Kawasaki Syndrome - Massachusetts
Plague - United States, 1980

## Current Trends

Rubella - United States, 1977-1980

## MORBIDITY AND MORTALITY WEEKLY REPORT

## Epidemiologic Notes and Reports

## Kawasaki Syndrome-Massachusetts

A cluster of 57 cases of Kawasaki syndrome (KS, also known as Kawasaki disease and mucocutaneous lymph node syndrome) occurred in eastern and central Massachusetts during the period March 30-June 28, 1980 (Figure 1).

Cases were identified by contacting hospitals throughout the state and by screening reports from individual physicians. Cases were considered confirmed if they had been observed by a physician to satisfy published diagnostic criteria (1).

FIGURE 1. Cases of Kawasaki syndrome, by date of onset, eastern and central Massachusetts, March 23-June 28, 1980

## Kawasaki Syndrome - Continued

Medical records of cases were reviewed. A questionnaire was administered by telephone to parents of KS patients and to parents of controls, matched for age, sex, and race and chosen from the same pediatric practice as the patient. Throat and rectal swabs and blood and urine samples were collected from acutely ill patients for microbial isolation studies. Sera were collected from patients and controls.

The cluster occurred in an 8-county area,* which had an overall attack rate of 16.5 cases $/ 100,000$ children under 5 years of age during the 3-month cluster period compared with a rate of $1.6 / 100,000$ during the preceding 12 months ( $p<0.0001$ ), and a rate of 4.1/100,000 elsewhere in Massachusetts during the cluster period ( $p<0.05$ ). Similar attack rates were observed for each county within the 8 -county area. No more than 3 KS patients lived in any single town, except for 5 patients in the city of Boston, where no more than 2 lived in any single neighborhood.

The mean age of the KS patients was 2.9 years (range 4 months- 14 years, median age 1.9 years). Of the 57 cases, 30 ( $53 \%$ ) were male and 27 ( $47 \%$ ) female; 46 ( $81 \%$ ) were white, 6 ( $11 \%$ ) black, 4 (7\%) Asian (3 Oriental, 1 Indian), and 1 (2\%) Hispanic. One 6-yearold boy had had a previous episode of KS at age 4. Fifty-one ( $89 \%$ ) of the 57 reported cases were hospitalized. There were no deaths.

Evidence of cardiac involvement was reported in 17/57 (29.8\%) cases. Of 57 children on whom electrocardiograms were done, $2(3.5 \%)$ had evidence of myocardial infarction, and 6 (10.5\%) had transient EKG changes consistent with diffuse ischemia or myocarditis. Of 47 children studied by echocardiography, 4 ( $8.5 \%$ ) had coronary artery aneurysms, 4 (8.5\%) had transient cardiomegaly and decreased left ventricular function, and 8 (17.0\%) had small pericardial effusions which spontaneously resolved.

Preliminary analysis of questionnaire data has yielded no evidence of person-to-person transmission of KS or of common exposures of KS patients or their household contacts. No patient had known contact with another KS patient. Neither patients nor any of their household contacts attended the same schools or day-care centers as other KS patients, nor did they attend the same social functions, such as sports events or church gatherings. No patients or household contacts had similar travel histories outside of eastern Massachusetts, nor had they traveled to the same towns inside of eastern Massachusetts to any noteworthy extent. Household members were not employed by the same companies, nor did they work in any single, common location.

For the month before onset of KS, there was no consistent history among cases of insect bites, contact with pets, use of medications, immunizations, new chemicals being used in the house (such as insect sprays, soaps, or paints) changes in the child's living environment (such as new furniture, toys, construction, renovation, or changes in heating or air conditioning systems), contact with visitors from Japan or Hawaii, or any other reported extraordinary events.

