311 Cholera - Worldwide, 1978

## Surveillance Summary

## Abortion-Related Mortality - United States, 1977

In 1977, for the first year since 1972, there was an increase in the total annual number of legally induced, illegally induced, and spontaneous abortion-related deaths (Figure 1).

FIGURE 1. Abortion-related deaths, by category* and quarter, United States, 1972-1977

U.S. DEPARTMENT OF HEALTH, EDUCATION, AND WELFARE / PUBLIC HEALTH SERVICE

Thirty-three women died from abortion in 1977 compared with 27 in 1976, 47 in 1975, 53 in 1974, 56 in 1973, and 90 in 1972. Despite the increases in absolute numbers, the death-to-case rates for legal abortion in both 1976 and 1977 were markedly lower than in the years 1972 through 1975.

In 1977, a total of $1,079,430$ legal abortions were reported to CDC. Fifteen women died in association with these procedures that year-compared with 11 in 1976, 29 in 1975, 25 in 1974, 25 in 1973, and 24 in 1972 (Figure 1). With the total number of reported legal abortions each year used as the denominator, the overall death-to-case rate for legal abortions was 1.4 per 100,000 abortions in 1977, compared with 1.1 in 1976, 3.4 in 1975, 3.3 in 1974, and 4.1 in both 1973 and 1972.

The aggregated data for the years 1972-1977 show the risk of death from legal abortion was lowest for women whose abortions were performed at $\leqslant 8$ menstrual weeks' gestation; the death-to-case rate was 0.6 per 100,000 procedures for this group (Table 1 ). The death-to-case rate increased by approximately $40 \%-60 \%$ for each week after the eighth week. Abortions performed at $9-10$ weeks carried nearly 3 times the risk in terms of mortality than those performed earlier. Abortions performed at $\geqslant 21$ weeks were associated with the greatest risk, with a death-to-case rate 34 times that of abortions performed at $\leqslant 8$ weeks.

For the years 1972-1977, mortality rates were highest for both hysterectomy and hysterotomy abortions and lowest for curettage (including both suction and sharp-curettage methods); dilatation and evacuation (D\&E) and instillation procedures were

TABLE 1. Death-to-case rate for legal abortions by weeks of gestation, United States, 1972-1977

| Hysterotomy/hysterectomy | 45.3 | 37.7 |
| Overall | 2.6 |  |

[^0]
## Abortion-Related Mortality - Continued

intermediate in terms of risk (Table 2). For these particular methods, the risk of death is also influenced by increasing gestational age. Curettage procedures had a death-to-case rate of 1.2 per 100,000 abortions, compared to 8.3 for D\&E procedures, 10.8 for instillation of prostaglandins and/or other agents, 15.5 for the instillation of hypertonic saline, and 45.3 for hysterotomy/hysterectomy operations.

Four deaths were associated with illegally induced abortion in 1977-the first increase in the annual number of such deaths since 1972. There were 2 illegal abortion deaths in 1976, 4 in 1975, 6 in 1974, 19 in 1973, and 39 in 1972 (Figure 1).

There were 14 deaths from spontaneous abortion in the United States in 1977, compared to 13 in 1976 (Figure 1). No deaths from spontaneous abortion associated with an intrauterine device in situ were reported in 1977.

## Reported by the Abortion Surveillance Br and the Statistical Services Br, Family Planning Evaluation Div, Bur of Epidemiology, CDC.

Editorial Note: In terms of the risk of death, legally induced abortion is a relatively safe surgical procedure. In 1977, over half of all legal abortions were performed within the first 2 months of pregnancy, when the risk of death is approximately 0.6 for every 100,000 procedures. Over $95 \%$ were performed during the first 4 months of pregnancy with an overall risk of about 2 per 100,000 procedures. This contrasts with the risk of death from other pregnancy- and childbirth-related causes of 10.6 per 100,000 live births $(1,2)$.

