peels' polyphenols microbeads." International Journal of Pharmaceutical Sciences and Research **4**(9): 3536-3540.

Sodium alginate and combinations of sodium alginate-pectin were used to study the effect on the loading efficiency and the radical scavenging activity of the polyphenols extracted from pomegranate peels (Punica granatum). The results indicate that the polyphenol content was less when the microbeads were prepared with a single type of polymer in comparison of the microbeads prepared with two types of polymers. Also there was an optimum ratio of these two polymers (2:1), which was responsible for the maximum polyphenol content. The microencapsulated particles provided to polyphenols an effective protection against the degradation phenomenon, whereas antioxidant activity remained identical. In-vitro release studies indicated that 64.87% and 48.81% of polyphenols was released in simulated gastric fluid from sodium alginate and sodium alginate-pectin microbeads respectively. 88.37% and 70.48% of polyphenols was released in simulated intestinal fluid from sodium alginate and sodium alginate-pectin microbeads respectively. The microcapsules described in this study represent an interesting food additive for incorporation into functional foods. © 2013 are reserved by International Journal of Pharmaceutical Sciences and Research.

Zambello, R., et al. (2015). "Immunophenotypic heterogeneity of T-LGLL: Clinical and biological implications." Hematological Oncology **1)**: 222.

Introduction: T-large granular lymphocytes leukaemia is a rare disease characterized by an abnormal expansion of large granular lymphocytes (LGLs). T-LGLs typically exhibit a terminally differentiated cytotoxic T-cell phenotype (CD3+/CD8+/ CD4-/abTCR+). Together with the most common CD8+ T-LGLL, rare forms of CD4+/CD8-/+dim LGL proliferation (CD4+ T-LGLL) have been described. In addition, LGLs variably express CD57, CD16, CD56 and NK receptors (NKR), originating different immunophenotype combinations. The disease generally follows an indolent clinical course with neutropenia representing the major feature along the natural history of the disease (40% of patients presenting with severe neutropenia). Recently, hotspot STAT3 and STAT5b mutations have been described in T-LGLL patients supporting the idea that mutations could lead to a cytokine-independent STAT activation. STAT3 mutations were described in 30-40% of T-LGLL patients, while STAT5b were found only in very few cases, these latters being more frequently detectable in patients with aggressive clinical course. The aim of this study was to correlate immunophenotypes with relevant biological and clinical features, namely STAT mutations and severe neutropenia in a series of 101 patients with T-LGLL. Method(s): The immunophenotypic characterization of patients with T-LGLL was obtained by flow cytometer analysis. T-LGLs were purified from PBMCs by FACSAria cell sorter or by microbeads system. For the screening of STAT mutations, all the exons covering the activation gene region, where all of the mutations are located, were analysed. Sanger sequencing was performed on DNA of LGLs and of remaining autologous PBMCs. The presence of D661Y and Y640F STAT3 mutations undetectable by direct sequencing was further analysed by a DNA amplification refractory mutation system (ARMS-PCR). Data are expressed as mean +/- median standard error (SEM), and statistical analysis and correlations were performed by Student t-test and chi²

test, respectively. Result(s): Our results show that CD8+ T-LGLL patients with CD16+/CD56-/CD57+/- immunophenotype (n = 54) were characterized by a high frequency of expression of NK receptors (KIRs and NKG2) and a significant association with STAT3 mutations (p < 0.001) and neutropenia (p < 0.001). Furthermore, the rare CD8+/CD56+/ CD16-/CD57- immunophenotype (n = 1 patient) was associated with aggressive clinical behaviour and STAT5b mutations. Interestingly, in this patient, different subclones characterized by different phenotypes and STAT5b mutations could be identified. Expression of CD4+ by LGL was typically associated with a very indolent clinical course. Conclusion(s): In conclusion, we provided further evidence of the heterogeneous pattern of immunophenotypes accounting for LGL leukaemia, suggesting that discrete LGL phenotypes might be predictive of different biological and clinical features of disease.

Zambello, R., et al. (2011). "Intrinsic and estrinsic mechanism contributes to maintain the JAK/STAT pathway aberrantly activated in T-type large granular lymphocyte leukemia." Blood. Conference: 53rd Annual Meeting of the American Society of Hematology, ASH **118**(21).

T-cell large granular lymphocyte (T-LGL) leukemia is a heterogeneous disorder characterized by the chronic expansion of a terminally differentiated cytotoxic T lymphocytes (CTLs) with a CD3+/CD8+/CD57+ phenotype. Although the pathogenesis of T-LGL leukemia is still unknown, the hallmark of the disease is the abnormal clonal expansion of antigen-primed mature CTLs that successfully escape activation-induced cell death (AICD) and remain long-term competent. Similar to normal activated CTLs, leukemic T-LGLs exhibit activation of multiple survival signaling pathways. Among the intracellular signaling pathways altered in T-LGL leukemia, JAK/STAT (Janus Kinase/signal transducer and transcription factor) signaling has been associated with LGL transformation. In particular, it has been demonstrated that the STAT3, a pivotal element of this pathway, is over-expressed and constitutively activated in leukemic LGLs as compared to normal peripheral blood mononuclear cells (PBMCs). STAT3 is a transcription factor inducing a number of genes promoting cell survival and the involvement of an aberrant STAT3 expression has been suggested to play a role in the pathogenesis of this disease. In order to investigate the mechanism through which STAT3 is maintained in a state of activation in T-LGL leukemia, in patients in 27 patients we studied the expression of "suppressor of cytokine signaling 3 protein" (SOCS3) which is the specific negative regulator of STAT3 signaling, and the interleukin 6 (IL-6), which strongly induces STAT3 activation. Expression analysis was performed by Real Time-PCR and Western Blot assay in highly purified LGLs from PBMCs of patients by magnetic microbeads system. By Real Time-PCR, the expression level of IL-6 was shown to be increased in patients' PBMCs (56.84 +/- 17.01) as compared to normal PBMCs (0.53 +/- 0.14, p<0.05). However, we found that SOCS3 was down-expressed, both at mRNA and protein level, in neoplastic LGLs as compared to control LGL (mRNA: 0.26 +/- 0.04 vs 0.63 +/- 0.17, p<0.01; protein: 0.59 +/- 0.05 vs 0.85 +/- 0.10, p<0.01). We also observed that in vitro SOCS3 was unresponsive to IL-6 in patients' LGL, whereas in LGLs of healthy individuals this cytokine was definitely able to increase SOCS3 expression level. To better understand the mechanism responsible for SOCS3 low expression and unresponsiveness to IL-6 and since we found that this epigenetic mechanism is implicated in the NK type of this disease (Haematologica 2010. 95:1722), we evaluated whether an aberrant methylation of SOCS3 promoter takes place in T-LGL patients. Neoplastic LGLs were treated with the demethylating agent 5-aza-2'-deoxycytidine (DAC) and we observed that DAC re-established SOCS3 expression after IL-6 stimulation. Interestingly, as consequence of IL-6-induced SOCS3 expression we observed the inhibition of STAT3 phosphorylation and a reduction of Mcl1 protein level. These results support that in LGLs, SOCS3 tightly controls STAT3 and is able to modulate STAT3-induced gene Mcl1, that could be involved in LGL survival.

Studies are now in progress to confirm the hypothesis that SOCS3 silencing is caused by the SOCS3 promoter methylation. In conclusion, our results suggest that the downregulation of SOCS3, likely related to aberrant methylation, cooperates with IL-6 in the activation of JAK/STAT pathway, leading to the constitutive phosphorylation of STAT3, and thus ultimately resulting into increased survival of leukemic LGLs.

Zaninovic, L., et al. (2018). "The frequency of ANA/ENA in patients with neuromyelitis optica positive for AQP4 autoantibodies." Biochemia Medica **28 (Supplement 1)**: S59.

Introduction: Neuromyelitis optica (NMO) is an autoimmune disease characterized with the presence of antibodies to aquaporin-4 (AQP4) that are sensitive and highly specific serum markers. Antinuclear antibodies (ANA) and antibodies to extractable nuclear antigens (ENA) are characteristic for systemic autoimmune rheumatic diseases (SARD). The aim of this study was to investigate the incidence of ANA/ENA autoantibodies in patients with NMO in order to investigate possible overlap of SARD with NMO. Material(s) and Method(s): The study was conducted in a group of 24 patients positive for AQP4 autoantibodies, which were simultaneously analyzed for ANA and ENA autoantibodies. Antibodies to AQP4 were determined by ELISA method (Iason, Austria). Antinuclear antibodies were determined on HEp-2 cells with indirect immunofluorescence (IIF) method (Euroimmun, Germany). Autoantibodies to: ds-DNA, histone, SS-A, SS-B, Sm, RNP, DNA topo I, Jo-1 and CENP B were determined by the AtheNA ANA-II Plus Multiplex Luminex microbead immunoassay (Zeus Scientific Inc., USA). Result(s): Out of 24 patients positive for AQP4 antibodies, 17(71%) were women. Positive ANA IIF were found in 12 (50%) positive AQP4 patients. All 12 patients were women. Seven of ANA positive samples (58%) were anti-SS-A positive and 3 (25%) were anti-SS-B positive while 3 (25%) were positive for dsDNA antibody and histone. Other tested antibodies were negative. Conclusion(s): Positive ANA/ENA antibodies were found in half of the patients with positive results of antibodies to AQP4, exclusively in women. Positive ANA antibodies were mostly related to SS-A and SS-B antibodies which are characteristic for Sjogren's syndrome. The obtained results indicate the possible high frequency of overlap between NMO and Sjogren's syndrome. Future studies on a larger number of patients could contribute to a better understanding of the association between these autoimmune diseases.

Zaragoza Arnaez, C., et al. (2015). "Diosmetin and diosmin: Changes in platelet structure and activity." Basic and Clinical Pharmacology and Toxicology **2)**: 46.

Cardiovascular diseases are major causes of death in the developed world. Platelets play a key role in hemostasis and in the initiation and propagation of thrombus formation. Anti-platelet therapies are used widely, but current are associated with side effects including problem bleeding. Drugs from medical plants with vascular protection properties such as flavonoids could exert an important role in the platelet function regulation. Blood was extracted from 10 free-drug normal volunteers. Drugs (flavonoids: diosmetin and diosmin) were dissolved in dimethyl sulfoxide and added to the samples blood with or without calcium ionophore. Flow cytometry and fluorescence microscopy were employed to detect, using microbeads, the characterization of platelet-derived microparticles, platelets, and aggregates generated by in vitro activation of platelets using calcium ionophore. Both flavonoids showed certain antiplatelet activity, compared to the control, reducing the potent effect of the pro-aggregant agent. A percentage antiplatelet activity index (ACI) of 29.48 +/- 3.21% was recorded for diosmin 2 mM, and 13.51 +/- 2.36% for diosmetin 2 mM achieved descended the 10% of the PDMPs generated by the calcium ionophore, therefore this product proved a moderate antiplatelet capacity index. These drugs could have a potentially use in the prevention of cardiovascular

events, taking to account the differences in the chemical structures of the heteroside and the aglycon here studied might explain their different ACIs.

Zarfl, C. and M. Matthies (2010). "Are marine plastic particles transport vectors for organic pollutants to the Arctic?" Marine Pollution Bulletin **60**(10): 1810-1814.

Plastic litter accounts for 50-80% of waste items stranded on beaches, floating on the ocean surface and lodged in the seabed. Organic pollutants can be absorbed onto plastic particles from sea water, attached to their surfaces or included in the plastic matrix as additives. Such chemicals may be transported to remote regions by buoyant plastics and ocean currents. We have estimated mass fluxes of polychlorinated biphenyls (PCBs), polybrominated diphenyl ethers (PBDEs), and perfluorooctanoic acid (PFOA) to the Arctic via the main ocean currents and compared them to those in the dissolved state and in air. Substance fluxes with atmospheric or sea water currents account for several tons per year, whereas those mediated by plastics are four to six orders of magnitude smaller. However, the significance of various pollutant transport routes does not depend only on absolute mass fluxes but also on bioaccumulation in marine food chains.

Zbyszewski, M. and P. Corcoran (2009). Plastics Distribution and Degradation on Lake Huron Beaches, American Geophysical Union, 2000 Florida Ave., N.W. Washington DC 20009 USA, [URL:http://www.agu.org].

The resistivity of plastic debris to chemical and mechanical weathering processes poses a serious threat to the environment. Numerous marine beaches are littered with plastic fragments that entangle and become ingested by organisms including birds, turtles and plankton. Although many studies have been conducted to determine the amount and effects of plastics pollution on marine organisms, relatively little is known about the distribution and quantity of polymer types along lacustrine beaches. Plastic particles sampled from selected beaches on Lake Huron were analyzed using Fourier Transform Infrared Spectroscopy (FTIR) to determine polymer composition. The majority of the plastic fragments are industrial pellets composed of polypropylene and polyethylene. Varying degrees of oxidation are indicated by multiple irregular peaks in the lower wavenumber region on the FTIR spectra. The oxidized pellets also represent the plastic particles with the most pronounced surface textures, as identified using Scanning Electron Microscopy (SEM). Crazes and flakey, fibrous, or granular textures are consistent with chemical weathering processes, whereas gauges and pits occur through abrasion during mechanical weathering. Further textural and compositional analysis will indicate which polymer types are more resistant to weathering processes. Additional investigation of the distribution of plastic debris along the beaches of Lake Huron will indicate the amount and primary transport directions of resistant plastic debris polluting one of Ontario's Great Lakes.

Zbyszewski, M. and P. L. Corcoran (2011). "Distribution and degradation of fresh water plastic particles along the beaches of Lake Huron, Canada." Water, Air, and Soil Pollution **220**(1-4): 365-372.

Resistivity of plastic litter to chemical weathering, mechanical erosion, and biological degradation poses a critical environmental threat. Plastic debris has increased in abundance over the past several decades along shorelines and at sea, where organisms mistake small particles including plastic pellets as a potential food supply. These pellets have been shown to adsorb persistent organic pollutants such as PCBs, which may endanger the organism and become ingested higher in the food chain. Although several studies have been conducted to determine the amount and effects of plastics pollution in marine environments, relatively little is known concerning fresh water plastics pollution. This study represents the first detailed examination of the distribution, types, and physical and chemical degradation processes of plastic particles in a fresh water setting. In conducting field surveys along the shoreline of Lake Huron, Canada, we were able to ascertain that the total number of pellets over multiple sampling localities comprise 94% of plastic debris. The majority of the pellets were found proximal to an industrial sector along the southeastern margin of the lake and their abundance steadily decreased northward, following the dominant lake current patterns. Laboratory analyses using Fourier transform infrared spectroscopy (FTIR) and scanning electron microscopy indicate predominant mechanical abrasion textures, including grooves, gauges, pits, and flakes, and less common chemical weathering features such as linear and crescentic fractures that developed from shrinkage during subaerial exposure. The predominant type of plastic, polyethylene, appears to be much more resistant to chemical weathering than polypropylene, as indicated by oxidation peaks on FTIR spectra suggesting that polypropylene degrades more readily under natural conditions on freshwater beaches. © 2011 Springer Science+Business Media B.V.

Zecheru, T., et al. (2010). "Poly(2-hydroxyethyl methacrylate-co-dodecyl methacrylate-co-acrylic acid): synthesis, physico-chemical characterisation and nafcillin carrier." Journal of Materials Science-Materials in Medicine **21**(10): 2793-2804.

In the present study polymeric microbeads of poly(2-hydroxyethyl methacrylate-co-dodecyl methacrylate-co-acrylic acid) or p(HEMA-co-dDMA-co-AA) were synthesised and characterized through FT-IR and scanning electron microscopy (SEM); their swelling behavior against saline solution was explored and their in vitro cytotoxicity was evaluated. Further, in order to elucidate kinetic aspects regarding the ternary system p(HEMA-co-dDMA-co-AA), a mathematical model of the reactivity ratios of the comonomers in the terpolymer has been conceived and analyzed. An intensified tendency of AA units accumulation in the copolymer has been noticed, in spite of HEMA units, while dDMA conserves in the copolymer the fraction from the feed. Three compositions have been selected for nafcillin-loading and their in vitro release capacity was evaluated. The compositions of 80:10:10 and 75:10:15 M ratios appear suitable for further in vivo testing, in order to be used as drug delivery systems in the treatment of different osseous diseases.

Zekusic, M. and K. Fumic (2015). "Tissue and cell biobank of patients with inborn errors of metabolism in Croatia." Regenerative Medicine **1)**: 111.

Objectives Rare diseases are a clinically heterogeneous group of disorders with prevalence less than 5/10000. Only 6-8% of the world's population is likely to be affected by some form of rare disease. Since these diseases affect multiple organ systems and do not have characteristic symptoms, interdisciplinary cooperation is essential to establish diagnosis and include appropriate treatment. Life expectancy in these patients is often reduced; however, if detected in time, many of these diseases can be successfully treated. Inherited metabolic diseases form a small group of rare diseases diagnosed not only using conventional biological material (blood, urine, cerebrospinal fluid) but also tissue biopsy specimens are often included in the diagnostic process. In the Clinical Unit for Hereditary Metabolic Diseases of the University Hospital Centre Zagreb, different types of progenitor cells (dermal fibroblasts and skeletal myoblasts) and various human biopsy specimens (muscle, liver) of patients with rare hereditary metabolic diseases have been collected, processed, stored and handled for many years. Until now, Croatia had no organized biobank that would meet common European standards and is currently in process of establishing the first non-profit tissue and cell biobank of patients with inborn errors of metabolism. The main goal is to optimize the establishment of cell cultures and ultimately implement and harmonize Standard Operating Procedures in accordance with the European Network of Biobanks (EuroBioBanks, EBB) and ISO 15189 standards. Materials and Methods Progenitor cells were isolated from skin and skeletal muscle biopsy specimens of patients with inborn errors of metabolism. After the establishment of primary and secondary cultures, the cells were frozen in liquid nitrogen. Dulbecco's modification of Eagle's medium supplemented with 20% of fetal bovine serum (FBS), 1% of L-glutamine and 1% of antibiotics was used in the cultivation of fibroblasts. Myoblasts, with a small number of fibroblasts, were cultured in a Skeletal Muscle Growth Medium, SGM (Promo Cell, Germany) supplemented with 5% of growth factors (epidermal growth factor, fibroblast growth factor and insulin). Into the medium 10% of FBS, 1.5% of glutamine and antibiotics were added. Purification of myoblasts from fibroblasts was performed using Magnetic-Activated Cell Sorting Technology (Miltenyi Biotec, Germany). IgG-microbeads coated in specific primary antibody NCAM/CD56 were used to label myoblasts and separate them from unlabelled cells. Purity of myoblasts obtained by immunomagnetic sorting was assessed using flow cytometer before the storage in liquid nitrogen. Results The number of established cell cultures (1002 human fibroblast cultures and 48 skeletal myoblast cultures) together with the number of human biopsy specimens (337) isolated from patients with rare hereditary diseases was entered in the first Croatian biobank database. The purity of myoblast cell cultures was nearly 90%. The entire process of collecting, processing, storage and handling of samples was performed in concordance with valid European standards. Conclusion The first step in establishment of Croatian tissue and cell biobank has been taken. Requirements for data networking and harmonization of Croatian biobank according to the EBB and ISO 15189 standards have been accomplished. Cell culture of human myoblasts opens up new possibilities in the field of research of adult stem cells.

Zeng, E. (2018). "Microplastics contamination in aquatic environments: an emerging matter of environmental urgency." Microplastics contamination in aquatic environments: an emerging matter of environmental urgency **424**.

This book comprehensively illustrates the traditional and advanced technologies on sampling, identification and quantification of microplastic from different environmental media. Contributors summarize and discuss recent research on microplastic and examine studies on nano-sized plastic particles. Chapters cover a full range of microplastic research, including global distribution, detection, environmental fate, biological effects and political legislation. Users will find the book to be a comprehensive overview of microplastic research that is ideal for research and understanding on the occurrence of microplastic in aquatic environments.

Zeng, H., et al. (2012). "Controllable construction of ordered three-dimensional microbeads structure and its application in enzyme-linked immunosorbent microarray." Sensors and Actuators B: Chemical **168**: 446-452.

In this paper, three-dimensional ordered microbeads structure (3 DOS) was controllably constructed, and was firstly adopted in the enzyme-linked immunosorbent assay (ELISA) for the detection of IgA. The 3 DOS analytical matrix greatly increased the reaction surface and improved the sensitivity of ELISA microassay. Briefly, the 3 DOS dot microarray for bio-analysis was dispensed by the ink-jet micro-device, and assembled in a close box with controlled relative humility (RH). The influence of supporting substrate material, concentration of microbeads suspension, and RH on the conformation of 3 DOS was also discussed in detail. Then the optimum conditions for the uniform and stable 3 DOS for microassay were achieved, and the uniform and stable 3 DOS microarray for the enzyme-linked immunosorbent assay (ELISA) was built up. Finally, the ELISA microassay on the 3 DOS microarray was done to detect IgA and

compared with the classic 96-well plate and blank PDMS surface. The results have shown that 15 times reaction time was shortened due to the decreasing of the mass transferring distance; Almost 10 times sensitivity was obtained owing to the increased reaction surface; the large dynamic range was achieved in the 3 DOS ELISA microarray.

Zeng, K., et al. (2019). "Allogeneic cord blood regulatory T cells can prevent graft Vs. Host disease and preserve graft vs leukemia effect: Update on phase I/II clinical trial." Blood. Conference: 61st Annual Meeting of the American Society of Hematology, ASH **134**(Supplement 1).

Previously, we presented the results of a phase I trial of using cord blood (CB) derived regulatory T cells (Tregs) at a dose of 1x10⁶ cells/kg in the prevention of graft vs. host disease (GVHD) in five patients undergoing allogeneic stem cell transplant (SCT). We now present an update of those patients and also the outcome of a single patient treated with CB Tregs at higher dose of 1x10⁷ cells/kg. At the last follow up of 3.5 years, 5 of 6 patients are alive, in complete remission, without GVHD and off immune-suppression (table 1). One patient died of head injury at day 45 posttransplant without GVHD. None of the patients relapsed in spite of having high risk disease including Flt3+ acute myeloid leukemia (AML) (pt#1); refractory mycosis fungoides/ sezary syndrome (pt#2); relapsed refractory multiple myeloma including two autologous SCT (pt#3); myeloid sarcoma (pt#4); AML with complex cytogenetics (pt#5). Specifically, the sixth patient (treated at CB Tregs cell dose of 1x10⁷ cells/kg) had a diagnosis of lymphoid blast crisis of chronic myelogenous leukemia (CML) and underwent allogeneic peripheral blood (PB) matched unrelated donor (MUD) SCT in second chronic phase with the conditioning regimen of fludarabine (40 mg/m2/d on day -5 to -2) and melphalan (140mg/m2 on day -2) and received CB Tregs at a dose of 1x10⁷ cells/kg on day -1. The CB Tregs were manufactured at the MD Anderson GMP facility. Tregs were isolated from 4 out of 6 HLA matched CB unit with a post-thaw total nucleated cell (TNC) count of 1295 x 10⁶ cells with 90% recovery. Enrichment of CD25+ Treg cells was accomplished with directly conjugated anti-CD25 magnetic microbeads and the LS column (Miltenyl) based selection. After selection, the total no. of isolated CB Tregs was 17.6 x 10⁶ cells. These cells were ex-vivo expanded in culture for a total of 14 days in the continued presence of CD3/28 microbeads and interleukin-2. On the day of harvest, a total of 1359 x 10⁶ Treg cells were generated with 96% viability. Based on patient's weight of 67 kg, a total of 67x10⁷ CB Treg cells were infused. The expanded CB Tregs were also evaluated for functionality by using an in vitro suppression assay, where the stimulated CD4+ Tcon cells stained with CellTrace Violet and Tregs were added into a 96-well plate at a 1:1 and 1:2 ratio and incubated for three days at 37oC. As shown in figure 1A, the clinically manufactured CB Tregs were functional and exerted 98% suppression of the proliferating Tcon cells. Subsequently, the patient received PB MUD graft on day 0. The graft had a TNC count of 1900 x10⁶ cells where the CD3+ T cells were at a dose of 400 x10⁶ cells/kg resulting in a Treg: Tcon ratio of 1:40, a significantly lower number of Tregs compared to other published clinical trials using Treg prophylaxis for GVHD. There was no infusion reaction related to the CB Treg infusion, the patient engrafted on day+12 with 100% donor chimerism on day +30. The patient did not develop any grade II-IV GVHD and was off immune suppression by +6 months. At the time of last follow up of 2 years and 4 months, the patient remains alive, in complete remission and without GVHD. We compared the inflammatory cytokine profile as well as GVHD biomarkers for pt #6 to the rest of the five patients who received the lower dose of CB Tregs at 1x10⁶ cells/kg (with up to 400 times Tcon cells in the graft), where 4 patients had developed acute GVHD. The inflammatory biomarkers of IL-6 (fig 1B) and IL-8 (fig 1C) for pt#6 were low to undetectable compared to the other patients. Similarly, the GVHD biomarkers of ST2 (fig 1D); MIG/ CXCL9 (fig 1E) and follistatin (fig 1F) were also low to undetectable in pt#6 compared to the rest. At the time of last follow up, all patients had resolved acute GVHD and were off-immune suppression and in complete remission. Based on these data, we conclude that CB Treg dose of 1x10⁷ cells/kg may be able to prevent GVHD without alleviati g the graft vs leukemia effect.

Zeng, M., et al. (2017). "Development of a fluorescent microbead-based immunoassay for the detection of porcine reproductive and respiratory syndrome virus IgG." Chinese Veterinary Science / Zhongguo Shouyi Kexue **47**(12): 1497-1502.

In order to establish a high-throughput, reproducible and highly specific method to detect swine reproductive and respiratory syndrome virus (PRRSV) antibodies, the purified non-structural protein 7 (Nsp7) recombinant protein was used as an antigen to establish a fluorescent microsphere-based immunoassay (FMIA). SDS-PAGE and Western-blot analysis showed that PRRSV Nsp7 recombinant was soluble and had good antigenicity. The intra-assay and inter-assay coefficient of variation of MFIA was 3.2% and 4.2%, respectively, and there were no cross-reactions with the positive sera of other swine diseases. When the concentration of mAb was as low as 1 ng/mL, the method still had high sensitivity. These results indicate that the FMIA is rapid, sensitive and specific for detecting antibodies against swine PRRSV.

Zennegg, M., et al. (2014). "Formation of PBDD/F from PBDE in electronic waste in recycling processes and under simulated extruding conditions." Chemosphere **116**: 34-39.

The increasing volumes of waste electrical and electronic equipment (WEEE) in Europe and developing economies demand for efficient disposal solutions. However, WEEE also contains toxic compounds and, therefore, there is a need for recycling technologies for WEEE that creates revenue without causing environmental harm. Among other fast developing economies, South Africa is tempting to make use of recycled plastic. Brominated flame retardants (BFRs) are additives used to protect plastic materials in electrical and electronic equipment (EEE) against ignition. Some BFRs are known persistent organic pollutants (POPs) and some BFRs can be transformed into highly toxic compounds such as polybrominated dibenzofurans and dioxins (PBDD/Fs). In this study, the contents of critical BFRs, i.e. polybrominated diphenyl ethers, and highly toxic PBDD/Fs were measured in WEEE material from Switzerland and South Africa. The formation of PBDD/Fs has been observed in two South African recycling processes and under controlled laboratory conditions. Total PBDE-contents in the South African and Swiss plastic waste varied between 1x10(3) and 7x10(6) mug kg(-1). A few WEEE plastic fractions exceeded the RoHS limit of 1x10(6) mug kg(-1) for PBDEs and thus they could not be used for recycling products without special treatment. The total content of PBDFs was around 1x10(3) mug kg(-1). Such contents in materials do not pose a risk for consumer under normal conditions. Workers at recycling plants might be at risk. The measured formation rates of PBDFs were between 2x10(-5) and 2x10(-4)PBDE(-1) min(-1).

Zerbato, J. and N. Sluis-Cremer (2013). "Development of a primary cell model of HIV-1 latency in naive CD4⁺ T-cells." Antiviral Therapy **1)**: A25.

BACKGROUND: HIV-1 DNA can be readily detected in naive CD4⁺ T-cells from ART-naive and -experienced HIV-infected individuals. In contrast, HIV-1 DNA was rarely detected in naive CD4⁺ T-cells from post-treatment controllers in the ANRS Visconti Study. Taken together, these studies suggest that naive CD4⁺ T-cells constitute a persistent reservoir of HIV-1 infection, and that reduction/elimination of this reservoir may be important to achieve a functional cure. In this regard, the goals of this study were: (i) to develop

a primary cell model of HIV-1 latency in naive CD4⁺ T-cells; and (ii) to compare the kinetics of virus reactivation in naive and central memory (T<inf>CM</inf>) CD4⁺ T-cells. METHOD(S): Total resting, naive and T<inf>CM</inf> CD4⁺ T-cells were isolated from uninfected donors. These cells were then treated with 100 nM CCL19 and infected with HIV-1<inf>LAI</inf>, as described previously. Infection was assessed by qPCR of total HIV-1 DNA and 2LTRs. T-cell activation was assessed by low analysis of CD69, CD25 and HLA-DR expression. Virus production was measured by quantification of viral RNA in the supernatant before and after exposure to 10 nM PMA+10 mg/ml PHA or anti-CD3/CD28 microbeads. RESULT(S): We found that CCL19-treated naive and T<inf>CM</inf> CD4⁺ T-cells were equally susceptible to HIV-1 infection. Neither CCL19 nor HIV-1 infection promoted T-cell activation. Following HIV-1 infection of the CCL19-treated cells we observed essentially no virus production. However, virus production could be stimulated by PMA/PHA or anti-CD3/CD28. Interestingly, robust virus production was observed as early as 3 days post-stimulation in the HIV-infected T<inf>CM</inf> CD4⁺ T-cells. In comparison, much less virus was produced from the HIV-infected naive CD4⁺ T-cells, and the kinetics of virus production was also much slower. Collectively, these data suggest that the two resting CD4⁺ T-cell subsets analysed here reactivate differently. CONCLUSION(S): We have developed a primary cell model of HIV-1 latency in naive CD4⁺ T-cells. This model can be used to determine whether the mechanisms responsible for the establishment and reversal of latency differ in naive versus memory CD4⁺ T-cells.

Zeri, C., et al. (2018). "Floating plastics in Adriatic waters (Mediterranean Sea): From the macro- to the micro-scale." Marine Pollution Bulletin **136**: 341.

Macro- and microplastics abundances were determined in the Adriatic Sea following the MSFD TG10 protocol. The studied areas included populated gulfs, river outlets and offshore waters in five Adriatic countries. The use of small ships enabled us to detect small sized plastics (2.5–5 cm) and record average macroplastics densities of 251 ± 601 items km−2, one order of magnitude higher than previously considered. Results from manta net tows for microplastics revealed an average abundance of 315,009 ± 568,578 items km−2 (217 ± 575 g km−2). We found significantly higher microplastics abundances in nearshore (≤4 km) than in offshore waters (>4 km) and this trend seems to affect also the small sized macro plastic fragments (2.5–5 cm). The dominant polymers were polyethylene and polypropylene while the presence of some rare polymers and waxes used in food and dentistry indicated waste water treatment plants as potential sources of microplastics.

Zerlaut, G. A. and A. M. Stake (1974). "Chemical aspects of plastic waste management, RECYCLING AND DISPOSAL OF SOLID WASTES: INDUSTRIAL, AGRICULTURAL, DOMESTIC (Yen, ed.)." Ann Arbor Sci.Publ.Inc: 175-184.

The role of polymers and plastics in the total municipal and industrial solid waste management picture is becoming increasingly important. Demands for broader ecological responsiveness are placing greater emphasis on the technical problems of plastic waste management. Recycling of plastics offers the possibility of new materials and useful products. The chemistry of plastic waste degradation is not unlike the polymerization chemistry of polymeric materials. In this paper, some of the chemical aspects of particular value to waste management are examined. The authors discuss classical degradation mechanisms, mixed waste plastics, and photodegradation. It is shown that the overall aspect of plastic waste management that is most promising is the fact that some aspects of the technology as well as most of the chemistry of plastic degradation and recycling are the same as the chemistry of plastic synthesis and fabrication. In order to make it readily available and useful, researchers will be required to adapt this chemical technology to specific aspects of plastic waste reuse, recycling, and disposal. The potential applications of this common technology are outlined. Utilization of the recycling technology should be justifiable if useful products and byproducts can be manufactured. In order to establish the specific procedures for economically sound recycling, it will be necessary to perform process development studies and market analyses.

Zevi, Y., et al. (2006). "Quantifying colloid retention in partially saturated porous media. (Special section: Colloid transport in subsurface environments.)." Water Resources Research **42**(12).
The transport of colloid-contaminant complexes and colloid-sized pathogens through soil to groundwater is of concern. Visualization and quantification of pore-scale colloid behaviour will enable better description and simulation of retention mechanisms at individual surfaces, in contrast to breakthrough curves which only provide an integrated signal. We tested two procedures for quantifying colloid movement and retention as observed in pore-scale image sequences. After initial testing with static images, three series of images of synthetic microbead suspensions passing through unsaturated sand were examined. The region procedure (implemented in ImageJ) and the Boolean procedure (implemented in KS400) yielded nearly identical results for initial test images and for total colloid-covered areas in three image series. Because of electronic noise resulting in pixel-level brightness fluctuations the Boolean procedure tended to underestimate attached colloid counts and conversely overestimate mobile colloid counts. The region procedure had a smaller overestimation error of attached colloids. Reliable quantification of colloid retention at pore scale can be used to improve current understanding on the transport mechanisms of colloids in unsaturated porous media. For example, attachment counts at individual air/water meniscus/solid interface were well described by Langmuir isotherms.

