## EPIDEMIOLOGIC NOTES AND REPORTS TULAREMIA - New York

During the second week of April 1968, three muskrat trappers in Crown Point, New York, developed fever, cutaneous ulcers on the hands and wrists, and regional adenopathy. Agglutination titers against Francisella tularensis on sera drawn from these three trappers between April 26 and May 1 were $1: 80,1: 320$, and $1: 1280$, respectively. Four additional trappers or fur handlers from this area, two of whom had slow healing hand lesions but no other symptoms, had negative serologies.

Crown Point lies on the western shore of Lake Champlain, 20 miles southwest of the counties in Vermont where 32 cases of tularemia in muskrat trappers and skinners

## TULAREMIA (Continued from front page)

their animals only in New York. One had skinned 20 muskrats, 15 of which he found dead along Putnam Creek near Crown Point, while the other trapper had taken some dead animals he found along the western shore of Lake Champlain. According to trappers, swamplands and lake shore areas near Crown Point harbored unusually large numbers of live muskrats this year and dead muskrats were also apparent.

## MENINGOCOCCAL MENINGITIS - Hawaii

Between February 23 and March 7, 1968, five of 24 persons in a closely-knit social unit in the district of Kona, Hawaii, developed meningococcemia and meningococcal meningitis. The index patient (Table 1) was a 17-year-old male who developed fever, confusion, and purpura, and progressed to a state of unresponsiveness within several hours. Cultures of the patient's blood and spinal fluid grew Neisseria meningitidis Group B. The organism was sulfonamide-resistant with a minimal inhibitory concentration of 10 mg percent of sulfadiazine, but was sensitive to penicillin at a concentration of 0.05 mi crogram per ml . This patient had intimate contact with members of another household in which 8 days later on March 3, three persons within 8 hours developed fever, headache, and diffuse petechiae or purpura. Although all three persons had received parenteral penicillin prophylaxis (Table 1), lumbar puncture revealed purulent meningitis in each case, and a Group B sulfonamide-resistant meningococcus was cultured from the spinal fluid of the fourth patient. Spinal fluid cultures on Cases 2 and 3 were negative.

The fifth patient, who lived near Cases 2, 3, 4, and had contact with Case 1, developed an identical illness consisting of fever, headache, and diffuse petechiae on March 7. Although he received 600,000 units of intramuscular procaine penicillin G in the 24 hours preceding symptoms, a sulfonàmide-resistant Group B meningococcus was cultured from spinal fluid obtained on admission to the hospital.

The five patients were treated with 12 million units of parenteral penicillin and 6 gm of chloramphenicol per
(Reported by J. S. Miller, M.D., Crown Point, New York; Clayton M. Steward, M.D., District Health Officer, Saranac Lake, New York; Joseph Dell, Ph.D., Chief Wildlife Biologist, and Ralph B. Colson, Chief, Bureau of Game, Department of Conservation, New York; Julia L. Freitag, M.D., Director, Bureau of Epidemiology, New York State Department of Health; and an EIS Officer.)

24 hours for a minimum of 10 days and all patients recovered. Nineteen contacts thought to be at risk had negative nasopharyngeal cultures for meningococci, but these negative findings may have resulted from administration of various antibiotics prior to the culture survey.
(Reported by R. Penington, Jr., M.D., Chief, Epidemiology Branch, Hawaii Department of Health; the Bacterial Reference Unit and Bacterial Serology Unit, Laboratory Program, NCDC; and an EIS Officer.)

## Editoral Comment

This epidemic is unusual in two respects. First, the overall attack rate of 20.8 percent ( 5 of 24 persons) is high for a Group B outbreak, and second, penicillin administration 24 to 48 hours prior to onset of symptoms did not prevent meningitis although it may have contributed to negative spinal fluid cultures in two cases with characteristic clinical illness. It has been reported that penicillin in doses from 1 to 6 million units a day administered orally fails to eradicate the meningococcal carrier state. $1,2,3$ In the parenteral doses used in these cases, penicillin failed to prevent overt disease.