Further surveillance and epidemiologic, laboratory, and clinical studies are continuing. Reported by RH Meade III, MD, Tufts-New England Medical Center, Boston; DE Keim, MD, Massachusetts General Hospital, Boston; SH Cheeseman, MD, University of Massachusetts Medical Center, Worcester; JM LeClair, MPH, Children's Hospital Medical Center, Boston; JF Modlin, MD, Beth Israel Hospital, Boston; NJ Fiumara, MD, MPH, State Epidemiologist, Massachusetts State Dept of Public Health; Respiratory and Special Pathogens Br, Viral Diseases Div, and Field Services Div, Bur of Epidemiologv, CDC.
Editorial Note: Kawasaki syndrome is an acute febrile illness of unknown etiology and unknown pathogenesis; it occurs predominantly in children under 5 years of age (2).

[^0]
## Kawasaki Syndrome - Continued

Features of the illness include fever lasting 5 or more days, conjunctival injection, oropharyngeal mucous membrane changes, peripheral extremity changes (edema, erythema, and/or desquamation), rash, and lymphadenopathy. Prominent laboratory findings include thrombocytosis and an elevated erythrocyte sedimentation rate. Cardiac involvement may occur, causing death in $0.5 \%-2.8 \%$ of KS cases reported in the United States (3) and in Japan (4), where the disease was first described and is endemic. In the cluster reported here, the age distribution of cases and features of the clinical illness are in general agreement with Japanese data (4).

The great majority of KS cases in Japan and the United States have occurred sporadically. Marked temporal and geographic clustering of KS cases is an unusual occurrence, which has only recently been recognized. The causes and significance of this phenomenon are unknown. The Massachusetts outbreak is the largest cluster reported in the United States, to date. In Japan, where more than 20,000 cases have been identified by nationwide surveillance begun in 1967, the first large cluster was not identified until 1979 (5). In the United States, where more than 650 cases have been reported to CDC since 1976, clusters have been identified in the following areas in addition to Massachusetts: New York City (October 1977-April 1978; 40 cases) ; Rochester, New York (Oct-ober-December 1979; 23 cases) (1); and Los Angeles County, California (FebruaryApril 1980; 20 cases).

Extensive investigation of the Rochester and Massachusetts clusters has thus far failed to reveal any evidence of person-to-person transmission of KS or of common exposures of KS patients or family members. No etiologic agent has yet been identified. Further epidemiologic studies, as well as laboratory studies on specimens collected in these investigations, are underway.

Since the etiology of KS is unknown, "Kawasaki syndrome" may be a more appropriate designation than the commonly used term "Kawasaki disease." Designation of the illness as a syndrome, however, should not detract from the need to diagnose cases according to clearly established criteria (1), among which is the stipulation that the illness cannot be explained by another known disease process.

Physicians are encouraged to report cases of KS to CDC through their local and state health departments. CDC can provide epidemiologic consultation and certain laboratory assistance, as needed.

## Plague - United States, 1980

Through July 31, 9 cases of plague that occurred in 1980 were reported to CDC (Table 1, p. 377). Five cases were acquired in New Mexico, 2 in California, and 2 in Ne vada. Three cases (33\%) were fatal.

## Plague - Continued

All patients had bubos. Three had abnormal chest X rays; 2 of these patients died, and 1 had areas of pneumonitis confirmed at autopsy. The following case report exemplifies some of the clinical features and management decisions which are common to many cases.

On June 4, a 40 -year-old woman with a past history of bronchitis, noted numerous erythematous papules, which she thought were insect bites, on her right thigh. Two days later, she developed shaking chills, myalgia, and arthralgia. On June 8, she complained of a severe frontal headache and dyspnea. The next day, she had a nonproductive cough that was more severe than usual, and her family thought she had a fever. Pain also developed in the right side of the groin, causing difficulty in walking, and she became intermittently delirious.