The main factors affecting the mortality risks for legally induced abortion are delay and the choice of abortion procedure. The relative risk of dying approximately doubles for each 2 weeks after 8 weeks' gestation (2). Until 16 weeks' gestation or later, uterine evacuation techniques appear to be safer than instillation procedures; at 16 weeks' gestation or later, prostaglandin is slightly safer than saline, although differences in death-to-case rates are not statistically significant.

Among the possible reasons for the decline in the death-to-case rates for legal abortion after 1975 are 1) the increasing percentage of abortions being performed during the earlier, safer gestational ages, 2) the increasing experience of practicing physicians in performing abortions, 3) the increasing percentage of safer curettage procedures, including D\&E, and 4) possible underreporting of legal abortion deaths during the most recent years.

The number of deaths from illegal abortion increased from 2 to 4 from 1976 to 1977. Before 1977, the decline in the number of illegal abortion deaths was thought to reflect the increasing availability of the safer legal procedures throughout the country (3); women who formerly terminated their pregnancies through illegal channels may have elected to Use the safer legal facilities. Of the 4 illegal abortion deaths reported during 1977, 3 occurred in the first 6 months and were not associated with the funding restriction resulting from a 1977 Supreme Court ruling that states had the right to restrict the use of public funds for abortion; 1 was associated with this non-availability of public funds (4).

Data for CDC's surveillance of abortion-related deaths are based primarily on reports from the vital statistics sections of state health departments; however, additional data have been obtained from such sources as state medical or hospital associations, CDC investigations, published case histories, state maternal mortality committees, as well as records from the National Center for Health Statistics (NCHS) and other federal agencies.

Comparison of CDC's surveillance data with vital statistics data from NCHS has shown CDC's surveillance techniques have identified more deaths as abortion-related and have
specifically categorized more cases-that is, as legal, illegal, or spontaneous (5).

## Abortion-Related Mortality - Continued

Nevertheless, because of the relatively small numbers of reported abortion-related deaths, it is difficult to determine long-term trends. It is therefore important that reports of all deaths related to abortions occurring in the United States be reported to state and local health departments and to CDC. The appropriate address and telephone number for the latter a'e: Abortion Surveillance Branch, Family Planning Evaluation Division, ATTN: Abortion Mortality, CDC, Atlanta, Georgia 30333. (404) 329-3131.

## Foliow-up on Poliomyelitis - United States, Canada

Since the last report (1), 2 additional epidemic-associated cases of paralytic poliomyelitis have been confirmed. One is in a 16 -year-old, unvaccinated Amish male from Buchanan County, lowa, where 2 other paralytic cases were previously reported (2); type 1 virus was isolated from this boy's stool. The other new case is in a 9 -month-old boy from Chester County, Pennsylvania (from a town adjacent to the Lancaster County residence of the most recently reported Pennsylvania case [1]). The infant became ill on June 3,5 days after receiving his first dose of trivalent oral poliovirus vaccine (TOPV). Poliovirus type $2 \cdot$ was isolated from this patient's stool; results of serologic tests are pending.

These additional cases bring the 1979 total, as of July 3, to 15 confirmed, epidemicassociated cases in Canada (2 cases) and the United States (Pennsylvania, 8; Iowa, 3; Wisconsin, 2). The total number of suspected paralytic cases is 2-1 each from Wisconsin and Missouri.