## CURRENT TRENDS <br> MENINGOCOCCAL DISEASE - United States

The adjusted incidence rate of meningococcal infections for April 1968 is 1.59 cases per 100,000 population. This rate is nearly identical to the rate of 1.60 cases per 100,000 population for April 1967 and is below the mean monthly rate of 1.77 for April 1960-1966. The South Atlantic Division reported 71 cases in April 1968 which is twice as many cases as any other division reported. Military cases comprised 12 percent of the April total. The present trend (Figure 1) suggests that the increased incidence of meningococcal disease noted during the first 2 months of 1968 represents an early peak in the epidemiologic year.

Of 274 meningococcal strains submitted to NCDC between January 1 and April 30, 1968, for antibiotic sensitivity testing, 48.5 percent were Serogroup $B$ and 42.7 percent were Serogroup C. During 1967, Serogroups B and C comprised 66 percent and 21 percent of 367 meningococeal isolates submitted to NCDC.
(Reported by the Bacterial Diseases Section and Statistics Section, Epidemiology Program, and the Bacterial Reference Unit and Bacterial Serology Unit, Laboratory Program, NCDC.)

MONTHLY INCIDENCE OF MENINGOCOCCAL INFECTIONS, UNITED STATES

## SURVEILLANCE SUMMARY TETANUS - 1965 and 1966 PART III

In the United States in 1965 and 1966, puncture wounds and lacerations accounted for 33 percent and 25 percent, respectively, of the wounds associated with tetanus cases reported to NCDC. No wound or obvious source of infection could be found in 7 percent of the cases. Nine cases occurred postoperatively resulting in six deaths, while six cases, all fatal, were related to abortion or parturition. Of the nine cases due to injections, seven were fatal. In addition to tetanus complicating overt traumatic injury, tetanus was also the sequel to a number of unusual wounds (Table 2). These unusual wounds, including animal and human bites, decubitus and varicose ulcers, frostbite, and dental abscesses, illustrate a variety of conditions that may be associated with tetanus.

Figure 2
DAYS FROM WOUND TO ONSET OF TETANUS UNITED STATES, 1965-1966

Unusual Wounds Associated with Tetanus United States, 1965-1966

## TETANUS (Continued from page 179)

The median incubation period for fatal cases and nonfatal cases was 7 and 8 days, respectively, with a range from 1 to 54 days (Figure 2). However, 88 percent of all cases had dates of onset within 14 days or less from the time of injury.

Trismus alone and trismus with local muscle spasm were the two most frequent presenting symptoms ( 33 and 29 percent, respectively). Convulsions were part of the initial manifestation of tetanus in 21 percent of the cases.

The overall case fatality ratio for patients with convulsions at any time during the illness was 76 percent and was significantly greater than the 60 percent for patients without convulsions. Of the patients who died, 53 percent died within 5 days after the onset of symptoms, while 82 percent died by the 10th day.
(Reported by Special Pathogens Unit, Bacterial Diseases Section, and Statistics Section, Epidemiology Program, NCDC.)

## EPIDEMIOLOGIC NOTES AND REPORTS SHIGELLOSIS - Washington

An outbreak of shigellosis occurred among 7 girls in a troup of 19 Girl Scouts who attended a camp in Washington between April 9 and 11, 1968. The index patient was a 10 -year-old girl who developed diarrhea on the evening of her arrival at the camp, April 9. Subsequently, three girls became ill on April 11, two others on April 12, and one on April 13. Of the seven girls, four had fever and diarrhea, two had diarrhea only, and one had fever only. Duration of illness ranged from 1 to 8 days. Two girls received medical attention. Eight secondary cases of diarrheal illness occurred among family members of the girls. Shigella sonnei, Group D, was isolated by the SeattleKing County Department of Health Laboratory from rectal swabs or stool specimens of all seven girls.