Zhai, J. P., et al. (2019). "[Establishment of Flow Cytometric Immunobead Array Assay for Quantitation of Platelet-Specific Antibodies and Its Application]." Zhongguo Shi Yan Xue Ye Xue Za Zhi **27**(6): 1955-1961.
OBJECTIVE: To establish a flow cytometric immunobead array assay (FCIA) to quantify platelet antibodies and to explore its application in the diagnosis and treatment of ITP.
METHODS: The guantitative standard curve was established by binding the human IgG of known concentration on antibody-coated microbeads; at the same time, the platelet-specific antigen and antibody complex was captured and levels of platelet antibodies were detected using the microbeads coated by 5 kinds of antibodies against platelets suca as GPIX (SZ1), GPIb (SZ2), GpIIIa (SZ21), GPIIb (SZ22) and p-selection (SZ51). The fluorescence signal detected by flow cytometry were transformed into the conentration of platelet antibodies in samples through the quantitative standard curve, thereby establishing the method for quantititive detection of platelet-specific antibodies in plasm samples (FCIA), moreover the property, efficiency and clinical application of establishod FCIA method were evaluated.
RESULTS: The FCIA could detect 5 kinds of antibodies against GPIX, GPIb, GpIIIa, GPIIb and beta-selection within a broad range of 33.29-1280 ng/ml, 45.17-1280 ng/ml, 42.07-1280 ng/ml, 46.40-1280 ng/ml, 42.48-1280 ng/ml and 42.48-1280 ng/ml respectively, and their recovery rates were 115.23%, 112.58%, 117.47%, 107.64% and 112.67% respectively. The intra-assay coefficient of variation (CV) for anti- GPIX, -GPIb, -GpIIIa, -GPIIb and p-selection antibodies was 3.54%, 3.63%, 4.66%, 6.43% and 6.67% respectively, and the inter-assay CV for above mentioned antibodies were 10.89%, 7.57%, 10.34%, 6.95% and 10.72% respectively. The detection showed that the levels of 5 kinds of platelet-specific antibodies in ITP group all were higher than those in non-ITP and healthy control groups ($P<0.01$). The sensitivity, specificity and accuracy of quantitatively

detecting 5 kinds of antibodies for diagnosis of ITP by FCIA were 68.29%, 84.98% and 78.95% respectively, while the sensitivity, specificity and accuracy of detecting 5 kinds of antibodies by modified indirect MAIPA were 41.46%, 90.41% and 72.81% respectively.

CONCLUSION: The established quantitative FCIA for detection of antibodies provides a powerful tool for diaghosis and evaluation of therapeutic efficacy and prognosis of ITP patients.

Zhan, H., et al. (2013). "First-in-man use of T cells engineered to express a HSVTKCD34 sort-suicide gene." Human Gene Therapy **24 (5)**: A10.

Introduction: Suicide gene modified donor T cells can treat leukaemic relapse and improve immune reconstitution after allogeneic haematopoietic stem cell transplantation (SCT), and can be safely eliminated in the event of graft versus host disease (GVHD). Here we report generation and first-in-man use of mismatched donor T cells modified with a MPSV gamma-retroviral vector engineered to express a splice site corrected herpes simplex thymidine kinase (HSVTK):truncated CD34 (tCD34) suicide gene/ selection marker in three children. Method(s): A stable PG13 packaging cell line was generated to produce Gibbon Ape Leukaemia Virus pseudotyped retroviral vector stocks. Both master cell bank and vector supernatant were characterised in detail. Donor peripheral blood lymphocytes were activated with anti-CD3/CD28 microbeads and interleukin-2, transduced and enriched to a high purity (92-97%) by anti-CD34 CliniMacs selection, and cryopreserved. Cells were administered in two escalating doses (5 x 10⁴/kg and 5 x 10⁵/kg) to three paediatric patients receiving T-depleted, CD34 stem cell enriched, mismatched allogeneic grafts. Result(s): All infusions were completed without acute toxicity or the development of acute GVHD. Circulating gene modified T cells were detectable by flow cytometry in all three subjects. There was resolution of Varicella zoster reactivation, Adenoviraemia and pandemic H1N1 influenza virus infections, concordant with donor derived antigen specific interferon-g T cell responses. In the longest surviving subject, gene modified cells persisted for over 12 months, albeit at low levels in peripheral blood. Conclusion(s): These findings demonstrate the feasibility of producing and administrating HSVTK-tCD34 suicide gene modified donor T cells under GMP compliant conditions.

Zhan, Y., et al. (2019). "Carbogen gas-challenge BOLD fMRI in assessment of liver hypoxia after portal microcapsules implantation." PLoS ONE [Electronic Resource] **14**(11): e0225665.

BACKGROUND: Hypoxia is one of the key factors affecting the survival of islet cells transplanted via the portal vein. Blood oxygen level dependent functional magnetic resonance imaging (BOLD-fMRI) is the only imaging technique that can detect the level of blood oxygen level in vivo. However, so far no study has indicated that BOLD-fMRI can be applied to monitor the liver oxygen level after islet transplantation.

OBJECTIVE: To evaluate the value of Carbogen-challenge BOLD MRI in assessing the level of hypoxia in liver tissue after portal microcapsules implanted.

METHODS: Fifty-one New Zealand rabbits were randomly divided into three experimental groups (15 in each group) were transplanted microencapsulated 1000 microbeads/kg (PV1 group), 3000 microbeads/kg (PV2 group), 5000 microbeads/kg (PV3 group), and 6 rabbits were injected with the same amount of saline as the control group, BOLD-fMRI was performed following carbogen breathing in each group after transplantation on 1d, 2d, 3d and 7d, T2* weighted image, R2* value and DELTAR2* value parameters for the liver tissue. Pathological examinations including liver gross pathology, H&E staining and pimonidazole immunohistochemistry were performed after BOLD-fMRI. The differences of pathological results among each group were compared. The DELTAR2* values and transplanted doses were analyzed.

RESULTS AND CONCLUSIONS: DELTAR2* values at the 1-3d and 7d after transplantation were significantly different in each groups (P<0.05). DELTAR2* values decreased gradually with the increase of transplanted dose, and was negatively correlated with transplant dose at 3d after transplantation (r = -0.929, P <0.001). Liver histopathological examination showed that the degree of hypoxia of liver tissue increased with the increase of transplanted doses, Carbogen-challenge BOLD-fMRI can assess the degree of liver hypoxia after portal microcapsules implanted, which provided a monitoring method for early intervention.

Zhan, Z., et al. (2016). "Sorption of 3,3',4,4'-tetrachlorobiphenyl by microplastics: A case study of polypropylene." Marine Pollution Bulletin **110**(1): 559-563.

Though plastics show good chemical inertness, they could sorb polychlorinated biphenyls (PCBs) and other toxic pollutants from the surrounding environment. Thus, ingestion of microplastics by marine organisms potentially enhances the transport and bioavailability of toxic chemicals. However, there is lack of studies on the sorption capacity, mechanism and factors affecting the sorption behavior. Here, sorption of PCBs by microplastics in the simulated seawater was studied using the batch oscillation equilibration technique, in which polypropylene (PP) and 3,3',4,4'-tetrachlorobiphenyl (PCB77) acted as model plastic and PCB, respectively. Factors including particle size, temperature and solution environment were investigated.

Zhang, B., et al. (2017). "Effects of crude antigen and excretory-secretory products of Clonorchis sinensis on T cells." Chinese Journal of Zoonoses **33**(6): 491-494.

We investigated the roles of the crude antigen (CA) of Clonorchis sinensis and excretory-secretory products (ESPs) in the polarization of Th1 and Th2 cells. Bone marrow-derived cells were generated from BALB/c mice and isolated into immature DCs; immature DCs were then treated with either CA (CA stimulated group), ESPs (ESPs stimulated group), LPS (positive control group) or PBS (negative control group) for 24 hours. Then the CD4⁺T cells were isolated from mouse spleen by using anti-mouse-CD4 Microbeads, and further cocultured with stimulated DCs for another 72 hours. The purities of DCs and CD4⁺ T cells were evaluated by flow cytometry and the expressing levels of T-bet mRNA and GATA-3 mRNA were detected by real-time PCR. ELISA was used to detect the levels of IFN- gamma and IL-4 cytokines in the supernatant. mRNA levels of T-bet and GATA-3 in the ESPs group were higher than those in PBS-stimulated group (P<0.05). The concentrations of IFN- gamma and IL-4 cytokines in the culture were increased in the ESPs group, compared with PBS stimulated group (P<0.05). IFN- gamma but not IL-4 was increased in CA group (P<0.05). The results implied that CA might play a role in Th1 type immune response, and ESPs likely play roles in both Th1 and Th2 immune responses.

Zhang, C., et al. (2017). "Toxic effects of microplastic on marine microalgae Skeletonema costatum: Interactions between microplastic and algae." Environmental Pollution **220**(Pt B): 1282-1288.

To investigate toxic effects of microplastic on marine microalgae Skeletonema costatum, both algal growth inhibition test and non-contact shading test were carried out, and algal photosynthesis parameters were also determined. The SEM images were used to observe interactions between microplastic and algae. It was found that microplastic (mPVC, average diameter 1 mum) had obvious inhibition on growth of microalgae and the maximum growth inhibition ratio (IR) reached up to 39.7% after 96 h exposure. However, plastic debris (bPVC, average diameter 1 mm) had no effects on growth of microalgae. High concentration (50 mg/L) mPVC also had negative effects on algal photosynthesis since both chlorophyll content and photosynthetic efficiency (PHIPSII) decreased under mPVC treatments. Shading effect was not one reason for toxicity of microplastic on algae in this study. Compared with non-contact shading effect, interactions between microplastic and microalage such as adsorption and aggregation were more reasonable explanations for toxic effects of microplastic on marine microalgae. The SEM images provided a more direct and reasonable method to observe the behaviors of microplastic.

Zhang, C., et al. (2019). "Transgenerational Proteome Plasticity in Resilience of a Marine Copepod in Response to Environmentally Relevant Concentrations of Microplastics." Environmental Science & Technology **53**(14): 8426.

Here, we examined the multigenerational effect of microplastics (6-µm polystyrene beads; with different environmentally relevant concentrations of 0.023 and 0.23 mg/L in seawater) on the marine copepod Tigriopus japonicus under two-generation exposure (F0–F1) followed by one-generation recovery (F2) in clean seawater. Also, the seven life-history traits (survival, sex ratio, developmental time of nauplius phase, developmental time to maturation, number of clutches, number of nauplii/clutch, and fecundity) were measured for each generation. Furthermore, to investigate within-generation proteomic response and transgenerational proteome plasticity, proteome profiling was conducted for the F1 and F2 copepods under the control and 0.23 mg/L microplastics treatment. The results showed successful ingestion of microplastics in F0–F1 under both exposure concentrations, while higher concentration (0.23 mg/L) of microplastics resulted in the significant reduction in survival rate, number of nauplii/clutch, and fecundity. However, the affected traits were totally restored in the recovery generation (F2). Proteomic analysis demonstrated that microplastics exposure increased several cellular biosynthesis processes and, in turn, reduced energy storage due to the trade-off, hence compromising survival and reproduction of the treated copepods in F1. Interestingly, the two-generational effect of microplastics in copepods had significant transgenerational proteome plasticity as demonstrated by increased energy metabolism and stress-related defense pathway, which accounts for regaining of the compromised phenotypic traits during recovery (i.e., F2). Overall, this study provides a molecular understanding on the effect of microplastics at a translational level under long-term multigenerational exposure in marine copepods, and also the transgenerational proteome plasticity is likely rendering the robustness of copepods in response to microplastics pollution.

Zhang, C., et al. (2011). "Terminal field specificity of forebrain efferent axons to the pontine parabrachial nucleus and medullary reticular formation." Brain Research **1368**: 108-118.

The pontine parabrachial nucleus (PBN) and medullary reticular formation (RF) are hindbrain regions that, respectively, process sensory input and coordinate motor output related to ingestive behavior. Neural processing in each hindbrain site is subject to modulation originating from several forebrain structures including the insular gustatory cortex (IC), bed nucleus of the stria terminalis (BNST), central nucleus of the amygdala (CeA), and lateral hypothalamus (LH). The present study combined electrophysiology and retrograde tracing techniques to determine the extent of overlap between neurons within the IC, BNST, CeA and LH that target both the PBN and RF. One fluorescent retrograde tracer, red (RFB) or green (GFB) latex microbeads, was injected into the gustatory PBN under electrophysiological guidance and a different retrograde tracer, GFB or fluorogold (FG), into the ipsilateral RF using the location of gustatory NST as a point of reference. Brain tissue containing each forebrain region was sectioned, scanned using a confocal microscope, and scored for the number of single and double labeled neurons. Neurons innervating the RF only, the PBN only, or both the medullary RF and PBN were observed, largely intermingled, in each forebrain region. The CeA contained the largest number of cells retrogradely labeled after tracer injection into either hindbrain region. For each forebrain area

except the IC, the origin of descending input to the RF and PBN was almost entirely ipsilateral. Axons from a small percentage of hindbrain projecting forebrain neurons targeted both the PBN and RF. Target specific and non-specific inputs from a variety of forebrain nuclei to the hindbrain likely reflect functional specialization in the control of ingestive behaviors. © 2010 Elsevier B.V. All rights reserved.

Zhang, C., et al. (2019). "Microplastics in offshore sediment in the Yellow Sea and East China Sea, China." Environmental Pollution **244**: 827-833.

Microplastic particles are a global concern due to their widespread and growing threat to marine and coastal environments. To improve knowledge of microplastic pollution in China, we investigated 25 sediment samples collected with a box corer in the Southern Yellow Sea and East China Sea off the coast of China. The microplastics were extracted from sediments via density separation, after which they were observed under a microscope and characterized according to shape, color, and size, while polymer type identification was performed using micro-Fourier transform infrared spectroscopy. The abundance of microplastics in the offshore region of the Southern Yellow Sea and East China Sea was mapped. The mean concentration of microplastics at the 25 sites was 13.4+/-0.6 particles 100g⁻¹ dry weight (range: 6.0-24.0 particles 100g⁻¹ dry weight). Based on the categorization according to shape, color, and size, fiber (77%) was the most abundant shape, while blue (35%) and transparent (29%) were the most prevalent colors. In addition, the dominant size of microplastics was smaller than 1000mum which accounted for 89%. Finally, polyethylene, polyethylene terephthalate, acrylic, polyester, cellulose, and cellophane were the most abundant types of microplastics identified. Our result highlighted the presence of microplastics in offshore sediments from the Yellow Sea and East China Sea, and provided useful information for evaluating the environmental risks posed by microplastics in China.

Zhang, C. Y. and L. W. Johnson (2008). "Simple and accurate quantification of quantum dots via single-particle counting." Journal of the American Chemical Society **130**(12): 3750-3751.

Quantification of quantum dots (QDs) is essential to the quality control of QD synthesis, development of QD-based LEDs and lasers, functionalizing of QDs with biomolecules, and engineering of QDs for biological applications. However, simple and accurate quantification of QD concentration in a variety of buffer solutions and in complex mixtures still remains a critical technological challenge. Here, we introduce a new methodology for quantification of QDs via single-particle counting, which is conceptually different from established UV-vis absorption and fluorescence spectrum techniques where large amounts of purified QDs are needed and specific absorption coefficient or quantum yield values are necessary for measurements. We demonstrate that single-particle counting allows us to nondiscriminately quantify different kinds of QDs by their distinct fluorescence burst counts in a variety of buffer solutions regardless of their composition, structure, and surface modifications, and without the necessity of absorption coefficient and quantum yield values. This single-particle counting can also unambiguously quantify individual QDs in a complex mixture, which is practically impossible for both UV-vis absorption and fluorescence spectrum measurements. Importantly, the application of this single-particle counting is not just limited to QDs but also can be extended to fluorescent microspheres, quantum dot-based microbeads, and fluorescent nano rods, some of which currently lack efficient quantification methods.

Zhang, D., et al. (2020). "Microplastic pollution in water, sediment, and fish from artificial reefs around the Ma'an Archipelago, Shengsi, China." Science of the Total Environment **703**: 134768.

In this study, the occurrence and distribution of microplastics in artificial reefs around the Ma'an Archipelago, a national marine ranching area in China, were investigated. The abundance of microplastics ranged from 0.2+/-0.1 to 0.6+/-0.2itemsL⁻¹ in surface water, 30.0+/-0.0 to 80.0+/-14.1itemskg⁻¹ dry weight in the sediment, and 2.3+/-1.5 to 7.3+/-3.5 items individual⁻¹ in fish. Most of the detected microplastics were fiber-shaped, blue or transparent, and smaller than 1mm. Polyethylene, polypropylene, and poly(ethylene:propylene:diene) copolymer were the most abundant polymer types in the surface water samples, whereas cellophane was dominant in the sediment and fish. The appearance of microplastic pollution around the artificial reefs could be attributed mainly to the activities of the fisheries in the area, whereas the microplastic ingestion by fish was affected by the extent of microplastic contamination of the sediment. The results highlight the widespread presence of microplastics in the water, sediment, and biota of the artificial reefs around the Ma'an Archipelago, thereby improving understanding of the environmental risks posed by microplastics to marine artificial reef ecosystems and fisheries in general.

Zhang, F., et al. (2019). "Direct and indirect effects of microplastics on bivalves, with a focus on edible species: A mini-review." Critical Reviews in Environmental Science and Technology.

Bivalves play important roles in the ecosystem. However, bivalve populations have suffered a global decline in recent decades. This decline has caused public concern, because bivalves provide ecosystem services and are important sources of protein and ornaments (such as pearls) that support the fishing industry in coastal zones worldwide. Microplastics are an emerging global threat for bivalves and have been commonly detected in commercial edible bivalves, including mussels, oysters and clams. To comprehensively understand impacts of microplastics on bivalves, the potential exposure pathways by which microplastics affect bivalves are reviewed. The existing scientific evidence indicates that microplastics not only directly affect the physiology of bivalves, but also indirectly affect them by changing the structure of their sedimentary habitats, impairing their food resources and delivering persistent organic pollutants. In addition, the consumption of contaminated bivalves is a main pathway of exposure to microplastics by humans, which raises potential human health concerns. An evaluation of the hazards associated with the consumption of bivalves that contain microplastics and associated toxic chemicals is urgently needed. More studies related to the effects of microplastic fibers on bivalves should be conducted, because microplastic fibers comprise the largest proportion of microplastics in the environment and bivalves. Zhang, F., et al. (2019). "Food-web transfer of microplastics between wild caught fish and crustaceans in East China Sea." Marine Pollution Bulletin **146**: 173.

Plastic pollution, including microplastics (MPs), poses a global threat to environmental and human health. Studies on the transference of MPs along marine food webs are limited. In the present study, we investigated MP pollution in 11 wild fish species (193 individuals) and 8 wild crustacean species (136 individuals) captured from the Zhoushan fishing ground, off the East China Sea. The average abundance of MPs found in two main tissues, the gill and gastrointestinal (GI) tract, were 0.77 ± 1.25 and 0.52 ± 0.90 items/individual, respectively. The MPs we found were predominantly fiber-shaped, blue, and composed of polyester polymers. Our results suggest that MP pollution is ubiquitous in the East China Sea. We suggest that MPs are likely aggregated in the higher trophic level fish species throughout the marine food web. Furthermore, we suggest that marine organisms which occupy higher trophic levels might be suitable MP indicator species.

Zhang, F., et al. (2019). "Aquatic toxicity of iron-oxide-doped microplastics to Chlorella pyrenoidosa and Daphnia magna." Environmental Pollution: 113451.

Novel metal-oxide-doped microplastic particles (MMPs) have become emerging particulate plastics. The toxicity of MMPs in the aquatic environment remains unknown yet. In this study, toxicological effects of a representative MMP (iron-oxide core) with the nominal diameter of 1mum and two different surface functional groups, amine-modified (MPS (Fe)-NH₂) and carboxyl-modified (MPS (Fe)-COOH) polystyrene, were investigated by toxicity testing using Chlorella pyrenoidosa and Daphnia magna. The aquatic toxicity of two microplastic particles (MPS-NH₂ and MPS-COOH) with the same particle size and surface modification in the absence of iron-oxide core was also observed and compared.

Zhang, G. S. and Y. F. Liu (2018). "The distribution of microplastics in soil aggregate fractions in southwestern China." Science of the Total Environment **642**: 12-20.

Plastic particle accumulation in arable soils is a growing contaminant of concern with unknown consequences for soil productivity and quality. This study aimed to investigate abundance and distribution of plastic particles among soil aggregate fractions in four cropped areas and an established riparian forest buffer zone at Dian Lake, southwestern China. Plastic particles (10-0.05mm) from fifty soil samples were extracted and then sorted by size, counted, and categorized. Plastic particles were found in all soil samples. The concentration of plastic particles ranges from 7100 to 42,960 particles kg⁻¹ (mean 18,760 particles kg⁻¹). 95% of the sampled plastic particles are in the microplastic size (1-0.05mm) range. The predominant form is plastic fibers, making up on average 92% of each sample followed by fragments and films that contributed with to 8%.

Zhang, G. S. and F. X. Zhang (2019). "Variations in aggregate-associated organic carbon and polyester microfibers resulting from polyester microfibers addition in a clayey soil." Environmental Pollution: 113716.

Organic carbon is an essential element for sustainable soil management. While the effects of microplastics on soil physical and biological properties are presenting, it remains unclear whether the organic carbon dynamics of soil are altered by increased microplastic accumulation. The objectives of this study were to evaluate the influences of different polyester microfiber (PMF 0, 0.1% and 0.3% of soil dry weight) and organic material (OM 0, 1%, 2% and 3% of soil dry weight) addition levels on soil organic carbon and to determine the PMF distribution in aggregates from a pot experiment. After 75 days of incubation under 6 wet-dry cycles, the concentrations of soil total organic carbon did not differ significantly between the PMF (9.7 +/- 6.6 g kg⁻¹) and control (9.7 +/- 6.9 g kg⁻¹) treatments. However, PMF addition significantly reduced the organic carbon concentration in the large (>2 mm) macro-aggregates compared to the control treatment (10.6 +/- 4.8 g kg⁻¹ vs. 11.7 +/- 4.4 g kg⁻¹), but the results were opposite in the small (2-0.25 mm)macro-aggregates (10.2 +/- 4.9 g kg⁻¹ vs. 8.4 +/- 3.8 g kg⁻¹). In this study, less than 30% of added PMFs were incorporated into soil aggregates. In addition, the abundance and average length of aggregate-associated PMF in the large (2210 +/- 180 particles per g aggregate and 2.08 +/- 0.17 mm) and small (1820 +/- 150 particles per g aggregate and 1.68 +/- 0.11 mm) macro-aggregates were significantly greater than those in the micro-aggregates (1010 +/- 70 particles per g aggregate and 0.72 +/- 0.05 mm). Our results demonstrate that the distribution of organic carbon in soil macro-aggregates is affected by PMFs addition. Thus, we propose that the behavior of microplastics inside soil aggregates should be further explored to clarify their effects on the physical protection of soil organic carbon.

Zhang, G. S., et al. (2019). "Effects of polyester microfibers on soil physical properties: Perception from a field and a pot experiment." Science of the Total Environment **670**: 1-7.

Understanding soil physical properties is essential for soil quality management and sustainable land use. With the growing accumulation of microplastics in soils, a better understanding of the impact of microplastics on soil physical properties is crucial to conserve and manage soil quality. This study explored the effects of polyester microfiber (PMF) concentrations (0, 0.1% and 0.3%) on bulk density, porosity, aggregation and hydraulic conductivity of a clayey soil from a field experiment (1year) and a pot experiment (6 wet-dry cycles). Polyester microfibers significantly increased the volume of >30mum pores and reduced the volume of <30mum pores compared to the control treatment. However, there were no detectable changes in the soil bulk density and saturated hydraulic conductivity between the PMF treatments and the control treatment. Interestingly, we observed that polyester microfibers significantly increased the contents of water stable large macroaggregates (>2mm) in the 0.3% PMF (44%) and 0.1% PMF (39%) treatments compared to the control treatment (31%) in the pot experiment, but this was not true in the field experiment. The efficient interaction between polyester microfibers and fine soil particles and the frequent wet-dry cycles enhanced the formation and stability of macro-aggregates induced by polyester microfibers in the pot experiment. Overall, our results provide valuable evidence for microplastic influences on soil physical properties. Because microplastics are long-term anthropogenic contaminants, it is necessary to further study the impacts of microplastics on soil quality for terrestrial ecosystem sustainability.

Zhang, H., et al. (2013). "Microfluidic bead-based multienzyme-nanoparticle amplification for detection of circulating tumor cells in the blood using quantum dots labels." Analytica Chimica Acta **779**: 64-71.

This study reports the development of a microfluidic bead-based nucleic acid sensor for sensitive detection of circulating tumor cells in blood samples using multienzyme-nanoparticle amplification and quantum dot labels. In this method, the microbeads functionalized with the capture probes and modified electron rich proteins were arrayed within a microfluidic channel as sensing elements, and the gold nanoparticles (AuNPs) functionalized with the horseradish peroxidases (HRP) and DNA probes were used as labels. Hence, two signal amplification approaches are integrated for enhancing the detection sensitivity of circulating tumor cells. First, the large surface area of Au nanoparticle carrier allows several binding events of HRP on each nanosphere. Second, enhanced mass transport capability inherent from microfluidics leads to higher capture efficiency of targets because continuous flow within micro-channel delivers fresh analyte solution to the reaction site which maintains a high concentration gradient differential to enhance mass transport. Based on the dual signal amplification strategy, the developed microfluidic bead-based nucleic acid sensor could discriminate as low as 5 fM (signal-to-noise (S/N)3) of synthesized carcinoembryonic antigen (CEA) gene fragments and showed a 1000-fold increase in detection limit compared to the off-chip test. In addition, using spiked colorectal cancer cell lines (HT29) in the blood as a model system, the detection limit of this chip-based approach was found to be as low as 1 HT29 in 1 mL blood sample. This microfluidic bead-based nucleic acid sensor is a promising platform for disease-related nucleic acid molecules at the lowest level at their earliest incidence.

Zhang, H., et al. (2012). "Microfluidic bead-based enzymatic primer extension for single-nucleotide discrimination using quantum dots as labels." Analytical Biochemistry **426**(1): 30-39.

This study reports the development of an on-chip enzyme-mediated primer extension process based on a microfluidic device with microbeads array for single-nucleotide discrimination using quantum dots as labels. The functionalized microbeads were independently introduced into the arrayed chambers using the loading chip slab. A single channel was used to generate weir structures to confine the microbeads and make the beads array accessible by microfluidics. The applied allele-specific primer extension method employed a nucleotide-degrading enzyme (apyrase) to achieve specific single-nucleotide detection. Based on the apyrase-mediated allele-specific primer extension with quantum dots as labels, on-chip single-nucleotide discrimination was demonstrated with high discrimination specificity and sensitivity (0.5 pM, signal/noise > 3) using synthesized target DNA. The chip-based signal enhancement for single-nucleotide discrimination resulted in 200 times higher sensitivity than that of an off-chip test. This microfluidic device successfully achieved simultaneous detection of two disease-associated single-nucleotide polymorphism sites using polymerase chain reaction products as target. This apyrase-mediated microfluidic primer extension approach combines the rapid binding kinetics of homogeneous assays of suspended microbeads array, the liquid handling capability of microfluidics, and the fluorescence detection sensitivity of quantum dots to provide a platform for single-base analysis with small reagent consumption, short assay time, and parallel detection.

Zhang, H., et al. (2013). "Microfluidic beads-based immunosensor for sensitive detection of cancer biomarker proteins using multienzyme-nanoparticle amplification and quantum dots labels." Biosensors & Bioelectronics **42**: 23-30.

This study reports the development of a microfluidic beads-based immunosensor for sensitive detection of cancer biomarker alpha-fetoprotein (AFP) that uses multienzyme-nanoparticle amplification and quantum dots labels. This method utilizes microbeads functionalized with the capture antibodies (Ab1) and modified electron rich proteins as sensing platform that was fabricated within a microfluidic channel, and uses gold nanoparticles (AuNPs) functionalized with the horseradish peroxidase (HRP) and the detection antibodies (Ab2) as label. Greatly enhanced sensitivity for the cancer biomarker is based on a dual signal amplification strategy: first, the large surface area of Au nanoparticle carrier allows several binding events of HRP on each nanosphere. Enhanced sensitivity was achieved by introducing the multi-HRP-antibody functionalized AuNPs onto the surface of microbeads through "sandwich" immunoreactions and subsequently multiple biotin moieties could be deposited onto the surface of beads resulted from the oxidation of biotin-tyramine by hydrogen peroxide. Streptavidin-labeled quantum dots were then allowed to bind to the deposited biotin moieties and displayed the signal. Secondly, enhanced mass transport capability inherent from microfluidics leads to higher capture efficiency of targets because continuous flow within micro-channel delivers fresh analyte solution to the reaction site which maintains a high concentration gradient differential to enhance mass transport. Based on the dual signal amplification strategy, the developed microfluidic bead-based immunosensor could discriminate as low as 0.2 pg mL-1 AFP in 10 muL of undiluted calf serum (0.2 fg/chip), and showed a 500-fold increase in detection limit compared to the off-chip test and 50-fold increase in detection limit compared to microfluidic beads-based immunoassay using single label HRP-Ab2. The immunosensor showed acceptable repeatability and reproducibility. This microfluidic beads-based immunosensor is a promising platform for disease-related biomolecules at the lowest level at their earliest incidence.

Zhang, H., et al. (2011). "Multienzyme-nanoparticles amplification for sensitive virus genotyping in microfluidic microbeads array using Au nanoparticle probes and quantum dots as labels." Biosensors & Bioelectronics **29**(1): 89-96.

A novel microfluidic device with microbeads array was developed and sensitive genotyping of human papillomavirus was demonstrated using a multiple-enzyme labeled oligonucleotide-Au nanoparticle bioconjugate as the detection tool. This method utilizes microbeads as sensing platform that was functionalized with the capture probes and modified electron rich proteins, and uses the horseradish peroxidase (HRP)-functionalized gold nanoparticles as label with a secondary DNA probe. The functionalized microbeads were independently introduced into the arrayed chambers using the loading chip slab. A single channel was used to generate weir structures to confine the microbeads and make the beads array accessible by microfluidics. Through "sandwich" hybridization, the enzyme-functionalized Au nanoparticles labels were brought close to the surface of microbeads. The oxidation of biotin-tyramine by hydrogen peroxide resulted in the deposition of multiple biotin moieties onto the surface of beads. This deposition is markedly increased in the presence of immobilized electron rich proteins. Streptavidin-labeled quantum dots were then allowed to bind to the deposited biotin moieties and displayed the signal. Enhanced detection sensitivity was achieved where the large surface area of Au nanoparticle carriers increased the amount HRP bound per sandwiched hybridization. The on-chip genotyping method could discriminate as low as 1fmol/L (10zmol/chip, SNR>3) synthesized HPV oligonucleotides DNA. The chip-based signal enhancement of the amplified assay resulted in 1000 times higher sensitivity than that of off-chip test. In addition, this on-chip format could discriminate and genotype 10copies/muL HPV genomic DNA using the PCR products. These results demonstrated that this on-chip approach can achieve highly sensitive detection and genotyping of target DNA and can be further developed for detection of disease-related biomolecules at the lowest level at their earliest incidence.

Zhang, H., et al. (2019). "A review of the potential utilisation of plastic waste as adsorbent for removal of hazardous priority contaminants from aqueous environments." Environmental Pollution: 113698.
There is growing global awareness of the presence and negative impacts of waste plastic in the marine environment. Risks to wildlife include ingestion and entanglement for macro-plastic (larger than 5 mm in length), alongside food chain transfer for micro-plastics (less than 5 mm in length). Plastics in the marine environment have also been shown to adsorb and accumulate contaminants from seawater, e.g., heavy metals and hydrophobic organic compounds. This means that plastics can additionally act as vectors for transport of contaminants, permitting ecotoxicological risks to be spatially extended. However, the ability of waste plastic to adsorb pollutants also offers potential opportunity, if they can be used for the decontamination of wastewater. Here, we provide an overview of marine plastic types and distribution, and then systematically assess their potential to be repurposed as novel adsorbents. Data published in recent years are interrogated to gain an overview of the interaction mechanisms between marine plastics and both organic and inorganic contaminants. In addition, factors that may be exploited to enhance their performance in removal of contaminants are also reviewed and prioritised, e.g., surface modification and activation. This paper highlights the novel potential of repurposing plastic waste for wastewater treatment applications and seeks to identify key knowledge gaps and future research priorities for scientists and engineers.

Zhang, H., et al. (2018). "Enhanced adsorption of oxytetracycline to weathered microplastic polystyrene: Kinetics, isotherms and influencing factors." Environmental Pollution **243**(Pt B): 1550-1557.
Microplastic polystyrene foam has been found widely in the environment and is readily transported by wind or water. Beached and virgin foams of size 0.45-1mm were prepared as sorbents to study oxytetracycline sorption. Enhanced adsorption were found in the beached foams compared to the virgin foams, corresponding to the higher specific surface area,

micropore area and the degree of oxidation of the former. The Freundlich K_f value was 894+/-84 ((mg kg⁻¹) (mg L⁻¹)^{1/n}) for oxytetracycline adsorption on the beached foams, approximately twice as high as on the virgin foams. Effects of solution pH on adsorption to the beached foams were more pronounced to the virgin foams. Maximum adsorption occurred at pH 5at which electrostatic repulsion between the microplastic surface and the oxytetracycline zwitterion was minimal, indicating that electrostatic interaction may have regulated adsorption. Moreover, H-bonding and multivalent cationic bridging mechanisms may also have affected the adsorption of oxytetracycline to the beached foams as reflected by the ionic effects. Adsorption was promoted more in the presence of humic acid than of fulvic acid, perhaps owing to pi-pi conjugation between the humic acid and the microplastic surface which led to enhanced electrostatic attraction for oxytetracycline. This study suggests that weathered polystyrene foams may act as carriers of antibiotics in the environment and their potential risks to ecosystem and human health merit further investigation.

Zhang, H., et al. (2010). "A microfluidic device with microbead array for sensitive virus detection and genotyping using quantum dots as fluorescence labels." Biosensors & Bioelectronics **25**(11): 2402-2407.
In this study, a novel microfluidic device with microbead array was developed and sensitive genotyping of HBV was demonstrated using quantum dot as labels. This device was assembled by using two PDMS slabs featured with different microstructures and channel depths for the construction of a functional region comprising a chamber array and a single sampling microchannel. Since the chamber array and its sampling channel are of different channel depths and are bonded face-to-face, weir structures are generated to confine the microbeads which could be addressed using the microfluidic channel. Highly sensitive virus DNA detection was achieved by the enhanced mass transport in the microfluidics and the rapid reaction dynamics of suspension microbead array. The device could detect 1000 copies/mL of HBV virus in clinical serum samples using in vitro transcribed RNA as the target molecules. Based on DNA hybridization with quantum dots labels, on-chip virus genotyping was also demonstrated with high discrimination specificity and sensitivity (4 pM, S/N >3) using synthesized HBV DNA probes. This microfluidic device combines the rapid binding kinetics of homogeneous assays of microbead array, the liquid handling capability of microfluidics, and the fluorescence detection sensitivity of quantum dots to provide a platform for high sensitivity virus DNA analysis with small reagent consumption, short assay time and parallel detection.