In addition, poliovirus type 1 has been isolated from asymptomatic Amish persons from 6 different areas where paralytic poliomyelitis has not yet appeared. These are Charles and St. Mary's counties, Maryland (January; 37 of 102 positive); Jefferson County, Pennsylvania (May 21; 14 of 25 positive); St. Joseph County, Michigan (June 1; 3 of 6 positive); Branch County, Michigan (June 4; 1 of 5 positive); Pike County, Missouri (June 7; 9 of 30 positive); and Eaton County, Michigan (June 15; 1 of 5 positive).
Reported by LE Wintermeyer, MD, State Epidemiologist, lowa State Dept of Health; JP Maher, MD, MPH, Chester County Health Dept, Pennsylvania; WE Parkin, DVM, DrPH, State Epidemiologist, Pennsy/vania State Dept of Health; NS Hayner, MD, State Epidemiologist, Michigan State Dept of Public Health; D Sorley, MD. Acting State Epidemiologist, Maryland State Dept of Health and Mental Hygiene; HD Donnell Jr, MD, State Epidemiologist, Missouri State Dept of Social Services; Immunization Div, Bur of State Services, Viral Diseases Div, Bur of Epidemiology, CDC.
Editorial Note: The origin of disease in the Amish infant from Pennsylvania has not yet been determined. The isolation of poliovirus type 2 from a recent TOPV recipient is not unusual and does not necessarily implicate that virus as the cause of disease. In a situation such as described here, when a person living in an epidemic area-and potentially exposed to wild poliovirus (type 1)-receives TOPV, more than 1 poliovirus type may be isolated from the stool. To explore this possibility, specimens are being retested in Pennsylvania and at CDC. Results of serologic tests may be useful in establishing the poliovirus type responsible for disease in this patient.

The circulation of wild poliovirus in areas without a paralytic case is not unusual, as the inapparent-to-apparent infection rate for poliovirus, though variable, can be quite high. For every 100 persons with poliovirus cultured from their stool, $90-95$ will be asymptomatic; 4-8 will have "minor illness" (gastroenteritis, upper-respiratory-tract symptoms, or an influenza-like illness); 1 or 2 will have aseptic meningitis; and 0.1 to 1 will have paralytic disease (3).

Immunization campaigns for the Amish (who have a total U.S. population of approximately 75,000 ) are continuing. Of the 23 states now known to have Amish residents, 18 have achieved immunization levels of $\geqslant 50 \%$ and 5 of these have achieved levels $\geqslant 90 \%$. In the 3 states with the largest Amish populations (Ohio, Pennsylvania, and Indiana; total of 56,000 Amish), 46\%-60\% immunization levels have been achieved, and campaigns are continuing. Most states are trying to achieve immunization of at least $80 \%$ of their total Amish populations.

## St. Louis Encephalitis - Ohio, 1978

Five serologically documented cases of St. Louis encephalitis (SLE), 1 fatal, were reported from Ohio in 1978. All of the patients had onset of symptoms between September 16 and November 11. Two cases occurred in Urbana, in Champaign County, and 1 case occurred in each of the following areas: Rocky River, Cuyahoga County; Columbus, Franklin County; and Chillicothe, Ross County. Cases of SLE have been diagnosed in Columbus each year since the 1975 epidemic, which involved much of the Mississippi and Ohio River valleys; however, human cases had not been detected in the other 3 counties since that time.

In a statewide arbovirus surveillance program conducted from June through midSeptember 1978, 6,081 avian blood samples were tested for SLE antibody by the hemag-glutination-inhibition (HI) test. The resulting rate of seropositivity was $0.25 \%$. A total of 39,204 Culex mosquitoes, tested on duck-embryo-cell culture, yielded a single isolate of of SLE virus. The virus isolation was made from a pool of 50 C . pipiens collected at Cedar Bog, approximately 6.4 km south of Urbana, on July 20.

SLE Case-Cuyahoga County: The Cuyahoga County Health Department initiated a surveillance program ( 41 hospitals in the 6 -county Cleveland metropolitan area) during the summer and fall of 1978 to monitor encephalitis-like illnesses. On September 19, a 23 -year-old woman with a 1 -day history of severe frontal headache and temperature of 39 C was examined and admitted to a hospital participating in the surveillance program. She reported minimal pain when flexing her neck, but otherwise her physical examination was unremarkable. Except for a brief visit, 3 weeks earlier, to a camping area in southern Ohio, she had no history of recent travel.

