## Current Trends

## Subacute Sclerosing Panencephalitis and Measles

Subacute sclerosing panencephalitis (SSPE) is a slow virus infection of the brain caused by a measles-like virus. A recently published study has revealed that SSPE follows measles at a rate of approximately $5-10$ cases for every million children developing measles (1). Live measles vaccine may be associated with SSPE at a rate of $0.5-1.1$ cases per million doses of measles vaccine distributed. Thus, the risk following natural measles is 5-20 times greater than following measles vaccination.

A case-control study evaluating in greater detail the association of measles and/or vaccine with SSPE is currently underway at CDC and the University of Tennessee. Fiftytwo children with SSPE diagnosed since January 1, 1974, were each matched by age, sex, and race with both a longterm playmate and a hospitalized child. Vaccination and disease histories, verified by medical records review, were available for atl cases and for 96 controls (Table 1). Children with SSPE were significantly more likely to have had natural measles than were controls ( $p<.001$ ). Control children were significantly more likely to have received measles vaccine than were SSPE cases ( $\mathrm{p}<.001$ ). There was no difference between cases and controls with regard to having received measles vaccine after having had natural measles ( $21.2 \%$ vs $20.8 \%$ ).
TABLE 1. History of measles infection and measles vaccination in 52 children with SSPE and 96 control children.

| Measles Disease/ | SSPE Cases <br> No. \%accine History | Controls <br> No. \% |
| :---: | :---: | :---: |
| Had natural measles; <br> no measles vaccination | $32(61.5)$ | $25(26)$ |
| Had natural measles; <br> received measles vaccine | $11(21.2)$ | $20(20.8)$ |
| Had no history of meastes; <br> received measles vaccine | $6(11.5)$ | $43(44.8)$ |
| Had no history of measles or <br> measles vaccination <br> Total | $3(5.8)$ | $8(8.3)$ |
|  | 52 | 96 |

Two SSPE cases ( $3.8 \%$ ) and 4 control children ( $4.2 \%$ ) had received 2 or more doses of measles vaccine. Eleven SSPE cases ( $21.2 \%$ ) had natural measles before they were 1 year old compared to 4 control children ( $4.2 \%$ ) ( $p<.01$ ). Four control children but none of the SSPE cases had received measles vaccine before they were 1 year old.
Reported by the Immunization Div, Bur of State Services, cDC.

Editorial Note: Although live measles vaccine may lead to SSPE on rare occasions, it seems apparent that the overall effect of the vaccine is to protect against SSPE by preventing measles with its attendant higher risk of SSPE.

Before the widespread use of measles vaccine as many as $15-30 \%$ of children without a clinical history of natural measles infection had serologic evidence of a previous measles infection $(2,3)$. Presumably, either measles infection occurred in the first year of life under the partial protection of maternal antibody, or the disease was misdiagnosed by parents and physicians. Therefore, a negative history of natural measles does not rule out the possibility of previous measles infection. This is also shown by the 3 children with SSPE in this study (Table 1) who had elevated measles antibody titers but no history of natural measles or measles vaccine.

There has been recent speculation that administration of measles vaccine either more than once or after natural measles infection might enhance the risk of developing SSPE. If that were true, one would expect to find that these events had occurred more frequently in children with SSPE than in control children; no such difference, however, was observed in this study. Vaccination of children who previously received live measles vaccine or who had previously had natural measles has not been shown to be associated with other neurologic disorders (4-8). In addition, rates of expected minor reactions such as fever and rash following vaccination in these children were less than those observed in susceptible children vaccinated for the first time.

Therefore, while measles vaccine is not needed in persons known to be immune, serologic screening of children with uncertain immune status before administering measles vaccine is not useful in preventing SSPE.