Zhang, H., et al. (2018). "Occurrences of organophosphorus esters and phthalates in the microplastics from the coastal beaches in north China." Science of the Total Environment **616-617**: 1505-1512.
Chemical pollution in the microplastics has been concerned worldwide as pollutants might potentially transfer from the environment to living organisms via plastics. Here, we investigate organophosphorus esters (OPEs) and phthalic acid esters (PAEs) in the beached microplastics collected from 28 coastal beaches of the Bohai and Yellow Sea in north China. The analyzed microplastics included polyethylene (PE) pellets and fragments, polypropylene (PP) flakes and fragments and polystyrene (PS) foams. The tris-(2-chloroethyl)-phosphate (TCEP), tris (1-chloro-2-propyl) phosphate (TCPP) and di-(2-ethylhexyl) phthalate (DEHP) were the three predominant compounds found overall. The maximum SIGMA4 OPEs concentration was 84,595.9ngg⁻¹, almost three orders of magnitude higher than the maximum SIGMA9 PAEs concentration. The PP flakes and PS foams contained the highest concentrations of the additives in contrast to the PE pellets which contained the lowest. The high concentration level of carcinogenic chlorinated OPEs and DEHP with endocrine disrupting effects implied the

suggested potential hazards to coastal organisms. Spatial differences and compositional variation of the additives among the different microplastics suggests different origins and residence times in the coastal environment. This indicates that the characteristics of chemical additives might be a useful approach when tracing sources of microplastics in the environment.

Zhang, J., et al. (2018). "Selection and evaluation of microorganisms for biodegradation of agricultural plastic film." 3 Biotech **8**(7): 308.

Three Bacillus amyloliquefaciens isolates (HK1, GSDM02, and GSDM15) were tested for effectiveness in biodegradation of plastic films. Isolates were screened by plate on carbon-free medium and by using the clear-zone formation test. Their biodegradation ability was analyzed based on: film weight reduction, pH change of the fluid medium, a soil microbial biomass carbon test, scanning electron microscopy (SEM), and Fourier transform infrared spectrometry (FTIR). Polyvinyl alcohol (PVA) clear-zone and film weight reduction results revealed that the strain with a bigger clear-zone had a better biodegradation effect, that PVA can be evenly distributed in the medium, and that PVA can be a substitution for polyethylene in screening the biodegradation of strains. SEM and FTIR revealed that HK1 can tear the film apart and make surface chemical changes within 30 days. HK1 exhibited a better biodegradation effect in all tests, indicating its potential for helping solve the plastic pollution problems.

Zhang, J., et al. (2017). "A generic label-free microfluidic microobject sorter using a magnetic elastic diverter." Biomedical Microdevices **19**(2): 43.

Cell sorters play important roles in biological and medical applications, such as cellular behavior study and disease diagnosis and therapy. This work presents a label-free microfluidic sorter that has a downstream-pointing magnetic elastic diverter. Different with most existing magnetic sorters, the proposed device does not require the target microobjects to be intrinsically magnetic or coated with magnetic particles, giving users more flexibility in sorting criteria. The diverter is wirelessly deformed by an applied magnetic field, and its deformation induces a fluid vortex that sorts incoming microobjects, e.g., cells, to the collection outlet. The diverter does not touch samples in this process, reducing the sample contamination and damage risks. This sorter uses a magnetic field generated by off-chip electromagnetic coils that are centimeters away from the device. With simple structure and no on-chip circuits or coils, this device can be integrated with other lab-on-a-chip instruments in a sealed chip, ameliorating the safety concerns in handling hazardous samples. The parallel and independent control of two such diverters on a single chip were demonstrated, showing the potential of doubling the overall throughput or forming a two-stage cascaded sorter. The sorter was modeled based on the Euler-Bernoulli beam theory and its reliability was demonstrated by achieving a raw success rate of 96.68% in sorting 1506 registered microbeads. With a simple structure, the sorter is easy and cheap to fabricate. The advantages of the proposed sorter make it a promising multi-purpose sorting tool in both academic and industrial applications.

Zhang, J., et al. (2018). "Identification and quantification of microplastics in table sea salts using micro-NIR imaging methods." Analytical Methods **10**(24): 2881-2887.

Microplastics have been one of the most serious environmental pollutants of concern over recent decades. These pollutants have been detected not only in the marine biota, but also in abiotic sea products such as sea salts, which might pose a threat to food safety. Although efficient methods for the analysis of microplastics in different matrices have been published, in many cases, part of the quantification protocol relies on counting by eye, which is inefficient and time consuming. In this study, a new method for the analysis of polyethylene terephthalate

(PET) microplastics in table sea salts was developed. After hydrogen peroxide (H₂O₂) pretreatment and filtration, the PET particles in vacuum-filtered retentates of table sea salts were imaged by micro-FT-NIR imaging and identified using spectral similarity methods including correlation coefficient mapping (CCM), spectral angle mapping (SAM) and Euclidean distance mapping (EDM) methods. The number of particles was acquired by a computer based automatic counting method. The results showed that, in most cases, the number of microplastics obtained by the automatic counting method was equal to that obtained by the counting by eye method, which proved that micro-NIR chemical imaging combined with chemometric methods can be an alternative way to identify and count the microplastics simultaneously. This method for detecting and quantifying PET microplastics in table sea salts could also be applied to other types of polymers in other environmental sample detection.

Zhang, J., et al. (2019). "Polyethylene Terephthalate and Polycarbonate Microplastics in Pet Food and Feces from the United States." Environmental Science & Technology **53**(20): 12035-12042.

Human exposure to microplastics has been a topic of interest, but measurements of exposure are limited. Pet animals are sentinels of human exposure, as they share a common living environment with humans. In this study, 58 pet (cat and dog) foods and 78 pet feces samples were collected from Albany, NY, USA, for the analysis of polyethylene terephthalate (PET) and polycarbonate (PC) by alkali-assisted thermal depolymerization and liquid chromatography-tandem mass spectrometry (HPLC-MS/MS) methods. PET was detected at concentrations in the range of <1,500 ng/g to 12,000 ng/g (median: <1,500 ng/g) and <1,500 to 4,600 ng/g (median: <1,500 ng/g) in cat and dog foods, respectively. The concentrations of PET in cat (<2,300-340,000 ng/g, median: 61,000 ng/g) and dog (7700-190,000 ng/g, median: 30,000 ng/g) feces were 1-2 orders of magnitude higher than those in pet food samples. A significant positive correlation was found between the concentrations of the monomers (i.e., TPA and BPA) and the corresponding MPs in cat feces. The calculated mean estimated daily intake of PET and PC (calculated from pet food) was lower than that of the mean cumulative daily intake (calculated from pet feces), which suggested that diet is a minor source of exposure to PET and PC in pets.

Zhang, J., et al. (2020). "Microplastics in house dust from 12 countries and associated human exposure." Environment International **134**: 105314.

Global marine pollution by microplastics (MPs) has received considerable attention in recent years. Nevertheless, little is known about the occurrence of MPs in indoor environments. A novel analytical method was used to quantitatively determine polyethylene terephthalate (PET)- and polycarbonate (PC)- based MPs in 286 indoor dust samples collected from 12 countries. PET-based MPs were detected in all dust samples at concentrations of 38-120,000micro g/g (median: 5900micro g/g), whereas PC-based MPs were measured at <0.11-1700micro g/g (median: 8.8micro g/g). Significant positive correlations were found between the concentrations of terephthalic acid (a PET monomer) and PET as well as between bisphenol A (a PC monomer) and PC. Based on the concentrations of MPs measured in indoor dust, the median daily intake of PET-based MPs calculated for infants was in the range of 4000-150,000ng/kg-bw/day.

Zhang, J.-x., et al. (2019). "Study on the legislation of the marine plastic and microplastic management." Haiyang Huanjing Kexue = Marine Environmental Science(2): 167.

Marine microplastic pollution is becoming a global concern in recent years. To prevent and reduce marine microplastic pollution,it is very necessary to control the sources including the

primary and secondary source i. e. plastic debris. To improve the legislation on plastic and microplastic management in China,the present legislation status in China and abroad was investigated. Totally most of the articles are on the plastic garbage management,however the detailed regulations are insufficient. The legislation on the microplastic management is lack,and it is mostly to limit the usage of the micro-beads in the cosmetics,pharmaceuticals and personal care products. Based on the international experience,it is necessary to enact the regulations of prohibiting the usage of micro-beads in the pharmaceuticals and personal care products,add the plastic garbage tax in the environmental taxes,improve the garbage reclamation system,promote the marine microplastic monitoring and assessment system,enhance the public participation institution and so on.

Zhang, K., et al. (2019). "The hydro-fluctuation belt of the Three Gorges Reservoir: Source or sink of microplastics in the water?" Environmental Pollution **248**: 279-285.

Reservoirs can be an important environmental compartment for microplastic pollution. Previous investigations have found that surface waters and sediments in the Three Gorges Reservoir (TGR) have had high microplastic abundance, and the Xiangxi River, which is one of the largest primary tributaries of the TGR, has had much higher microplastic abundance than several marine and freshwater systems in China. A strip of land on the bank of the reservoir area, which is called the hydro-fluctuation belt (HFB), is periodically exposed due to the special hydrodynamic conditions in the TGR. The HFB may be an important source and/or sink of microplastics in TGR. In this study, microplastic occurrence in sediments from the Xiangxi River HFB was investigated to reflect the local microplastic pollution status and to evaluate its potential to serve as a source/sink of microplastics in the TGR. Seven sampling sites were selected, and sediments within the HFB and above the belt were collected in summer when the water level was low. The results showed that the microplastic abundance ranged from 0.55+/-0.12x10³ to 14.58+/-5.67x10³ particles m⁻², which was one to two orders of magnitude higher than that in sediments from the Xiangxi River in our previous study (80-846 particles m⁻²). Statistical analysis revealed that the microplastic abundance within the HFB was significantly higher than that of the area above the HFB. The results indicate that the HFB can be an important microplastic sink when the water level is low, and the belt can turn into a potential source when the water level is high. Cluster analysis was applied to reveal the characteristics of the microplastics collected at different sites, and the results suggest that the cluster analysis may be a useful tool in elucidating the source and fate of microplastics.

Zhang, K., et al. (2015). "Accumulation of floating microplastics behind the Three Gorges Dam." Environmental Pollution **204**: 117-123.

We investigated the occurrence and distribution of microplastics in surface water from the Three Gorges Reservoir. Nine samples were collected via trawl sampling with a 112 mum mesh net. The abundances of microplastics were from 3407.7 x 10³ to 13,617.5 x 10³ items per square kilometer in the main stream of the Yangtze River and from 192.5 x 10³ to 11,889.7 x 10³ items per square kilometer in the estuarine areas of four tributaries. The abundance of microplastics in the main stream of the Yangtze River generally increased as moving closer to the Three Gorges Dam. The microplastics are made exclusively of polyethylene (PE), polypropylene (PP), and polystyrene (PS). Together with microplastics, high abundance of coal/fly ash was also observed in the surface water samples. Comparing with previously reported data, microplastics in the TGR were approximately one to three orders of magnitudes greater, suggesting reservoirs as potential hot spot for

microplastic pollution. Copyright © 2015 Elsevier Ltd. All rights reserved.

Zhang, K., et al. (2020). "Efficient particle and droplet manipulation utilizing the combined thermal buoyancy convection and temperature-enhanced rotating induced-charge electroosmotic flow." Analytica Chimica Acta **1096**: 108-119.

Efficient granular sample manipulation is crucial for various microfluidic-based applications such as material synthesis and drug delivery. Herein we present a novel method to efficiently manipulate microbeads and droplets using the combined thermal buoyancy convection and temperature-enhanced rotating induced-charge electroosmotic flow. Within the granular fluid, a pair of counter-rotating microvortices is formed above the floating electrode, leading to the formation of a flow stagnation region at the bottom center. Granular samples then can be effectively transported to this region by the Stokes drag, and the concentration performance can be flexibly manipulated by adjusting the energization strategies of the chip. The contributions of fluid convection, dielectrophoresis, thermophoresis, and gravity force to particle migration are first studied and compared, proving that the convection flow and gravity force are mainly responsible for particle migration and deposition respectively. Then the systematic enriching experiments of 4-mum silica particles demonstrate that the particle migration velocity can be highly improved by the combined thermal-electrical field. Finally, the effective concentration of nanocopper particles and the assembly of oil-in-water/water-in-oil-in-water droplets indicate that this approach is capable of manipulating diverse granular samples. Therefore, this strategy can be attractive for lots of microfluidic-based applications because of its high efficiency and simplicity.

Zhang, K., et al. (2019). "Efficient Micro/Nanoparticle Concentration using Direct Current-Induced Thermal Buoyancy Convection for Multiple Liquid Media." Analytical Chemistry **91**(7): 4457-4465.

Thermal-based microparticle focusing has recently received increasing attention due to its noninvasive nature and simple manipulation mechanism. However, its further application is limited by current complicated fluid heating systems and low particle focusing velocity. Using simple indium tin oxide-made microheaters, herein we propose a flexible and novel approach for efficient particle focusing based on direct current-induced thermal buoyancy convection. Importantly, for avoiding possible electrochemical reactions on the electrode, the microheaters are isolated from the granular fluids of interest by a thin glass slide. The concentration performance of the designed chip was first demonstrated by statically focusing 4-mum silica particles, yeast cells, silica particles in insulating buffer, and 100-nm copper microspheres. Also the trapping of a mixture of 5-mum and 2-mum polystyrene microbeads indicated that the chip can either simultaneously concentrate two kinds of particles or selectively focus the heavier ones by adjusting the voltages. Then the different concentration patterns of microbeads exhibited that the microspheres can be flexibly manipulated by changing the configurations of microheaters. Furthermore, for the first time, we achieved thermal-based continuous particle focusing in both conducting and insulating solutions using buoyancy convection, demonstrating that this method can be utilized to achieve both static and continuous particle manipulations in multiple liquid media. Finally, the feasibility of this device in effective wear measurement of machines was demonstrated by conducting systematic experiments of focusing nanocopper particles in the hydraulic oil. Therefore, this presented approach would be promising for a broad range of on-chip applications.

Zhang, K., et al. (2018). "Microplastic pollution in China's inland water systems: A review of findings, methods, characteristics, effects, and management." Science of the Total Environment **630**: 1641-1653.

The pollution of marine environments and inland waters by plastic debris has raised increasing concerns worldwide in recent years. China is the world's largest developing country and the largest plastic producer. In this review, we gather available information on microplastic pollution in China's inland water systems. The results show that microplastics are ubiquitous in the investigated inland water systems, and high microplastic abundances were observed in developed areas. Although similar sampling and analytical methods were used for microplastic research in inland water and marine systems, methods of investigation should be standardized in the future. The characteristics of the detected microplastics suggest secondary sources as their major sources. The biological and ecological effects of microplastics have been demonstrated, but their risks are difficult to determine at this stage due to the discrepancy between the field-collected microplastics and microplastics used in ecotoxicological studies. Although many laws and regulations have already been established to manage and control plastic waste in China, the implementation of these laws and regulations has been ineffective and sometimes difficult. Several research priorities are identified, and we suggest that the Chinese government should be more proactive in tackling plastic pollution problems to protect the environment and fulfill international responsibilities. Zhang, K., et al. (2017). "Occurrence and Characteristics of Microplastic Pollution in Xiangxi Bay of Three Gorges Reservoir, China." Environmental Science & Technology **51**(7): 3794-3801.

Microplastic pollution in inland waters is receiving growing attentions. Reservoirs are suspected to be particularly vulnerable to microplastic pollution. However, very limited information is currently available on pollution characteristics of microplastics in reservoir ecosystems. This work studied the distribution and characteristics of microplastics in the backwater area of Xiangxi River, a typical tributary of the Three Gorges Reservoir. Microplastics were detected in both surface water and sediment with concentrations ranging from 0.55 × 105 to 342 × 105 items km-2 and 80 to 864 items m-2, respectively. Polyethylene, polypropylene, and polystyrene were identified in surface water, whereas polyethylene, polypropylene, and polyethylene terephthalate, and pigments were observed in sediment. In addition, microplastics were also detected in the digestion tracts of 25.7% of fish samples, and polyethylene and nylon were identified. Redundancy analysis indicates a weak correlation between microplastics and water quality variables but a negative correlation with water level of the reservoir and Secchi depth. Results from this study confirm the presence of high abundance microplastics in reservoir impacted tributaries, and suggest that water level regulated hydrodynamic condition and input of nonpoint sources are important regulators for microplastic accumulation and distribution in the backwater area of reservoir tributaries. Zhang, K., et al. (2010). "A microfluidic system with surface modified piezoelectric sensor for trapping and detection of cancer cells." Biosensors & Bioelectronics **26**(2): 935-939.

We present a microfluidic system with integrated surface modified piezoelectric sensor for trapping and label-free detection of target samples that can be used for cancer diagnosis. To introduce active magnetic force control to the piezoelectric sensor and obtain a fast regenerative system, a nickel pillar array was patterned onto the surface of quartz crystal microbalance. The functionalities of the system were tested by trapping suspended superparamagnetic micro-beads (SPMBs) in fluids onto the nickel pillar array with a manually controlled magnetic field and by detecting the accumulated mass from the resonant characterization of the piezoelectric sensor at the same time. The results showed the efficiency of the system in manipulating the SPMBs and the sensitivity of the device was of 5 Hz mm2/ng. With surface-functionalized SPMBs, the microfluidic system succeeded in trapping and detecting target cancer cells. A549 cancer cells were captured on the nickel pillar array with WGA protein-functionalized SPMBs and detected with a total mass of 90.6 ng. With its simplicity, low production cost and high efficiency, this new device configuration would be useful for the future point-of-care clinical applications.

Zhang, L., et al. (2016). "Polysaccharide-based micro/nanocarriers for oral colon-targeted drug delivery." Journal of Drug Targeting **24**(7): 579-589.

Oral colon-targeted drug delivery has attracted many researchers because of its distinct advantages of increasing the bioavailability of the drug at the target site and reducing the side effects. Polysaccharides that are precisely activated by the physiological environment of the colon hold greater promise for colon targeting. Considerable research efforts have been directed towards developing polysaccharide-based micro/nanocarriers. Types of polysaccharides for colon targeting and in vitro/in vivo assessments of polysaccharide-based carriers for oral colon-targeted drug delivery are summarised. Polysaccharide-based microspheres have gained increased importance not just for the delivery of the drugs for the treatment of local diseases associated with the colon (colon cancer, inflammatory bowel disease (IBD), amoebiasis and irritable bowel syndrome (IBS)), but also for it's potential for the delivery of anti-rheumatoid arthritis and anti-chronic stable angina drugs. Besides, Polysaccharide-based micro/nanocarriers such as microbeads, microcapsules, microparticles, nanoparticles, nanogels and nanospheres are also introduced in this review.

Zhang, L., et al. (2018). "Interaction of Lumbricus terrestris with macroscopic polyethylene and biodegradable plastic mulch." Science of the Total Environment **635**: 1600-1608.

Polyethylene mulch films used in agriculture are a major source of plastic pollution in soils. Biodegradable plastics have been introduced as alternative to commonly-used polyethylene. Here we studied the interaction of earthworms (Lumbricus terrestris) with polyethylene and biodegradable plastic mulches. The objective was to assess whether earthworms would select between different types of mulches when foraging for food, and whether they drag macroscopic plastic mulch into the soil. Laboratory experiments were carried out with earthworms in Petri dishes and mesocosms. The treatments were standard polyethylene mulch, four biodegradable plastic mulches (PLA/PHA [polylactic acid/polyhydroxy alkanoate], Organix, BioAgri, Naturecycle), a biodegradable paper mulch (WeedGuardPlus), and poplar litter, which served as control. Four and three replicates for the Petri dish and mesocosm experiments were used, respectively. Macroscopic plastic and paper mulch pieces (1.5 cm x 1.5 cm and 2 cm x 2 cm) were collected from an agricultural field after a growing season, after being buried in the soil for 6 and 12 months, and after being composted for 2 weeks. We found that earthworms did not ingest polyethylene. Field-weathered biodegradable plastic mulches were not ingested either, however, after soil burial and composting, some biodegradable plastics were eaten and could not be recovered from soil any longer. Earthworms, when foraging for food, dragged plastic mulch, including polyethylene and biodegradable plastic, and poplar leaves into their burrows. The burial of macroscopic plastic mulch underground led to a redistribution of plastics in the soil profile, and likely enhances the degradation of biodegradable mulches in soil, but also can lead to leaching of plastic fragments by macropore flow.

Zhang, L., et al. (2019). "The spatial distribution of microplastic in the sands of a coral reef island in the South China Sea: Comparisons of the fringing reef and atoll." Science of the Total Environment **688**: 780-786.

Microplastic pollution of coral reef ecosystems has received increasing attention since the discovery that several typical coral types have the ability to ingest (micro-) plastics. However, data on the distribution of microplastics in coral reef ecosystems are still very limited. The study reported here selected sands/sediments from coral reef islands located in the South China Sea as a representative study site. The abundance of microplastics was found to reach 90+/-5 items/kg and 530+/-7 items/kg at the Weizhou Island and Sanya Lu Hui Tou (LHT) sites (fringing reef), respectively. Each of these qualities are lower than the quantity of microplastics collected from the Xisha Islands (atoll) (60+/-3 to 610+/-11 items/kg), which experiences less human activity and pollution. Moreover, further investigation demonstrated that the differences in the microplastics in the sands of these atolls and fringing reefs were determined not only by their sources, but were also dependent on their water exchange rates. The primary type and color of the microplastics found in these four sampling zones was red polypropylene and there was a greater proportion of smaller size particles (<1mm) in the remote atolls of the Nansha and Xisha islands than in the other fringing reef sites. Additionally, there were no obvious differences found in the abundance of microplastics and the compositions/structures of coral sand in the Weizhou Island and Sanya LHT sites.

Zhang, M., et al. (2015). "T Cells Derived From Human Melanoma Draining Lymph Nodes Mediate Melanoma-specific Antitumor Responses In Vitro and In Vivo in Human Melanoma Xenograft Model." Journal of Immunotherapy **38**(6): 229-238.

It has been established in murine models that lymph nodes draining a progressively growing tumor contain antigen-specific T cells capable of mediating protective immune responses upon adoptive transfer. However, naturally occurring human tumor-draining lymph nodes (TDLNs) have yet to be fully investigated. In this study, we analyzed TDLNs from patients with stage III melanoma who were undergoing routine lymph node dissection. Following short-term (14 d) culture activation with anti-CD3/anti-CD28 microbeads and expansion in low concentrations of IL-2, the melanoma-draining lymph node (MDLN) cells were ~ 60% CD4-activated and ~ 40% CD8-activated T cells. The activated MDLN cells demonstrated reactivity in response to overlapping peptides spanning the sequence of 4 different known melanoma antigens MAGEA1, Melan-A/MART-1, NY-ESO-1, and Prame/OIP4, suggesting the presence of melanoma-specific T cells. Coculture of activated MDLN T cells with cancer cells in vitro resulted in preferential apoptosis of human cancer cell lines that were cocultured with T cells with high degree of MHC matching. Adoptive transfer of MDLN T cells with high degree of MHC matching to A375 to mice-bearing human A375 melanoma xenografts resulted in dose-dependent improvement in survival. Although prior human studies have demonstrated the immune responses within melanoma vaccine-draining lymph nodes, this study presents evidence for the first time that naturally occurring human MDLN samples contain melanoma-experienced CD4 and CD8 T cells that can be readily cultured and expanded to mediate protective immune responses both in vitro and in vivo in a human melanoma xenograft model.

Zhang, M., et al. (2019). "Microplastics from mulching film is a distinct habitat for bacteria in farmland soil." Science of the Total Environment **688**: 470-478.

Microplastics, as an emerging pollutant of global importance, have been well documented in

aquatic ecosystems. However, little is known about the effects of microplastics on agroecosystems, particularly for soil microbial communities. Herein, microplastics collected from cotton fields in Xinjiang, China, were analysed with a scanning electron microscope (SEM) and high-throughput sequencing to investigate the attached bacterial communities. Microplastic surfaces, especially pits and flakes, were colonized by various microorganisms, suggesting active hydrolysis of plastic debris. The bacterial communities colonizing microplastics were significantly different in structure from those in the surrounding soil, plant litter and macroplastics. In addition, statistical analysis of differentially abundant OTUs showed that microplastics serve as a "special microbial accumulator" in farmland soil, enriching some taxa that degrade polyethylene, such as Actinobacteria, Bacteroidetes and Proteobacteria. Co-occurrence network analysis revealed that the biotic interactions between microorganisms on microplastics are as complex as those in soil, and Acidobacteria, Chloroflexi, Gemmatimonadetes, and Bacteroidetes are considered keystone species in bacterial communities. Collectively, the findings imply that microplastics acted as a distinct habitat for bacteria in farmland soil, which increases our understanding of microplastic pollution.

Zhang, P., et al. (2012). "Fabrication of quantum dots-encoded microbeads with a simple capillary fluidic device and their application for biomolecule detection." Journal of Colloid and Interface Science **385**(1): 8-14.

Monodispersed quantum dots (QDs)-encoded polymer microbeads were generated using a simple capillary fluidic device (CFD). The polymer and QDs solution was emulsified into monodispersed microdroplets by the CFD and obtained droplets were solidified via solvent evaporation. Polymer microbeads can be fabricated in a range of different sizes through changing the flow rates of the two immiscible phases, and have a highly narrow size distribution and uniform shape. QDs-encoding capacity of the microbeads was investigated through adjusting the concentrations and ratios of QDs in the polymer solution. Mono-color encoded microbeads with five intensities and a dual-color QDs-encoded 5 x 5 microbeads array were obtained, and the spectral profiles of the microbeads were examined by a fluorescent microscope coupled with a spectral imaging system. QDs-tagged microbeads prepared with this method were more stable than the porous beads swollen with QDs in the buffer with various pH and crosslinking chemicals. Finally, the application of such microbeads for biomolecule detection was demonstrated by conjugation of rabbit IgG molecules on the surface of the microbeads via carboxyl groups, which were then detected by fluorophores-labeled goat-anti-rabbit IgG antibodies. © 2012 Elsevier Inc.

Zhang, P., et al. (2018). "The variations in major aroma compounds in 'Olinda' Valencia orange (Citrus sinensis) during storage." Journal of Fruit Science **35**(7): 859-869.

This paper presents the results of studies conducted to determine the variation patterns of the major aroma compounds in Valencia orange cv. Olinda during 3 months of storage treated with different preservatives, i.e. 5 g bellkute, 5 ml prochloraz and 1.0 g 2,4-D dissolved in 20 litres of tap water. It was shown that a degradation turning point of monoterpenes, such as d-limonene and beta -myrcene occurred at 63 days of storage in fruits treated by preservatives or under cold storage. Apart from this, a mixed treatment with different preservatives combined with nano-plastic bagging maintained the basic sensory quality of Olinda orange fruits during storage and significantly inhibited the variations in the major aroma compounds during the first month of storage.

Zhang, P., et al. (2019). "Single and combined effects of microplastics and roxithromycin on <i>Daphnia magna</i>." Environmental science and pollution research international **26**(17): 17010-17020.

There is a rising concern about the pollution of microplastics (plastic particles < 5 mm) in water due to their physicochemical properties, especially their interaction with organic contaminants; however, such knowledge is still limited. The mass production and consumption of medication for the treatment of infectious diseases in human and animals have led to the ubiquity of antibiotics in the environment. We studied the single and joint effects of microplastics (1-μm and 10-μm polystyrene particles, PS) and roxithromycin (ROX) on Daphnia magna through the acute and sublethal toxicity tests. The 48-h median effective concentration (EC50) of 1-μm and 10-μm PS to D. magna was 66.97 mg/L and 199.94 mg/L, respectively, while the value of ROX was 20.28 mg/L. Malondialdehyde (MDA) levels and the activities of four enzymatic biomarkers, including superoxide dismutase (SOD), catalase (CAT), glutathione peroxidase (GPx), and glutathione S-transferase (GST), were further detected to assess the oxidative stress caused in D. magna caused. The results showed that 48-h exposure to PS (0.1 mg/L) or ROX (0.01 mg/L) alone activated the activities of CAT and GST and MDA levels. When compared with the ROX alone, the responses of GPx and MDA in D. magna co-exposed to 1-μm PS were significantly decreased, while co-exposure to 10-μm PS significantly decreased the responses of GST and MDA. Furthermore, the integrated biomarker response version 2 (IBRv2) analysis revealed that co-exposure to 1-μm PS and ROX led to the strongest biological responses in D. magna. Our findings underlined that microplastics should be a concern when they interact with the co-existence of pollutants in the aquatic environment.

Zhang, Q., et al. (2017). "A double-label time-resolved fluorescent strip for rapidly quantitative detection of carbofuran residues in agro-products." Food Chemistry **231**: 295-300.

A rapid and quantitative time-resolved fluorescent immunochromatographic assay (TRFICA) for detecting carbofuran residues in agro-products was reported in this paper. This assay was developed based on double-label immunoprobes, one of which was a carbofuran-specific antibody coupled with europium microbeads for the test (T) line signal while the other was mouse IgG coupled with europium microbeads for the control (C) line signal. Quantitative relationships between carbofuran concentrations and T/C ratios were established to determine the analyte concentration. To increase assay accuracy, four standard curves were established for the agro-products (green bean, cabbage, apple, and pear). The limits of detection (LODs) ranged from 0.04 to 0.76 mg L⁻¹. The spiked recoveries of carbofuran in the agro-products were in the range of 81-103%, which was in good agreement with a standard HPLC method. Therefore, we provided a new and reliable method for determination of N-methylcarbamate pesticide carbofuran residues in agro-products including vegetables and fruits. Copyright © 2017

Zhang, Q., et al. (2018). "The combined toxicity effect of nanoplastics and glyphosate on Microcystis aeruginosa growth." Environmental Pollution **243**: 1106-1112.

Waste plastics can be degraded to nanoplastics (NPs, diameter<1 μm) by natural forces. NPs not only directly affect aquatic organisms but also adsorb other pollutants, causing combined pollution. Glyphosate is one of the most widely used herbicides and is commonly monitored in freshwater systems. In this study, the effects of the combined toxicity of polystyrene cationic amino-modified nanoparticles (nPS-NH 2) and glyphosate on a blue-green alga, Microcystis aeruginosa , were investigated. Our results demonstrated that 5 mg/L glyphosate had a strong inhibitory effect on M. aeruginosa (the 96-h inhibitory rate was 27%), while 5 mg/L nPS-NH 2 had no apparent effect on the growth of M. aeruginosa. Interestingly, nPS-NH 2 combined with glyphosate showed antagonistic effects on the inhibition of algal growth because nPS-NH 2

displayed a strong adsorption capacity for glyphosate, which significantly alleviated the inhibitory effect of glyphosate on M. aeruginosa growth. However, the presence of glyphosate enhanced the stability of the dispersion system, which allowed more nPS-NH 2 to adsorb on the surface of M. aeruginosa and may result in greater enrichment of nPS-NH 2 in the food chain to show potential repercussions to human life. Our current study provides a new theoretical basis for the combined effects of NPs and pesticide pollution. Graphical abstract Image 1 Highlights • PS-NH 2 alleviated the inhibitory effect of glyphosate on M. aeruginosa growth. • PS-NH 2 displayed an excellent adsorption capacity for glyphosate. • Glyphosate induced more PS-NH 2 to adsorb on M. aeruginosa. [ABSTRACT FROM AUTHOR]

Zhang, Q., et al. (2019). "Concentrations and distribution of phthalate esters in the seamount area of the Tropical Western Pacific Ocean." Marine Pollution Bulletin **140**: 107-115.

A total of 14 phthalate esters (PAEs) were analysed by gas chromatography-mass spectrometry (GC-MS) to better understand its occurrence and distribution in seawater samples of M2 seamount in the Tropical Western Pacific Ocean (TWPO). The concentrations of SIGMAPAEs in the seawater ranged from 12.13ngL⁻¹ to 60.69ngL⁻¹ (av. 28.86ngL⁻¹), dominated by dibutyl phthalate (DBP), di(2-ethylhexyl) phthalate (DEHP) and diisobutyl phthalate (DiBP). SIGMAPAEs concentrations in the southwest of the seamount were lower than those in the northeast, with the minima appearing above the seamount summit. Current-seamount interaction was reckoned to be the principal driving factors in the distribution of PAEs. DEHP posed a medium risk in seawater, suggesting that marine plastic pollution has become an urgent environmental issue that calls for more attention and actions. Microplastics leaching and atmospheric deposition might be the potential sources of PAEs.

Zhang, R., et al. (2005). "Sequential injection chemiluminescence immunoassay for anionic surfactants using magnetic microbeads immobilized with an antibody." Talanta **68**(2): 231-238.

A rapid and sensitive immunoassay for the determination of linear alkylbenzene sulfonates (LAS) is described. The method involves a sequential injection analysis (SIA) system equipped with a chemiluminescence detector and a neodymium magnet. Magnetic beads, to which an anti-LAS monoclonal antibody was immobilized, were used as a solid support in an immunoassay. The introduction, trapping and release of the magnetic beads in the flow cell were controlled by means of a neodymium magnet and adjusting the flow of the carrier solution. The immunoassay was based on an indirect competitive immunoreaction of an anti-LAS monoclonal antibody on the magnetic beads and the LAS sample and horseradish peroxidase (HRP)-labeled LAS, and was based on the subsequent chemiluminscence reaction of HRP with hydrogen peroxide and p-iodophenol, in a luminol solution. The anti-LAS antibody was immobilized on the beads by coupling the antibody with the magnetic beads after activation of a carboxylate moiety on the surface of magnetic beads that had been coated with a polylactic acid film. The antibody immobilized magnetic beads were introduced, and trapped in the flow cell equipped with the neodymium magnet, an LAS solution containing HRP-labeled LAS at constant concentration and the luminol solution were sequentially introduced into the flow cell based on an SIA programmed sequence. Chemiluminescence emission was monitored by means of a photon counting unit located at the upper side of the flow cell by collecting the emitted light with a lens. A typical sigmoid calibration curve was obtained, when the logarithm of the concentration of LAS was plotted against the chemiluminescence intensity using various concentrations of standard LAS samples (0-500ppb) under optimum conditions. The time required for analysis is less than 15min.

Zhang, R., et al. (2007). "Sequential injection chemiluminescence immunoassay for nonionic surfactants by using magnetic microbeads." Analytica Chimica Acta **600**(1-2 SPEC. ISS.): 105-113.

A rapid and sensitive immunoassay based on a sequential injection analysis (SIA) using magnetic microbeads for the determination of alkylphenol polyethoxylates (APnEOs) is described. An SIA system was constructed from a syringe pump, a switching valve, a flow-through type immunoreaction cell equipped with a photon counting unit and a neodymium magnet. Magnetic beads, to which an anti-APnEOs monoclonal antibody was immobilized, were used as a solid support in an immunoassay. The introduction, trapping and release of the magnetic beads in and from the immunoreaction cell were controlled by means of a neodymium magnet and adjusting the flow of a carrier solution. The immunoassay was based on an indirect competitive immunoreaction of an anti-APnEOs monoclonal antibody immobilized on the magnetic beads with a sample APnEOs and a horseradish peroxidase (HRP)-labeled APnEOs in the same sample solution, and was based on the subsequent chemiluminscence reaction of HRP on the magnetic microbeads with a luminol solution containing hydrogen peroxide and p-iodophenol. The anti-APnEOs antibody was immobilized on the magnetic microbeads by coupling the antibody with the magnetic beads after activation of a carboxylate moiety on the surface of the magnetic beads that had been coated with a polylactic acid film. The antibody immobilized magnetic beads were introduced in the immunoreaction cell and trapped in it by the neodymium magnet, which was equipped beneath the immunoreaction cell. An APnEOs sample solution containing the HRP-labeled APnEOs at a constant concentration, and a luminol solution containing hydrogen peroxide and p-iodophenol were sequentially introduced into the immunoreaction cell, according to an SIA programmed sequence. Chemiluminescence emission was monitored by means of a photon counting unit located at the upper side of the immunoreaction cell by collecting the emitted light with a lens. A typical sigmoidal calibration curve was obtained, when the logarithm of the concentration of APnEOs was plotted against the chemiluminescence intensity as the number of photons in 100 ms using standard APnEOs sample solutions at various concentrations (0-1000 ppb) under optimum conditions. The lower detection limit defined as IC<inf>80</inf> is ca 10 ppb. The time required for analysis is less than 15 min per a sample. The present method was successfully applied to the determination of APnEOs in river water.