Upon admission to a hospital in Santa Fe, New Mexico, on June 10, she was lethargic and had an oral temperature of $103.2 \mathrm{~F}(39.5 \mathrm{C})$, blood pressure of $90 / 60$, a heart rate of 130, and a respiratory rate of 24 . Rales were noted in the left lung field, and there was exquisite tenderness in the right inguinal region. A pea-sized inguinal lymph node was palpable, and there was minimal induration on the overlying skin. Seven small erythematous papules were seen on the right thigh.

The white blood cell count was $18,800 / \mathrm{mm}^{3}$ with $79 \%$ neutrophils, $13 \%$ bands, $5 \%$ monocytes, and $3 \%$ lymphocytes. A chest $X$ ray revealed a small, basilar infiltrate in the left lung.

| 9 | 12 | F | July | Recovered | Washoe | Nevada |

*Presumptive case, based on a high convalescent-phase passive-hemagglutination-inhibition titer.
Bubonic plague with possible secondary plague pneumonia was suspected, and the patient was placed in strict isolation. An aspirate from the inguinal lymph node showed rare, bipolar, gram-negative rods, and a fluorescent-antibody stain done 1 hour later was positive for Yersinia pestis. After cultures of the blood and throat were obtained (she was not producing sputum), tetracycline, 500 mg orally 4 times a day for 10 days, and streptomycin, 1 g intramuscularly every 12 hours for 5 days, were administered. Over the next several days, the patient improved. Strict isolation was discontinued on the third hospital day. A chest X ray taken on this day was normal. Bubo, but not blood or throat, cultures were positive for $Y$. pestis.

Twenty-one family members who had close contact with the patient on or after June 7 . the day respiratory symptoms developed, were contacted within several hours of the diagnosis. All were placed under surveillance and on prophylactic antimicrobials for 7 days. In the hospital, because the patient had not been placed in isolation until approximately 4 hours after entry to the emergency room, 25 persons potentially exposed to respiratory secretions were placed under surveillance; most were given antimicrobials. No secondary cases occurred.
Reported by W Lafferty, MD, D Romig, MD, C Bodelson, RN, Santa Fe, New Mexico; JM Mann, MD, Asst Director, M Burkhart, MPH, Director, Health Sciences Div, New Mexico Health and Environment Dept; M Ford, MPH, Washoe County (Nevada) Health Dept; WM Edwards, MD, MPH, State Epidemiologist, Nevada Dept of Human Resources; J Chin, MD, State Epidemiologist, California Dept of Health Services; Plague Br, Vector-Borne Diseases Div, Bur of Laboratories, Field Services Div, and Bacterial Zoonoses Br, Bacterial Diseases Div, Bur of Epidemiology, CDC.
Editorial Note: Patients with bubonic plague may have minimal or no adenopathy when initially seen, although pain and tenderness at the bubo site are characteristically present. In fact, some patients may never develop clinically detectable adenitis (septicemic plague).

With any patient, once the diagnosis of plague is considered strict isolation should be instituted to minimize potential exposure to contacts while procedures are underway to Confirm the diagnosis rapidly and to determine if plague pneumonia is present. Plague pneumonia may result from direct inhalation of organisms or from hematogenous spread to the lung. It is not always possible, with someone with plague and a pulmonary infiltrate, to determine if that infiltrate is caused by plague pneumonia; the management of contacts of these persons must be decided on an individual case basis.

Because of this patient's history of cough and dyspnea in conjunction with an abnormal chest $X$ ray, she was handled as a patient with bubonic plague with secondary pneumonia. In retrospect, however, it is not clear if the infiltrate represented an infectious process. The lack of sputum production and the rapid disappearance of the infiltrate suggest that this patient was not infectious.

## Current Trends

## Rubella - United States, 1977-1980

For the first 30 weeks of 1980 (ending July 26), 3,093 cases of rubella were reported to CDC, compared to 10,309 cases reported in the same 30 -week period in 1979 . This $70 \%$ decrease in reported rubella activity represents a continuation in the decline noted since 1977 (Figure 2).