## Epidemiologic Notes and Reports

## Follow-up on Salmonella organisms in Precooked Roast Beef

New cases of salmonellosis related to consumption of precooked roast beef continue to be reported; the total number of such cases in the current outbreak now exceeds 181 cases. In addition to new cases in New York, Pennsylvania, New Jersey, and Connecticut, cases have been found in Georgia and Massachusetts. Investigation in Massachusetts has revealed 3 cases caused by Salmonella bovis-morbificans, the serotype involved in a precooked roast beef outbreak in 1976 (1). In early September, Canada reported salmonellosis in an 11-year-old boy in Montreal who had eaten precooked roast beef in upstate New York.

Reported by S Handel, MD, Bureau of Epidemiology, Dept of National Health and Welfare, Ottawa, Canada; JE McCroan, PhD, State Epidemiologist, Georgia State Dept of Human Resources; NJ Fiumara, MD, MPH, State Epidemiologist, Massachuserts State Dept of Public Health; JN Lewis, MD, State Epidemiologist, Connecticut State Dept of Health; R Altman, MD, State Epidemiologist, New Jersey State Dept of Health; D Lyman, MD, State Epidemiologist, New York State Dept of Health; W Parkin, DVM, State Epidemi-
ologist, Pennsylvania State Dept of Health; Enteric Diseases Br, Bacterial Diseases Div, Bur of Epidemiology, CDC.
Editorial Note: Although the cases of salmonellosis caused by $S$. newport originally drew attention to the problem of salmonella contamination of precooked roasts of beef (1), further study has revealed that 7 different Salmone/la serotypes are associated with this outbreak. Several of these (S. newport, S. chester, S. typhimurium, S. waycross, and S. bovis-morblficans) have been isolated from unopened precooked roast beef during the current outbreak.

The total number of cases in this outbreak is difficult to assess, since interviews, necessary to determine the association of a case with precooked roast beef, have not been completed on all persons with Salmonella isolates. The finding of cases in Georgia indicates that contaminated beef is not a problem limited to the northeastern part of the United States.

## Tick Paralysis - Georgia

On July 9, 1977, a 7 -year-old female was admitted to a northern Georgia Hospital with an admitting diagnosis of acute cerebellar ataxia.

The child displayed symptoms of unsteady gait and the inability to walk. Her temperature was recorded at 99 F. No recent illnesses or other symptoms were evident. Lumbar puncture showed no white cells, with a spinal fluid glucose of $55 \mathrm{mg} / \mathrm{ml}$ and a protein of $22 \mathrm{mg} / \mathrm{ml}$. Bacterial culture of the spinal fluid revealed no growth. The day following admission the child became markedly worse with generalized paralysis. She had a very weak grip and was able to move her toes only slightly.

Because tick paralysis was suspected, she was searched for ticks. Two ticks, a male and a female Dermacentor variabilis, were discovered attached to her scalp. The female tick was fully engorged, indicating prolonged attachment. It was removed from the back of the head near the neck. The male tick was removed from the midline area of the scalp.

Within 6-8 hours following removal of the ticks, there was obvious clinical improvement. Over the next $24-36$
hours the child made a rapid recovery. She was discharged on July 14, able to walk without any difficulty.

Reported bv L Morris, MD, JE McCroan, PhD, State Epidemiologist, JD Smith, Georgia Dept of Human Resources; and Respiratory and Special Pathogens Br, Viral Diseases Div, Bur of Epidemiology, CDC.
Editorial Note: Tick paralysis is a toxin-induced disorder associated with the attachment and feeding of the female member of any of a number of tick species, including, in the continental United States, D. andersoni, D. variabilis, Amblyomma americanum, and A. maculatum. The tick must feed for several days before symptoms develop.

The neurotoxin injected by the engorging tick acts upon spinal and bulbar neurons slowing motor neuron conduction. Sensory involvement is rare.

Clinically, diarrhea, ataxia, and areflexia may appear 24 hours prior to a steadily ascending paralysis which can lead to respiratory embarassment and death. Symptoms may resemble poliomyelitis, Guillain-Barré syndrome, botulism, and myasthenia gravis. Removal of the tick usually results in complete remission within 24 to 72 hours.