Zhang, S., et al. (2019). "Interactive effects of polystyrene microplastics and roxithromycin on bioaccumulation and biochemical status in the freshwater fish red tilapia (Oreochromis niloticus)." Science of the Total Environment **648**: 1431-1439.

There are hundreds of thousands metric tons of microplastics (MPs) present in aquatic environments. The MPs coexist with other pollutants in water bodies, such as pharmaceuticals, and may carry and transfer them into aquatic organisms, consequently causing unpredictable ecological risks. The purpose of the present study was to evaluate the effect of the presence of polystyrene microplastics (PS-MPs) on the distribution and bioaccumulation of roxithromycin (ROX) in freshwater fish red tilapia (Oreochromis niloticus) as well as their interactive biochemical effects in red tilapia. PS-MPs were found to enhance the bioaccumulation of ROX in fish tissues compared to ROX-alone exposure. In the treatment of PS-MPs (100 micro g L⁻¹) combined with ROX (50 micro g L⁻¹), the highest concentrations of ROX reached 39,672.9+or-6311.4, 1767.9+or-277.8, 2907.5+or-225.0, and 4307.1+or-186.5 micro g kg⁻¹ in gut, gills, brain, and liver, respectively. Furthermore, compared to the ROX alone, the neurotoxicity caused by ROX was alleviated due to the presence of MPs after 14 d of exposure. The activities of cytochrome P450 (CYP) enzymes [7-ethoxyresorufin O-deethylase (EROD) and 7-benzyloxy-4-trifluoromethyl-coumarin O-dibenzyloxylase (BFCOD)] in fish livers exposed to all co-exposure treatments exhibited great variability compared to ROX alone after 14 d of exposure, suggesting that the presence of MPs may affect the metabolism of ROX in tilapia. Compared with ROX alone, the superoxide dismutase (SOD) activity increased significantly, and malondialdehyde (MDA) contents decreased in the co-exposure treatments, showing that oxidative damage in situations of co-exposure to MPs and ROX was mitigated in fish livers after 14 d of exposure. Collectively, the presence of MPs could affect the fate and toxicity of other organic pollutants in fish. The results emphasize the importance to study the interactions between MPs and other organic pollutants in aquatic environments.

Zhang, S., et al. (2019). "Microplastics influence the adsorption and desorption characteristics of Cd in an agricultural soil." Journal of Hazardous Materials: 121775.

Microplastics (MPs) in terrestrial ecosystems particularly agroecosystem are attracting increasing attention worldwide. However, the influences of MPs on adsorption and desorption of contaminants in agricultural soils remain unknown. Here, batch experiments were conducted to study the effects of polyethylene MPs on Cd adsorption and desorption in a farmland soil under varying conditions. Both Cd adsorption and desorption in soils with or without MPs reached equilibrium within 120min. Cd adsorption kinetics followed the pseudo-second order model, and the adsorption isotherm fitted to the Langmuir model more precisely than the Freundlich model. Overall, addition of MPs decreased Cd adsorption but increased desorption, and the effects varied with MPs dose and particle size, and solution pH. MPs-induced decrease in Cd adsorption and increase in Cd desorption were more pronounced at higher MPs dose and larger particle size, but varied differently from solution pH. EDS analysis confirmed Cd adsorption on MPs surface. Both MPs before and after Cd adsorption showed similar XRD patterns, indicating MPs maintained a high crystallinity and no new crystalline phases formed. In conclusion, the input of MPs into soil might enhance the mobility of Cd via mitigating soil adsorbing capacity, thereby posing additional risks of Cd to agroecosystem.

Zhang, S., et al. (2019). "A novel fluorescent biosensor based on dendritic DNA nanostructure in combination with ligase reaction for ultrasensitive detection of DNA methylation." Journal of Nanobiotechnology **17**(1): 121.

BACKGROUND: DNA methylation detection is indispensable for the diagnosis and prognosis of various diseases including malignancies. Hence, it is crucial to develop a simple, sensitive, and specific detection strategy.

METHODS: A novel fluorescent biosensor was developed based on a simple dual signal amplification strategy using functional dendritic DNA nanostructure and signal-enriching polystyrene microbeads in combination with ligase detection reaction (LDR). Dendritic DNA self-assembled from Y-DNA and X-DNA through enzyme-free DNA catalysis of a hairpin structure, which was prevented from unwinding at high temperature by adding psoralen. Then dendritic DNA polymer labeled with fluorescent dye Cy5 was ligated with reporter probe into a conjugate. Avidin-labeled polystyrene microbeads were specifically bound to biotin-labeled capture probe, and hybridized with target sequence and dendritic DNA. LDR was triggered by adding Taq ligase.

When methylated cytosine existed, the capture probe and reporter probe labeled with fluorescent dye perfectly matched the target sequence, forming a stable duplex to generate a fluorescence signal. However, after bisulfite treatment, unmethylated cytosine was converted into uracil, resulting in a single base mismatch. No fluorescence signal was detected due to the absence of duplex.

RESULTS: The obtained dendritic DNA polymer had a large volume. This method was time-saving and low-cost. Under the optimal experimental conditions using avidin-labeled polystyrene microbeads, the fluorescence signal was amplified more obviously, and DNA methylation was quantified ultrasensitively and selectively. The detection range of this sensor was 10⁻¹⁵ to 10⁻⁷ M, and the limit of detection reached as low as 0.4 fM. The constructed biosensor was also successfully used to analyze actual samples.

CONCLUSION: This strategy has ultrasensitivity and high specificity for DNA methylation quantification, without requiring complex processes such as PCR and enzymatic digestion, which is thus of great value in tumor diagnosis and biomedical research.

Zhang, S., et al. (2020). "Distribution of low-density microplastics in the mollisol farmlands of northeast China." Science of the Total Environment **708**: 135091.

Plastic pollution, especially microplastic (MP), which is small in size (<5 mm) is one of the main environmental problems in global ecosystems and can cause harm to organisms. Low-density plastic has been widely used in farmlands, but the factors that influence Low-density microplastic (LDMP) distribution are still not clear. In this study, both field investigations at small and large scales and laboratory simulations, and both geostatistics and classical statistics were used to examine LDMP distributions and the main driving factors in farmland soils. The results showed the following. (1) Only polyethylene (PE) of LDMP was found in farmland. (2) The means of LDMP weight content (LDMP-W), LDMP abundance (LDMP-AB) and LDMP area content (LDMP-A) were 0.27 mg kg⁻¹, 107 N kg⁻¹ and 12.6 mm² kg⁻¹ in mollisol farmlands, respectively. (3) LDMPs were positively correlated with macroplastics (MAP) at the large scale, while any correlations were not obvious at small scales. (4) LDMPs were not only transported by surface soil-water loss (>96%) but were also transported by infiltration through soil pores (<4%). (5). LDMP loss increased with soil bulk density (BD) increasing, and low BD tends to increase LDMP loss by interflow. (6) LDMP distribution was not only influenced by water movement but also maybe influenced by microorganisms and crops. For LDMP pollution control, the focus on both surface soil-water loss and the infiltration processes is necessary, and a combination of the functions of microorganisms and crops probably accelerate LDMP decomposition in soils.

Zhang, S., et al. (2019). "Situation and harm of micro-nano plastic pollution in seafood." Journal of Food Safety and Quality **10**(9): 2689-2696.

In recent years, the pollution of plastics to the marine environment is increasing. Among them, the damage caused by micro-nano plastic fragments to the marine environment and animal and plant communities has become a research hotspot in the international scientific community. Many commercially important ingredients and marine foods, such as crustaceans, bivalves and fish, are often contaminated with micro-nano plastics, while micro-nano particles are often adsorbed with toxic chemicals or pathogenic microorganisms. These micro-nano particles and harmful substances can be enriched in the human body through the food chain, posing a potential threat to food safety and human health. This paper reviewed the research results of micro-nano plastic pollution and its hazards in marine products in recent years, and provided reference for future research and food safety management. The future research of micro-nano

plastic pollution should focus on 3 aspects: first, the research methods needed to be innovative and standardized; second, micro-nano plastics needed to conduct comprehensive and in-depth research on human health hazards; third, strengthening research on prevention and control measures for micro-nano plastics to endanger food safety.

Zhang, S., et al. (2018). "Effects of micro-plastics on sulfamethoxazole (SMZ) residues in tilapia (Oreochromis niloticus) muscle." Journal of Ecology and Rural Environment **34**(9): 857-864.

Micro-plastics are widely distributed pollutants in China's water environment. Sulfamethoxazole (SMZ) is frequently-used as antibiotics in aquaculture. However, the effect of micro-plastics on SMZ residues in tilapia muscle is unclear. The micro-plastics and sulfamethoxazole dosage in fishponds have been manipulated based on the ambient concentration, and the application of sulfonamides in aquaculture specified by SC/T 1084-2006. Three concentrations including: zero (NP), low (LP) and high (HP) micro-plastics in fishponds; and four doses of SMZ [zero (NS), low (LS), medium (MS) and high (HS)] in forages were fabricated. For understanding the effect of micro-plastics on SMZ residues in tilapia (Oreochromis niloticus) muscle, an 8-weeks breeding experiment was conducted. Tilapia was fed in the first four weeks on a SMZ diet, followed by non SMZ diet for the next four weeks. SMZ content in fish meat was determined during the fourth, sixth and eighth weeks. The fourth week's results of SMZ residue in fish meat reveal that environmental microplastics could significantly reduce the residual value of SMZ in fish-meat. Single factor analysis of variance for the residual value of SMZ in fish meat at the 4th, 6th and 8th weeks, reveal that after the 4th week, all micro-plastic exposure groups at different SMZ dosage diets were significantly lower than those in the non-micro-plastic groups (P<0.05), and there was no significant differences between the micro-plastic concentrations (P>0.05). After the 6th week, only HP and NP groups with MS diet had significant differences (P<0.05), and no significant difference was found in other SMZ feed groups of different micro-plastic treatments (P>0.05). Similarly, the results from the 8th week, show that there was no significant difference in all groups fed on SMZ diet for the different micro-plastics treatments (P>0.05). In conclusion, the findings indicate that the effect of micro-plastics on sulfamethoxazole residues in fish-meat is limited by sulfamethoxazole dosage.

Zhang, S., et al. (2019). "Microplastics in the environment: A review of analytical methods, distribution, and biological effects." TrAC - Trends in Analytical Chemistry **111**: 62-72.

Microplastics (MP) (<5 mm) are crucial pollution which are widely distributes in the environment. Recently, the studies of MP have increased rapidly due to increasing awareness of the potential and growing risks of biological effects during storage and disposal. However, due to limitations in analytical methods and the methods of environmental risk assessment, the distribution and biological effects of MP are still debatable issues. To clarify the potentially environmental and biological impacts of MP in the consecutive environment, (1) analytical methods to assess MP, (2) environmental transportation and distribution of MP and (3) the effects of MP on biota, including the additives and sorption-desorption of MP in both terrestrial ecosystem and aquatic ecosystems were summarized. Based on the reviewed publications, we propose considerations for addressing the insufficiencies of analytical methods, distribution and biological effects of MP in ecosystems so we can adequately safeguard global ecosystems. Zhang, S., et al. (2018). "A simple method for the extraction and identification of light density microplastics from soil." Science of the Total Environment **616-617**: 1056-1065.

This article introduces a simple and cost-saving method developed to extract, distinguish and

quantify light density microplastics of polyethylene (PE) and polypropylene (PP) in soil. A floatation method using distilled water was used to extract the light density microplastics from soil samples. Microplastics and impurities were identified using a heating method (3-5s at 130degreeC). The number and size of particles were determined using a camera (Leica DFC 425) connected to a microscope (Leica wild M3C, Type S, simple light, 6.4x). Quantification of the microplastics was conducted using a developed model.

Zhang, W., et al. (2020). "Transcriptional response provides insights into the effect of chronic polystyrene nanoplastic exposure on Daphnia pulex." Chemosphere **238**: 124563.

Nanoplastic pollution is widespread and persistent across global water systems and can cause a negative effect on aquatic organisms, especially the zooplankter which is the keystone of the food chain. The present study uses RNA sequencing to assess the global change in gene expression caused by 21 days of exposure to 75nm polystyrene (PS) nanoplastics on Daphnia pulex, a model organism for ecotoxicity. With the threshold value at P value<0.05 and fold change >2, 244 differentially expressed genes were obtained. Combined with real-time PCR validation of several selected genes, our results indicated that a distinct expression profile of key genes, including downregulated trehalose transporter, trehalose 6-phosphate synthase/phosphatase, chitinase and cathepsin-L as well as upregulated doublesex 1 and doublesex and mab-3 related transcription factor-like protein, contributed to the toxic effects of chronic nanoplastic exposure on Daphnia, such as slowed growth, subdued reproductive ability and reproductive pattern shifting. Our study also showed that chronic exposure to nanoplastic changed the sex ratio of D. pulex neonates. By integrating the gene expression pattern in an important model organism, this study gained insight into the molecular mechanisms of the toxic effect of chronic PS nanoplastic exposure on D. pulex, which may also extend to other nanoplastics or aquatic animals.

Zhang, W., et al. (2015). "Persistent organic pollutants carried on plastic resin pellets from two beaches in China." Marine Pollution Bulletin **99**(1-2): 28-34.

Microplastics provide a mechanism for the long-range transport of hydrophobic chemical contaminants to remote coastal and marine locations. In this study, plastic resin pellets were collected from Zhengmingsi Beach and Dongshan Beach in China. The collected pellets were analyzed for PAHs, PCBs, HCHs, DDTs, chlordane, heptachlor, endosulfan, aldrin, dieldrin and endrin. The total concentration of PCBs ranged from 34.7-213.7 ng g(-1) and from 21.5-323.2 ng g(-1) in plastic resin pellets for Zhengmingsi Beach and Dongshan Beach respectively. The highest concentrations of PCBs were observed for congeners 44, 110, 138, 155 and 200. The total concentration of PAHs ranged from 136.3-1586.9 ng g(-1) and from 397.6-2384.2 ng g(-1) in the plastic pellets, whereas DDTs concentration ranged from 1.2-101.5 ng g(-1) and from 1.5-127.0 ng g(-1) for the two beaches. The elevated concentrations of pollutants appear to be related to extensive industrial development, agricultural activity and the use of coal in the area.

Zhang, W., et al. (2019). "The mechanism for adsorption of Cr(VI) ions by PE microplastics in ternary system of natural water environment." Environmental Pollution: 113440.

More attention was paid to the attachment between microplastics and environmental pollutants. The adsorption performance of Polyethylene (PE) beads (a typical type of microplastics) and Cr(VI) ions with the existence of sodium dodecyl benzene sulfonate (SDBS) was investigated in this paper. The adsorption experiments of Cr(VI) ions by PE microplastics were conducted at different conditions, i.e. PE doses, pH and SDBS concentrations, respectively. The adsorption capability of Cr(VI) ions was increased from 0.39 to 1.36mgg⁻¹

when the dosage of PE microplastics was increased from 2 to 14gL⁻¹ at pH of 5 with addition of SDBS, compared with increasing adsorption capability from 0.03 to 0.32mgg⁻¹ without addition of SDBS. The pH would influence the adsorption capability with and without the addition of SDBS. When the pH was less than 6, the adsorption capability of Cr(VI) would be promoted by the addition of SDBS; however, there was a contrast tendency when the pH was more than 6, which was attributed to that SDBS would compete with CrO₄²⁻ for occupying the adsorption sites of PE microplastic. The SDBS concentration would affect the adsorption performance of Cr(VI) ions onto PE microplastics. The peak of the adsorption capacity was at SDBS concentration between 1 and 1.5mM. This research would provide a basis for investigating the influence of SDBS on adsorption performance of heavy metal by PE microplastics to simulate the surface attachment model of those three kinds of pollutants.

Zhang, W., et al. (2017). "Microplastic pollution in the surface waters of the Bohai Sea, China." Environmental Pollution **231**(Pt 1): 541-548.

The ubiquitous presence and persistency of microplastics in aquatic environments is of particular concern because these pollutants represent an increasing threat to marine organisms and ecosystems. An identification of the patterns of microplastic distribution will help to understand the scale of their potential effect on the environment and on organisms. In this study, the occurrence and distribution of microplastics in the Bohai Sea are reported for the first time. We sampled floating microplastics at 11 stations in the Bohai Sea using a 330 mum trawling net in August 2016. The abundance, composition, size, shape and color of collected debris samples were analyzed after pretreatment. The average microplastic concentration was 0.33 +/- 0.34 particles/m³. Micro-Fourier transform infrared spectroscopy analysis showed that the main types of microplastics were polyethylene, polypropylene, and polystyrene. As the size of the plastics decreased, the percentage of polypropylene increased, whereas the percentages of polyethylene and polystyrene decreased. Plastic fragments, lines, and films accounted for most of the collected samples. Accumulation at some stations could be associated with transport and retention mechanisms that are linked to wind and the dynamics of the rim current, as well as different sources of the plastics.

Zhang, X., et al. (2018). "A system to monitor statin-induced myopathy in individual engineered skeletal muscle myobundles." Lab on a Chip **18**(18): 2787-2796.

Microphysiological tissue engineering models of human skeletal muscle (myobundles) provide a platform to investigate the mechanism of muscle diseases and to study the response to drugs and toxins in vitro. To examine the dynamic response to drugs, which often take several days to induce responses, we developed a system to monitor the contractile force of the same human skeletal muscle myobundles over time before and after treatment with drugs. Myobundles were formed in series with Ecoflex films (platinum-catalyzed silicones) with embedded microbeads. The displacement of the microbeads in Ecoflex exhibited a linear relation between muscle force production and Ecoflex film stretch. Forces measured with the microbeads embedded in Ecoflex agreed well with simultaneous measurements with a force transducer. Application of the Hill model for the myobundles showed that the Ecoflex affected the magnitude of the response, but not the kinetics. After continuous exposure to 100 nM cerivastatin, both active and passive forces were reduced relative to controls after 2-4 days. The decline in force was associated with a decline in the muscle myofiber organization. The inhibitory effect of cerivastatin was reduced when 0.1-1 mM mevalonate was added with cerivastatin. Although addition of co-enzyme Q10 with cerivastatin inhibited degradation of sarcomeric alpha-actinin (SAA) in myoblasts, the contractile force still declined, suggesting that statin-induced myopathy was related to mevalonate pathway but the addition of co-enzyme Q10 was insufficient to overcome the effect of statins on the mevalonate pathway. Thus, cerivastatin rapidly induces myopathy which can be reversds with mevalonate but not co-enzyme Q10.

Zhang, X., et al. (2015). "Rare Earth Ion Mediated Fluorescence Accumulation on a Single Microbead: An Ultrasensitive Strategy for the Detection of Protein Kinase Activity at the Single-Cell Level." Angewandte Chemie. International Ed. in English **54**(50): 15186-15190.

A single microbead-based fluorescence imaging (SBFI) strategy that enables detection of protein kinase activity from single cell lysates is reported. We systematically investigated the ability of various rare earth (RE) ions, immobilized on the microbead, for specific capturing of kinase-induced phosphopeptides, and Dy(3+) was found to be the most prominent one. Through the efficient concentration of kinase-induced fluorescent phosphopeptides on a Dy(3+) -functionalized single microbead, kinase activity can be detected and quantified by reading the fluorescence on the microbead with a confocal fluorescence microscope. Owing to the extremely specific recognition of Dy(3+) towards phosphopeptides and the highly-concentrated fluorescence accumulation on only one microbead, ultrahigh sensitivity has been achieved for the SBFI strategy which allows direct kinase analysis at the single-cell level.

Zhang, X., et al. (2019). "Rapid fingerprinting of source and environmental microplastics using direct analysis in real time-high resolution mass spectrometry." Analytica Chimica Acta.

Microplastics are ubiquitous in the aquatic and terrestrial environment. To prevent further contamination, methods to determine their sources are needed. Techniques to quantify and characterize microplastics in the environment are still evolving for polymers and the additives and leachable substances embedded therein, which constitute the "chemical fingerprint" of an environmental microplastic. There is a critical need for analytical methods that yield such diagnostic information on environmental microplastics that enables identification of their composition and sources of pollution. This study reports on a novel approach for rapid fingerprinting of environmental microplastics and the screening of additives using Direct Analysis in Real Time (DART)-high resolution mass spectrometry. A variety of plastic samples were investigated, including virgin pre-production pellets, microbeads from personal care products, microplastics found in the aquatic environment, and synthetic fibers. The resulting mass spectra display ~10,000 discrete peaks, corresponding to plastic additives released by thermal desorption and polymer degradation products generated by pyrolysis. These were used to characterize differences among plastic types, microplastic source materials, and environmental samples. Multivariate statistics and elemental composition analysis approaches were applied to analyze fingerprints from the mass spectra. This promising analytical approach is sensitive, (potentially) high-throughput, and can aid in the elucidation of possible sources of microplastics and perhaps eventually to the analysis of bulk environmental samples for plastics. Zhang, X. and G. A. Truskey (2017). "In situ monitoring of engineering muscle to assess myopathy." Tissue Engineering - Part A **23 (Supplement 1)**: S117.

Tissue engineered human skeletal muscle provides a new platform to model muscle diseases and to study the muscle function in response to drugs and toxins in vitro [Stem Cell Research and Therapy, 4(1): S10 (2013)]. In this work, we developed a novel in situ system to monitor the muscle force with higher throughput and low cost. Myobundles were fabricated from human myoblasts using a hydrogel molding technique. PDMS molds with four seeding chamber were designed to fabricate multi-myobundles array. Each myobundle was independently bonded in series with an ecoflex (platinum-catalyzed silicone) film containing beads (53-63mm). Then force generation of myo-bundles in the frame was obtained from mapping the displacement of the beads and the measured elastic modulus of ecoflex membrane. Myobundle contractile forces measured with the microbeads em-bedded in ecoflex agreed well with simultaneous measurements with a force transducer. This novel system was tested through monitoring the force change of myobundles treated with doxorubicin and cer-ivastatin. For doxorubicin (1mg/ml), the contractile force generation of myobundles in all groups were maintained or increased in first three days after shifting to differentiation media (then doxorubicin was added) and this trend was maintained for another 5 days in control groups. In contrast, the tetanus force for myobundles treated with doxorubicin continuously dropped from 5 day onward. The force declines after day4 of continuous exposure to 100 nM cerivastatin and the inhibitory effect of cerivastatin could be eliminated by incubation with 0.3mM mevalonate. This method opens new possibilities for investigating the mechanical stresses of muscle.

Zhang, X., et al. (2015). "Graphene oxide caged in cellulose microbeads for removal of malachite green dye from aqueous solution." Journal of Colloid and Interface Science **437**: 277-282.

A simple sol-gel method using non-toxic and cost-effective precursors has been developed to prepare graphene oxide (GO)/cellulose bead (GOCB) composites for removal of dye pollutants. Taking advantage of the combined benefits of GO and cellulose, the prepared GOCB composites exhibit excellent removal efficiency towards malachite green (>96%) and can be reused for over 5 times through simple filtration method. The high-decontamination performance of the GOCB system is strongly dependent on encapsulation amount of GO, temperature and pH value. In addition, the adsorption behavior of this new adsorbent fits well with the Langmuir isotherm and pseudo-second-order kinetic model.

Zhang, X., et al. (2018). "Sorption of three synthetic musks by microplastics." Marine Pollution Bulletin **126**: 606-609.

Microplastics and synthetic musks (SMs) are two typical organic pollutants in the marine environment. In this study, the sorption of three SMs to microplastics in a simulated seawater environment was examined. Tonalide (AHTN), musk xylene (MX), and musk ketone (MK) were the musks investigated, while polypropylene (PP) was used as the microplastic. It was found that the equilibrium sorption time was about 10h and the adsorption kinetics model conformed to a Lagergren adsorption model. The adsorption capacity increased with decreasing particle size. Adsorption reached a peak at 25degreeC, and the adsorption capacity was not sensitive to the concentration of sodium chloride. There is a need for more research and monitoring of microplastics in the marine environment due to their strong ability to absorb organic pollutants.

Zhang, X., et al. (2019). "Sorption of 3,6-dibromocarbazole and 1,3,6,8-tetrabromocarbazole by microplastics." Marine Pollution Bulletin **138**: 458-463.

Microplastics and organic pollutants are typical contaminants in the marine environment. However, little is known about their interactions. In this study, the sorption of 3,6-Dibromocarbazole(3,6-BCZ) and 1,3,6,8-Tetrabromocarbazole (1,3,6,8-BCZ) by Polypropylene microplastic in simulated seawater was studied. Factors, including particle size, salinity and concentration, were investigated, and the experimental results were simulated using a mathematical model.

Zhang, X., et al. (2011). "Macrophages, rather than T and B cells are principal immunostimulatory target cells of Lycium barbarum L. polysaccharide LBPF4-OL. (Special Issue: Immunomodulators.)." Journal of Ethnopharmacology **136**(3): 465-472.

Aim of the study: Lycium barbarum L. is a renowned Yin strengthening agent in traditional Chinese medicine. Lycium barbarum L. polysaccharide-protein complex is well-known for its immunoregulatory and antitumor effects. LBPF4-OL is the glycan part of Lycium barbarum L. polysaccharide-protein complex fraction 4 (LBPF4). LBPF4-OL's active contribution in LBPF4 is still blank. In the study, we enrich the polysaccharide part of Lycium barbarum L. polysaccharide-protein complex, and investigate its immunostimulatory effects on mouse spleen cells, T cells, B cells and macrophages. Materials and methods: Balb/C mice were used in vitro and in vivo studies. In in vitro study, lymphocyte proliferations were analyzed with ³H-TdR incorporation method. Miltenyi MicroBeads were used in the purification of lymphocytes. Activation of T and B cells was analyzed by flow cytometry. In order to obtain the peritoneal macrophages, mice were injected i.p. with 1 mL of sodium thioglycollate 3 days prior to killing. Spleen cells were stimulated with LBPF4-OL and cytokine concentrations in the supernatants were determined by multiplex bead analysis. In in vivo study, mice were injected i.p. with 1 mL of normal saline or 100 micro g/mL LBPF4-OL daily for 6 days. Peritoneal macrophage functions were analyzed by enzyme-linked immunosorbent assay and flow cytometry assay.

Zhang, Y., et al. (2014). "A duplex recombinant viral nucleoprotein microbead immunoassay for simultaneous detection of seroresponses to human respiratory syncytial virus and metapneumovirus infections." Journal of Virological Methods **206**: 55-62.

Serologic diagnosis of human respiratory syncytial virus (hRSV) and human metapneumovirus (hMPV) infections has been shown to complement virus detection methods in epidemiologic studies. Enzyme immunoassays (EIAs) using cultured virus lysate antigens are often used to diagnose infection by demonstration of a >=4-fold rises in antibody titer between acute and convalescent serum pairs. In this study, hRSV and hMPV nucleocapsid (recN) proteins were expressed in a baculovirus system and their performance compared with virus culture lysate antigen in EIAs using paired serum specimens collected from symptomatic children. The recN proteins were also used to develop a duplex assay based on the Luminex microbead-based suspension array technology, where diagnostic rises in antibody levels could be determined simultaneously at a single serum dilution. Antibody levels measured by the recN and viral lysate EIAs correlated moderately (hRSV, r(2)=0.72; hMPV, r(2)=0.76); the recN EIAs identified correctly 35 of 37 (94.6%) and 48 of 50 (96%) serum pairs showing diagnostic antibody rises by viral lysate EIAs. Purified recN proteins were then coupled to microbeads and serum pairs were tested at a single dilution on a Luminex MAGPIX() analyzer. The duplex recN assay identified correctly 33 of 39 (85%) and 41 of 47 (86.7%) serum pairs showing diagnostic rises to hRSV and hMPV, respectively. The recN assay permits simultaneous testing for acute hRSV and hMPV infections and offers a platform for expanded multiplexing of other respiratory virus assays.

Zhang, Y., et al. (2019). "Importance of atmospheric transport for microplastics deposited in remote areas." Environmental Pollution **254**(Pt A): 112953.

Atmospheric transport is an important pathway for the deposition of micro- and nano-plastics in remote areas. However, the sources and fate of atmospheric microplastics remain poorly understood. A study on atmospheric transport and deposition in the Pyrenean Mountains highlights the movement of microplastics away from known sources (cities, agriculture, and industry) into remote areas. Following this first evidence of atmospheric microplastic deposition in a pristine location, it is necessary to reconsider previous studies on atmospheric microplastic

deposition and behavior in remote areas.

Zhang, Y. J., et al. (2017). "[Research on the negative immune regulation of NK cells in patients with primary immune thrombocytopenia]." Chung-Hua Hsueh Yeh Hsueh Tsa Chih: Chinese Journal of Hematology **38**(5): 399-403.

Objective: To investigate the levels of NK cells and their relevant cytokines (IL-10, TGF-beta and IFN-gamma) in patients with primary immune thrombocytopenia (ITP) . Methods: All samples were obtained from 42 patients (22 newly diagnosed and 20 in remission) and 20 healthy volunteers. The levels of IL-10 and IFN-gamma in blood serum were detected by enzyme-linked immunosorbent assay (ELISA) . The percentage of CD3(-) CD56(+) NK cell, CD3(-) CD56(bright) CD16(-) NK cell, CD3(-) CD56(dim) CD16(+) NK cell in peripheral blood lymphocyte were detected by flow cytometry. The NK cells were isolated by immunomagnetic microbeads. The mRNA expression levels of IL-10, TGF-beta, and IFN-gamma in NK cells were detected by real-time fluorescent quantitative PCR. Correlation between the above measured results was analyzed. Results: 1 The blood serum level of IFN-gamma in newly diagnosed ITP patients [(653.0+/-221.6) ng/L] was higher than that in remission ITP patients [(484.4+/-219.5) ng/L] and healthy control [(390.9+/-253.5) ng/L] (P=0.022, P=0.001) . The blood serum level of IL-10 in newly diagnosed ITP patients was lower than that in healthy control [(52.09+/-26.66) ng/L vs (79.44+/-38.43) ng/L, P=0.007]. 2The percentage of NK cell in newly diagnosed and remission ITP patients [(9.53+/-3.93) %, (9.03+/-3.78) %] were significantly lower than that in healthy control [(13.72+/-7.42) %] (P=0.013, P=0.007) . The ratio of CD3(-) CD56(bright) CD16(-) NK cell/total NK cells in newly diagnosed ITP patients was higher than that in healthy control [(6.85+/-4.43) % vs (4.05+/-2.81) %, P=0.032]. The ratio of CD3(-)CD56(dim) CD16(-) NK cell/total NK cells in newly diagnosed ITP patients was lower than that in healthy control [(93.14+/-4.43) % vs (95.94+/-2.81) %, P=0.032]. 3 There was no significant difference in the mRNA expression level of IFN-gamma in NK cells of ITP patients and healthy control (all P>0.05) . The mRNA expression levels of IL-10 and TGF-beta in NK cells in newly diagnosed ITP patients were significantly higher than that in healthy control (1.82+/-1.32 vs 1.02+/-1.03, P=0.023; 2.80+/-2.31 vs 1.46+/-1.37, P=0.028) . The ratio of CD3(-)CD56(bright) CD16(-) NK cell/total NK cells was positively correlated with the mRNA expression levels of IL-10, TGF-beta in NK cells (r=0.424, P=0.001; r=0.432, P<0.001) . Conclusion: NK cells may compensate for the deficiency of the number by enhancing the secretion of negative regulation cytokines, acting as "protective" roles in the disease.

Zhang, Y. X., et al. (2012). "Target cells and binding sites for immunomodulatory action of Lycium barbarum polysaccharides LBPF4-OL." Zhongguo Yaolixue yu Dulixue Zazhi - Chinese Journal of Pharmacology and Toxicology **26**(5): 715-716.

AIM Lycium barbarum L. is a renowned Yin strengthening agent in traditional Chinese medicine. Lycium barbarum L. polysaccharide-protein complex is well-known for its immunoregulatory and antitumor effects. LBPF4-OL is the glycan part of Lycium barbarum L. polysaccharide-protein complex fraction 4 (LBPF4). The purpose of this study was to identify the immune target cell and binding site of LBPF4-OL. METHODS Miltenyi MicroBeads were used to purify the lymphocyte. Lymphocyte proliferation was analyzed with [super(3)H] TdR incorporation method. Activation of T and B cells was analyzed by flow cytometry (FCM). Cytokine concentration was determined by multiplex bead analysis or ELISA. TLR4 gene mutation mice C3H/HeJ, antibody block and biolayer interferometry (BLI) were used to verify the binding sites. RESULTS Lymphocyte proliferation assay indicated that LBPF4-OL could not induce T and B lymphocytes proliferation spontaneously, but B cell proliferation could take place in the presence of activated macro-phages or LPS. FCM analysis found that LBPF4-OL could not activate T and B cells when co-cultured with splenocyte for 24 h in vitro. But it significantly prompted CD86 and MHC-II molecules expression on macrophage in vivo. ELISA assay showed that LBPF4-OL greatly increased the levels of TNF- alpha and IL-1 beta on macrophage supernatant. Multiplex bead analysis showed that LBPF4-OL induced IL-6, IL-8, IL-10 and TNF- alpha production in a concentration dependent manner, but had no effect on IL-2 and IL-13 production. The possible binding sits of CD19 on B lymphocyte, TLR4, TLR2 and CR3 on macrophages were studied, and TLR4 as the binding site of LBPF4-OL was further verified in C3H/HeJ mice. Results showed that LBPF4-OL obviously induced the proliferation of splenocyte and the secretion of TNF- alpha and IL-1 beta in macrophage from wildtype mice C3H/HeN. But the proliferation of splenocyte from mutation mice C3H/HeJ reduced significantly. BLI results showed that LBPF4-OL could bind directly with TLR4 in vitro. CONCLUSION Both B lymphocytes and macrophage are target cells of LBPF4-OL, and TLR4 is one of the binding sites on macrophage.

