## Epidemiologic Notes and Reports

## Viral Hepatitis OutbrearsANIGeofkizalabama

Ten recent cases of probable hepatitis $A$ associated with consumption of raw oysters from Florida have been identified in Albany, Georgia, and Mobile, Alabama.

An investigation of 3 Albany residents in whom hepatitis was diagnosed during the week of October 28 disclosed that 2 had eaten raw oysters on October 13, and the Other had eaten raw oysters on October 15. The oysters had all come from a single sack Purchased in Florida.

An investigation of 5 Mobile residents with onset of hepatitis from November 5-7 found that their only common exposure was having eaten raw oysters at a club dinner on October 11. Two other Mobile hepatitis patients who had eaten raw oysters purchased from the same store at the same time as the oysters purchased to serve at the club dinner, were also identified.

The Food and Drug Administration, CDC, and state and local health authorities are trying to trace the source of the oysters for both outbreaks. Preliminary results suggest that the oysters came from a single area in Florida. The investigation is continuing.
Reported by D Smith, Georgia Dept of Human Resources; J Cutts, DVM, Mobile County Health Dept; T Chester, MD, State Epidemiologist, Alabama Dept of Public Health; R Gunn, MD, State Epidemi${ }^{\circ} /$ ogist, Florida Dept of Health and Rehabilitative Services; U.S. Food and Drug Administration; ${ }^{\text {Enteric }}$ Diseases Br, Bacterial Diseases Div, and Epidemiology Section, Hepatitis Laboratories Div, $B_{u r}$ of Epidemiology, CDC.
Editorial Note: Raw oysters have been implicated as the vehicle for transmission of hepatitis in several outbreaks in the United States, most recently in 1973, when 285 People became ill after eating raw oysters harvested in Louisiana (1). The number of cases involved in the 2 outbreaks reported here is small compared with such previous outbreaks, although there may be cases which have not yet been identified. Physicians are urged to
report all cases of hepatitis to the appropriate public health authorities and to be particulariy alert to possible oyster-associated cases.

## Measles Mortality - Guatemala

From 1963 through 1971, Guatemala reported an average of 3,632 deaths due to measles each year, or 76.2 deaths per 100,000 population.

In 1972, the Ministry of Public Health and Social Assistance began an annual mass immunization campaign, using live, further-attenuated measles vaccine, directed during the first year at children 1 through 4 years of age and subsequently at children 9 months to 2 years. The campaign's goal was to vaccinate $80 \%$ of children in the selected age range; the vaccine was given during 1 month each year, usually February. Vaccine coverage was estimated by taking the doses of vaccine that health centers and health posts reported using, and dividing that figure by the target population.

From 1972 through 1974, reported measles deaths declined by $90 \%$, with a low of 3.9 deaths per 100,000 population in 1973 (Figure 1). Estimated vaccine coverage was high, increasing from $82 \%$ in 1972 to $94 \%$ in 1974. Coverage dropped from 1975 through 1978, and reported measles deaths rose disproportionately, reaching 102.1 per 100,000 in 1976, an incidence above the average for the period before the mass campaigns. The geographic distribution of reported deaths was not uniform: the highest rates occurred in the highland areas, where the majority of the people are Mayan Indians. For example, in 1977 and 1978, the Department of Baja Vera Paz reported an average of 221.3 measles deaths per 100,000 , compared with 12.1 in the capital city. Eighty percent of measles deaths occurred in children under 5 years ( $20 \%$ under 1 year), but a number of deaths were reported in neonates 28 days or younger and in adults 25 years or older.

FIGURE 1. Measles mortality, Guatemala, 1966-1978

Immunization levels and measles cases were evaluated in Santiago Sacatapequez, a town which had experienced measles outbreaks during the past 2 years in spite of presumably good vaccine coverage. Of the 486 households in 25 randomly selected blocks, a responsible adult was interviewed in 335 (69\%). Only 101 of 231 (44\%) children 1 to 4 years old had a record of measles immunization; the records of 39 children had been lost, and 91 children had not received measles vaccine. Of 73 measles cases that occurred between January 1977 and May 1979, 48 were in children 1 to 4 years old; 10 of these had a documented record of measles immunization. Vaccine efficacy was calculated using person months at risk, that is, the number of months in which a child 12 through 59 months old had been unvaccinated or vaccinated. Children were excluded from either the vaccinated or the unvaccinated group after they had had measles. Since all vaccinated children who developed measles had received vaccine either in 1976 or 1978, vaccine efficacy was calculated specifically for each of these years. Vaccine efficacy was low in both years, and remained low for all years combined (Table 1).