## Outbreak of Scarlet Fever - California

An outbreak of scarlet fever and post-streptococcal acute glomerulonephritis (AGN) occurred among residents of Santa Catalina Island, California, from March through July, 1977. The epidemic organism, M2T2 SOR+ group A Streptococcus, was previously implicated in recent outbreaks of scarlet fever and AGN occurring in Los Angeles (1) and Mexico City (2).

Sixty-five cases of streptococcal pharyngitis ( 53 of them with scarlet fever) were identified by physician reports and a school survey since the end of March. Symptoms among all patients with streptococcal disease consisted of fever (in $93 \%$ ), sore throat ( $89 \%$ ), rash or desquamation ( $82 \%$ ), vomiting ( $62 \%$ ), headache ( $59 \%$ ), and cervical adenopathy ( $44 \%$ ).

Six cases were diagnosed between the end of March and the end of May, but the incidence increased dramatically in June, peaked in the third week, and declined after school recessed June 18. Sporadic cases continued to occur in July; the most recent onset was July 23. Distribution of cases over the 4 -month period suggested person-to-person transmission. Except for 7 adults and 10 preschoolers, illness was confined to a single school (grades K-12) but involved only grades K-6; fifth graders experienced the highest attack rate $(14 / 23,61 \%)$. The teacher in that class was also affected, and the attack rate for children sitting at the front of that classroom was higher than for those in the back. The secondary attack rate in family members who did not attend the elementary school or a local preschool was 12.2\%.

All cases were screened for signs and symptoms of AGN. Three definite and 3 probable cases of nephritis were diagnosed on the basis of hematuria, cylinduria, and hypocomplementemia. Only 1 child had symptoms of nephritis; the others were asymptomatic and would not have been identified without screening efforts. Streptococci from 31 of 32 ill persons from whom the isolate was available for typing
were identified as belonging to the epidemic strain, M2T2 SOR+ group A Streptococcus.

The first 2 cases in the outbreak were in a preschool child and his mother who had recently returned from an area of Mexico in which scarlet fever had been prevalent. The organism may have been introduced to the island at this point, although there was ample opportunity for transmission from elsewhere on the mainland.
Reported by AJ Brinkman, MD, RH Caneday, MD, Santa Catalina Island; B Adler, MD, S Fannin, MD, Los Angeles County Health Dept; RR Roberto, MD, California State Dept of Health, in the California Morbidity Weekly Report, No. 30, August 5, 1977; Staphylococcus and Streptococcus Section, Clinical Bacteriology Br, Bacteriology Div, Bur of Laboratories, Field Services Div, Special Pathogens Br, and Epidemiologic Investigations Laboratorv Br, Bacterial Diseases Div, Bur of Epidemiology, CDC.

Editorial Note: This is the third reported outbreak of scarlet fever and AGN associated with M2T2 SOR+ group A Streptococcus. The 2 previous outbreaks were among children in a Los Angeles County School in 1971 (1) and in the environs of Mexico City in the period 1968-1970 (2).

The large proportion of persons with AGN who were asymptomatic is consistent with the known broad clinical spectrum of post-streptococcal AGN. The clinical presentation can range from no symptoms to renal insufficiency, and urinalysis may be normal or only transiently abnormal (3). Screening patients with streptococcal disease, as was done in this outbreak, as well as screening their sibling contacts (4) improves ascertainment of post-streptococcal AGN.

# Primary and Secondary Syphilis - United States, July 1977 

Reported cases of primary and secondary syphilis numbered 1,605 in July 1977, down 14.9\% from the 1,887 cases reported in July 1976 (Table 2). This represents the 16th consecutive month in which a decline in cases has been reported. In the first 7 months of 1977 (January-July) 2,329 fewer cases ( $-16.7 \%$ ) were reported compared to the same time period of the previous year. Sixteen areas re-
ported more cases during the first 7 months of 1977 compared to the same time period of 1976. Early latent (less than 1 -year duration) syphilis declined $18.7 \%$ in July 1977 versus July 1976. During the first 7 months of 1977 versus the same time period of 1976 such cases decreased $15.6 \%$.
Reported by the Venereal Disease Control Div, Bur of State Services, $C D C$.