Zhang, Z. Y. and J. M. Wu (2007). "[Anti-tumor effects induced by fusion of interleukin-18 gene transfected NCI-H460 lung cancer cell line with dendritic cells]." Chung-Hua Chung Liu Tsa Chih [Chinese Journal of Oncology] **29**(1): 17-20.

OBJECTIVE: To explore the anti-tumor effects induced by fusion of interleukin (IL)-18 gene transfected lung cancer cell line NCI-H460 cells with dendritic cells (DC).

METHODS: (1) DC were induced from human monocytes and fused with IL-18 transfected NCI-H460 cells. Fusion was selected using MACS microbeads. (2) Four groups (group GT, group PT, group NT and group BC) were set up. T cells activated by IL-18 gene transfected fusion or pcDNA3. 1 + vector transfected fusion and non-transfected fusion were taken as effetor cells. No effector cells was in group BC. Lactic dehydrogenase (LDH) method was used to evaluate the antitumor effect in vitro. (3) Tumor-bearing nude mice were inoculated with effector cells mentioned above. The tumor size and weight in the 4 groups were compared.

RESULTS: The killing rate in vitro of 3 groups were 53. 14% ,30. 10% and 31.49% , respectively. The tumor size and weight in the 3 groups were lower than group BC, among which group GT was the lowest.

CONCLUSION: Fusion of IL-18 gene transfected NCI-H460 lung cancer cells with dendritic cells can effectively induce anti-tumor immunity in the host.

Zhao, C., et al. (2019). "No-tillage reduces competition and enhances compensatory growth of maize (Zea mays L.) intercropped with pea (Pisum sativum L.)." Field Crops Research **243**(107611).

Compensatory growth is a mechanism that explains the recovery in stature and yield of a subordinate crop after the dominant competitor is harvested from an intercropping system. This mechanism might be affected by agronomic practices, particularly those related to the crop water supply in arid regions. The objective of this study was to evaluate the effects of tillage and irrigation practices on competition and compensatory growth in pea-maize intercropping systems at Wuwei station in northwest China from 2014 to 2016. The field experiment included two forms of tillage with plastic film (no-tillage, NT; conventional tillage CT) and three irrigation levels (450 mm, I1; 495 mm, I2; 540 mm, I3). As pea was planted first, it was the dominant competitor and caused greater suppression of maize when crops were grown under I1 > I2 > I3 levels in NT than at the corresponding irrigation levels in CT. Compensatory growth of maize after pea harvest was, on average, 8 to 16% greater in the NT than CT. Growing the intercropped maize strip under NT with plastic mulch was as effective as CT with plastic mulch to achieve a favorable yield outcome. However, the intercropped pea yield was 20-29% greater, with 0-5% more maize yield under deficit irrigation level (I1) and the land equivalent ratio was 3-15%

greater in NT than CT plots during this study. Yield gains were related to improved water use efficiency, which was 8 to 18% greater in the intercropping system under NT than CT management. We recommend the NT with plastic mulch method as a water-saving strategy that can sustain the productivity of maize-pea intercropping systems while reducing plastic pollution from agricultural activities in arid regions.

Zhao, D., et al. (2016). "Preparation and characterization of Ganoderma lucidum spores-loaded alginate microspheres by electrospraying." Materials Science & Engineering. C, Materials for Biological Applications **62**: 835-842.

Ganoderma lucidum spores (GLSs), popular functional food in preventive medicine, are susceptible to oxidative and acidic degradation during processing, storage and oral administration, resulting in the loss of sensory and nutritional qualities. The main objective of the study was to encapsulate the GLS in order to fully preserve the bioactivity of the ingredients as well as providing controlled and targeted delivery. Electrospraying was applied to prepare GLS-Alginate (GLS/A) micro beads in the current study. The size of GLS/A beads can be tailored by varying the applied voltage and drying processes. pH responsive release profiles of GLS/A beads were revealed from in vitro study in a simulated gastrointestinal environment: no release of GLS encapsulated beads in the simulated gastric fluid (pH of 1.8) was observed; while a rapid, size dependent release was found in the simulated intestinal solution (pH of 7.5). The release from smaller beads (e.g. 600 mum) was 1.5 times faster than that of larger beads (e.g. 2000 mum). In addition, the GLS release from freeze dried beads was almost 3 times faster than those of air and vacuum dried beads in the first 90 min. The present results illustrate the potential to protect GLS by encapsulation using electrospraying to achieve the controlled release of GLS ingredients. This will pave the way to develop effective GLS products with desirable bioactive components for healthcare applications.

Zhao, G., et al. (2015). "Large-scale expansion of Wharton's jelly-derived mesenchymal stem cells on gelatin microbeads, with retention of self-renewal and multipotency characteristics and the capacity for enhancing skin wound healing." Stem Cell Research & Therapy **6**: 38.

INTRODUCTION: Successful stem cell therapy relies on large-scale generation of stem cells and their maintenance in a proliferative multipotent state. This study aimed to establish a three-dimension culture system for large-scale generation of hWJ-MSC and investigated the self-renewal activity, genomic stability and multi-lineage differentiation potential of such hWJ-MSC in enhancing skin wound healing.

METHODS: hWJ-MSC were seeded on gelatin microbeads and cultured in spinning bottles (3D). Cell proliferation, karyotype analysis, surface marker expression, multipotent differentiation (adipogenic, chondrogenic, and osteogenic potentials), and expression of core transcription factors (OCT4, SOX2, NANOG, and C-MYC), as well as their efficacy in accelerating skin wound healing, were investigated and compared with those of hWJ-MSC derived from plate cultres (2D), using in vivo and in vitro experiments.

RESULTS: hWJ-MSC attached to and proliferated on gelatin microbeads in 3D cultures reaching a maximum of 1.1-1.30x10(7) cells on 0.5 g of microbeads by days 8-14; in contrast, hWJ-MSC derived from 2D cultures reached a maximum of 6.5 -11.5x10(5) cells per well in a 24-well plate by days 6-10. hWJ-MSC derived by 3D culture incorporated significantly more EdU ($P<0.05$) and had a significantly higher proliferation index ($P<0.05$) than those derived from 2D culture. Immunofluorescence staining, real-time PCR, flow cytometry analysis, and multipotency assays showed that hWJ-MSC derived from 3D culture retained MSC surface markers and multipotency potential similar to 2D culture-derived cells. 3D culture-derived hWJ-MSC also retained the

expression of core transcription factors at levels comparable to their 2D culture counterparts. Direct injection of hWJ-MSC derived from 3D or 2D cultures into animals exhibited similar efficacy in enhancing skin wound healing.
CONCLUSIONS: Thus, hWJ-MSC can be expanded markedly in gelatin microbeads, while retaining MSC surface marker expression, multipotent differential potential, and expression of core transcription factors. These cells also efficiently enhanced skin wound healing in vivo, in a manner comparable to that of hWJ-MSC obtained from 2D culture.

Zhao, J., et al. (2007). "Synthesis of Zn(II) ion-imprinted solid-phase extraction material and its analytical application." Analytica Chimica Acta **603**(1): 87-92.

Zn(II) ion-imprinted polymer materials used for solid-phase extraction (SPE) column were prepared by the copolymerization of 8-acryloyloxyquinoline (8-AOQ) monomer and a crosslinker ethylene glycol dimethacrylate (EGDMA) in the presence of 2,2'-azobisisobutyronitrile (AIBN) as an initiator. After removing Zn(II) ion from the polymer, molecularly imprinted polymers (MIPs) capable of selectively rebinding Zn(II) ion were obtained. The maximum adsorption capacity of Zn(II) on MIPs beads was about 3.9 mg g(-1). The effect of pH and flow rate for quantitative enrichment was also investigated. The Zn(II)-imprinted microbeads have a greater affinity for Zn(II) with respect to Cu(II), Co(II) and Ni(II) ions. A detection limit of 0.65 microg L(-1)(3sigma) and a relative standard deviation (R.S.D., n=7) of 2.9% were obtained. The MIPs-SPE preconcentration procedure showed a linear calibration curve within concentration range from 0.65 to 130 microg L(-1). Zn(II) ion-imprinted beads enabled the selective extraction of zinc ions from a complex matrix, and after 20 times of adsorption and desorption cycle, the recovery of adsorption capacity of Zn(II) on MIPs beads was only decreased 3.2%. The results suggested that these MIPs can be used several times without considerable loss of adsorption capacity.

Zhao, J. and Z. You (2016). "Using binary optical elements (BOEs) to generate rectangular spots for illumination in micro flow cytometer." Biomicrofluidics **10**(5): 054111.

This work introduces three rectangular quasi-flat-top spots, which are provided by binary optical elements (BOEs) and utilized for the illumination in a microflow cytometer. The three spots contain, respectively, one, two, and three rectangles (R1, R2, and R3). To test the performance of this mechanism, a microflow cytometer is established by integrating the BOEs and a three-dimensional hydrodynamic focusing chip. Through the experiments of detecting fluorescence microbeads, the three spots present good fluorescence coefficients of variation in comparison with those derived from commercial instruments. Benefiting from a high spatial resolution, when using R1 spot, the micro flow cytometer can perform a throughput as high as 20 000 events per second (eps). Illuminated by R2 or R3 spot, one bead emits fluorescence twice or thrice, thus the velocity can be measured in real time. Besides, the R3 spot provides a long-time exposure, which is conducive to improving fluorescence intensity and the measurement stability. In brief, using the spots shaped and homogenized by BOEs for illumination can increase the performance and the functionality of a micro flow cytometer.

Zhao, L., et al. (2017). "Transgenerational toxicity of nanopolystyrene particles in the range of micro g L⁻¹ in the nematode Caenorhabditis elegans." Environmental Science: Nano **4**(12): 2356-2366.

The potential toxicity of nanoplastics to environmental organisms has gradually received great attention recently. We employed the in vivo assay system of Caenorhabditis elegans to investigate the possible transgenerational toxicity of nanopolystyrene particles and the underlying cellular mechanisms. After prolonged exposure, we observed the toxicity of

nanopolystyrene particles at concentrations higher than 10 micro g L⁻¹. The transgenerational toxicity was further detected in nematodes exposed to nanopolystyrene particles at concentrations higher than 100 micro g L⁻¹. This observed transgenerational toxicity of nanopolystyrene particles might be mainly due to the translocation of nanopolystyrene particles into reproductive organs such as the gonad, which potentially in turn led to the transfer of nanopolystyrene particles to the next generation. Leachates from nanopolystyrene particles at concentrations in the range of micro g L⁻¹ did not contribute to the development of this transgenerational toxicity. Enhancement of intestinal permeability and extension of defecation cycle length provide the explanation for the observed accumulation and translocation of nanopolystyrene particles in reproductive organs. Therefore, our results demonstrate the potential transgenerational toxicity of nanopolystyrene particles in the range of micro g L⁻¹ in environmental organisms.

Zhao, L., et al. (2020). "Exposure to polyamide 66 microplastic leads to effects performance and microbial community structure of aerobic granular sludge." Ecotoxicology & Environmental Safety **190**: 110070.

Microplastic polyamide 66 (PA66) was used to explore its mechanism of influence on the contaminants removal from aerobic granular sludge (AGS) and the corresponding change to the microbial community.

Zhao, L., et al. (2011). "Osteogenic media and rhBMP-2-induced differentiation of umbilical cord mesenchymal stem cells encapsulated in alginate microbeads and integrated in an injectable calcium phosphate-chitosan fibrous scaffold." Tissue engineering. Part A. **17**(7-8): 969-979.

The need for bone tissue engineering has increased as the world population ages. The objectives of this study were to (1) develop a novel human umbilical cord mesenchymal stem cell (hUCMSC)-encapsulating, fiber-reinforced injectable calcium phosphate cement (CPCF) scaffold, and (2) investigate the effects of osteogenic media delivery, preosteodifferentiation, and bone morphogenetic protein-2 (BMP-2) delivery on hUCMSC osteodifferentiation inside CPCF for the first time. CPCF was developed using calcium phosphate powders, chitosan, and absorbable fibers. Four types of hUCMSC-encapsulating constructs were fabricated: control media in alginate hydrogel microbeads in CPCF; osteogenic media in microbeads; preosteodifferentiation; and recombinant human BMP-2 (rhBMP-2) in microbeads. The hUCMSCs inside CPCF maintained good viability, successfully differentiated into the osteogenic lineage, and synthesized bone minerals. The preosteodifferentiation method yielded high gene expressions of alkaline phosphatase, osteocalcin, collagen, and osterix, as well as alkaline phosphatase protein synthesis. The mineralization for the preosteodifferentiation constructs exceeded those of the rhBMP-2 group at 1-7 days, and was slightly lower than the rhBMP-2 group at 21 days. Mineralization of the rhBMP-2 group was 12-fold that of the control constructs at 21 days. In conclusion, although the BMP-2 delivery promoted osteodifferentiation, the preosteodifferentiation method and the ostegenic media method with hUCMSCs in CPCF were also promising for bone regeneration. hUCMSCs may be an effective alternative to the gold-standard bone marrow MSCs, which require an invasive procedure to harvest. The novel injectable stem cell-CPCF construct may be useful in minimally invasive and other orthopedic surgeries.

Zhao, M., et al. (2016). "Immunofluorescence chromatographic assay of tumor cells in dried blood spot." Cancer Research. Conference: 107th Annual Meeting of the American Association for Cancer Research, AACR **76**(14 Supplement).

Blood droplet, when desiccated on a surface, forms a ring-like deposit, akin to the coffee ring left after a coffee spill. When blood, coffee, or other aqueous suspensions of the colloidal particles, evaporate with contract line pinned on the underlying hydrophilic surface, a capillary force is generated by the evaporative flux, which drags nearly all the particles to the edge. As the evaporation extends, the volume of the droplet decreases, and the solgel transition occurs. The gelation gradually moves inward from the edge to the center, eventually immobilizes all particles, and develops the ring effect. Because smaller sized particles diffuse much more quickly and efficiently than the larger ones, smaller particles tend to preferentially accumulate on the rim, forming multilayered self-assembly. Contrarily, the majority of the larger particles congregate in the central area. This natural phenomenon simply presents a size-dependent chromatography of variously sized particles in solution. Separation of normal blood cells or break-free tumor cells has been widely utilized for blood disease diagnosis and cancer prognosis. Traditional preparation via blood smear and advanced separation by the external driving forces, e.g. centrifugation and powered microfluidics, could be limited by the technical difficulty, assay complexity, and cell integrity. Coffee-ring based blood cell separation and detection, namely dried spot biopsy, is however a handfree, cellharmless, spontaneous process. To perform a dried spot biopsy, 3x1 inch microscope slides were first cleaned to remove surface impurities and residues. 200 uL of freshly collected, anti-coagulated whole blood, bearing fluorescent microbeads (1 and 10 um sized) or prestained breast tumor cells (MDAMB231, ~15 um sized), was dispensed onto the slide and allowed to dry statically or acceleratedly on a moving stage at controlled temperature and humidity. Three hydrophilic coatings and five surfactants were examined to balance the outward capillary flow with the inward Marangoni flow for optimal coffee ring effect. It is demonstrated that two sizes of microbeads formed separate rings, a few hundreds of microns in average apart from each other, while tumor cells, acting differently, concentrated in the central area with random dispersion, probably because of the diversified cell sizes. The dried spot biopsy could have a potential for detecting blood borne biomarkers in the form of dried blood specimens that poses longer shelf life, less biohazardous risk, and easier transportation protocol than the liquid form. Additionally, specific cells of interest from microscopic regions of dried blood film can be retrieved by laser microdissection for downstream analyses. Particularly, this method could be valuable for use in low-resourced regions and countries.

Zhao, R. J., et al. (2018). "Property of filler-loaded magnetic ferrite from plastic waste bottle used to treat municipal domestic sewage." Environmental Technology **39**(12): 1607-1613.

The present work investigates the properties of self-made magnetic filler from plastic waste bottle and explores a new technology approach of waste plastic resource utilization. The magnetic filler was prepared by air plasma modification and loading magnetic ferrite on the plastic strip from waste plastic bottle. The surface properties of magnetic filler were characterized by Atomic Force Microscope (AFM), contact angle system and Fourier Transform Infrared (FTIR). AFM images of original and modified plastic strip showed that low-temperature plasma treatment markedly increased the surface roughness of plastic strip. The mean roughness (Ra) of plastic strip rose from 1.116 to 5.024 nm. FTIR spectra indicated that a lot of polar oxygenic groups were introduced onto the surface of plastic by plasma modification. Modification by low-temperature plasma increased the hydrophilicity of plastic strip surface. When treatment time is 40 s, water contact angle of plastic strip surface reduced from 78.2degree of original plastic strip to 25.3degree. When used in bioreactor, magnetic filler had very favorable microenvironment for microorganism growth. Magnetic filler was more efficient for removing chemical oxygen demand (COD) and [Formula: see text] in sewage than

nonmagnetic filler. The resource utilization of plastic wastes will become reality if the magnetic filler is applied widely.

Zhao, S., et al. (2019). "Analysis of suspended microplastics in the Changjiang Estuary: Implications for riverine plastic load to the ocean." Water Research **161**: 560-569.

The role of rivers as a major transport pathway for all sizes of plastic debris into the ocean is widely recognized. Global modelling studies ranked the Changjiang River as the largest contributor of plastic waste to the marine environment, but these estimates were based on insufficient empirical data. To better understand the role of rivers in delivering terrestrial plastic debris to the ocean, the spatial and temporal patterns of microplastics (MP) in the Changjiang Estuary (CE) and the East China Sea (ECS) were studied based on surface water samples in February, May, and July 2017. A total of 3225 MP (60-5000 mum) were identified by Fourier-transform infrared (FTIR) spectrometry. MP abundance in July was higher than in February and May due to higher river discharge. Density stratification in CE significantly influenced the surface MP abundances. A temporal accumulation zone within the river-sea interface for plastics was indicated by stations with apparently higher abundances in the river plume. Fibers were the most common MP (>80%) over three months. Small MP (<1000 mum) composed 75.0% of the total plastics on average. The average mass of MP was 0.000033 g/particle, which was two orders of magnitude lower than the empirical mass in literature. Without considering tidal effects, we estimate 16-20 trillion MP particles, weighing 537.6-905.9 tons, entered the sea through the surface water layer of the Changjiang River in 2017. These findings of this study provide reliable information on MP waste in a large river, which should be considered in further studies for estimating the riverine plastic loads. Zhao, S., et al. (2018). "Field-Based Evidence for Microplastic in Marine Aggregates and Mussels: Implications for Trophic Transfer." Environmental Science & Technology **52**(19): 11038.

Marine aggregates incorporate particles from the environment, including microplastic (MP). The characteristics of MP in aggregates and the role of aggregates in linking MP with marine organisms, however, are poorly understood. To address these issues, we collected aggregates and blue mussels, Mytulis edulis, at Avery Point, CT, and analyzed samples with microspectrometers. Results indicate that over 70% of aggregates sampled harbored MP (1290 ± 1510 particles/m3). Fifteen polymer types were identified, with polypropylene, polyester and synthetic-cellulose accounting for 44.7%, 21.2% and 10.6%, respectively, of the total MP count. Over 90% of MP in aggregates were ≤1000 μm, suggesting that aggregations are a sink for this size fraction. Although size, shape, and chemical type of MP captured by mussels were representative of those found in aggregates, differences in the sizes of MP in pseudofeces, feces and digestive gland/gut were found, suggesting size-dependent particle ingestion. Over 40% of the MP particles were either rejected in pseudofeces or egested in feces. Our results are the first to identify a connection between field-collected marine aggregates and bivalves, and indicate that aggregates may play an important role in removing MP from the ocean surface and facilitating their transfer to marine food webs.

Zhao, S., et al. (2015). "Microplastic in three urban estuaries, China." Environmental Pollution **206**: 597-604.

Estuarine Microplastics (MPs) are limited to know globally. By filtering subsurface water through 330 mum nets, MPs in Jiaojiang, Oujiang Estuaries were quantified, as well as that in Minjiang Estuary responding to Typhoon Soulik. Polymer matrix was analyzed by Raman spectroscopy.

MP (<5 mm) comprised more than 90% of total number plastics. The highest MPs density was found in Minjiang, following Jiaojiang and Oujiang. Fibers and granules were the primary shapes, with no pellets found. Colored MPs were the majority. The concentrations of suspended microplastics determine their bioavailability to low trophic organisms, and then possibly promoting the transfer of microplastic to higher trophic levels. Polypropylene and polyethylene were the prevalent types of MPs analyzed. Economic structures in urban estuaries influenced on MPs contamination levels. Typhoon didn't influence the suspended MP densities significantly. Our results provide basic information for better understanding suspended microplastics within urban estuaries and for managerial actions.

Zhao, S., et al. (2016). "Microscopic anthropogenic litter in terrestrial birds from Shanghai, China: not only plastics but also natural fibers." Science of the Total Environment **550**: 1110-1115.

The level of contamination by microscopic anthropogenic litter (0.5-5 mm) in terrestrial ecosystems is not well understood. After chemical digestion in 10% KOH, microscopic anthropogenic litter from the gastrointestinal tracts of 17 terrestrial birds was identified and categorized under a stereomicroscope based on its physical properties and melting tests. In total, 364 items from 16 birds were identified as microscopic anthropogenic litter, ranging in size from 0.5 to 8.5 mm. No relationship between plastic load and body condition was found. Natural fibers, plastic fibers and fragmented plastics represented, respectively, 37.4% (136 items), 54.9% (200 items) and 7.7% (28 items) of total litter items. Small sample sizes limited our ability to draw strong conclusions about the metabolism of natural fibers, but the decline in the proportion of natural fibers from the esophagus to stomach to intestine suggested that they may be digestible. Particles smaller than 5 mm represented more than 90% of the total number of pollutant items. Particles with colors in the mid-tones and fibrous shapes were overwhelmingly common particles. The results reflect pollution by microscopic anthropogenic litter in the terrestrial ecosystem of the study area. Microscopic natural fibers, which may disperse and adsorb chemical pollutants differently from microplastic and may pose an even greater risk, are in urgent need of further research.

Zhao, T., et al. (2019). "The interactions between micro polyvinyl chloride (mPVC) and marine dinoflagellate Karenia mikimotoi: The inhibition of growth, chlorophyll and photosynthetic efficiency." Environmental Pollution **247**: 883-889.

Microplastics pose a great threat to entire marine ecosystems, but little is known about their impacts on phytoplankton, especially for the harmful dinoflagellates. In this study, effects of micro polyvinyl chloride (mPVC) on the growth, chlorophyll content and photosynthetic efficiency of the dinoflagellate Karenia mikimotoi at different periods (0, 24, 48, 72 and 96 h) were assessed using gradient concentrations (0, 5, 25, 50 and 100 mg L−1) of mPVC with a size of 1 µm. PVC microplastics had dose-dependent adverse effects on K. mikimotoi growth, chlorophyll content and photosynthetic efficiency. The density of algal cell decreased with increasing mPVC concentrations and the highest inhibitory rate (IR) was 45.8% at 24 h under 100 mg L−1 of mPVC. The total chlorophyll content and chlorophyll content in a single algal cell decreased at 96 h and the ΦPSⅡ and Fv/Fm decreased 25.3% and 17.1%, respectively. The SEM images provided an intuitive visual method to observe the behaviors and interactions between microplastics and microalgae. It was found from the SEM images that microalgae was wrapped by microplastic beads. The physical blockage and aggregation were also responsible for the cytotoxicity of K. mikimotoi. Our study clarified that PVC microplastics can reduce algal growth, chlorophyll content and photosynthetic efficiency, and it is beneficial to evaluate the possible impact of plastics on aquatic ecosystems. Graphical abstract Image 104227 Highlights • The

interactions between mPVC and Karenia mikimotoi were investigated. • mPVC had toxic effects on Karenia mikimotoi. • The toxic effects depended on the exposure concentration and treatment time. • Physical blockage and aggregation were likely responsible for cytotoxicity. mPVC inhibited the growth, chlorophyll content and photosynthetic efficiency of the algae. The physical blockage and aggregation were responsible for the inhibition. [ABSTRACT FROM AUTHOR]

Zhao, W., et al. (2018). "Molecular distribution and compound-specific stable carbon isotopic composition of dicarboxylic acids, oxocarboxylic acids and α -dicarbonyls in PM 2.5 from Beijing, China." Atmospheric Chemistry and Physics **18**(4): 2749-2767.

This study investigates the seasonal variation, molecular distribution and stable carbon isotopic composition of diacids, oxocarboxylic acids and α-dicarbonyls to better understand the sources and formation processes of fine aerosols (PM2.5) in Beijing. The concentrations of total dicarboxylic acids varied from 110 to 2580 ng m^{-3}, whereas oxoacids (9.50–353 ng m^{-3}) and dicarbonyls (1.50–85.9 ng m^{-3}) were less abundant. Oxalic acid was found to be the most abundant individual species, followed by succinic acid or occasionally by terephthalic acid (tPh), a plastic waste burning tracer. Ambient concentrations of phthalic acid (37.9 ± 27.3 ng m^{-3}) and tPh (48.7 ± 51.1 ng m^{-3}) were larger in winter than in other seasons, illustrating that fossil fuel combustion and plastic waste incineration contribute more to wintertime aerosols. The year-round mass concentration ratios of malonic acid to succinic acid (C3 ⁄ C4) were relatively low by comparison with those in other urban aerosols and remote marine aerosols. The values were less than or equal to unity in Beijing, implying that the degree of photochemical formation of diacids in Beijing is insignificant. Moreover, strong correlation coefficients of major oxocarboxylic acids and α-dicarbonyls with nss-K+ suggest that biomass burning contributes significantly to these organic acids and related precursors. The mean δ13C value of succinic acid is the highest among all species, with values of −17.1 ± 3.9 ‰ (winter) and −17.1 ± 2.0 ‰ (spring), while malonic acid is more enriched in 13C than others in autumn (−17.6 ± 4.6 ‰) and summer (−18.7 ± 4.0 ‰). The δ13C values of major species in Beijing aerosols are generally lower than those in the western North Pacific atmosphere, the downwind region, which indicates that stable carbon isotopic compositions of diacids depend on their precursor sources in Beijing. Therefore, our study demonstrates that in addition to photochemical oxidation, high abundances of diacids, oxocarboxylic acids and α-dicarbonyls in Beijing are largely associated with anthropogenic primary emissions, such as biomass burning, fossil fuel combustion and plastic waste burning.

Zhao, W., et al. (2013). "An integrated microfluidic device for rapid serodiagnosis of amebiasis." Biomicrofluidics **7**(1): 11101.

A microfluidic device was successfully fabricated for the rapid serodiagnosis of amebiasis. A micro bead-based immunoassay was fabricated within integrated microfluidic chip to detect the antibody to Entamoeba histolytica in serum samples. In this assay, a recombinant fragment of C terminus of intermediate subunit of galactose and N-acetyl-D-galactosamine-inhibitable lectin of Entamoeba histolytica (C-Igl, aa 603-1088) has been utilized instead of the crude antigen. This

device was validated with serum samples from patients with amebiasis and showed great sensitivity. The serodiagnosis can be completed within 20 min with 2 mul sample consumption. The device can be applied for the rapid and cheap diagnosis of other infectious disease, especially for the developing countries with very limited medical facilities.

Zhao, X., et al. (2013). "The inhibitory effect of dendritic cell subsets from mice immunized with the soluble egg antigen of Schistosoma japonicum on asthma and levels of CCL-11 and IL-13Ra2 expression." Zhongguo Bingyuan Shengwuxue Zazhi / Journal of Pathogen Biology **8**(8): 680-685.

Objective: This paper sought to study the inhibitory effect of adoptive transfer of dendritic cell (DC) subsets from mice immunized with the soluble egg antigen (SEA) of Schistosoma japonicum on asthma and its mechanisms.

Zhao, X. Y., et al. (2015). "CCL3 serves as a potential plasma biomarker in knee degeneration (osteoarthritis)." Osteoarthritis & Cartilage **23**(8): 1405-1411.

OBJECTIVE: To explore the ability of chemokines in plasma to detect the presence of pre-X-rays defined knee degeneration and the extent (burden).

METHODS: A total of 181 subjects (75 control subjects, 47 pre-X-KD patients and 50 X-KOA patients) were included and subdivided into three subgroups. Articular cartilage loss in pre-X-KD patients were scored on the basis of the ICRS classification during the arthroscopy or documented on MRI with chondral WORMS. The severity of X-KOA was graded using the Kellgren-Lawrence classification through the posterior-anterior knee X-rays. The concentrations of the inflammatory cytokines and chemokines in plasma were quantified using Luminex microbead-based suspension array (SA) and were cross-validated by enzyme-linked immunosorbent assay (ELISA).

RESULTS: CCL3 in plasma showed the highest ability to discriminate pre-X-KD patients from the controls with an AUC of 0.799. At a cutoff value of 0.168 pg/ml, the sensitivity was 70.21%, the specificity was 96.00%, the positive predictive value was 91.67% and the negative predictive value was 83.72%. As to define disease burden, the plasma levels of resistin, IL6, IL8, CCL3 and CCL4 showed significant association with the severity of X-rays defined knee OA, with regard to the KL classification. Moreover, significant elevation of IL6, IL8, CCL3 and CCL4 levels in plasma were observed in severe knee OA patients (KL grade IV) compared with those with pre-X-KD (KL grade 0-I).

CONCLUSION: We firstly showed that the plasma CCL3 could be potential serum biomarker for knee OA with the capacity to detect pre-X-rays defined changes and stage the severity of damage in knee.

Zhao, Y., et al. (2019). "Polystyrene microplastic exposure disturbs hepatic glycolipid metabolism at the physiological, biochemical, and transcriptomic levels in adult zebrafish." Science of the Total Environment **710**: 136279.

Microplastics (MPs), which are new types of environmental pollutants, have recently received widespread attention worldwide. MPs can accumulate in the bodies of animals and in plants, and they can also enter the human body through the food chain. However, knowledge of the effects of MPs on the health of animals is still limited. In this experiment, adult male zebrafish were exposed to 20 or 100 mug/L of 5 mum polystyrene MP for 21 days in an attempt to determine the hepatic effects related to glycolipid metabolism at the biochemical and transcriptomic levels. It was found that body weight and condition factor decreased significantly in zebrafish after exposure to 20 and 100 mug/L polystyrene MP for 21 days. The transcription levels of major genes related to glycolipid metabolism decreased significantly in the liver.

Correspondingly, the levels of major biochemical parameters, including Glu, pyruvic acid, alpha-ketoglutaric acid and IDH, were also decreased in the livers of exposed zebrafish, especially those in the 100 mug/L polystyrene MP-treated group. Moreover, the data on the hepatic transcriptome also confirmed that some genes related to fatty acid metabolism, amino acid metabolism and carbon metabolism tended to be decreased in the livers of exposed zebrafish. Taken together, our data confirmed that polystyrene PS-MP can induce hepatic glycolipid metabolism disorder at the physiological, biochemical, and transcriptomic levels in adult zebrafish after 21 days of exposure.

Zhao, Y., et al. (2019). "Data on microplastics in the digestive tracts of 19 fish species from the Yellow Sea, China." Data in Brief **25**: 103989.

Microplastics (MPs) are the predominant form of marine plastic debris, and small enough to be ingested by marine organisms. Fish inhabiting coastal environments are susceptible to the ingestion of MPs. Presented data include the information of MPs level in the digestive tracts of 19 fish species which were caught from the Yellow Sea (31degree28'52.380"~38degree49'15.540 N, 120degree42'36.840"~124degree49'06.180E). For discussion and interpretation of the presented data, refer to the research article entitled "Characteristics and retention of microplastics in the digestive tracts of fish from the Yellow Sea" [1].

Zhao, Y. B., et al. (2017). "Laboratory simulations of the mixed solvent extraction recovery of dominate polymers in electronic waste." Waste Management **69**: 393-399.

The recovery of four dominant plastics from electronic waste (e-waste) using mixed solvent extraction was studied. The target plastics included polycarbonate (PC), polystyrene (PS), acrylonitrile butadiene styrene (ABS), and styrene acrylonitrile (SAN). The extraction procedure for multi-polymers at room temperature yielded PC, PS, ABS, and SAN in acceptable recovery rates (64%, 86%, 127%, and 143%, respectively, where recovery rate is defined as the mass ratio of the recovered plastic to the added standard polymer). Fourier transform infrared spectroscopy (FTIR) was used to verify the recovered plastics' purity using a similarity analysis. The similarities ranged from 0.98 to 0.99. Another similar process, which was denoted as an alternative method for plastic recovery, was examined as well. Nonetheless, the FTIR results showed degradation may occur over time. Additionally, the recovery cost estimation model of our method was established. The recovery cost estimation indicated that a certain range of proportion of plastics in e-waste, especially with a higher proportion of PC and PS, can achieve a lower cost than virgin polymer product. It also reduced 99.6%, 30.7% and 75.8% of energy consumptions and CO<inf>2</inf> emissions during the recovery of PC, PS and ABS, and reduced the amount of plastic waste disposal via landfill or incineration and associated environmental impacts. Zhao, Y.-B., et al. (2019). "A Chemical Time Bomb: Future Risks of Microplastics." Water, Air & Soil Pollution **230**(11): N.PAG-N.PAG.

Despite the controversy, the ecological risk of microplastics research has increased sharply from only one in 1966 to 495 in 2018, according to Web of Science with microplastics as keyword. To date, an upward trend of global microplastics mass emission was confirmed by many environmental scientists. The ocean is the ultimate destination of land-based microplastics sources; therefore, most of efforts were concentrated on microplastics in aquatic environment. In this brief article, the global release of microplastics and flux into the ocean in the recent decade were estimated roughly. The plastics fragmentation in the marine environment only

accounted for 22% of total microplastics release (assuming defined emission rate per capita and fragmentation rate of plastics). Future research is needed for microplastics generation and retention in the terrestrial system, especially indoor environments. The accumulated microplastics over the environmental self-purification capacity certainly increases stress for the marine, freshwater and terrestrial ecosystem. [ABSTRACT FROM AUTHOR]

Zhao, Y.-B., et al. (2018). "Solvent-based separation and recycling of waste plastics: A review." Chemosphere **209**: 707-720.
Since the creation of first man-made plastic, the global production and consumption of plastics have been continuously increasing. However, because plastic materials are durable and very slow to degrade, they become waste with high staying power. The over-consumption, disposal, and littering of plastics result in pollution, thus causing serious environmental consequences. To date, only a fraction of waste plastics is reused and recycled. In fact, recycling plastics remains a great challenge because of technical challenges and relatively insufficient profits, especially in mixed plastics. This review focuses on an environmentally friendly and potentially profitable method for plastics separation and recovery and solvents extraction. It includes the dissolution/reprecipitation method and supercritical fluid extraction, which produce high-quality recovered plastics comparable to virgin materials. These methods are summarized and discussed taking mass-produced plastics (PS, PC, Polyolefins, PET, ABS, and PVC) as examples. To exploit the method, the quality and efficiency of solvent extraction are elaborated. By eliminating these technical challenges, the solvent extraction method is becoming more promising and sustainable for plastic issues and polymer markets. [ABSTRACT FROM AUTHOR]

Zheng, J., et al. (2018). "Heavy Exposure of Waste Collectors to Polycyclic Aromatic Hydrocarbons in a Poor Rural Area of Middle China." Environmental Science & Technology **52**(15): 8866-8875.
Manual collection and open-air incineration of waste materials is a common practice in rural regions of China and beyond. Low-temperature combustion of rubber and plastic waste generates high levels of airborne polycyclic aromatic hydrocarbons (PAHs). We investigated ten urinary hydroxylated PAH metabolites (OH-PAHs), the oxidative damage biomarker (8-hydroxy-deoxyguanosine, 8-OHdG), and four serum biomarkers including gamma-glutamyl transferase (GGT) and alanine aminotransferase (ALT) in 41 waste collectors and 122 control subjects residing in the same or a distant rural village in Henan Province. The level of PAH metabolites in urine (median: 17.24 mug/g Cre) was twice that of controls living in the same area without an occupational history involving waste collection (median: 8.16 mug/g Cre) and thrice that of controls living 30 km away (median: 6.07 mug/g Cre). The concentrations of OH-PAHs were positively associated with urinary 8-OHdG levels (beta = 0.283, $p < 0.05$). Serum

GGT and ALT were slightly increased in waste collectors. Urinary 8-OHdG levels were similar in one-year and longer-term workers, suggesting that rubber and plastic waste collection/incineration carries a high PAH exposure risk. These data provide solid baseline information, emphasizing the importance of monitoring the long-term health outcomes of waste collectors and changes in exposure patterns associated with rural development and regulation of waste disposal.