Laboratory results included a white blood cell (WBC) count of $9,800 / \mathrm{mm}^{3}$ with normal differential, a hemoglobin of $13.4 \mathrm{~g} / \mathrm{dl}$, and a normal chest X ray. Cerebrospinal fluid (CSF) contained $799 \mathrm{WBC} / \mathrm{mm}^{3}$ ( $99 \%$ polymorphonuclear leukocytes, $1 \%$ lymphocytes), a protein level of $50 \mathrm{mg} / \mathrm{dl}$, and a glucose level of $55 \mathrm{mg} / \mathrm{dl}$. The blood sugar level was $37 \mathrm{mg} / \mathrm{dl}$. On examination of Gram-stained spinal fluid, numerous polymorphonuclear cells and 2 or 3 questionable gram-negative diplococci were seen, but blood and CSF cultures yielded no bacterial growth.

The patient was started on intravenous penicillin. On the night of admission she had a transient macular rash covering her extremities and experienced a left-sided, focal seizure. A repeat lumbar puncture after 48 hours revealed $160 \mathrm{WBC} / \mathrm{mm}^{3}(80 \%$ lymphocytes, $20 \%$ polymorphonuclear leukocytes) and a red blood cell count of $2,000 / \mathrm{mm}^{3}$. The protein level was $71 \mathrm{mg} / \mathrm{dl}$, and the glucose, $67 \mathrm{mg} / \mathrm{dl}$. Her blood sugar level was $110 \mathrm{mg} / \mathrm{dl}$. No organisms were seen in the Gram-stained smear. On the fourth hospital day the patient became confused and rapidly deteriorated into a comatose state. At this stage, chloramphenicol was added. She remained febrile and developed a decerebrate posture and early signs of papilledema. On the seventh hospital day, she became hypotensive, had a cardiorespiratory arrest, and died.

At autopsy, the brain appeared grossly normal. Serum from the acute phase of illness had an HI antibody titer to SLE of $<1: 10$ and a complement-fixing (CF) antibody titer of $<1: 8$; serum collected on the seventh day had an HI titer of 1:20 and a CF titer of 1:32. Testing of 351 C . pipiens and serum specimens from 26 house sparrows from the areas frequented by the patient did not demonstrate SLE virus or other evidence of recent SLE activity.

SLE Field Studies, Champaign and Ross Counties: After the first reports of human SLE cases, which had occurred in the area in mid- to late September, field investigations were initiated to determine the extent of SLE infection in the mosquito and avian populations in Champaign and Ross counties. Resting mosquitoes were aspirated from
culverts and storm sewers in Urbana and Chillicothe from October 23 through November 7, 1978. C. pipiens accounted for over $90 \%$ of collections in both cities. A single isolation of SLE virus was made from 7,381 mosquitoes collected from Urbana, and another, from 1,718 mosquitoes collected in Chillicothe. In both instances, virus was detected in a pool of 50 C . pipiens.