The vaccine cold chain (i.e., the process of shipping and storing vaccine at various points from its manufacture to its ultimate destination) was evaluated in several areas in Guatemala. Storage of vaccine in the capital and in the regional health departments was generally satisfactory, as was shipment from the capital. However, vaccine was shipped from the health departments to rural health centers in poorly insulated containers that could not adequately protect the vaccine. Kerosene refrigerators in health centers often lacked replacement parts or fuel, and electricity for electric refrigerators was sometimes unreliable. Personnel were often inadequately trained in vaccine handling or refrigerator maintenance. No errors in vaccine storage or handling were identified at the health center in Santiago Sacatapequez, but the center accounted for only 1 point in an extended cold chain for the measles vaccine given in 1976 and 1978.
Reported by A Paz Cojulún, MD, Director General of Health Services; O Zeissig, MD, Director, Division of Epidemiology, Ministry of Public Health and Social Assistance, Guatemala; A Romero, MD, Pan American Health Organization; Bur of Smallpox Eradication, Immunization Div, Bur of State Services, and Bur of Tropical Diseases, CDC.
Editorial Note: Measles death rates vary widely from country to country. In Guatemala measles was reported to be the third ranked cause of death for all ages in 1975, accounting for $6 \%$ of all deaths.

There are several possible explanations for Guatemala's high measles mortality rates. First, there is some uncertainty about the reliability of the diagnosis of causes of death, as $80 \%$ of deaths are reported by town officials without medical training. The reporting

## Measles Mortality - Continued

of measles deaths in neonates and in adults 25 and older suggests that some of the deaths may be incorrectly attributed to measles.

Secondly, it is difficult to maintain the momentum of a mass vaccination campaign, as illustrated by the resurgence of measles mortality in Guatemala after 1974, despite dramatic reductions in 1972 and 1973. Improper handling of vaccine along the cold chain is also a factor, as the low measles vaccine efficacy in Santiago Sacatapequez points out.

Inadequate vaccine coverage is the major problem, however. Guatemala is building new health centers and training additional rural health workers to extend health services to more Guatemalans. For the present, health personnel and facilities are most effective in a twice-a-year campaign. Guatemala is also actively participating in the Pan American Health Organization's Expanded Program on Immunization, which is addressing such immunization problems throughout the Western Hemisphere.

## Varicella-Zoster Immune Globulin

Varicella-Zoster Immune Globulin (VZIG) continues to be available for immunodeficient children exposed to chickenpox. It is being released at no cost through the Division of Clinical Microbiology, Sidney Farber Cancer Institute (SFCI), 44 Binney Street, Boston, Massachusetts (617-732-3121). The Immunization Division, CDC (404-329-3747), the SFCI, and former VZIG consultants are available for consultation regarding alternative modes of therapy.

Since VZIG is still an investigational drug and its supply is limited, several criteria for release apply. These 5 criteria have been previously published in the MMWR in tabular form (1), but this year several clarifications are needed.

First, the term "newborn contact" (See Table 2, II-D) was previously described as a "newborn whose mother contracted varicella within 4 days before delivery or within 48 hours after delivery." In the revised table, the italicized term has been changed to "less than 5 days" because an appropriate newborn contact includes infants whose mothers develop the varicella rash up to but not including the fifth day before delivery. (Such infants have a $30 \%$ mortality rate $[2,3]$.) No mortality has been associated with infants whose mothers contract varicella 5 or more days before delivery.

Second, the criterion concerning the age of patients, as listed on the table (item IV), is for patients less than 15 years old. However, on an individual basis, VZIG will be made available for certain patients between 15 and 21 years old.

Finally, the fifth criterion indicates that the request for treatment must be initiated within 72 hours of exposure. While any request for treatment must be initiated within this time period, treatment may be expected to modify or even prevent disease if started within 96 hours of exposure.
Reported by the Sidney Farber Cancer Institute, Boston, Massachusetts; and the Immunization Div, Bur of State Services, CDC.

## TABLE 2. Five criteria for release of Varicella-Zoster Immune Globulin (VZIG) for the prophylaxis of varicella

## I. One of the following underlying illnesses or conditions

A. Leukemia or lymphoma
B. Congenital or acquired immunodeficiency
C. Under immunosuppressive medication
D. Newly born of mother with varicella
II. One of the following types of exposure to varicella or zoster patient
A. Household contact
B. Playmate contact ( $>1$ hour play indoors)
C. Hospital contact (in same 2- to 4 -room bedroom or adjacent beds in a large ward)
D. Newborn contact (newborn whose mother contracted varicella less than 5 days before delivery or within 48 hours after delivery)
III. Negative or unknown prior disease history
IV. Age of less than 15 years
V. The request for treatment must be initiated within $\mathbf{7 2}$ hours of exposure.