Zheng, J. M., et al. (2011). "Both secretions of interferon and expressions of phospho-IRF3 were decreased in murine liver dendritic cells after intervened by HBV." Hepatology International **5 (1)**: 152.

Objective: Study of the secretions of type I interferon and the expressions of phospho-IRF3 in murine liver dendritic cells after intervened by HBV. Method(s): The murine liver dendritic cells were isolated via anti- CD11c microbeads, and were co-incubated with GM-CSF and IL-4 for inducing the DCs generation and proliferation. HBV virions were isolated via ultracentrifugation, and were detected by quantitative Realtime-PCR. DCs were divided into two groups at day 5. One group was cultured with HBV virons in 24 h; the other group was cultured without HBV as a control group. Then, harvesting the cells and supernatants were detected the expressions of p-IRF3 by western blot and the concentration of IFN-beta by ELISA, after stimulated by poly I:C in different time. Result(s): IFN-beta concentration was 12.38 +/- 3.71 pg/ml at 0 h, 88.67 +/- 9.01 pg/ml at 6 h, 69.89 +/- 5.80 pg/ml at 24 h in supernatants of HBV group, and was 10.83 +/- 4.11 pg/ml at 0 h, 137.68 +/- 12.28 pg/ml at 6 h, 72.25 +/- 8.61 pg/ml at 24 h in supernatants of control group, respectively, in 24-well culture plates. There was no statistically significant difference at 0 h (t = 0.8398, P>0.05) and at 24 h (t = 0.6820, P>0.05) between two groups. But, there was statistically significant difference at 6 h (t = 9.653, P<0.01) between two groups. The expressions of phospho-IRF3 in HBV group were lower than those in control group, when multiplicity of infection is 25. Conclusion(s): Both the secretions of type I interferon and the expressions of phospho-IRF3 were decreased in murine liver dendritic cells after intervened by HBV.

Zheng, K., et al. (2019). "Occurrence and Species-Specific Distribution of Plastic Debris in Wild Freshwater Fish from the Pearl River Catchment, China." Environmental Toxicology & Chemistry **38**(7): 1504-1513.

Freshwater systems are an important source and vector of plastic debris found in oceans. However, plastic debris in freshwater organisms has not been well studied. The occurrence, characterization, polymer composition, and seasonal and spatial distribution of plastic debris were investigated in 9 species of wild freshwater fish from the Pearl River catchment, south China. Approximately 50% of the total fish (n = 279) belonging to 9 species were found to ingest plastic debris with an average abundance of 7.0 ± 23.8 items/individual, indicating wide plastic contamination in the Pearl River catchment. Plastic debris were predominantly transparent or white in color, fibers or fragments in shape, and polyethylene, polypropylene, ethylene–propylene copolymer (PE-PP), and polyethylene terephthalate (PET) in polymer composition. A species-specific distribution of the plastic debris was observed in terms of abundance, shape, and polymer composition. Redbelly tilapia had the highest (27.4 ± 54.0 items/individual), whereas common carp had the lowest (0.2 ± 0.4 items/individual) abundance of the plastic debris in their gastrointestinal tracts. Fibers of PET were predominant in the freshwater species except in barbel chubs, which had mostly PE-PP fragments. Omnivores and bottom-dwellers were more likely to ingest plastic debris. Seasonal variation was observed, with generally higher abundance of plastic debris in fish collected in the dry season than in the wet season. Environ Toxicol Chem 2019;38:1504–1513. © 2019 SETAC [ABSTRACT FROM AUTHOR]

Zheng, T., et al. (2019). "Molecular toxicity of nanoplastics involving in oxidative stress and desoxyribonucleic acid damage." Journal of Molecular Recognition **32**(11): e2804.

Microplastic pollution attracted extensive attention because of its global presence and adverse effects on ecosystem. However, it is insufficient to clear the effects of nanoplastics on organisms at the molecular level. Herein, a nanopolystyrene (50 nm) was used to examine molecular responses of superoxide dismutase (SOD) and desoxyribonucleic acid (DNA) using spectroscopy (UV-vis, circular dichroism spectra, and fluorescence measurements) and single cell gel electrophoresis methods.

Zheng, W., et al. (2001). "Miniaturization of a hepatitis C virus RNA polymerase assay using a -102 degrees C cooled CCD camera-based imaging system." Analytical Biochemistry **290**(2): 214-220.

Innovations in detection technologies have allowed us to develop a novel assay in 1536-well plate format and assess the advantages of screen miniaturization compared with conventional high-throughput compound screening in 96- or 384-well plates. An HCV RNA polymerase assay has been miniaturized in 1536-well plates by using a new detection technology known as LEADseeker homogeneous imaging system. It uses a -102 degrees C cooled charge-coupled device (CCD) camera and newly designed scintillation proximity microparticles. The miniaturized assay used europium-doped streptavidin-coated yttrium oxide (YO(x)) or polystyrene (PS) microspheres to capture biotin-labeled [(3)H]RNA product transcripts. Beads in proximity to the radioisotope convert the emitted beta(-) particles into photons having wavelengths in the red region of the visible spectrum, optimal for detection by the CCD camera. Because the camera collects light from all wells of the plate simultaneously, 1536-well plates are imaged as rapidly as 384-well plates, on the order of 10 min per plate. The assay has a signal to background of approximately 20-fold, satisfactory for high-throughput robotics screening. The enzyme kinetics and potency of a known inhibitor were similar to those obtained from the conventional assay using scintillation proximity assay (SPA) beads and a scintillation plate counter. Furthermore, the newly developed microbeads (emitting at 610 to 620 nm) are less prone to quenching effects caused by yellow-colored compounds, than conventional SPA beads or scintillation fluid (emitting at 400 to 480 nm region). Thus, the LEADseeker imaging system is a useful new tool for miniaturization of assays for high-throughput screening.

Zheng, X., et al. (2010). "Evaluation of the transforming growth factor-beta activity in normal and dry eye human tears by CCL-185 cell bioassay." Cornea **29**(9): 1048-1054.

PURPOSE: To develop a new bioassay method using human lung epithelial cells (CCL-185) to assess activity of transforming growth factor beta (TGF-beta) in human tear fluid from normal subjects and patients with dry eye.

METHODS: Two epithelial cell lines, mink lung cells (CCL-64) and human lung cells (CCL-185), were compared to detect the active form of TGF-beta by BrdU incorporation (quantitation of cell DNA synthesis) and WST assay (metabolic activity of viable cells). The effect of TGF-beta on the growth of CCL-185 cells was observed microscopically. Human tears from normal control subjects and patients with dry eye (DE) with and without Sjogren syndrome were evaluated for

TGF-beta concentration by Luminex microbead assay, and TGF-beta activity by the CCL-185 cell growth inhibition bioassay.
RESULTS: The metabolic activity of viable CCL-185 cells, measured by WST, was shown to be proportional to the TGF-beta1 concentration (R = 0.919) and confirmed by BrdU assay (R = 0.969). Compared with CCL-185, metabolic activity of viable cells and DNA synthesis, measured by WST and BrdU incorporation assays, were shown to be less proportional to the TGF-beta1 concentration in the CCL-64 line (R = 0.42 and 0.17, respectively). Coincubation with human anti-TGF-beta1 antibody (MAB-240) yielded a dose-dependent inhibition of TGF-beta1 (0.3 ng/mL) activity. CCL-185 cell growth observed microscopically was noted to decrease in response to increasing TGF-beta1 concentrations. Levels of immuodetectable TGF-beta1 and TGF-beta2 were similar in normal and DE tears. TGF-beta bioactivity in DE human tears measured by the CCL-185 cells assay was found to be higher (9777.5 +/- 10481.9 pg/mL) than those in normal controls (4129.3 +/- 1342.9 pg/mL) (P < 0.05). Among patients with DE, TGF-beta bioactivity was highest in those with Sjogren syndrome. Approximately, 79.1% of TGF-beta in DE tears and 37.6% TGF-beta in normal tears were found to be biologically active.
CONCLUSIONS: The CCL-185 cell assay was found to be a suitable tool for assessing TGF-beta activity in human tears. Tear TGF-beta bioactivity increases in DE, particularly in Sjogren syndrome, where elevated levels of TGF-beta1 transcripts in the conjunctival epithelium have been previously detected.

Zheng, X., et al. (2016). "Expression of TSLP and Downstream Molecules IL-4, IL-5, and IL-13 on the Eye Surface of Patients with Various Types of Allergic Conjunctivitis." Journal of Ophthalmology: 1-7.
Background. The pathogenesis of allergic conjunctivitis has not been clearly established. Moreover, previous studies fail to consider human models of allergic conjunctivitis. This study investigated the expression of thymic stromal lymphopoiet in TSLP and its downstream molecules in conjunctival scrappings and tear. Methods. This cross-sectional study compares patients with vernal keratoconjunctivitis (VKC), seasonal allergic conjunctivitis (SAC), and perennial allergic conjunctivitis (PAC) with normal controls. There are 80 people recorded in Shanxi Eye Hospital. Increasingly, 20 are with VKC, 20 are with SAC, 20 are with PAC, and the remaining 20 are normal controls. Conjunctiva were harvested for total RNA extraction and gene expression by real-time polymerase chain reaction. Epithelial cells were collected to make pathological sections for immunohistochemical staining. Human tears were evaluated by Luminex microbead assay. A P value less than 0.05 from Dunnett's post hoc test in SPSS means a statistical significant distinction. Results. Positive expression in conjunctival cells of patients with allergic conjunctivitis. The expression of TSLP and IL-4, IL-5, and IL-13 mRNA shows a statistically significant difference (P<0.05). TSLP and IL-4, IL-5, and IL-13 concentrations show a statistically significant difference (P<0.01). Conclusions. This study suggests that TSLP and downstream molecules are expressed in patients with various types of allergic conjunctivitis.

Zhong, S. and J. M. Pearce (2018). "Tightening the loop on the circular economy: Coupled distributed recycling and manufacturing with recyclebot and RepRap 3-D printing." Resources, Conservation and Recycling **128**: 48-58.
A promising method of enhancing the circular economy is distributed plastic recycling. In this study plastic waste is upcycled into 3-D printing filament with a recyclebot, which is an open source waste plastic extruder. The recyclebot is combined with an open source self-replicating rapid prototyper (RepRap) 3-D printer, to enable post-consumer ABS plastic filament from computer waste to be further upcycled into valuable consumer products pre-designed in the digital commons. The total electrical energy consumption for the combined process is

monitored and an economic evaluation is completed. The coupled distributed recycling and manufacturing method for complex products reduces embodied energy by half, while reducing the cost of consumer products to pennies. This economic benefit provides an incentive for consumers to both home recycle and home manufacture, which tightens the loop on the circular economy by eliminating waste associated from transportation and retail. It is clear from the results that waste plastic can be significantly upcycled at the individual level using this commons-based approach. This tightening of the loop of the circular economy benefits the environment and sustainability as well as the economic stability of consumers/prosumers. Copyright © 2017 Elsevier B.V.

Zhou, B., et al. (2019). "Microplastics in agricultural soils on the coastal plain of Hangzhou Bay, east China: Multiple sources other than plastic mulching film." Journal of Hazardous Materials: 121814.

Microplastic contamination in agroecosystems raises great concerns. Here, we investigated the impacts of mulching and irrigation on microplastic accumulation in cropped soils. Sixty soil samples covering mulching and no-mulching farmlands, and forty-five irrigation water samples were collected for analysis. Microplastics were obtained from the soils using continuous air flotation followed by density separation. Stereomicroscopy and micro-Fourier transform infrared spectroscopy (mu-FTIR) were used for identification. Mulching soils contained larger amounts of microplastics than non-mulching soils, with 571 pieces kg⁻¹ and 263 pieces kg⁻¹, respectively, on average. The abundances of films and fibers were significantly ($p < 0.05$) higher in the mulching soils. Microplastics in the soils and waters were dominated by fragments and fibers, respectively. The particle size of the microplastics in soils mostly ranged from 1 to 3 mm, and primarily from 90 mum to 1 mm in waters. Multiple polymers, e.g. polyethylene, polypropylene, polyester, rayon, acrylic and polyamide, and shapes found in the soil microplastics indicate contributions from irrigation and plastic waste residues other than plastic mulching. Future studies might include the long-term accumulation of microplastics in agroecosystems from multiple sources under intensively managed cropping systems.

Zhou, C., et al. (2014). "Characteristics and the recovery potential of plastic wastes obtained from landfill mining." Journal of Cleaner Production **80**: 80-86.

Plastics have been the most consumed materials of human societies in recent decades and, in the mean time, one of the major products obtained from landfill mining. Characteristics of the landfill mined plastic wastes and their recovery potential were the key points to determine the feasibility of landfill mining projects. We collected municipal solid waste samples of different storage years from the landfill and did mechanical screening and manual separating to sort out plastic wastes, and a typical old landfill, which is of 24 storage years and located in central China, was taken as our studied case. According to our research, plastic wastes accounted for 10.62 ± 5.12% of the total stored wastes in the old landfill, among which, 69.13% was plastic bags (white PE plastic bags accounted for 11.34%; colored PE plastic bags 29.77%; other plastic bags 28.02%), and 30.87% was other plastics (incl. PP, PVC, PS, etc.). The average moisture content in the plastic waste was 19.96 ± 4.65% and the average impurities content was 71.02 ± 6.31% before manual washing and cleaning. The VS, ash, fixed carbon and calorific value of manually cleaned plastic wastes were 87.09 ± 0.55%, 10.84 ± 1.19%, 2.07 ± 0.85% and 43.18 ± 1.49 MJ kg-1, respectively. Elements testing (C, N, O, S, Cl, Si, Al) and surface images analysis under scanning electron microscope showed that normal cleaning techniques had a difficulty in thoroughly getting rid of all the impurities on the surface of plastic bags excavated from old landfill, which will impede plastic wastes from being mechanical recycled as renewable materials or being chemically recycled by either pyrolysis, gasification, hydrogenation. Incineration or treating as residue derived fuels (RDFs) for recovering energy was the most practical way to process landfill mining plastic wastes under the normal cleaning techniques. © 2014 Elsevier Ltd. Zhou, H. and H. H. Xu (2011). "The fast release of stem cells from alginate-fibrin microbeads in injectable scaffolds for bone tissue engineering." Biomaterials **32**(30): 7503-7513.

Stem cell-encapsulating hydrogel microbeads of several hundred microns in size suitable for injection, that could quickly degrade to release the cells, are currently unavailable. The objectives of this study were to: (1) develop oxidized alginate-fibrin microbeads encapsulating human umbilical cord mesenchymal stem cells (hUCMSCs); (2) investigate microbead degradation, cell release, and osteogenic differentiation of the released cells for the first time. Three types of microbeads were fabricated to encapsulate hUCMSCs: (1) Alginate microbeads; (2) oxidized alginate microbeads; (3) oxidized alginate-fibrin microbeads. Microbeads with sizes of about 100-500 mum were fabricated with 1 x 10(6) hUCMSCs/mL of alginate. For the alginate group, there was little microbead degradation, with very few cells released at 21 d. For oxidized alginate, the microbeads started to slightly degrade at 14 d. In contrast, the oxidized alginate-fibrin microbeads started to degrade at 4 d and released the cells. At 7 d, the number of released cells greatly increased and showed a healthy polygonal morphology. At 21 d, the oxidized alginate-fibrin group had a live cell density that was 4-fold that of the oxidized alginate group, and 15-fold that of the alginate group. The released cells had osteodifferentiation, exhibiting highly elevated bone marker gene expressions of ALP, OC, collagen I, and Runx2. Alizarin staining confirmed the synthesis of bone minerals by hUCMSCs, with the mineral concentration at 21 d being 10-fold that at 7 d. In conclusion, fast-degradable alginate-fibrin microbeads with hUCMSC encapsulation were developed that could start to degrade and release the cells at 4 d. The released hUCMSCs had excellent proliferation, osteodifferentiation, and bone mineral synthesis. The alginate-fibrin microbeads are promising to deliver stem cells inside injectable scaffolds to promote tissue regeneration.

Zhou, H., et al. (2019). "The spin-coating-based immobilization of ZnTPP-dyed cation exchange resin microbeads for reversible ammonia detection." Analytical Methods **11**(16): 2155-2162.

During the fabrication of a microfluidic chip for reversible ammonia detection, we applied a spin-coating-based method to immobilize cation exchange resin microbeads on which zinc tetraphenylporphyrin was dyed as an indicator material. The 4-layered microfluidic chip and a portable spectrometer constituted the core part of the integrated system. The results obtained for various wavelengths were compared, and the spectral intensity change at 450 nm was selected. The PDMS films at 2000–5000 rpm were investigated at ammonia concentrations ranging from 0.5 to 50 mg L−1. The reversibility of zinc tetraphenylporphyrin was assessed by the results obtained after each cycle. After conducting the tests 75 times for various microfluidic chips, the stability of the method was confirmed with the maximal relative deviation being less than 10%. The introduced method exhibited significant potential for the detection of ammonia.

Zhou, L., et al. (2018). "Flexible Assembly of an Enzyme Cascade on a DNA Triangle Prism Nanostructure for the Controlled Biomimetic Generation of Nitric Oxide." Chembiochem **19**(19): 2099-2106.

Spatial organization of multiple enzymes at specific positions for a controlled reaction cascade has attracted wide attention in recent years. Here, we report the construction of a biomimetic enzyme cascade organized on DNA triangle prism (TP) nanostructures to enable the efficient catalytic production of nitric oxide (NO) on a single microbead. Two enzymes, glucose oxidase

(GOx) and horseradish peroxidase (HRP), were assembled at adjacent locations on a DNA TP nanostructure by using DNA-binding protein adaptors with small interenzyme distances. In the cascade, the first enzyme, GOx, converts glucose into gluconic acid in the presence of oxygen. The produced H₂ O₂ intermediate is rapidly transported to the second enzyme, HRP, which oxides hydroxyurea into NO and other nitroxyl species. The pH near the surface of the negatively charged DNA nanostructures is believed to be lower than that in the bulk solution; this creates an optimal pH environment for the anchored enzymes, which results in higher yields of the NO product. Furthermore, the multienzyme system was immobilized on a microbead mediated by a DNA adaptor, and this enabled the efficient catalytic generation of gas molecules in the microreactor. Therefore, this work provides an alternative route for the biomimetic generation of NO through enzyme cascades. In particular, the dynamic binding capability of the DNA sequence enabled the positions of the protein enzyme and the DNA nanostructure to be reversed, which allowed the cascade catalysis to be modulated.

Zhou, L., et al. (2012). "Impact of human granulocyte and monocyte isolation procedures on functional studies." Clinical & Vaccine Immunology: CVI **19**(7): 1065-1074.

One of the first lines of defense against infection is the activation of the innate immune system. It is becoming clear that autoimmune diseases, such as rheumatoid arthritis and Crohn's disease, may be caused by disturbed innate immunity, and relating granulocyte and monocyte functions to the patient genotype has become an important part of contemporary research. Although it is essential to move this field forward, a systematic study comparing the efficacy and suitability for functional studies of the various available protocols for the isolation of these immune cells has not been performed. Here, we compare human granulocyte functionality under three enrichment protocols: (i) Ficoll density gradient centrifugation, (ii) anti-CD15 antibody-conjugated microbeads (positive selection), and (iii) Polymorphoprep. Primary monocytes were isolated in parallel using (i) anti-CD14 magnetic microbeads, (ii) non-monocyte depletion by antibody-conjugated magnetic microbeads (negative selection), (iii) RosetteSep antibody cocktail, and (iv) the classical adherence protocol. The best results in terms of purity and cell functionality were obtained with positive selection by magnetic microbeads for both human granulocytes and monocytes. Whereas phagocytosis of Escherichia coli bacteria was identical in all isolation procedures tested, the granulocyte respiratory burst was higher in positively selected cells. In addition, different granulocyte enrichment procedures affect cell surface receptor expression to different extents. In toto, we propose that positive selection of granulocytes and monocytes be adopted as the procedure of choice for studies of human granulocyte and monocyte functions but caution investigators to be aware of possible alterations in cell phenotypes with different isolation procedures.

Zhou, Q., et al. (2020). "Characteristics and distribution of microplastics in the coastal mangrove sediments of China." Science of the Total Environment **703**: N.PAG-N.PAG.

• First comprehensive study on MPs in mangrove sediments along the coast of China. • The MPs abundance in mangrove sediments was up to 8.5 times higher than in mangrove free sediments. • The sandy sediments were dominated by foams, and the muddy sediments by fibers and fragments. Mangroves are a unique and important type of coastal wetlands in the tropical and subtropical zones worldwide. The abundance and spatial distribution of microplastics in the mangrove sediments however are still poorly understood. The present study aimed to illustrate the characteristics, abundance and spatial distribution of microplastics in different mangrove sediments along the south-eastern coastal zones of China. Microplastic samples (roughly 10–20 kg fresh sediments at each site) taken from 21 sampling sites showed various shapes, colors,

composition, sizes, surface morphology, abundance and strong spatial heterogeneity. Five different shapes of microplastics with a variety of colors were detected in the mangrove sediments, among which foams (74.6%) and fibers (14.0%) were the dominant types. The polymer composition of the microplastics identified based on the FT-IR and μ-FTIR covered polystyrene (75.2%), polypropylene (11.7%), rayon (4.6%), polyester (3.4%), polyethylene (2.8%) and acrylic (2.4%). The observed microplastics with a size range of less than 2 mm made up 58.6% of the total microplastic particles. The microplastics had various surface morphologies, exhibiting complicated weathered surfaces. The abundance of microplastics showed a substantial variation among the sampling sites, ranging from 8.3 to 5738.3 items kg−1 (dry sediment). Altogether, our study provides a better understanding of microplastic pollution status and prevention policy-making of mangrove habitats in China. [ABSTRACT FROM AUTHOR]

Zhou, Q., et al. (2018). "The distribution and morphology of microplastics in coastal soils adjacent to the Bohai Sea and the Yellow Sea. (Special section on coastal wetland soils.)." Geoderma **322**: 201-208.

Microplastics (<5 mm) are considered to be emerging pollutants of global concern. Investigations on microplastics pollution in coastal and marine environments have increased recently but knowledge gaps still exist regarding microplastics in coastal beach soils with high-intensity human activities. In the present study a total of 120 soil samples were taken from 53 sites along >3000 km of coastline in Shandong province, east China, adjacent to both the Bohai Sea and the Yellow Sea coastlines under different land use management. Microplastics were separated from the soil samples using a continuous flow and floating separation apparatus. The shape type, size, abundance, spatial distribution, polymer composition and surface morphology of the microplastics were identified by a range of advanced microscopic and micro-analytical methods. The analytical results show that seven shape types, namely foams, pellets, fragments, flakes, fibers, films and sponges, were present in the beach soils. The polymer composition of the microplastics included polyethylene, polypropylene, polystyrene, polyether urethane and a polymer blend of both polyethylene and polypropylene. Approximately 60% of the observed microplastics had a size range <1 mm. Microplastic abundance varied greatly among the soils, ranging from 1.3 to 14,712.5 N kg⁻¹ (dry weight) as influenced by high-intensity human activities such as mariculture, tourism, and port construction. The seven shape types of microplastics from the coastal environment had different weathering surface morphologies, showing scratches, creases, micropores, cracks, either concave or convex, and of various shapes and sizes, possibly due to physical friction, photochemical oxidation and/or animal attack. Algae or crude oil was observed on the surface of some microplastics. The weathered surfaces of microplastics might act as a high-capacity carrier with adhering microorganisms and chemicals. Further studies are required on the weathering processes, sorption capacity and transport of microplastics especially in smaller size (<1 mm) under coastal conditions.

Zhou, Q. Z., et al. (2008). "Multi-stage premix membrane emulsification for preparation of agarose microbeads with uniform size." Journal of Membrane Science **322**(1): 98-104.

Uniform-sized agarose beads with diameters less than 10 mum and agarose content as high as

14 wt% were prepared by premix membrane emulsification. Agarose aqueous solution was used as the water phase. A mixture of liquid paraffin and petroleum ether containing hexaglycerin penta ester (PO-500) was used as the oil phase. The water phase was mixed with the oil phase at 60 degreeC and a coarse W/O emulsion was produced in a homogenizer. Then, the coarse emulsion was extruded through a hydrophobic membrane under high pressure to form an emulsion, which was slowly cooled under gentle agitation to form gel beads. The effects of preparation conditions on emulsification resultswere investigated and it showed that the pressure, number of passes, petroleum ether/liquid paraffin (v/v) in the oil phase, the concentration of PO-500 and concentration of agarose in the water phase, all affected the size and uniformity; coarse emulsion did not affect the emulsification results. The coefficient variation (C.V.) of agarose beads under optimal preparation conditions was 9.8%. This method realized microbeads with both uniform sizes and high agarose contents that are difficult to be prepared by conventional emulsion methods. © 2008 Elsevier B.V. All rights reserved.

Zhou, X., et al. (2009). "A convenient method for synthesis of glyco-nanoparticles/ beads for glycan function analysis." Glycoconjugate Journal **26 (7)**: 887.

Carbohydrate functionalized nanoparticles, i.e., the glyconanoparticles, have wide application ranging from studies of carbohydrate-protein interactions, in vivo cell imaging, biolabeling, etc. We report a simple and versatile method for preparing glyconanoparticles and microbeads. This method is based on the utilization of Clean and convenient microwave irradiation energy for one-step, site-specific conjugation of unmodified carbohydrates onto hydrazide-functionalized nanoparticle/beads surface. A gold nanoparticle-based colorimetric assay that utilizes the ensemble of Concanavalin A (ConA) and gold glyconanoparticle was also presented. This feasible assay system was developed to analyze multivalent interactions and to determine the dissociation constant (Kd) for carbohydrate derivatives coated with mannose binding lectins. Shifts in UV-Vis absorption wavelength as a function of ConA-carbohydrate derivatives molar ratios were plotted and the dissociation constants were determined based on nonlinear curve fitting. The dissociation constant for mannosecoated gold nanoparticles was determined at 4.4nM, while the maltose-coated gold nanoparticles suppress the binding by increasing the dissociation constant. Fluorescent glyconanoparticles and magnetic glyconanoparticles are also synthesized for glycan extraction and function analysis.

Zhou, X., et al. (2019). "Natural killer cells regulate Th17/Treg cell immune response through modulating the function of dendritic cells during chlamydial lung infection." Shan Dong Da Xue Xue Bao. Yi Xue Ban = Journal of Shandong University. Health Sciences **57**(4): 15.

Objective To explore the mechanism of natural killer(NK)cells in regulating of Th17/Treg cell responses during chlamydia muridarum(Cm)lung infection. Methods A pulmonary infection model of Cm was established. The spleen dendritic cells(DCs)from Cm-infected mice with or without NK cells depletion were obtained by application of CD11c+ MicroBeads. The naïve mice were given intravenous injection of DCs from different groups of mice, and divided into NK-DCs recipients group(n=13)and NK+DCs recipients group(n=13). After adoptive transfer, the same infection method was used to recipient mice with Cm. The degree of disease was compared between the two groups. Flow cytometry was used to detect the changes of Th17 and Treg cells in the spleen and lung of mice. Results Compared with NK+DCs recipients, NK-DCs recipients exhibited aggravated disease, higher weight loss and severe lung injury. Immunological analysis showed the proportion of Th17 cells in spleen and lung was reduced while the proportion of Treg cell response was enhanced, which contributed to imbalance of Th17/Treg response in NK-DCs recipients. 山 东 大 学 学 报 (医 学 版)57卷4期 -周小青,等.自然杀伤细胞通过

树突状细胞调控衣原体肺部感染中Th17/Treg免疫应答平衡 \=- Conclusion NK cells can effectively initiate Th17 cells response and inhibit Treg cell response by modulating DCs and thus play an important role in controlling chlamydial infection.

Zhou, X., et al. (2014). "Synthesis, labeling and bioanalytical applications of a tris(2,2'-bipyridyl)ruthenium(II)-based electrochemiluminescence probe." Nature Protocols **9**(5): 1146-1159.

Assays using probes labeled with electrochemiluminescent moieties are extremely powerful analytical tools that are used in fields such as medical diagnostics, environmental analysis and food safety monitoring, in which sensitive, reliable and reproducible detection of biomolecules is a requirement. The most efficient electrochemiluminescence (ECL) reaction to date is based on tris(2,2'-bipyridyl)ruthenium(II) (Ru(bpy) 3²⁺) with tripropylamine (TPrA) as the co-reactant. Here we present a detailed protocol for preparing Ru(bpy) 3²⁺ probes and their bioanalytical applications. This protocol includes (i) the synthesis of a biologically active Ru(bpy) 3 ²⁺ -N-hydroxysuccinimide (NHS) ester, (ii) its covalent labeling with both antibodies and DNA probes and (iii) the detection and quantification of ECL in a microfluidic system with a paramagnetic microbead solid support. In our magnetic bead-based ECL system, two probes are required: a capture probe (labeled with biotin to be captured by a streptavidin-coated magnetic bead) and a detector probe (labeled with Ru(bpy) 3²⁺). The complex consisting of the analyte, the capture probe, the detector probe and the magnetic bead is brought into contact with the electrode by using a magnetic field. The Ru(bpy) 3²⁺ reacts with TPrA in solution to generate the ECL signal. The full protocol, including the synthesis and labeling of the bioactive Ru(bpy) 3 ²⁺, requires 5-6 d to complete. ECL immunoassays or nucleic acid tests only require 1.5-2 h, including the sample preparation time. © 2014 Nature America, Inc.

Zhou, X. X., et al. (2019). "Cloud-Point Extraction Combined with Thermal Degradation for Nanoplastic Analysis Using Pyrolysis Gas Chromatography-Mass Spectrometry." Analytical Chemistry **91**(3): 1785-1790.

The contamination of micro- and nanoplastics in marine systems and freshwater is a global issue. Determination of micro- and nanoplastics in the aqueous environment is of high priority to fully assess the risk that plastic particles will pose. Although microplastics have been detected in a variety of aquatic ecosystems, the analysis of nanoplastics remains an unsolved challenge. Herein, for the first time, a Triton X-45 (TX-45)-based cloud-point extraction (CPE) was proposed to preconcentrate trace nanoplastics in environmental waters. Under the optimum extraction conditions, an enrichment factor of 500 was obtained for two types of nanoplastics with different compositions, polystyrene (PS) and poly(methyl methacrylate) (PMMA), without disturbing their original morphology and sizes. Additionally, following thermal treatment at 190 degreeC for 3 h, the CPE-obtained extract could be submitted to pyrolysis gas chromatography-mass spectrometry (Py-GC/MS) analysis for mass quantification of nanoplastics. Taking 66.2 nm PS nanoplastics and 86.2 nm PMMA nanoplastics as examples, the proposed method showed excellent reproducibility, and high sensitivity with respective detection limits of 11.5 and 2.5 fM. Feasibility of the proposed approach was verified by application of the optimized procedure to four real water samples. Recoveries of 84.6-96.6% at a spiked level of 88.6 fM for PS nanoplastics and 76.5-96.6% at a spiked level of 50.4 fM for PMMA nanoplastics were obtained. Consequently, this work provides an efficient approach for nanoplastic analysis in environmental waters.

Zhou, Y., et al. (2019). "Characterization of microplastics and the association of heavy metals with microplastics in suburban soil of central China." Science of the Total Environment **694**: 133798.

Microplastics (MPs) are ubiquitous in the aquatic and terrestrial environment and can absorb other kinds of pollutants on surfaces due to strong hydrophobicity and higher specific surface area. This study investigated the occurrence and distribution of MPs and the interaction of MPs and heavy metals in three different land types of central China.

Zhou, Y., et al. (2018). "Rapid Regeneration and Reuse of Silica Columns from PCR Purification and Gel Extraction Kits." Scientific Reports **8**(1): 12870.

Silica columns from PCR purification and gel extraction kits are widely used in laboratories worldwide to assist in gene cloning. However, the use of these columns can generate plastic waste that has an environmental impact due to their one-off design and massive consumption. Thus, it is important to develop a novel method that can reduce the utilization of silica columns but not affect research efficiency. In this study, various chemical and nonchemical reagents were used to eliminate residual DNA within used columns from PCR purification and gel extraction kits. We show that phosphoric acid is the most effective reagent among those tested to remove DNA contamination from used columns. Columns regenerated using 1 M phosphoric acid have a DNA purification capability that is comparable to that of fresh columns. We demonstrate that silica columns can be regenerated and reused a minimum of five times. The lab-made buffers are compatible with the regenerated columns for DNA purification, and DNA that is prepared with the regenerated columns can be used for gene cloning without affecting the gene cloning efficiency. Thus, the use of this novel method greatly reduces the production of laboratory waste and benefits numerous laboratories worldwide.

Zhu, B., et al. (2018). "Exposure to nanoplastics disturbs the gut microbiome in the soil oligochaete Enchytraeus crypticus." Environmental Pollution **239**: 408-415.

Microplastics are emerging pollutants that have recently aroused considerable concern but most toxicological studies have focused on marine biota, with little investigation of the influence of microplastics on terrestrial ecosystems. Here, we fed the soil oligochaete Enchytraeus crypticus with oatmeal containing 0, 0.025, 0.5, and 10% (dry weight basis) nano-polystyrene (0.05-0.1 micro m particle size) to elucidate the impact of microplastics on the growth and gut microbiome of Enchytraeus crypticus. We observed a significant reduction of weight in the animals fed 10% polystyrene and an increase in the reproduction of those fed 0.025%. More importantly, using 16S rRNA amplification and high-throughput sequencing we found a significant shift in the microbiome of those fed 10% microplastics with significant decreases in the relative abundance of the families Rhizobiaceae, Xanthobacteraceae and Isosphaeraceae. These families contain key microbes that contribute to nitrogen cycling and organic matter decomposition.