## Epidemiologic Notes and Reports

## Rocky Mountain Spotted Fever - California

Three cases of Rocky Mountain spotted fever (RMSF) have been documented in California during 1977; 2 of these were fatal.

Case 1: A 9-year-old boy from Alameda County became ill on May 2 with severe headache, high fever, and a macular rash on the abdomen and his extremities; later the rash became petechial. Initial treatment with amoxicillin was unsuccessful, and abdominal pains, vomiting, and changes in sensorium developed, requiring hospitalization. His condition worsened: he developed a low platelet count, coagulopathy, gastrointestinal bleeding, severe electrolyte imbalance, and hypotension. Coma and grand mal seizure followed. It was then learned that he had had a tick bite during a trip April 21-29 to Oklahoma; the exact place of exposure was unknown, however. He was transferred to another hospital with the diagnosis of probable RMSF. Sup-
portive treatment, ampicillin, gentamicin, and chloramphenicol were given, but he died the same day. The diagnosis was confirmed by isolation of rickettsiae from the blood, spleen, and liver.

Case 2: The second fatal case was in a 9 -year-old boy from a small town in Missouri. On June 15, after arriving in Orange County for a visit, he became ill with high fever, edema of the face and extremities, vomiting, and changes in sensorium. He was seen at a hospital on June 18, where a rash on his arms, legs, and feet was noted, but he was sent home. He again saw a doctor on June 21 and was hospitalized because of continuing high fever, petechial rash, and incoherence. Thrombocytopenia, electrolyte imbalance, and inappropriate antidiuretic hormone secretion were found. On June 24 he was transferred to another hospital,

## Rocky Mountain Spotted Fever - Continued

where RMSF was suspected, and tetracycline was begun. Although the fever subsided and mental status improved, thrombocytopenia persisted, the rash became purpuric, and renal and liver damage and disseminated intravascular coagulation developed. By June 30, encephalopathy and coma occurred. He died July 7. His RMSF CF antibody titer, drawn on June 23 and on July 6, was 1:128. Attempts to isolate rickettsiae from autopsy tissues were negative.

Case 3: A 41-year-old man from San Francisco vacationed in Shasta, Modoc, Lassen, and Plumas Counties April 30-May 5, with tick exposure at various campsites. On approximately May 8 or 9 , he became ill with severe headache, muscle aches, fever, and a maculopapular rash on his arms and legs, palms, soles, and thorax. He was hospitalized on May 12 and recovered rapidly with tetracycline.

Diagnosis was confirmed by rising CF antibody titers and isolation of rickettsiae from acute-phase blood.
Reported by the California State Dept of Health in the California Morbidity Weekly Report, No. 31, 1977; and the Respiratory and Special Pathogens Br, Viral Diseases Div, Bur of Epidemiology, CDC. Editorial Note: Reported cases of RMSF have been steadily rising in the United States since 1960. The case-fatality rate $(5-10 \%)$ has remained fairly constant during that period. To date, 968 cases have been reported in 1977. In 1976, 937 were reported, 2 of these from California. Most cases are reported from the Mid-Atlantic and Southeastern states. Although a rare disease on the Pacific Coast, when either case history or clinical picture suggests RMSF prompt initiation of treatment with appropriate antibiotics (tetracycline or chloramphenicol) is indicated, pending laboratory confirmation.

## International Notes

## Foodborne Pesticide Poisoning - Jamaica

Five fishermen in Knightsbridge, Clarendon Parish, Jamaica, became ill on September 1, 1977, after eating a meal of pork, cow skin, green bananas, and roti (an unleavened bread made of flour, water, salt, and baking powder); 3 died. Symptoms, which began within 5 minutes after the meal, consisted of abdominal cramps, vomiting, diarrhea, profuse sweating, muscular fasciculations, bronchospasms, convulsions, and coma. Death occurred within $2-4$ hours.