At the camp, each of the four patrols composing the troop had its own cabin and participated in activities as a unit. With the exception of the index case, all girls helped with the preparation of two meals. Of the seven girls who became ill, four were in the same patrol and three were in
two other patrols. Sanitary facilities at the camp consisted of two rustic latrines, two outside cold water faucets, and running water in the kitchen. The girls admitted sharing hand towels and drinking cups. Another troop who simultaneously used the camp, but in a separate location, experienced no diarrheal illness.

Although a common source of infection could not be definitely ruled out, the epidemic was thought to have been propagated by person-to-person transmission and by fomites after introduction of the disease agent by the index case. The source of infection for the index patient is unknown. Her family denied any prior diarrheal illness, and her teacher recalled no school absenteeism by the girl's classmates because of diarrheal illness.
(Reported by Jean G. Spearmen, B.S., R.N., M.N., Public Health Nurse Epidemiologist, and Donald R. Peterson, M.D., M.P.H., Epidemiologist, Director, Division of Epidemiology, Seattle-King County Department of Public Health, Seattle, Washington.)

## INTERNATIONAL NOTES CHOLERA

Beginning in 1960, cholera, due to the El Torbiotype of Vibrio cholerae, spread from its endemic focus in Indonesia. By the summer of 1966 this pandemic, the seventh in recorded history, had encompassed most of Southeast and South Asia as far west as Iraq in the Middle East. Abruptly, the pandemic abated late in 1966. No further spread was noted during 1967 , and the disease disappeared in most of the countries previously infected.

During April 1968, the World Health Organization received official notification of the presence of cholera in three previously infected areas, Singapore, West Pakistan, and Cambodia. It is not yet established whether the infecting strain causing these current outbreaks is the same El Tor biotype which caused the seventh pandemic or whether it is the classical strain, which has long been responsible for outbreaks in the endemic focus of East Pakistan.

Because the disease has an unpredictable pattern of geographic spread, there is once again concern of further
extension facilitated by rapid means of ground and air travel from infected foci. It is not uncommon for health authorities in countries neighboring infected areas to impose on unvaccinated travelers stringent quarantine measures and other restrictions such as chemoprophylaxis not authorized by the International Sanitary Regulations. It lehooves the traveler, therefore, to familiarize himself with such restrictions and to maintain a current vaccination status. It is important to note that the International Certificate of Vaccination against cholera does not become valid until 6 days after the injection is given.

These epidemics pose little serious threat to the health of travelers who maintain reasonable sanitary discipline. Precautions should be exercised in the choices of drinking water and food when visiting infected areas. (Reported by the Enteric Diseases Unit, Bacterial Diseases Section, Epidemiology Program, and the Foreign Quarantine Program, NCDC.)

# RECOMMENDATION OF THE PUBLIC HEALTH SERVICE adVISORY COMmITTEE ON IMMUNIZATION PRACTICES 

The Public Health Service Advisory Committee on Immunization Practices meeting on February 15, 1968, issued the following recommendation on cholera vaccine.

## CHOLERA VACCINE

## CHOLERA

Cholera generally occurs in endemic and epidemic form only in South and Southeast Asia. In recent years, however, it has also been epidemic in certain areas of the Middle East.

Infection is acquired from contaminated water or food. It is believed to result from personal contact only in rare instances.

## CHOLERA VACCINE

Various cholera vaccines have been widely used, but until recently their efficacy was unproved. Carefully controlled field studies have now clearly demonstrated the effectiveness of current vaccines against both the classical and El Tor strains of cholera vibrios. However, severe cases of cholera have occurred in vaccinated persons.

The duration of immunity induced by vaccine is relatively brief. Antibody titers reach a peak within 4 weeks of vaccination and are maintained for about 3 months. Protection against disease seems to last no more than 6 months after the primary series or a booster dose.

Vaccine available in the United States is prepared from a combination of inactivated suspensions of classical Inaba and Ogawa strains of cholera vibrios grown on agar or in broth and preserved with phenol.