During the period October 24-December 1, 1978, avian serum samples were collected in Urbana and Chillicothe and at sites within an $18-\mathrm{km}$ radius of both cities. Immature house sparrows accounted for over $97 \%$ of all specimens obtained. Hl-testing revealed SLE seropositivity rates of $8.2 \%(33 / 401)$ in Urbana and $5.6 \%(11 / 196)$ in Chillicothe. Over one-third (34.1\%) of all seropositive birds from Urbana and Chillicothe were found to have antibody titers of $\geqslant 1: 120$, strongly suggesting recent infection with SLE virus. Seropositivity rates were substantially lower ( $0-0.5 \%$ ) in birds collected $6-18 \mathrm{~km}$ from both cities, indicating that SLE activity was concentrated in the urban areas. The highest rate of seropositivity outside either city ( $2.5 \%$ ) was detected at a farm located 7.1 km from Urbana and 1.6 km from Cedar Bog, the site from which the mosquitoes that originally vielded SLE virus were collected on July 20.
Reported bv J Berner, MD, KV Gopalakrishna, MD, K Kapoor, MD, L Malm, MD, W Wilder, MD, Lutheran Medical Center, Cleveland, Ohio; OG Glasser, MD, J Jackson, RS, Cuyahoga County Board of Health; SW Gordon, ED Peterson, RL Berry, PhD, RA Restifo, JA Kertesz, MA Parsons, VectorBorne Disease Unit, GT Bear, DVM, Veterinary Unit, TJ Halpin, MD, State Epidemiologist, Bur of Preventive Medicine, D Keiper, K Elliot, Bur of Laboratories, Ohio Dept of Health; Enteric and Neurotropic Viral Diseases Br, Viral Diseases Div, CDC.
Editorial Note: These observations suggest that SLE activity was concentrated in the locations associated with the human cases. The seropositivity rates of avian samples collected at points surrounding the Urbana and Chillicothe cases declined from greater than $5 \%$ to less than $1 \%$ within a $15-\mathrm{km}$ radius. Similarly, geographically limited activity may be the reason mosquito and bird specimens collected in Cuyahoga County were negative.

Close, active surveillance was an important factor in establishing the cause of encephalitis in the Cuyahoga County patient. Most clinical cases of SLE are described in association with outbreaks, and fatalities in patients less than 40 years old are infrequently observed.
International Notes

## Cholera - Worldwide, 1978

A total of 74,632 cases of cholera were reported, worldwide, for 1978 , compared with 58,087 cases in 1977 and 66,020 in 1976. Cholera was more widespread in 1978, affecting 40 countries; this number is the maximum recorded since the beginning of the present pandemic in 1961.

Eight new countries were infected in 1978-the highest number in any 1 year since 1970 and 1971, when cholera first spread to the African continent. The newly infected

[^4] United States.

Eighteen countries in Africa reported 23,317 cases, as compared with 12 countries reporting 8,388 cases in 1977. Nearly two-thirds of the reported cases were from Burundi and the United Republic of Tanzania, where large outbreaks occurred. Ten of these 18 countries did not report cholera in 1977. A marked decrease in the number of cases from 1977 was noted in Ghana, Liberia, Malawi, and Togo.

In Asia, 50,765 cases ( 22 of them imported) were reported by 19 countries. Although this situation appears very similar to that of 1977 , when 48,937 cases were reported by 20 countries, in fact, most countries showed considerably decreased figures when compared with the previous year. On the other hand, 5 Asian countries that reported cholera irr 1978 had not been infected in 1977. A large outbreak of 11,336 cases in the Maldives was rapidly brought under control by measures which included purifying the drinking water and establishing careful epidemiologic surveillance of cases. For the first time since 1973, a large outbreak, which involved 906 cases, occurred in Bahrain; this outbreak was unique in that the highest attack rates were in children under 1 year of age, especially those who were bottle-fed. Outbreaks also occurred in India and Thailand associated with post-monsoon flooding.

As in 1977, a small number of cases occurred in Japan (1). A small outbreak also occurred in the United States-the first on the North American Continent during the present pandemic (2). Nontoxigenic Vibrio cholerae organisms with some atypical characteristics were also isolated from the sewerage system of Santos, Brazil, where no cholera cases or carriers were identified. Cholera spread to yet another country in Oceania: a small outbreak of 38 cases occurred on Nauru.

Editorial Note: In at least 1 country where cholera vaccination was required from all travelers on entry, this measure failed to prevent the introduction of cholera. Consideration should be given to the cost-effectiveness of using medical and paramedical personnel to establish diarrheal disease surveillance-even if it is of the most elementary form-in preference to assigning such personnel to recognized ports of entry for the ritualistic examination of cholera yaccination certificates.
Reported by the World Health Organization in the Weekly Epidemiological Record 54(17), April 27, 1979.