Initial evaluation of the suspect foodstuffs was undertaken in Kingston by the laboratory of the Jamaican Government Chemist. Since parathion, a highly toxic organophosphorus pesticide, had been responsible for a major Outbreak of foodborne poisoning with similar symptoms in Jamaica in 1976 (1), the laboratory looked initially for evidence of this chemical; none was found. However, ultraviolet spectroscopy did reveal the presence of another low molecular weight organic compound in the roti.

Specimens of the 4 food items eaten and of the patients' stomach contents were sent to CDC for further analysis. The stomach contents of the deceased patients were tube fed to adult female Sherman rats. Within $3-4$ minutes of feeding the animals began to exhibit a syndrome of muscular fasciculation, unsteady gait, and increased salivation which in severe cases progressed to respiratory distress, coma, convulsions, and death - a syndrome closely resembling that seen in the fishermen. Aqueous extracts of the cooked food samples were then fed to adult rats. Each of these specimens produced a similar syndrome in the rats. However, the specimens had been shipped to CDC in a single vial, introducing the possibility of cross-contamination. Because onset was most rapid and the symptoms most severe in the rats fed roti, attention was focused on its components.

Flour was examined first. A massive feeding ( $7 \mathrm{gm} / \mathrm{kg}$ ) of an aqueous suspension of commercial flour obtained from a flour sack in the fishermen's hut produced no symptoms in 2 adult rats. The flour also showed no evidence of any toxins when examined by gas chromatography, mass
spectroscopy, and odor analysis. Likewise, no evidence for toxin was noted in salt from the fishermen's hut. However, a small unlabeled bag that had been left in a baking powder tin in the hut was found to contain a highly toxic white powder. In rats, this powder produced, with extreme rapidity and severity, the same syndrome observed in the rats fed patients' stomach contents.

The powder, when analyzed by gas chromatography, high pressure liquid chromatography, mass spectroscopy, infrared spectroscopy, and nuclear resonance spectroscopy, was shown to contain an almost pure preparation of the carbamate insecticide, methomyl. Identification of the powder as methomyl was confirmed by comparison of the spectroscopic tracings obtained on the powder with those produced by a more than $99 \%$ pure specimen of methomyl supplied to CDC by the U.S. Environmental Protection Agency.

Pure methomyl, when fed to rats, produced a syndrome identical to that which had been produced by the white powder, food samples, and stomach contents. Furthermore, the food samples and the stomach contents were shown by the spectrochemical analytic techniques to contain methomyl. No evidence for the presence of parathion was found in any sample.

The Government of Jamaica is conducting further investigations to determine the source of the methomyl and to learn whether it has had any other distribution within Jamaica.
Reported by W Davidson, MD, AC Ellington, PhD, D Manley, PhD, W Pattarson, MD, Ministry of Health, Government of Jamaica; $\checkmark$ Worslay, RN, Foraign Disaster Coordination Center, Agency for International Development, District of Columbia; Toxicology Br, Clinical Chamistry Div, Bur of Laboratories, and the Special Pathogens Br, Chronic Diseases Div, Bur of Epidemiology, CDC.

## Encephalitis - United States, 1975

In 1975, 4,308 cases of encephalitis, resulting in 340 deaths, were reported to CDC. This was the highest number of cases reported since reporting began in 1960, and 20\% more than the previous highest year, 1964.

For the first year since reporting began, a specific etiology was identified for the majority $(2,599)$ of cases (Table 3 ), Arboviral encephalitis was responsible for about half (49\%) of all cases, with St. Louis encephalitis (SLE) alone responsible for $42 \%$ of all cases. Cases of indeterminate etiology accounted for 40\% of all cases. Encephalitis associated with childhood infections was responsible for $6 \%$ of all cases, with mumps virus responsible for most (70\%) of these. Confirmed enteroviral-associated encephalitis accounted for about $3 \%$, herpes simplex for $2 \%$, and other cases of confirmed etiology for less than $1 \%$ of all the cases.

The monthly distribution of cases in each etiologic group was similar to patterns of previous years. Arboviral and enteroviral activity occurred predominantly in the summer and early fall; arboviruses peaked in September, and enteroviruses peaked in August. Childhood disease-associated cases occurred mostly in the first half of the year.