## RECOMmENDATIONS FOR VACCINE USE

A primary vaccination or a booster dose within the previous 6 months is generally required for persons traveling to or from countries with cholera.* Vaccination requirements are published annually by the World Health Organization and summarized by the Public Health Service in its booklet Immunization Information for International Travel (PHS Publication No. 384). Because cholera sometimes reappears in countries free of the disease for several years, travelers should seek up-to-date information to determine the need for a valid International Certificate of Vaccination.

Physicians administering vaccine to travelers should emphasize that an International Certificate of Vaccination must be validated for it to be acceptable to quarantine authorities. Validation can be obtained at most city, county, and State health departments. Failure to secure validation can cause travelers to be revaccinated or quarantined during the course of travel. The Certificate remains valid for 6 months.

The traveler's best protection against cholera, as well as against many other enteric diseases, is to avoid po-

[^0]tentially contaminated food and water. Persons following the usual tourist itinerary through countries reporting cholera and using standard accommodations run virtually no risk of acquiring cholera.

## Vaccination Schedule

Injections may be given subcutaneously or intramuscularly.

Primary: For travelers vaccinatedin the United States, a single 0.5 ml . dose of cholera vaccine is considered adequate to satisfy the International Sanitary Regulations. The single dose for children is proportionately smaller (see table below).

Two doses of cholera vaccine, 0.5 ml . and 1.0 ml , preferably given a month or more apart, are recommended for adults traveling or working in areas where cholera is epidemic or known to be endemic and living under conditions in which sanitation is less than adequate. The doses for children are suggested in the summary table. A two-dose schedule of vaccination is also advisable for persons working with cholera vibrios in the laboratory.

Boosters: Booster injections should be given every 6 months as long as the likelihood of exposure persists. In areas where cholera only occurs in a two to three month "season", protection is optimal when the booster dose is given at the beginning of the season. The primary series need never be repeated for booster doses to be effective.

Summary: The following table summarizes the recommended doses for primary and booster vaccination:

| Dose <br> Number | Under 5 | Age (Years) <br> $5-10$ | Over 10 |
| :---: | :---: | :---: | :---: |
| 1 | 0.1 ml. | 0.3 ml. | 0.5 ml. |
| $2 \&$ Boosters | 0.3 ml. | 0.5 ml. | 1.0 ml. |

## Reactions

Vaccination often results in discomfort at the site of injection for one or more days. The local reaction may be accompanied by fever, malaise, and headache.

## Contraindication

Rarely, several reactions of various kinds follow administration of cholera vaccine. If one experiences such a reaction, revaccination is not advisable. Most governments will permit such an individual to proceed provided he carries a physician's statement of the medical contraindication. However, any inadequately vaccinated travler coming from an infected area may be quarantined or placed under surveillance for 5 days.

## CURRENT TRENDS <br> MEASLES

For the week ending May $18,1968,927$ cases of measles were reported to NCDC. This is 898 fewer cases than the 1,825 cases reported for the corresponding week ir 1967.

The 4-week total for April 21 through May 18, 1968 (weeks $17-20$ ), is 3,354 cases (Figure 3), which is 38 percent of the 8,853 cases reported for the comparable 4 weeks in 1967.

During the first 32 weeks of the current measles epidemiologic year*, 17,746 cases were reported to NCDC.

This total is 30 percent of the 58,405 cases reported during the comparable 32 -week period in epidemiologic year 1966-67.
(Reported by State Services Section, and Statistics Section, Epidemiology Program, NCDC.)

[^1]REPORTED CASES OF MEASLES BY 4-WEEKPERIODS - UNITED STATES EPIDEMIOLOGIC YEAR 1967-68, COMPARED WITH 1966-67

## POST -INFECTIOUS ENCEPHALITIS - United States

For the first quarter of 1968 , a preliminary total of 114 cases of post-infectious encephalitis were reported to NCDC (Table 3). This is the lowest first quarter total of cases since this kind of reporting began in 1964 (Table 4).

This low quarterly total may result in part from a marked decline in the number of reported cases of measles encephalitis (Table 4 and MMWR, Vol. 17, No. 8).
(Reported by Neurotropic Viral Diseases Unit, Viral Diseases Section, and Statistics Section, NCDC.)