Zhu, B., et al. (2015). "Ultra-high-throughput screening of an in vitro-synthesized horseradish peroxidase displayed on microbeads using cell sorter." PLoS ONE **10 (5) (no pagination)**(e0127479).

The C1a isoenzyme of horseradish peroxidase (HRP) is an industrially important hemecontaining enzyme that utilizes hydrogen peroxide to oxidize a wide variety of inorganic and organic compounds for practical applications, including synthesis of fine chemicals, medical diagnostics, and bioremediation. To develop a ultra-high-throughput screening system for HRP, we successfully produced active HRP in an Escherichia coli cell-free protein synthesis system, by adding disulfide bond isomerase DsbC and optimizing the concentrations of hemin and calcium ions and the temperature. The biosynthesized HRP was fused with a single-chain Cro (scCro) DNA-binding tag at its N-terminal and C-terminal sites. The addition of the scCro-tag at both ends increased the solubility of the protein. Next, HRP and its fusion proteins were successfully synthesized in a water droplet emulsion by using hexadecane as the oil phase and SunSoft No. 818SK as the surfactant. HRP fusion proteins were displayed on microbeads attached with double-stranded DNA (containing the scCro binding sequence) via scCro-DNA interactions. The activities of the immobilized HRP fusion proteins were detected with a tyramide-based fluorogenic assay using flow cytometry. Moreover, a model microbead library containing wild type hrp (WT) and inactive mutant (MUT) genes was screened using fluorescence-activated cell-sorting, thus efficiently enriching the WT gene from the 1:100 (WT:MUT) library. The technique described here could serve as a novel platform for the ultra-high-throughput discovery of more useful HRP mutants and other heme-containing peroxidases. Copyright © 2015 Zhu et al. Zhu, C., et al. (2019). "Plastic debris in marine birds from an island located in the South China Sea." Marine Pollution Bulletin **149**: 1.

Plastic debris has become one of the most serious issues in the marine environment, but little information is available on the occurrence of plastic debris in marine birds from China. In this study, one seabird species and two shorebird species were collected from Yongxing Island of South China Sea to investigate the accumulation of plastic debris. A total of 56 items of plastic debris were observed in 4 of 9 birds, with size ranging from 0.67 to 8.64 mm. Microplastics (<5 mm, 52 items) accounted for 92.9% of the total items. The main color of plastic debris in marine birds was blue (91.1%), followed by dark (5.4%) and white (3.6%). The primary shape of plastic debris was thread (89.2%), followed by sheet (8.9%) and foam (1.8%). Plastic fragments were predominated by polypropylene-polyethylene copolymer (83.9%). This study highlighted that marine birds can mistake plastic debris as food items.

Zhu, D., et al. (2018). "Trophic predator-prey relationships promote transport of microplastics compared with the single Hypoaspis aculeifer and Folsomia candida." Environmental Pollution **235**: 150-154.
Although the roles of earthworms and soil collembolans in the transport of microplastics have been studied previously, the effects of the soil biota at different trophic levels and interspecific relationships remain poorly understood. Here, we examine three soil microarthropod species to explore their effects on the transport of microplastics. The selected Folsomia candida and Hypoaspis aculeifer are extensively used model organisms, and Damaeus exspinosus is a common and abundant indigenous species in China. A model food chain (prey-collembolan and predator-mite) was structured to test the role of the predator-prey relationship in the transport of microplastics. Commercial Polyvinyl chloride (PVC) particles (Diameter: 80-250 micro m) were selected as the test microplastics, because large amounts of PVC have persisted and accumulated in the environment. Synchronized soil microarthropods were held in plates for seven days to determine the movement of microplastics. The 5000 microplastic particles were carefully placed in the center of each plate prior to the introduction of the animals. Our results clearly show that all three microarthropod species moved and dispersed the microplastics in the plates. The 0.54%, 1.8% and 4.6% of the added microplastic particles were moved by collembolan, predatory mite and oribatid mite, respectively. Soil microarthropods (<0.2 cm) transported microplastic particles up to 9 cm. The avoidance behavior was observed in the collembolans in respect of the microplastics. The predatory -prey relationship did promote the transport of microplastics in the plates, increasing transport by 40% compared with the effects of adding single species (P<.05). Soil microarthropods commonly occur in surface soils (0-5 cm) and, due to their small body size, they can enter soil pores. Our results therefore suggest that the movement of microplastics by soil microarthropods may influence the exposure of other soil biota to microplastics and change the physical properties of soils.

Zhu, D., et al. (2018). "Exposure of soil collembolans to microplastics perturbs their gut microbiota and alters their isotopic composition." Soil Biology & Biochemistry **116**: 302-310.
Effects of microplastics on aquatic organisms have been widely studied in recent years but effects on soil biota, and especially on the gut microbiota of soil animals, remain poorly understood. An experiment was therefore conducted using the common soil collembolan Folsomia candida exposed to microplastics for 56 days to investigate the effects of plastics on gut microbiota, growth, reproduction and isotopic turnover of collembolans in the soil ecosystem. A diverse microbial community was observed in the collembolan gut, consisting of (at phylum level) Actinobacteria (~44%), Bacteroidetes (~30%), Proteobacteria (~12%) and Firmicutes (~11%). Distinctly different bacterial communities and lower microbial diversity were found in the collembolan gut compared with the surrounding soil. We also found that exposure to microplastics significantly enhanced bacterial diversity and altered the microbiota in the collembolan gut. Moreover, collembolan growth and reproduction were significantly inhibited (by 16.8 and 28.8%, respectively) and higher delta ¹⁵N and delta ¹³C values were observed in the tissues after exposure to microplastics. These results indicate that exposure to microplastics may impact non-target species via changes in their microbiota leading to alteration of isotopic and elemental incorporation, growth and reproduction. The collembolan gut microbial data acquired fill a gap in our knowledge of the ecotoxicity of microplastics.

Zhu, F., et al. (2018). "Closed-system manufacturing of CD19 and dual-targeted CD20/19 chimeric antigen receptor T cells using the CliniMACS Prodigy device at an academic medical center." Cytotherapy

20(3): 394-406.

BACKGROUND AIMS: Multiple steps are required to produce chimeric antigen receptor (CAR)-T cells, involving subset enrichment or depletion, activation, gene transduction and expansion. Open processing steps that increase risk of contamination and production failure are required. This complex process requires skilled personnel and costly clean-room facilities and infrastructure. Simplified, reproducible CAR-T-cell manufacturing with reduced labor intensity within a closed-system is highly desirable for increased availability for patients.

METHODS: The CliniMACS Prodigy with TCT process software and the TS520 tubing set that allows closed-system processing for cell enrichment, transduction, washing and expansion was used. We used MACS-CD4 and CD8-MicroBeads for enrichment, TransAct CD3/CD28 reagent for activation, lentiviral CD8 TM-41BB-CD3 zeta-cfrag vectors expressing scFv for CD19 or CD20/CD19 antigens for transduction, TexMACS medium-3%-HS-IL2 for culture and phosphate-buffered saline/ethylenediaminetetraacetic acid buffer for washing. Processing time was 13 days.

RESULTS: Enrichment (N = 7) resulted in CD4/CD8 purity of 98 +/- 4.0%, 55 +/- 6% recovery and CD3⁺ T-cell purity of 89 +/- 10%. Vectors at multiplicity of infection 5-10 resulted in transduction averaging 37%. An average 30-fold expansion of 10⁸ CD4/CD8-enriched cells resulted in sufficient transduced T cells for clinical use. CAR-T cells were 82-100% CD3⁺ with a mix of CD4⁺ and CD8⁺ cells that primarily expressed an effector-memory or central-memory phenotype. Functional testing demonstrated recognition of B-cells and for the CAR-20/19 T cells, CD19 and CD20 single transfectants were recognized in cytotoxic T lymphocyte and interferon-gamma production assays.

DISCUSSION: The CliniMACS Prodigy device, tubing set TS520 and TCT software allow CAR-T cells to be manufactured in a closed system at the treatment site without need for clean-room facilities and related infrastructure.

Zhu, F., et al. (2013). "Identification of a protein interacting with the spore wall protein SWP26 of Nosema bombycis in a cultured BmN cell line of silkworm." Infection, Genetics and Evolution **17**: 38-45.

Nosema bombycis is a silkworm parasite that causes severe economic damage to sericulture worldwide. It is the first microsporidia to be described in the literature, and to date, very little molecular information is available regarding microsporidian physiology and their relationships with their hosts. Therefore, the interaction between the microsporidia N. bombycis and its host silkworm, Bombyx mori, was analyzed in this study. The microsporidian spore wall proteins (SWPs) play a specific role in spore adherence to host cells and recognition by the host during invasion. In this study, SWP26 fused with enhanced green fluorescence protein (EGFP) was expressed in BmN cells by using a Bac-to-Bac expression system. Subsequently, the turtle-like protein of B. mori (BmTLP) was determined to interact with SWP26 via the use of anti-EGFP microbeads. This interaction was then confirmed by yeast two-hybrid analysis. The BmTLP cDNA encodes a polypeptide of 447 amino acids that includes a putative signal peptide of 27 amino acid residues. In addition, the BmTLP protein contains 2 immunoglobulin (IG) domains and 2 IGc2-type domains, which is the typical domain structure of IG proteins. The results of this study indicated that SWP26 interacts with the IG-like protein BmTLP, which contributes to the infectivity of N. bombycis to its host silkworm.

Zhu, F., et al. (2019). "Occurrence and ecological impacts of microplastics in soil systems: a review." Bulletin of environmental contamination and toxicology **102**(6): 741-749.

Microplastics, as a group of emerging contaminants, are receiving growing attention. During the

last decade, their occurrence and toxicity in aquatic ecosystems have been intensively studied and reviewed, but less attention has been paid on soil ecosystems. Given the importance of soil ecosystems and the call for increasing research on soil from scientific communities, it is predicted that relevant studies will boom in the following years. The present review intends to provide a comprehensive overview of current knowledge on microplastic pollution in soil environments. We critically summarize the source, contamination level and fate of microplastics in (industrial and arable) soils. Then, we thoroughly describe what effects have been observed on soil microbes, animals and plants, and analyze what insights we can get from available information. Finally, we identify knowledge gaps that need to be filled and give suggestions for future research.

Zhu, H., et al. (2003). "Determination of thiamine in pharmaceutical preparations by sequential injection renewable surface solid-phase spectrofluorometry." Analytical Sciences **19**(2): 289-294.
Fluorometric determination of thiamine requires the conversion of the analyte to fluorescent thiochrome by hexacyanoferrate(III) oxidation in alkaline solution and the isolation of the produced thiochrome from the reaction medium by solvent extraction. It was observed that thiochrome could be concentrated and separated from the reaction medium by solid-phase extraction. The thiochrome sorpted on the surface of octadecyl-alklylated poly[styrene/divinylbenzene] (C18-PS/DP) microbeads emitted strong fluorescence upon excitation, the maximum excitation and emission wavelengths being 385 nm and 433 nm, respectively. Based on this observation, a sequential injection renewable surface solid-phase spectrofluorometry was developed for the determination of thiamine. A sequential injection system on-line coupled to a chip-based flow-through cell was employed to handle the chemical reaction, bead injection and discharging, and adsorption of thiochrome. Solid-phase fluorometric detection was realized by coupling the chip-based flow-through cell to a spectrofluorometer with a multistrand bifurcated optical fiber. Under the optimized condition, a detection limit of 0.03 microg ml(-1) was achieved at the sample throughput of 30 h(-1) and consumption of 1 mg C18-PS/DP microbeads for each run. Eleven runs of a 2 microg ml(-1) thiamine standard solution gave a relative standard deviation of 1.0%. The developed approach was successfully applied for the determination of thiamine contents in pharmaceutical preparations.

Zhu, H., et al. (2011). "Wide-field fluorescent microscopy on a cell-phone." Conference Proceedings: ... Annual International Conference of the IEEE Engineering in Medicine & Biology Society **2011**: 6801-6804.
We demonstrate wide-field fluorescent imaging on a cell-phone, using compact and cost-effective optical components that are mechanically attached to the existing camera unit of the cell-phone. Battery powered light-emitting diodes (LEDs) are used to side-pump the sample of interest using butt-coupling. The pump light is guided within the sample cuvette to excite the specimen uniformly. The fluorescent emission from the sample is then imaged with an additional lens that is put in front of the existing lens of the cell-phone camera. Because the excitation occurs through guided waves that propagate perpendicular to the detection path, an inexpensive plastic color filter is sufficient to create the dark-field background needed for fluorescent imaging. The imaging performance of this light-weight platform (~28 grams) is characterized with red and green fluorescent microbeads, achieving an imaging field-of-view of ~81 mm(2) and a spatial resolution of ~10 mum, which is enhanced through digital processing of the captured cell-phone images using compressive sampling based sparse signal recovery. We demonstrate the performance of this cell-phone fluorescent microscope by imaging labeled white-blood cells separated from whole blood samples as well as water-borne pathogenic

protozoan parasites such as Giardia Lamblia cysts.

Zhu, J., et al. (2019). "Cetaceans and microplastics: first report of microplastic ingestion by a coastal delphinid, Sousa chinensis." Science of the Total Environment **659**: 649-654.

In the Anthropocene, marine microplastic debris has been rapidly increasing and interacting with wildlife. As apex predators, cetaceans have been proven to be ideal sentinel species to indicate ecosystem changes and umbrella and flagship species to help develop environmental management strategies. Here, we report the presence of microplastics in the intestines of Sousa chinensis for the first time, which highlights the potential impacts of microplastic pollution in coastal environments. Microplastics were detected in the intestinal contents of both adult and calf individuals, indicating that consumption of prey and unintentional ingestion are the potential pathways for microplastic accumulation in Sousa chinensis. The properties of the microplastics indicated that fibers, white and blue items, 1-5 mm items, and polyester were the predominant shapes, colors, sizes and plastic materials, respectively. More microplastics were detected in the foreguts and midguts than in the hindguts, which may be correlated with the specific intestinal structure of Sousa. This study indicates that coastal delphinids might suffer from microplastic pollution, even young calves. The sample size in this study is limited, whereas it's a starting point for assessing microplastics in the endangered coastal delphinid, Sousa. We suggest that assessments of the risks of microplastic consumption by cetaceans and the presence of microplastics in their habitats should be conducted at a global scale. Moreover, further works should be done to look for evidence of adverse effects of microplastics pollution on cetaceans.

Zhu, J., et al. (2019). "Microplastic pollution in the Maowei Sea, a typical mariculture bay of China." Science of the Total Environment **658**: 62-68.

The ingestion of microplastics by organisms presents a potential exposure route for humans via seafood consumption. Although mariculture has become an essential source of seafood worldwide, the content of microplastics in the mariculture zone has received less scrutiny than in the wild environment. The Maowei Sea is a semi-closed bay that is rich in fishery resources. The specific levels of microplastics in the Maowei Sea and its fishery products remain undetermined. In this paper, we detail the distributions and characteristics of microplastics in the aquaculture water and biota of the Maowei Sea. Microplastics were detected in the range of 1.2-10.1particles/L in Maowei Sea surface water, with high microplastic content in estuarine oyster nursery (10.1particles/L) and Qinzhou harbor (8.8-9.5 particles/L) sites. In water samples from the three inflowing rivers, the abundances ranged from 2.9 to 4.5particles/L, which is comparable to that in Maowei Sea surface water. Of 66 collected fish belonging to 12 species, microplastics were observed in all of the gastrointestinal tracts (GITs) and in the gills of 40 individuals. In the GIT and gill tests, the abundances of microplastics ranged from 2.0 to 14.0 and from 0.0 to 8.5 particles/individual, respectively. The enhanced particles/individual figures in the GIT relative to the gill are particularly noteworthy. Demersal species showed significantly higher abundances of microplastics than pelagic species ($p<0.05$). Microplastics were also detected in the soft tissues of all oyster samples, with abundances ranging from 3.2 to 8.6 particles/individual. The microplastic composition was dominated by rayon and polyester and tended to be white in color and fibrous in shape. Altogether, these results correspond to high levels of microplastics in the Maowei Sea. As the study region is a mariculture bay, the observed microplastics contamination in its fishery products presents a route for human exposure. CAPSULE ABSTRACT: Microplastics are widespread in the aquaculture water and biota in the Maowei Sea, a mariculture bay.

Zhu, K., et al. (2019). "Formation of Environmentally Persistent Free Radicals on Microplastics under Light Irradiation." Environmental Science and Technology **53**(14): 8177-8186.

Microplastics (MPs) are presumed to be inert during aging under ambient conditions. In this study, four types of virgin MPs, including polystyrene (PS), phenol-formaldehyde resin (PF), polyethylene (PE), and polyvinyl chloride (PVC), were aged under simulated solar light irradiation. Surprisingly, several environmentally persistent free radicals (EPFRs), which are considered to be a type of emerging contaminant, were detected on the irradiated PS and PF, rather than PE and PVC, by electron paramagnetic resonance (EPR) spectroscopy. Depending on the photoaging duration time, the characteristic g-factors of the EPFRs produced on PS and PF were 2.0044-2.0049 and 2.0043-2.0044, respectively. The generated EPFRs on PS and PF decayed rapidly at the initial stage and then slowly disappeared with the elapsed aging time. Analyses by attenuated total reflectance-Fourier transform infrared spectroscopy (ATR-FTIR), X-ray photoelectron spectroscopy (XPS), nuclear magnetic resonance (NMR), and gel permeation chromatography (GPC) suggested that MPs might experience chemical chain scission, O<inf>2</inf>/H<inf>2</inf>O addition, and EPFR formation under the light irradiation. Accompanying with the formation of EPFRs, reactive oxygen species, such as O<inf>2</inf>^{*-} and *OH, were also observed. The findings provide a novel insight to evaluate the potential hazards of MPs to organisms and ecosystems. Copyright © 2019 American Chemical Society.

Zhu, L., et al. (2018). "Microplastic pollution in North Yellow Sea, China: observations on occurrence, distribution and identification." Science of the Total Environment **636**: 20-29.

Microplastics are emerging contaminants and have attracted widespread environmental concerns about their negative effects on the marine ecosystems. In this study, we investigated the abundances, distributions and characteristics of microplastics in surface seawater and sediments from the North Yellow Sea. The results showed that the abundance of microplastics was 545+or-282 items/m³ in surface seawater and 37.1+or-42.7 items/kg dry weight in sediments, representing a medium microplastic pollution level compared with other sea areas. Small microplastics (<1 mm) made up >70% of the total microplastic numbers. Films and fibers were the dominant shapes of microplastics in both the surface seawater and sediments. Transparent microplastics were generally more common than microplastics of other colors. Based on the identification by a Fourier transform infrared microscope, polyethylene (PE) was the dominant composition of microplastics in surface seawater, while polypropylene (PP) was the most common polymer type in sediments. These results will improve our understanding of the environmental risks posed by microplastics to marine ecosystems.

Zhu, L., et al. (2017). "Exosomes Derived From Natural Killer Cells Exert Therapeutic Effect in Melanoma." Theranostics **7**(10): 2732-2745.

Objective: Exosomes are nanovesicles that are released from normal and tumor cells and are detectable in cell culture supernatant and human biological fluids. Although previous studies have explored exosomes released from cancer cells, little is understood regarding the functions of exosomes released by normal cells. Natural killer (NK) cells display rapid immunity to metastatic or hematological malignancies, and efforts have been undertaken to clinically exploit the antitumor properties of NK cells. However, the characteristics and functions of exosomes derived from NK cells remain unknown. In this study, we explored NK cell-derived exosome-mediated antitumor effects against aggressive melanoma in vitro and in vivo. Methods: B16F10 cells were transfected with enhanced firefly luciferase (effluc) and thy1.1

genes, and thy1.1-positive cells were immunoselected using microbeads. The resulting B16F10/effluc cells were characterized using reverse transcriptase polymerase chain reaction (RT-PCR), western blotting, and luciferase activity assays. Exosomes derived from NK-92MI cells (NK-92 Exo) were isolated by ultracentrifugation and density gradient ultracentrifugation. NK-92 Exo were characterized by transmission electron microscopy and western blotting. We also performed an enzyme-linked immunosorbent assay to measure cytokines retained in NK-92 Exo cells. The in vitro cytotoxicity of NK-92 Exo against the cancer cells was determined using a bioluminescence imaging system (BLI) and CCK-8 assays. To investigate the possible side effects of NK-92 Exo on healthy cells, we also performed the BLI and CCK-8 assays using the human kidney PhoenixTM-Ampho cell line. Flow cytometry and western blotting confirmed that NK-92 Exo induced apoptosis in the B16F10/effluc cells. In vivo, we used a B16F10/effluc cell xenograft model to detect the immunotherapeutic effect of NK-92 Exo. We injected NK-92 Exo into tumors, and tumor growth progression was monitored using the IVIS Lumina imaging system and ultrasound imaging. Tumor mass was monitored after in vivo experiments. Results: RT-PCR and western blotting confirmed effluc gene expression and protein levels in B16F10/effluc cells. B16F10/effluc activity was found to increase with increasing cell numbers, using BLI assay. For NK-92 Exo characterization, western blotting was performed on both ultracentrifuged and density gradient-isolated exosomes. The results confirmed that NK cell-derived exosomes express two typical exosome proteins, namely CD63 and ALIX. We demonstrated by western blot analysis that NK-92 Exo presented two functional NK proteins, namely perforin and FasL. Moreover, we confirmed the membrane expression of FasL. The enzyme-linked immunosorbent assay results indicated that NK-92 Exo can secrete tumor necrosis factor (TNF)-alpha, which affected the cell proliferation signaling pathway. The antitumor effect of NK-92 Exo against B16F10/effluc cells in vitro was confirmed by BLI ($p < 0.001$) and CCK-8 assays ($p < 0.001$). Furthermore, in normal healthy cells, even after 24 h of co-culture, NK-92 Exo did not exhibit significant side effects. In the in vivo experiments, tumors in the vehicle control group were significantly increased, compared with those in the NK-92 Exo-treated group ($p < 0.05$). Conclusion: The results of the current study suggest that exosomes derived from NK cells exert cytotoxic effects on melanoma cells and thus warrant further development as a potential immunotherapeutic strategy for cancer.

Zhu, L., et al. (2019). "Microplastic ingestion in deep-sea fish from the South China Sea." Science of the Total Environment **677**: 493-501.

Monitoring the ingestion of microplastics by fish in the environment is crucial to understanding the risks posed by microplastics in the marine ecosystem. In this study, we investigated the ingestion of microplastics in deep-sea fish from the northern continental slope of the South China Sea. All fish samples were contaminated by microplastics, reflecting a high level of microplastic pollution in this region. The average abundance of microplastics in the stomachs of sampled fish was 1.96+or-1.12 items/individual and 1.53+or-1.08 items/g, and levels in the intestines of sampled fish were 1.77+or-0.73 items/individual and 4.82+or-4.74 items/g. Fish were collected from depths of 200 to 209 m and 453 to 478 m, and no significant difference in the quantity of microplastics ingested was detected among different depths in this range. The microplastics ingested by fish were dominated by plastics that were <1 mm in size, film-like in shape, transparent in color and composed of cellophane. Our results suggest that the ingestion of microplastics by fish is closely related with the microplastic pollution in the marine environment.

Zhu, L., et al. (2020). "Photochemical dissolution of buoyant microplastics to dissolved organic carbon:

Rates and microbial impacts." Journal of Hazardous Materials **383**: 121065.

Trillions of plastic fragments are afloat at sea, yet they represent only 1-2% of the plastics entering the ocean annually. The fate of the missing plastic and its impact on marine life remains largely unknown. To address these unknowns, we irradiated post-consumer microplastics (polyethylene, PE; polypropylene, PP; and expanded polystyrene, EPS), standard PE, and plastic-fragments collected from the surface waters of the North Pacific Gyre under a solar simulator. We report that simulated sunlight can remove plastics from the sea surface. Simulated sunlight also fragmented, oxidized, and altered the color of the irradiated polymers. Dissolved organic carbon (DOC) is identified as a major byproduct of sunlight-driven plastic photodegradation. Rates of removal depended upon polymer chemistry with EPS degrading more rapidly than PP, and PE being the most photo-resistant polymer studied. The DOC released as most plastics photodegraded was readily utilized by marine bacteria. However, one sample of PE microplastics released organics or co-leachates that inhibited microbial growth. Thus, although sunlight may remove plastics from the ocean's surface, leachates formed during plastic photodegradation may have mixed impacts on ocean microbes and the food webs they support.

Zhu, M., et al. (2019). "Chronic dietary exposure to polystyrene microplastics in maturing Japanese medaka (Oryzias latipes)." Aquatic Toxicology **220**: 105396.

Fish studies report consumption of microplastics (MPs) in the field, and concern exists over associated risks. However, laboratory studies with adult fish are scarce. In this study, outbred and see-through Japanese medaka (Oryzias latipes) were fed diets amended with 500, 1000, or 2000 mug/g 10 mum fluorescent spherical polystyrene microplastics (MPs) for 10 weeks during their maturation from juveniles to spawning adults. No behavioral changes, growth differences, or mortalities occurred. In vivo examinations and histologic sections showed no evidence of translocation of MPs from the gut to other internal organs. Mature females experienced dose-dependent decreases in egg number. Scanning electron microscopic examination of gills and gut revealed MPs in both areas. Swollen enterocytes were observed on apices of gut folds only in exposed fish. These were particularly apparent in foreguts of the high exposure group. Enterocytes with eroded brush borders were found in foregut of high and medium exposure groups. Increased mucus production, in long strands and sheets, was seen over primary and secondary lamellae of gills. Histological analysis showed alteration in buccal cavity, kidney, and spleen. Thickening and roughening of epithelium in headgut and pharynx and cellular alterations in spleen occurred. Head kidney was the primary site of alteration. Glomerulopathy and nephrogenesis were observed in exposed fish, increasing in severity with exposure level.

Zhu, Q. and D. Trau (2012). "Multiplex detection platform for tumor markers and glucose in serum based on a microfluidic microparticle array." Analytica Chimica Acta **751**: 146-154.

We present a multiplex detection platform based on a microfluidic microparticle array to detect proteins and glucose in serum simultaneously. Multiplex detection of proteins and glucose was performed using biofunctionalized microparticles arrayed on gel-based microstructures integrated in microfluidics. The microparticles immobilized on these microstructures showed high stability under microfluidic flow conditions. With arrays of antibody-coated microbeads, microfluidic quantitative immunoassays for two protein tumor markers, human chorionic gonadotropin (hCG) and prostate specific antigen (PSA) were performed in serum samples with detection limits bellow the cut-off values for cancer diagnosis. Parallel to the immunoassays, quantitative enzymatic assays for glucose in the physiological concentration range were performed. Multiplex detection was achieved by using a spatially encoded microarray. By patterning antibody-coated microbeads and enzyme-containing microparticles on a novel mixed

structure array, we successfully demonstrated simultaneous immunoassays (binding based assay) for proteins and an enzymatic assay (reaction kinetic based assay) for glucose. Our microparticle arrays could be potentially used for the detection of multiple categories of biomolecules (proteins, small metabolites and DNA) for clinical diagnostics and other biological applications.

Zhu, X. (2015). "Optimization of elutriation device for filtration of microplastic particles from sediment." Marine Pollution Bulletin **92**(1-2): 69-72.

The increasing presence of plastic pollution in marine ecosystems has become a major concern. In the environment, plastics break down into smaller and smaller pieces of microplastics. Methods of microplastic recovery are needed to reduce the dangers they can pose to a variety of organisms. An elutriation device was manufactured and optimized to achieve maximum microplastic recovery. The parameters flow rate and diameter of elutriation column were varied and their domain of variation was determined. A composite factorial experimental design was generated using MODDE 10.1 and was undergone. The optimal values of flow rate and column diameter were determined to be 385Lh⁻¹ and 5.06cm respectively, under constraints, to achieve a maximum feasible microplastics recovery percentage of 50.2%. The elutriation process can be improved through further testing, and can be tested in the field to compare its efficiency to that of manual microplastics filtration. Copyright © 2015 Elsevier Ltd.

Zhu, X., et al. (2007). "Simultaneous monitoring of PCDD/Fs and PCBs in contaminated air with semipermeable membrane devices and fresh spruce needles." Chemosphere **68**(9): 1623-1629.

The contaminated air with burning plastic floor and electronic scrap was monitored with semipermeable membrane devices (SPMDs) and fresh unpolluted spruce needles at the same time for polychlorinated dibenzo-p-dioxins and polychlorinated dibenzofurans (PCDD/Fs) and polychlorinated biphenyls (PCBs). It was found that there were more polychlorinated dibenzofurans (PCDFs) than polychlorinated dibenzo-p-dioxins (PCDDs) collected from contaminated air. The total amounts of PCBs were much higher than that of PCDD/Fs, but the contribution of them to the WHO-TEQ was less than that of PCDD/Fs. Triolein-containing SPMDs can absorb much more PCDD/Fs and PCBs than spruce needles when they were exposed in contaminated air simultaneously. The logarithm of the concentrations of PCDD/Fs and PCBs in SPMDs and in spruce needles at the same sampling time exhibited a significant linear correlation, the correlation coefficients were larger than 0.86 for PCDD/Fs and 0.92 for PCBs. SPMDs and spruce needles are effective passive air sampler for PCDD/Fs and PCBs. SPMDs and spruce needles can complement each other in passive air sampling. [Copyright &y& Elsevier]

Zhu, X. T., et al. (2018). "[Distribution and Settlement of Microplastics in the Surface Sediment of Yangtze Estuary]." Huanjing Kexue/Environmental Science **39**(5): 2067-2074.

This study is designed to understand the microplastic contamination in the coastal area of Yangtze estuary. The abundance and distribution profiles of microplastics in the surface sediment of six sampling sites along the Yangtze estuary were examined throughout one year. The detected average concentration of microplastic, including fibers and fragments, in the

surface sediment of Yangtze estuary was (3.42+/-1.31) items .g⁻¹ (DW). Sampling during four seasons, in the months of January, April, July, and November, indicated that the highest abundance of microplastics in Yangtze estuary surface sediment occurred in January. A re-suspension experiment showed that microplastics tend to settle in the surface sediment after re-suspension. The distribution and settlement of microplastics along the coastal area has a high concordance with the dynamic erosion-accretion process of the Yangtze estuary. Microplastics tend to settle in accretion sites rather than in erosion sites.

Zhu, Y., et al. (2019). "Impacts of (micro) plastics on soil ecosystem: progress and perspective." Journal of Agro Environment Science **38**(1): 1-6.

Plastics and their derived products are widely used in modern society, hence they are becoming indispensable. However, their wide and intensive use has caused global environmental contamination of plastics. In recent years, soil pollution with microplastics has also received increasing attention. This paper aims to provide a review on recent developments in understanding the impacts of microplastic pollution on soil ecosystem, and it will cover: (1) effects of microplastics on soil physiochemical properties; (2) effects of microplastics on soil microbial communities; and (3) the interactions between microplastics and soil fauna. Finally, future research directions are discussed.

Zhu, Z. L., et al. (2019). "Joint toxicity of microplastics with triclosan to marine microalgae Skeletonema costatum." Environmental Pollution **246**: 509-517.

Toxicity of single microplastics on organisms has been reported widely, however, their joint toxicity with other contaminants on phytoplankton is rarely investigated. Here, we studied the toxicity of triclosan (TCS) with four kinds of microplastics namely polyethylene (PE, 74 mum), polystyrene (PS, 74 mum), polyvinyl chloride (PVC, 74 mum), and PVC800 (1 mum) on microalgae Skeletonema costatum. Both growth inhibition and oxidative stress including superoxide dismutase (SOD) and malondialdehyde (MDA) were determined. We found that TCS had obvious inhibition effect on microalgae growth within the test concentrations, and single microplastics also had significant inhibition effect which followed the order of PVC800 > PVC > PS > PE. However, the joint toxicity of PVC and PVC800 in combination with TCS decreased more than that of PE and PS. The higher adsorption capacity of TCS on PVC and PVC800 was one possible reason for the greater reduction of their toxicity. The joint toxicity of PVC800 was still most significant (PE < PVC < PS < PVC800) because of the minimum particle size. According to the independent action model, the joint toxicity systems were all antagonism. Moreover, the reduction of SOD was higher than MDA which revealed that the physical damage was more serious than intracellular damage. SEM images revealed that the aggregation of microplastics and physical damage on algae was obvious. Collectively, the present research provides evidences that the existence of organic pollutants is capable of influencing the effects of microplastics, and the further research on the joint toxicity of microplastics with different pollutants is urgent. Joint toxicity effect of microplastics and triclosan on microalgae was antagonism. Copyright © 2018 Elsevier Ltd

Zhuang, J., et al. (2017). "Propulsion and Chemotaxis in Bacteria-Driven Microswimmers." Advanced science **4**(9): 1700109.

Despite the large body of experimental work recently on biohybrid microsystems, few studies have focused on theoretical modeling of such systems, which is essential to understand their underlying functioning mechanisms and hence design them optimally for a given application task. Therefore, this study focuses on developing a mathematical model to describe the 3D

motion and chemotaxis of a type of widely studied biohybrid microswimmer, where spherical microbeads are driven by multiple attached bacteria. The model is developed based on the biophysical observations of the experimental system and is validated by comparing the model simulation with experimental 3D swimming trajectories and other motility characteristics, including mean squared displacement, speed, diffusivity, and turn angle. The chemotaxis modeling results of the microswimmers also agree well with the experiments, where a collective chemotactic behavior among multiple bacteria is observed. The simulation result implies that such collective chemotaxis behavior is due to a synchronized signaling pathway across the bacteria attached to the same microswimmer. Furthermore, the dependencies of the motility and chemotaxis of the microswimmers on certain system parameters, such as the chemoattractant concentration gradient, swimmer body size, and number of attached bacteria, toward an optimized design of such biohybrid system are studied. The optimized microswimmers would be used in targeted cargo, e.g., drug, imaging agent, gene, and RNA, transport and delivery inside the stagnant or low-velocity fluids of the human body as one of their potential biomedical applications.

Ziady, A. G., et al. (2012). "Combinatorial transcriptomic, proteomic, and metabolomic analyses reveal dysregulation of glycolysis in primary CF airway epithelia and neutrophils." Pediatric Pulmonology **35)**: 311-312.