All states reported cases of encephalitis, except Maine, Rhode Island, Wyoming, and Nevada. Eight states reported $62 \%$ of all cases: Ohio (705), Illinois (544), Indiana (334), Minnesota (261), Mississippi (258), Iowa (203), Tennessee (194), and California (190). The highest incidence occurred in the Central Divisions, primarily the West North Central, East North Central, and East South Central Divisions (Figure 1). Variations in attack rates from state to state were greatly influenced by arboviral epidemics in 1975; however,

## Epidemiologic Notes and Reports

## Abdominal Wall Abscess due to Salmonella typhi - California

Two cases of abdominal wall abscess due to Salmonella typhi were reported in 1976 in California.

The first case was in an elderly man who presented with a tender right upper quadrant mass, $6 \times 8 \mathrm{~cm}$ in size, which had developed over 6 months' time. He had had diarrhea in the 2 weeks before hospitalization but otherwise felt well. Twenty-five years previously he had had a cholecystectomy, and the abdominal mass was located near the right subcostal incision. The white blood cell count was normal at 6,100 , but $15 \%$ of neutrophils were band forms. At surgery the abdominal mass area was found to be an abscess in the rectus muscle. Pus was evacuated and cultured; the wound was irrigated, and a drain placed. Culture vielded S. typhi phage type B2, and the patient was treated with antibiotics. He had no history of typhoid fever. Since surgery, he has consistently had negative stool and urine examinations for bacterial pathogens.

The second case was in an elderly schizophrenic woman who had lived in mental hospitals for the past 40 years. In July 1969, she was hospitalized with symptoms of acute cholecystitis. Cholecystectomy showed stones in the gall bladder and the common duct. Her immediate postopera-
tive course was unremarkable, and after drains were removed, the drain sites closed spontaneously. However, from December 1970 through September 1972 she was seen on 5 occasions for drainage at the incisional site. Stitch abscesses were diagnosed each time. On 4 of these visits, 1 to 4 cotton sutures were removed. She next appeared 4 years later-in August 1976-with a large fluctuant abscess at the right lateral margin of the scar. The abscess was incised and drained, and it healed uneventfully. Culture of the pus grew S. typhi phage type E1. This patient also had no history of acute typhoid fever.

Reported by RL Holtzer, MD, Sonoma County Health Dept; C Kennedy, MD, E Taylor, MD, SO Smelsey, MD, San Joaquin Local Health District; C Powers, BS, SB We:ner, MD, California State Dept of Health, in the California Morbidity Weekly Report, No. 21. June 3, 1977.

Editorial Note: Salmonella infections can result in chronic focal infections with only local symptoms. In these 2 cases, the patients apparently were gallbladder carriers of $S$. typhi whose surgical sites became contaminated but presented no problems until many years later.

## International Notes

## Cholera - Middle East and the Gilbert Islands

The World Health Organization (WHO) has received confirmed reports of outbreaks of cholera in the Gilbert Islands ( 280 cases) and in Jordan (324), Lebanon (20), the Syrian Arab Republic ( 1,996 ), and Saudi Arabia (17). Vibrio cholerae, biotype El Tor, serotype Ogawa, has been isolated in Syria and Jordan. Other Middle Eastern countries may be affected, but they have not submitted confirmed reports to the WHO. Imported cases have been reported by several Western European Countries, but no secondary transmission within these countries is known to have occurred.

Reported by the World Health Organization; Quarantine Div, and Enteric Disease Br, Bacterial Diseases Div, Bur of Epidemiology, CDC.
Editorial Note: Although cholera vaccine is of limited effectiveness and should not be relied upon to protect travelers against cholera, during this outbreak, a cholera vaccination and an International Certificate of Vaccination Against Cholera may be indicated to facilitate travel across borders. Cholera vaccination is not required for re-entry into the United States.