## Epidemiologic Notes and Reports

## Human Rabies - Kentucky

On December 6, 1979, the diagnosis of rabies was made by fluorescent antibody (FA) staining of a brain tissue specimen from a 45 -year-old man from Frankfort, who died on November 30. This is the fifth case of human rabies in the United States in 1979-the most cases in any year since 1959.

The man had been in good health until November 20, when dizziness, vomiting, diaphoresis, and an unstable gait developed. Over the next 2 days dysarthria, difficulty swallowing, diplopia, and spasms in his extremities also developed, and he was admitted to a hospital in Frankfort with the presumptive diagnosis of tetanus. There he was noted to be alert, with a temperature of 38.7 C , tremors, and generalized spasms of the muscles of his extremities. The spasms were precipitated by noise, change in lighting, or passive movement of his body. The patient was treated with human immune tetanus globulin and penicillin.

Late on November 23, he was transferred to a hospital in Lexington, where he was intubated and treated with dopamine for hypotension. He then had mild renal failure and was treated for presumed tetanus with a muscle relaxant and a neuromuscular blocking agent. On November 26, then off medication, he was found to be comatose and have a flaccid paralysis. He remained comatose and developed diabetes insipidus, pulmonary infiltrates, and raised intracerebral pressures. He died on November 30.

Cerebral spinal fluid (CSF) obtained on November 22 was normal, and a repeat study 5 days later showed 23 white blood cells $/ \mathrm{mm}^{3}$ ( $95 \%$ lymphocytes) and a protein level of $146 \mathrm{mg} / \mathrm{d}$. Serum and CSF specimens, a neck skin biopsy, and buccal mucosal, nasal mucosal, and tongue scrapings, all taken on November 28, were negative. A corneal im. pression test from November 28, however, was positive.

When he was lucid, the patient gave no history of a potential rabies exposure, and his family and friends have similarly been unable to recall any bites by animals. He worked as a mechanic in a distillery near Frankfort, raised tobacco, and hunted deer occasionally. His next-door neighbor had a dog that died of rabies 5 years ago, to which the patient presumably was not exposed, and he killed an ill-appearing groundhog in the spring of 1979. He had not been outside his county of residence (Franklin) in the last 2 years. In that county, no animals have been reported rabid in 1979, although 11 skunks have been reported rabid in the 6 surrounding counties.
Reported by HJ Cowherd, MD, Frankfort; S Reeves, RN, S Riegler, MD, PD Walzen, MD, Universitl of Kentucky Medical Center; C Hernandez, MD, State Epidemiologist, JW Skaggs, DVM, Kentuokl State Dept for Human Resources; Viral Zoonoses Br, Virology Div, Bur of Laboratories; Respiraton' and Special Pathogens Br, Viral Diseases Div, Bur of Epidemiology, CDC.
Editorial Note: The increase in cases of human rabies in the United States this year parallels an increase in reports of rabies in animals.

The case reported here is the second one this year-and the fourth in 2 years-in which no potential bite exposure could be identified, despite intensive questioning of families and friends. There are 3 possible explanations: these patients knew of, but did not relate to others, an animal bite; the patients were unaware of a bite exposure (e.g., a bat bite while sleeping); or the patients had a nonbite exposure to rabies.

Although this patient's clinical symptoms were not classic for rabies and he had no exposure history, the diagnosis was suspected. The staff, therefore, took extra precal tions to avoid contact with his respiratory secretions, and a laboratory confirmation of a diagnosis was sought. Because of the extra precautions, few hospital personnel were exposed or needed postexposure prophylaxis. The diagnostic studies performed while

## Rabies - Continued

the patient was alive were negative except for the corneal impression test, which has given frequent false-positive and false-negative results in possible human rabies cases investigated by CDC, making the results difficult to interpret. Thus, in this instance the diagnosis of rabies could not be made until after the patient died.

Serum and CSF specimens can be negative as late as 2 weeks after onset of symptoms (1). Laboratory confirmation of clinical rabies may be difficult during the early stages of illness because of the lack of diagnostic changes in body tissues or fluid or the unreliability of diagnostic tests.