We conducted a multimodal analysis of primary CF and nonCF airway epithelia grown in normal glucose at an air-liquid interface (HBE), and neutrophils collected from the blood (PMN) of CF and nonCF subjects. To better understand the link between the dysfunction of CFTR and secondary defects like inflammation and the dysregulation of redox balance, we treated primary nonCF airway epithelia from 6 donors with the CFTR-inh-172 (20 muM) for 72 hr to inhibit CFTR. We then used mass spectrometry to analyze differences in metabolites and proteins to determine which pathways were significantly impacted by CFTR inhibition. In this initial discovery phase we found a significant change in a number of pathways, but the most pronounced change was an increase in glycolysis and glucose metabolism. Given the link between altered glycolysis and abnormalities in redox balance and inflammatory signaling, we designed a study using gene array and proteomic analyses to examine differences in CF HBE and PMN. The purpose of this study was to evaluate whether CFTR dysfunction results in abnormalities in glycolysis in the two cell types most implicated in inflammatory signaling and lung deterioration in CF. First, we studied the expression profile of PMN from CF subjects and from healthy controls aged 16 to 40 years. PMN were separated by Ficoll method and selected by CD16+ magnetic microbeads. RNA was immediately extracted and Illumina HT12 microarray platform used for analysis. We studied 11 healthy controls and 26 CF patients. Genes, enriched for glucose and carbohydrate metabolism were differentially expressed in CF vs. nonCF, which is characteristic of a metabolic shift to a glycolytic phenotype. In addition, CF PMN exhibited higher levels of two glucose transporters (GLUT1 and GLUT3). These data indicate a previously undescribed abnormality in the metabolism of CF PMN. Follow up proteomic studies in PMN and HBE cells also revealed the increased expression of glycolytic enzymes in CF vs. nonCF controls. The similarities in the regulation of glycolysis in CFTR inhibited (pharmacological model) and CF primary PMN and HBE cells suggest that the metabolic shift toward a glycolytic phenotype is due to CFTR dysfunction and may be a basic defect in CF cells. The data on a metabolic shift toward glycolysis in CF primary cells, using transcriptomic, proteomic, and metabolomic analyses were also confirmed by biochemical measures that indicated an upregulation in phosphoenolpyruvate and pyruvate. We conclude that the upregulation of glycolysis is related to CFTR dysfunction as evidenced by the impact of CFTR inhibition in nonCF primary cells, and independent studies conducted in 2 different primary cell types in 2 different labs. The implication of these results is that CFTR dysfunction is linked to a glycolytic metabolism, which in nonCF related studies has been extensively shown to promote redox imbalance and inflammatory signaling.

Ziajahromi, S., et al. (2019). "Effects of polyethylene microplastics on the acute toxicity of a synthetic pyrethroid to midge larvae (Chironomus tepperi) in synthetic and river water." Science of the Total Environment **671**: 971-975.

Microplastics are ubiquitous pollutants in the aquatic environment. However, our understanding of the interaction of chemicals, particularly synthetic pyrethroids, with microplastics and the potential toxic effects of sorbed contaminants on aquatic organisms under realistic conditions is still extremely limited. In this study, we examined whether the presence of polyethylene (PE) microplastics can affect the acute toxicity of the synthetic pyrethroid bifenthrin to an invertebrate Chironomus tepperi in both synthetic and river water. Bifenthrin alone was, as expected, acutely toxic to exposed larvae (LC₅₀ of 0.5 micro g/L after 48 h exposure). The addition of microplastics to synthetic water significantly reduced the toxicity of bifenthrin (apparent LC₅₀=1.3 micro g/L), most likely because sorption of bifenthrin to microplastics reduced its bioavailability to the exposed larvae. A sorption capacity experiment showed that >92% of bifenthrin was sorbed to microplastics. In river water containing 9.6 mg/L organic carbon, bifenthrin alone was less toxic (LC₅₀=1.3 micro g/L) than in synthetic water. Strikingly, the addition of microplastics to river water did not mitigate bifenthrin toxicity (apparent LC₅₀=1.4 micro g/L), most likely due to greater interaction of bifenthrin with organic carbon than with microplastics. While PE microplastics reduced the negative effects of bifenthrin in synthetic water, the presence of organic carbon in river water without microplastics also reduced toxicity. This suggests that while sorption of contaminants to microplastics does occur, it may not be as relevant under environmentally realistic conditions with mg/L concentrations of organic matter.

Ziajahromi, S., et al. (2019). "Microplastic pollution in a stormwater floating treatment wetland: Detection of tyre particles in sediment." Science of the Total Environment **713**: 136356.

Synthetic rubber particles released from car tyres are expected to be an important type of microplastics in the environment, with road runoff and stormwater likely to transport tyre particles to the aquatic environment. Stormwater treatment wetlands are one of the key methods for treating road runoff and stormwater, but the presence and concentration of synthetic rubber microplastics from tyre particles in wetlands are largely unknown. In addition, constructed floating wetlands can be built using recycled PET plastic bottles, raising concerns about potential release of microplastics to the environment. In this study, we measured the concentrations of microplastics in water and sediment from the inlet and outlet of a stormwater floating treatment wetland on Queensland's Gold Coast. An average of 0.9 +/- 0.3 and 4.0 +/- 2.4 microplastic particles/L were detected in the water phase in the inlet and outlet samples, respectively. The sediment contained an average of 595 +/- 120 and 320 +/- 42 microplastic particles/kg dry sediment in inlet and outlet sediments, respectively. Between 15 and 38% of microplastics in the sediment were identified by FTIR as synthetic rubber-carbon filled particles, most likely derived from car tyres. The presence of synthetic rubber microplastics confirms that tyres can contribute to microplastic pollution in stormwater, with road runoff likely to be an important pathway. No microplastics with the same characteristics and polymer composition as the floating wetland construction material were detected in the water and sediment samples, indicating that the microplastics in the water and sediment detected here did not originate from

the floating wetland's material. However, further investigation of older treatment wetlands is required to better understand the potential role of floating treatment wetlands as a source of microplastics.

Ziajahromi, S., et al. (2017). "Impact of Microplastic Beads and Fibers on Waterflea (Ceriodaphnia dubia) Survival, Growth, and Reproduction: Implications of Single and Mixture Exposures." Environmental Science & Technology **51**(22): 13397-13406.

There is limited knowledge regarding the adverse effects of wastewater-derived microplastics, particularly fibers, on aquatic biota. In this study, we examined the acute (48 h) and chronic (8 d) effects of microplastic polyester fibers and polyethylene (PE) beads on freshwater zooplankton Ceriodaphnia dubia. We also assessed the acute response of C. dubia to a binary mixture of microplastic beads and fibers for the first time. Acute exposure to fibers and PE beads both showed a dose-dependent effect on survival. An equitoxic binary mixture of beads and fibers resulted in a toxic unit of 1.85 indicating less than additive effects. Chronic exposure to lower concentrations did not significantly affect survival of C. dubia, but a dose-dependent effect on growth and reproduction was observed. Fibers showed greater adverse effects than PE beads. While ingestion of fibers was not observed, scanning electron microscopy showed carapace and antenna deformities after exposure to fibers, with no deformities observed after exposure to PE beads. While much of the current research has focused on microplastic beads, our study shows that microplastic fibers pose a greater risk to C. dubia, with reduced reproductive output observed at concentrations within an order of magnitude of reported environmental levels. Ziajahromi, S., et al. (2016). "Wastewater treatment plant effluent as a source of microplastics: review of the fate, chemical interactions and potential risks to aquatic organisms." Water Science and Technology **74**(10): 2253-2269.

Wastewater treatment plant (WWTP) effluent has been identified as a potential source of microplastics in the aquatic environment. Microplastics have recently been detected in wastewater effluent in Western Europe, Russia and the USA. As there are only a handful of studies on microplastics in wastewater, it is difficult to accurately determine the contribution of wastewater effluent as a source of microplastics. However, even the small amounts of microplastics detected in wastewater effluent may be a remarkable source given the large volumes of wastewater treatment effluent discharged to the aquatic environment annually. Further, there is strong evidence that microplastics can interact with wastewater-associated contaminants, which has the potential to transport chemicals to aquatic organisms after exposure to contaminated microplastics. In this review we apply lessons learned from the literature on microplastics in the aquatic environment and knowledge on current wastewater treatment technologies, with the aim of identifying the research gaps in terms of (i) the fate of microplastics in WWTPs, (ii) the potential interaction of wastewater-based microplastics with trace organic contaminants and metals, and (iii) the risk for aquatic organisms. Copyright © IWA Publishing 2016.

Ziajahromi, S., et al. (2017). "Wastewater treatment plants as a pathway for microplastics: Development of a new approach to sample wastewater-based microplastics." Water Research **112**: 93-99.

Wastewater effluent is expected to be a pathway for microplastics to enter the aquatic environment, with microbeads from cosmetic products and polymer fibres from clothes likely to enter wastewater treatment plants (WWTP). To date, few studies have quantified microplastics in wastewater. Moreover, the lack of a standardized and applicable method to identify microplastics in complex samples, such as wastewater, has limited the accurate assessment of microplastics and may lead to an incorrect estimation. This study aimed to develop a validated method to sample and process microplastics from wastewater effluent and to apply the developed method to quantify and characterise wastewater-based microplastics in effluent from three WWTPs that use primary, secondary and tertiary treatment processes. We applied a high-volume sampling device that fractionated microplastics in situ and an efficient sample processing procedure to improve the sampling of microplastics in wastewater and to minimize the false detection of non-plastic particles. The sampling device captured between 92% and 99% of polystyrene microplastics using 25 mum-500 mum mesh screens in laboratory tests. Microplastic type, size and suspected origin in all studied WWTPs, along with the removal efficiency during the secondary and tertiary treatment stages, was investigated. Suspected microplastics were characterised using Fourier Transform Infrared spectroscopy, with between 22 and 90% of the suspected microplastics found to be non-plastic particles. An average of 0.28, 0.48 and 1.54 microplastics per litre of final effluent was found in tertiary, secondary and primary treated effluent, respectively. This study suggests that although low concentrations of microplastics are detected in wastewater effluent, WWTPs still have the potential to act as a pathway to release microplastics given the large volumes of effluent discharged to the aquatic environment. This study focused on a single sampling campaign, with long-term monitoring recommended to further characterise microplastics in wastewater.

Ziccardi, L. M., et al. (2016). "Microplastics as vectors for bioaccumulation of hydrophobic organic chemicals in the marine environment: A state-of-the-science review." Environmental Toxicology & Chemistry **35**(7): 1667-1676.

A state-of-the-science review was conducted to examine the potential for microplastics to sorb hydrophobic organic chemicals (HOCs) from the marine environment, for aquatic organisms to take up these HOCs from the microplastics, and for this exposure to result in adverse effects to ecological and human health. Despite concentrations of HOCs associated with microplastics that can be orders of magnitude greater than surrounding seawater, the relative importance of microplastics as a route of exposure is difficult to quantify because aquatic organisms are typically exposed to HOCs from various compartments, including water, sediment, and food.

Zieba, Z. (2017). "Influence of soil particle shape on saturated hydraulic conductivity." Journal of Hydrology and Hydromechanics; Vodohospodarsky Casopis **65**(1): 80.

The aim of this paper is to define the correlation between the geometry of grains and saturated hydraulic conductivity of soils. The particle shape characteristics were described by the ZC index (Parylak, 2000), which expresses the variability of several shape properties, such as sphericity, angularity and roughness. The analysis was performed on samples of four soils, which were characterised by the same grain size distribution and extremely different particle structure. The shape characteristics varied from ideally spherical, smooth grains (glass microbeads GM) to highly irregular and rough particles (fly ash FA). For each soil, laboratory tests of saturated hydraulic conductivity (constant head test CHT and falling head test FHT) were performed. Additionally, an empirical analysis of effective pore diameter was conducted with use of the

analytical models developed by Pavchich (Wolski, 1987) and Indraratna and Vafai (1997). The models were modified by introducing the Z0C index. Experiments have shown that saturated hydraulic conductivity depends on grains shape and surface roughness. This parameter decreases with the increase in the irregularity of soil particles. Moreover, it was proven that the Z0C reflects the relationship between effective pore diameter and grain shape characteristics.

Zilberberg, J., et al. (2018). "An ex vivo 3D bone metastasis model for prostate cancer." Cancer Research. Conference **78**(13 Supplement 1).

Introduction: Bone is the preferred site for prostate cancer (PCa) metastases and there is virtually no cure once the tumor is established within this niche. The development of therapeutic strategies against metastatic PCa has been limited by the lack of an all-human preclinical model to: (1) study PCa-bone interactions under physiologically relevant three dimensional (3D) microenvironments, (2) understand how these interactions result in the development of drug resistance, and (3) explore paradigm-changing precision medicine concepts. Method(s): Conditionally reprogrammed primary PCa cells (CR-PCa, derived from a lymph node metastatic site) were integrated with our ex vivo human 3D bone tissue platform, as a transformative approach for modeling tumor behavior at the bone niche. The 3D bone tissue was engineered using primary osteoblastic (OSB) cells from human bone samples. These cells were biomimetically assembly with biphasic calcium phosphate microbeads (BCPm) in perfusion microfluidic culture devices. BCPm were used to replicate the 3D cellular network of OSTs in human bone. This 3D tissue model was successfully used to support the osteocytic differentiation of primary human OSB cells within the BCPm structure, while maintaining a single cell layer of osteoblasts on the surface of the 3D tissue resembling the bone endosteum. Result(s): Integration of the 3D bone tissue with CR-PCa cells resulted in a compromised endosteal layer after only 4 days of coculture, with more apoptotic OSTs in the tissues with CR-PCa vs. no PCa cells controls (P<0.01). For functional analysis, we stained 5 mum sections of the 3D tissues for alkaline phosphatase (ALP, an OSB marker) and sclerostin, an osteocytic marker and major signaling molecule released by embedded OSTs that suppresses osteoblastogenesis. Quantification of immunofluorescence staining revealed that ALP was significantly increased (P<0.05), whereas sclerostin significantly decreased (P<0.01) with the introduction of CR-PCa cells. This OSB phenotype, induced by PCa-bone interactions ex vivo, is entirely consistent with the OSB prostate cancer-bone metastasis niche seen in patients with advanced disease. Conclusion(s): Our model recapitulates: (1) an OSB monolayer closely resembling the endosteum at the bone/ bone marrow interface, (2) the complex microphysiological features and functions of 3D-networked OSTs, and (3) the interactions of primary PCa cells with osteoblasts and OSTs.

Zilberman, Y. and S. R. Sonkusale (2015). "Microfluidic optoelectronic sensor for salivary diagnostics of stomach cancer." Biosensors & Bioelectronics **67**: 465-471.

We present a microfluidic optoelectronic sensor for saliva diagnostics with a potential application for non-invasive early diagnosis of stomach cancer. Stomach cancer is the second most common cause of cancer-related deaths in the world. The primary identified cause is infection by a gram-negative bacterium Helicobacter pylori. These bacteria secrete the enzyme urease that converts urea into carbon dioxide (CO_2) and ammonia (NH_3), leading to their elevated levels in breath and body fluids. The proposed optoelectronic sensor will detect clinically relevant levels of CO_2 and NH_3 in saliva that can potentially be used for early diagnosis of stomach cancer. The sensor is composed of the embedded in a microfluidic device array of microwells filled with ion-exchange polymer microbeads doped with various organic dyes. The

optical response of this unique highly diverse sensor is monitored over a broad spectrum, which provides a platform for cross-reactive sensitivity and allows detection of CO_2 and NH_3 in saliva at ppm levels.

Zima, P., et al. (2017). THE STUDY OF WATER POLLUTION OF THE LOWER VISTULA RIVER BY PLASTIC PARTICLES. Sofia, Surveying Geology & Mining Ecology Management (SGEM). **17:** 729-736.

Since the beginning of widespread use of plastic its consumption and production has been constantly increasing. As a result of human activity part of waste ends up in our environment and is deposited in each of the elements of the biosphere. These impurities can be in the form of large elements, small particles fragmented to macroscopic level (pellets, facial scrub grains) and the microparticles visible under a microscope. Particularly harmful for the environment are microplastic particles, which can be deposited in living organisms. Impurities get into surface waters, and then through rivers into the seas and oceans, as the final reservoir. Currently greater attention is paid to rivers. In rivers plastic can undergo further fragmentation and be transported along with water and bed sediment. The article describes the trial attempt to determine the content of plastic in the water of the lower Vistula- the largest river flowing into the Baltic Sea. The material extraction for the research was done in the Tczew gauge profile (Km 33+080). During this process the hydrometric measurements and the velocity distribution and flow rate using ADCP device was completed. For sampling were used plankton nets - the first with the mesh size of 0.5 mm and the inlet dimensions of 0.2x0.4 m and second with the 0.2 mm and 0.2x0.3 m. 0.5 mm nets were placed in the mainstream (velocity of approx. 1m/s) at the surface and at a depth of 0.5 m. 0.2 mm net was put at the bottom and left for sampling. After filtration of approx. 100 m3 of water, nets with samples were preserved and transported to the laboratory. The resulting catch at the surface and at a depth of 0.5 m contained plant parts and wood fragments, and the mesh placed at the bottom caught sand, wood fragments and shells. Then the samples were dried at room temperature. In order to reduce the organic matter, the dry samples were placed in a 20% solution of H_2O_2 and then in a 20% solution of HCl. The acquired portion of bed sediment (705g dry weight) after etching was subjected to flotation in a 40% $ZnCl_2$ solution (solution density approx. 1.4 g/cm3). After the sand sedimentation, the solution was filtered. The samples were examined microscopically. During the investigation, some plastic particles were found plastic (size of 1-2 mm or more). While examining under a microscope at 60 times magnification were noticed single plastic fibers. The study helped to identify the presence of forms of plastic on the macroscopic and microscopic level. Various forms of plastic were found both in water and bed sediment. Due to the size of the mesh, smaller particles have not been studied.

Zink, L. and G. G. Pyle (2019). "Contrary to Marine Environments, Common Microplastics in Freshwater Systems May Not Emit Dimethyl Sulfide: An Important Infochemical." Bulletin of Environmental Contamination & Toxicology **103**(6): 766-769.

The ingestion of microplastics by marine species has been at least partially attributed to plastics emitting a dimethyl sulfide signature when exposed to marine conditions. Dimethyl sulfide, a member of the volatile organic sulfur compounds group, is an infochemical that many species rely on to locate and identify prey while foraging. Microplastic ingestion is also observed in freshwater systems; however, this study shows that the same dimethyl sulfide signature is not obtained by three common types of plastic (high-density polyethylene, low-density polyethylene, and polystyrene) in freshwater systems, suggesting that there may be an alternate mechanism driving plastic ingestion by freshwater species.

Zitko, V. and M. Hanlon (1991). "Another Source of Pollution by Plastics: Skin Cleaners with Plastic Scrubbers." Marine Pollution Bulletin MPNBAZ, Vol. 22, No. 1, p 41-42, January 1991. 1 fig, 13 ref.

Skin cleaners containing plastic scrubber particles (polyethylene, polypropylene, or polystyrene, 40-200 mesh) were patented in the United States many years ago, but the extent, volume, and pattern of their use are unknown. Meanwhile, polystyrene spherules, presumably derived from the manufacture and disposal of plastics, have been found in the environment. The effect of these spherules in unknown. The possibility of intestinal blockage in smaller fish exists. The spherules might also adsorb and accumulate toxic hydrophobic organic compounds and deliver them to the biota. Two commercially available cleaners containing plastic scrubbers were examined. A water-based formulation was dispersed in water and the plastic particles left to settle. The particles were irregular in shape and about 0.1-0.2 mm in the largest dimension. Infrared analysis confirmed their identity as polystyrene. A hydrocarbon-based cleaner was extracted with acetone and hexane, yielding a liquid, presumably the C11-C13 isoparaffins declared on the label. A gelatinous residue was obtained from the acetone phase. The plastic particles were best seen on a smear of the original formulation; their concentration in the formulation is quite small. Given their persistence in the environment, accumulation could occur if these plastic scrubber-containing cleaner become more widely used in the marketplace. (Doria-PTT)

Zizka, J. and J. Weiser (1993). "Effect of beauvericin, a toxic metabolite of Beauveria bassiana, on the ultrastructure of Culex pipiens autogenicus larvae." Cytobios **300**: 13-19.

Larvae of C. pipiens exposed to 0.1 mg ml⁻¹ beauvericin on silica gel microbeads had a mortality of 44% after 48 h. Symptoms of intoxication with intensive vacuolization were evident in all specimens. The toxic effect was concentrated in the mitochondria which were inflated and appeared as spherical vacuoles with vestigial cristae. The chromatin in the nuclei was concentrated in large granules mainly on the nuclear membrane. Most affected was the epithelium of the midgut where the basal membrane was ruptured and the labyrinth heavily dissolved. In the fat body and the muscles intensive vacuolization had affected the compact tissues. The cytoplasm was vacuous, without endoplasmic reticulum, and ribosomes were dissolved.

Zlatkov, D., et al. (2012). Recycling of construction waste. 12th International Multidisciplinary Scientific GeoConference and EXPO, SGEM 2012, June 17, 2012 - June 23, 2012, Varna, Bulgaria, International Multidisciplinary Scientific Geoconference and EXPO.

This paper deals with recycling of construction waste, i.e. process of collecting and treating waste to be re-used as raw material in the creation of an identical or similar products. The paper advocates the sustainable development that meets the needs of present generations without compromising the rights of future generations to meet their needs. Natural resources are general and common good and their use should be planned and directed and purpose controlled. The rapid technological development in recent decades has necessitated serious human addressing the issues related to management of waste generated in various technological operations, and as a final waste in the use of final products. Recycling Technology of CWM (Construction Waste Material) resulting from construction, and more frequently from demolition of various types of buildings. CWM usually consists of: waste wood, various metals, concrete, bricks, blocks, tiles, glass, asphalt, etc. There are also several types of devices and procedures for the recycling of CWM. CWM recycling process includes: demolition of old or damaged structures, development of towns and villages, various destructions, earthquakes, floods, etc. Construction waste is the second largest waste type, immediately after the

municipal solid waste. Construction waste is divided into rubble, soil, waste from the reconstruction of roads, and waste from the construction sites. The rubble itself can be dangerous because it may contain asbestos, which is very harmful to human health, or acids, paints, varnishes, thinners, means for removing rust, paint or varnish, wood coatings, oil filters, mineral oils and others. Glass is one of the building materials that can be fully recycled. To reduce the amount of plastic waste, which is not selfdegradable, it must be recycled. The first center for recycling of construction waste started operation in Kragujevac (Serbia) where the waste will be disposed of and processed for reuse. Zobkov, M. and E. Esiukova (2017). "Microplastics in Baltic bottom sediments: Quantification procedures and first results." Marine Pollution Bulletin **114**(2): 724-732.

Microplastics in the marine environment are known as a global ecological problem but there are still no standardized analysis procedures for their quantification. The first breakthrough in this direction was the NOAA Laboratory

Zobkov, M. B., et al. (2019). "Microplastic content variation in water column: The observations employing a novel sampling tool in stratified Baltic Sea." Marine Pollution Bulletin **138**: 193-205.

A new tool was developed for microplastics (MPs) investigation in the water column. It can collect several cubic meters of water from predefined water layers down to 100 m. The tool was tested in the Baltic Sea during the period of spring thermocline formation. Strong MPs stratification was observed at all of the sampled stations. On coastal stations (~30 m deep), stratification with high fibers content was associated with the proximity of terrestrial sources and estuarine discharges, while on off-shore stations the variability of MPs was related to vertical thermohaline structure. Mean MPs content was the 32.2 (SD 50.4) pcs/m³. Elevated MPs concentrations were observed in subsurface, near-bottom and thermohaline layers compared with intermediate layers. The heterogeneity of MPs distribution suggests that MPs particles can be retained above the density-gradient layers in coastal seas and the World Ocean. Copyright © 2018 Elsevier Ltd

Zocchi, M. and R. Sommaruga (2019). "Microplastics modify the toxicity of glyphosate on Daphnia magna." Science of the Total Environment **697**: N.PAG-N.PAG.

Plastic contamination is an environmental problem spreading to even the most remote aquatic and terrestrial habitats and in particular, microplastics represent an uncertain threat for organisms. Microplastics can have a direct negative effect, but they can also potentially modify the toxicity and bioavailability of pollutants. Here, we tested over 1 week the combined effect of three different glyphosate chemical formulations (glyphosate acid, glyphosate-monoisopropylamine salt, and Roundup Gran) and two types of microplastics (polyethylene (PE) microbeads and polyethylene terephthalate/polyamide (PET/PA) fibers), on Daphnia magna. Glyphosate-monoisopropylamine salt caused the highest mortality after 1 week exposure (23.3%), whereas glyphosate acid the lowest (12.5%), when tested in the absence of microplastics. These results were inverted, however, when the individuals were exposed in combination with the PE microbeads (glyphosate acid: 53.3% and glyphosate-monoisopropylamine salt: 18.3%) or the PET/PA fibers (glyphosate acid: 30.0% and glyphosate-monoisopropylamine salt: 8.3%). The mortality in the Roundup Gran formulation also increased when combined with the two microplastics, though the effect was less pronounced. In all experiments, the effect of the treatments and time was significant, though there was no significant interaction between them. In most treatments, negative effects were

not observed after 48 h or later. The change in toxicity of the glyphosate formulations caused by microplastics can be linked to the different sorption properties of the glyphosate-based chemicals formulations. The outcome of this study highlights that beside the potential direct negative effects of microplastics, they can modify the toxicity of pollutants, such as herbicides. Unlabelled Image • Microplastics modified the toxicity of glyphosate on Daphnia magna. • Two different types of microplastics elicited similar changes in toxicity. • Additive effects depended on glyphosate's chemical formulation. [ABSTRACT FROM AUTHOR]

Zuccarello, P., et al. (2019). "Exposure to microplastics (<10 micro M) associated to plastic bottles mineral water consumption: the first quantitative study." Water Research **157**: 365-371.

The uncontrolled introduction into the environment of plastic polymers have caused the dispersion of plastic fragments, known as Microplastics (MPs), that represent an important topic for public health. This study was the first to investigate the cause of the release of MPs in mineral waters and to estimate the concentration of MPs smaller than 10 micro m both in number of particles and in mass unit. This study was carried out using a patent method regarding the extraction and analysis of MPs in more kind of matrix. Therefore, aims of this study were (a) to assess the number of MPs with diameters of between 0.5 and 10 micro m in mineral waters contained in plastic bottles, (b) to evaluate if the physical-chemical properties of mineral waters and bottle quality could influence the release of MPs and, finally, (c) to estimate the human daily exposure to MPs due to mineral water consumption. The Mps were found in every sample. The main concentration of MPs was 656.8 micro g/L+or-632.9 or 5.42E+07 p/L+or-1.95E+07. The main diameter of detected MPs was 2.44 micro m+or-0.66 (where p/L, where p was the number of MPs). The Estimated Daily Intake (EDI) for adults and children were 1,531,524 p/kg/body-weight/day corresponding to 40.1 micro g/kg/body-weight/day and 3,350,208 p/kg/body-weight/day corresponding to 87.8 micro g/kg/body-weight/day, respectively. The number of MPs contamination in bottled mineral waters was strongly correlated to the pH of waters and to plastic density of bottle. Otherwise, micrograms of MPs per liter and the MPs diameters were strongly affected by plastic thickness. The most mineral water brand contaminated by MPs was the one whose bottles were made from poor quality plastic. In absence of reference values, it was no possible carried out a risk assessment for MPs exposure. It is fundamental to establish the reference method of analysis to monitoring every source of human intake.

Zuccarello, P., et al. (2019). "Exposure to microplastics (<10mum) associated to plastic bottles mineral water consumption: The first quantitative study." Water Research **157**: 365-371.

In absence of reference values, it was no possible carried out a risk assessment for MPs exposure. It is fundamental to establish the reference method of analysis to monitoring every source of human intake.

Zulkifley, M. A., et al. (2014). "Robust identification of polyethylene terephthalate (PET) plastics through Bayesian decision." PLoS ONE [Electronic Resource] **9**(12): e114518.

Recycling is one of the most efficient methods for environmental friendly waste management. Among municipal wastes, plastics are the most common material that can be easily recycled and polyethylene terephthalate (PET) is one of its major types. PET material is used in consumer goods packaging such as drinking bottles, toiletry containers, food packaging and many more. Usually, a recycling process is tailored to a specific material for optimal purification and decontamination to obtain high grade recyclable material. The quantity and quality of the sorting process are limited by the capacity of human workers that suffer from fatigue and boredom. Several automated sorting systems have been proposed in the literature that include using chemical, proximity and vision sensors. The main advantages of vision based sensors are its environmentally friendly approach, non-intrusive detection and capability of high throughput. However, the existing methods rely heavily on deterministic approaches that make them less accurate as the variations in PET plastic waste appearance are too high. We proposed a probabilistic approach of modeling the PET material by analyzing the reflection region and its surrounding. Three parameters are modeled by Gaussian and exponential distributions: color, size and distance of the reflection region. The final classification is made through a supervised training method of likelihood ratio test. The main novelty of the proposed method is the probabilistic approach in integrating various PET material signatures that are contaminated by stains under constant lighting changes. The system is evaluated by using four performance metrics: precision, recall, accuracy and error. Our system performed the best in all evaluation metrics compared to the benchmark methods. The system can be further improved by fusing all neighborhood information in decision making and by implementing the system in a graphics processing unit for faster processing speed.

Zuo, L.-Z., et al. (2019). "Sorption and desorption of phenanthrene on biodegradable poly(butylene adipate co-terephtalate) microplastics." Chemosphere **215**: 25-32.

Biodegradable plastics, as alternatives to conventional plastics, are increasingly used, but their interactions with organic pollutants are still unknown. In this study, the sorption and desorption behaviors on a type of biodegradable plastic−poly(butylene adipate co-terephtalate) (PBAT) were investigated, and at the same time two types of conventional plastics−polyethylene (PE c and PE v) and polystyrene (PS) were used for comparison. Phenanthrene (PHEN) was chosen as one of representative organic pollutants. Results indicated that the sorption and desorption capacities of PBAT were not only higher than those of the other types of microplastics, but also higher than those of carbonaceous geosorbents. The surface area normalized results illustrated that sorption and desorption of the microplastics were positively correlated with their abundance of rubbery subfraction. The sorption kinetic results showed that the sorption rates of PBAT and PE c were higher than PE v and PS. The effects of water chemistry factors including salinity, dissolved organic matter and Cu2+ ion on the sorption process displayed the same trend, but the degrees of influence on the four microplastics differed. The degrees of influence were mainly dependent on the abundance of rubbery subfraction for microplastics. These findings indicate that the biodegradable poly(butylene adipate co-terephtalate) microplastics are actually stronger vectors than the conventional microplastics, and crystallization characteristics of the microplastics have great influences on the vector effect. Graphical abstract Image 1 Highlights • Biodegradable microplastics sorbed/desorbed more PHEN than conventional ones. • Sorption/desorption capacities depended on the content of rubbery subfraction. • Plastic additives didn't alter the microplastics adsorption process. • High salinity and low DOM strengthen the sorption of PHEN onto microplastics. Zuza, M. G., et al. (2017). "Design and characterization of alcalase-chitosan conjugates as potential biocatalysts." Bioprocess & Biosystems Engineering **40**(11): 1713-1723.

In this study, alcalase (protease from Bacillus licheniformis) immobilization by adsorption, enzyme crosslinking and covalent enzyme binding to activated chitosan microbeads were examined. The biocatalysts highest activity was obtained by covalent immobilization of alcalase onto a solid support. The alcalase covalent immobilization onto different types of chitosan beads obtained by inverse emulsion technique and electrostatic extrusion was studied. Parameters examined under different conditions were beads diameter, enzyme loading, enzyme capacity yield, and biocatalyst activity. The highest activity and enzyme loading of 23.6 IU/mg protein and 340.2 mg/g, respectively, were achieved by the enzyme immobilized onto chitosan microbeads obtained by the electrostatic extrusion technique. FT-IR analysis was used to confirm formation of alcalase-chitosan conjugates. The activity of optimally produced alcalase-chitosan microbeads was then verified in the industrially feasible reaction systems of egg white and soy protein hydrolysis. The high degree of hydrolysis of 29.85 +/- 0.967% after 180 min and five successive reuses obtained under real conditions (50 degreeC, pH 8) verified the covalently bound alcalase to chitosan beads a promising candidate for use in industrial egg white protein hydrolysis process.

Zwissler, B., et al. (1995). "Effects of inhaled prostacyclin as compared with inhaled nitric oxide in a canine model of pulmonary microembolism and oleic acid edema." Journal of Cardiothoracic and Vascular Anesthesia **9**(6): 634-640.

Objective: Recently, it has been shown that the inhalation of nitric oxide (NO) and of prostacyclin (PGI<inf>2</inf>) elicits selective pulmonary vasodilation in a canine model of pulmonary hypertension induced by hypoxic pulmonary vasoconstriction. The present study was designed to investigate whether inhaled NO or PGI<inf>2</inf>-aerosol, respectively, is also effective in decreasing pulmonary artery pressure in a canine model of acute pulmonary

microembolism and oleic acid edema. Design(s): Prospective, randomized, cross-over design. Setting(s): University animal research laboratory. Participant(s): Eight anesthetized, mechanically ventilated dogs (28 +/- 1 kg). Intervention(s): Acute pulmonary microembolization (PME) was induced using glass microbeads (mean diameter: 100 mum) and 0.01 mL/kg of oleic acid. Subsequently, inhaled PGI<inf>2</inf> (concentration: 10 mug/mL) or NO (50 ppm), respectively, was randomly administered for 15 minutes each and then withdrawn. Measurements and Main Results: Central hemodynamics (heart rate [HR], cardiac output [CO], stroke volume [SV], mean arterial pressure [MAP], systemic vascular resistance [SVR], mean pulmonary artery pressure [PAP], pulmonary vascular resistance [PVR]) and gas exchange (PaO<inf>2</inf>/F<inf>1</inf>O<inf>2</inf> ratio, intrapulmonary shunt [Qs/Qt], alveolar-arterial oxygen difference, [AaDO<inf>2</inf>]) were assessed. Measurements were performed at control, after PME, and during administration of PGI<inf>2</inf> and NO, respectively. PME induced a significant increase ($p < 0.001$) of MAP (+9%), PAP (+68%), and PVR (+163%), whereas HR, CO, and SV remained unchanged and lung function deteriorated. Inhalation of NO slightly decreased PAP (- 10%; $p<0.05$) and PVR (-26%; $p<0.01$) and improved AaDO<inf>2</inf> and PaO<inf>2</inf>/F<inf>1</inf>O<inf>2</inf>. In contrast, inhalation of PGI<inf>2</inf> had no consistent effect on pulmonary vascular tone or gas exchange. Conclusion(s): The data demonstrate that inhaled NO may elicit selective pulmonary vasodilation and improve gas exchange in a canine model of pulmonary microembolism and respiratory insufficiency. However, the degree of these effects was relatively small. The aerosolization of PGI<inf>2</inf> under conditions of positive-pressure ventilation did not exert a significant vasodilatory effect on pulmonary vessels and did not improve pulmonary gas exchange in this model.