## Epidemiologic Notes and Reports

## Legionnaires' Disease - Pennsylvania

Pennsylvania has reported the first 2 serologically confirmed cases of Legionnaires' disease in Philadelphia since the outbreak there last summer. The 2 patients, a 70 -yearold woman and a 50 -year-old man, had onset on July 18 and July 20, 1977, respectively; they had no common contacts. Details of their cases follow.

The woman developed sharp anterior-lateral leftsided chest pain on July 18, and was hospitalized on July 19. Her admission diagnosis was pulmonary embolism with infarction. Initial chest X-ray showed an alveolar density in the left mid-lung field. The leucocyte count was 17,000 with $86 \%$ segmented neutrophils and $2 \%$ band forms. She was admitted to the hospital with a temperature of 103 F , rales at the left base, and a pleural friction rub. During hos-
pitilization her fever increased, and she developed a nonproductive cough and became dyspneic. She was treated with ampicillin ( 500 mg ) intravenously every 6 hours. Her antimicrobial therapy was changed to cephalothin and then to tetracycline. Her clinical course deteriorated, requiring mechanical ventilation and tracheotomy. By July 30, however, she had become afebrile, and on August 22 she was discharged from the hospital. Sera tested by the indirect fluorescent antibody (IFA) method at the Bureau of Laboratories of the Pennsylvania Department of Health revealed titers of $<1: 64$ and 1:256 on Juily 27 and August 10, respectively.

The male patient, a previously healthy self-employed radiator repair service operator, developed fever and chills
on July 20. Over the next few days his symptoms progressed, and he was hospitalized on July 22 with a temperature of 102.6 F and a right lower lobe pneumonia. His white blood cell count was 14,500 with $69 \%$ segmented neutrophils and $6 \%$ band forms. The patient was placed on erythromycin and was afebrile within 3 days. His hospital stay was uneventful, and he was discharged on July 31. Sera tested by the IFA method at the state laboratory revealed titers of $<1: 64$ and 1:128 on July 25 and August 8, respectively.

Reported by R Sharrar, MD, M Yanak, Philadelphia Dept of Public Health; L Sideman, V Pidcoe, DrPH, WE Parkin, DVM, State Epidemiologist, Pennsy/vania Dept of Health; Special Pathogens Br, Bacterial Diseases Div, Bur of Epidemiology, CDC.

Editorial Note: The clinical response to therapy in these patients provides additional anecdotal experience that erythromycin may be an effective drug in the treatment of Legionnaires' disease. Controlled clinical evaluation of antibiotic efficacy is lacking.

## International Notes

## Quarantine Measures

The following changes should be made in the Supplement - Health Information for International Travel, Morbidity and Mortality Weekly Report, Vol. 25, October 1976:

## BRITISH SOLOMON ISLANDS

Smallpox - Delete all information. Insert code II. Insert: A Certificate is ALSO required from travelers who within the preceding 14 days have been in a country any part of which is infected.

## COSTA RICA

Smallpox - Delete note. Insert: A Certificate is ALSO required from travelers who within the preceding 14 days have been in: Africa: Ethiopia, Mozambique, Somali Asia: Bangladesh, India, Nepal

## CZECHOSLOVAKIA

Smallpox - Delete all information. Insert code II, Insert: A Certificate is ALSO required from travelers arriving from all countries any part of which is infected. A Certificate is ALSO required from travelers arriving from:

Africa: Ethiopia, Somalia, Sudan
Asia: Bangladesh, India, Nepal, Pakistan

DOMINICAN REPUBLIC
Smallpox - Delete note: Insert: A Certificate is ALSO required from travelers who within the preceding 14 days have been in a country any part of which is infected.

NEW CALEDONIA AND DEPENDENCIES
Smallpox - Delete all information. Insert code II. Insert: A Certificate is ALSO required from travelers who within the preceding 14 days have been in a country any part of which is infected.

## SURINAM

Smallpox - Delete all information. Insert code II. Insert: A Certificate is ALSO required from travelers who within the preceding 14 days have been in a country any part of which is infected.

TONGA
Smallpox - Delete all information. Insert code II. Insert: A Certificate is ALSO required from travelers who within the preceding 14 days have been in a country any part of which is infected.