The provisional 1979 total of 11,795 cases, an all time low, is $35.4 \%$ less than the 1978 total of 18,269 cases which, in turn, represented a $10.4 \%$ decline from the 20,395 cases reported in 1977 (Table 2).

Age data were available for $7,653(64.9 \%)$ of the reported 1979 cases. The reported incidence rate in children continues to decline progressively. Approximately 70\% of the cases with known age still occur in those 15 years of age and older, with the highest incidence rate occurring in the 15- to 19 -year-olds (1). However, both the proportion of cases and the risk of disease have continuously declined in this age group for the first

FIGURE 2. Reported rubella, by year, United States, 1966-1980*

[^2]
## Rubella - Continued

time since 1969 (based on limited reporting) and since age data became available from a large number of U.S. reporting areas in 1975. On the other hand, individuals 20 years of age and older accounted for $35.8 \%$ of cases with known age in 1979; they accounted for only $21.9 \%$ in 1977. More importantly, this age group has experienced virtually no decline in attack rate ( 2.9 cases per 100,000 population in 1979 compared to 3.1 cases per 100,000 population in 1977) (1).
Reported by Immunization Div, Bur of State Services, CDC.

| Total with known age | 12,078 | 59.2 | - | 10,296 | 56.4 | - | 7,653 | 64.9 | - | - |
| Unknown age | 8,317 | 40.8 | - | 7,973 | 43.6 | - | 4,142 | 35.1 | - | - |
| TOTAL | 20,395 | 100.0 | 9.4 | 18,269 | 100.0 | 8.4 | 11,795 | 100.0 | 5.4 | -42.6 |

*Incidence rate = cases per 100,000 population extrapolated from the age distribution of cases reported by age from 40 (in 1977) to 47 (in 1979) reporting areas.
$\dagger 1979$ figures are provisional.
Editorial Note: Since the licensure of rubella vaccine in 1969, reported rubella activity has declined overall by approximately $70 \%$ (1). Initially, there were reports of higher seronegativity rates among clinic- and office-vaccinated individuals than among fieldtrial vaccinees $(2,3)$. However, the continuous decline in the number of rubella cases in children less than 15 years of age-greater than $80 \%$ since 1969 (1)-suggests that higher-than-expected rates of seronegativity have not generally been the case.

The $15 \%-20 \%$ seronegativity rates and continued rubella incidence among those in the childbearing-age group do not represent an accumulation of individuals who have waning vaccine immunity (1), since these cases are primarily occurring in previously unvaccinated individuals. Based on currently available data, those who previously received either the HPV-77:DE-5 or Cendehill vaccines (4) need not be routinely revaccinated with the newly licensed RA27/3 rubella vaccine. Nor does a change in immunization policy to a routine 2 -dose schedule, as has been suggested ( 3,5 ) , appear to be necessary.

[^3]
## Rubella - Continued

To reduce rapidly the incidence of rubella in adolescents and adults-and the consequent risk of congenital rubella syndrome-increased emphasis should be directed toward effectively vaccinating older susceptible individuals, especially women of childbearing age.

In this regard, the Immunization Practices Advisory Committee (ACIP) has recently approved the following statements, which will be included in future revisions of the appropriate ACIR staterments.
On rubella:
OOfficial health agencies should take steps, including development and enforcement of immunization requitements, to assure that all students in schools and children in "day-care settings are protected against rubella, unless contraindicated."
On the immunization of adults against measles and rubella:
"Current patterns of 球easles and rubella occurrence indicate that outbreaks of these diseases continue to be reported in adolescent and young-adult population groups. Increased attention to school immunization requirements should reduce the incidence in those of school age. Further control of these diseases will require increased emphasis on vaccinating susceptible individuals who have left high school. The military services have instituted routine measles and rubella immunization of susceptible recruits. Officials of colleges and other settings where young adults congregate should strongly consider immunization requirements for entry. Health care providers should carefully review immunization status of young adults and provide vaccination to those who are not immune and who do not have contraindications."
