## EPIDEMIOLOGIC NOTES AND REPORTS SALMONELLA THOMPSON - Maine

On Aug. 7, 1971, 33 persons attended a christening in Kittery Point, Maine. Lunch was served between 12 and I p.m., and within 2 days, 17 of those who ate the meal became ill with gastroenteritis. The mean incubation period was 29 hours. Typical symptoms included diarrhea, abdominal pain, fever, headache, and myalgia. These symptoms lasted for 1-7 days, with a mean duration of 4 days. Three families sought medical attention. Cultures of stool specimens from 14 persons were positive for Salmonella thompson.

Questionnaires including food histories were completed by all 33 persons (Table 1). Sixteen of 21 ( 76.0 percent) persons who ate chicken salad became ill, whereas only one of 12 ( 8.0 percent) who did not eat this food were similarly affected ( $\mathrm{p}<.001$ ).

Ingredients of the chicken salad included homegrown lettuce and celery, mayonnaise, and three chickens, all pur-

chased at a local supermarket. On August 5, the chickens were gutted on a marble slab in the kitchen and boiled for 1 hour. They were then placed in a refrigerator. The next day, they were deboned and cut into small pieces which were returned to the refrigerator. Approximately 30 minutes before the meal was served on August 7, all ingredients were mixed

and served on lettuce leaves. There were no ingredients or food samples left for laboratory analysis. Environmental cultures of the cutting board, marble slab, refrigerator shelf, and knife used to cut the chicken were all negative for salmonellae. There was no evident error in food handling or medical history to suggest recent salmonellosis in the single food handler.
(Reported by James R. Hughes, M.D., private physician, Norwich, Vermont; Dean Fisher, M.D., Commissioner of Health and Welfare, Department of Health and Welfare, State House, Augusta, Maine; and three EIS Officers.)

## Editorial Note

The food specific attack rates in this outbreak clearly implicate the chicken salad as the vehicle of infection. Fifty percent of all non-human isolates of $S$. thompson reported to CDC in 1970 were obtained from chickens. Boiling the chicken for 1 hour should have been sufficient to kill all salmonellae. Recontamination presumably occurred after it was boiled, though no specific food handling error was documented.

## INTERNATIONAL NOTES POLIOMYELITIS IN 1970* - Worldwide

Poliomyelitis is of international importance, and outbreaks of this disease in its paralytic form, together with other selected communicable diseases, are subject to notification through the World Health Organization (WHO) on a worldwide basis. For the world as a whole, close to 7,800 cases were reported for 1970, a considerable decline compared to the average number of cases reported annually for the period 1966-1969. However, these global figures reflect on greatly varying situations in the six regions discussed.

This report is based on notifications of the occurrence of poliomyelitis received by WHO through weekly, monthly, or annual summaries submitted by health administrations. It must be borne in mind, however, that reporting both on the national as well as the international level is frequently incomplete. Furthermore, for 1969 and 1970 the data are in many instances provisional, including only a portion of the indicated calendar year. Consequently, this report is intended only to give approximate trends in recent years based on the best available information at the time of writing (but excluding special surveys and other scientific investigations beyond the scope of this summary).

In the African Region, the total number of cases for 1970 is unusually low, but this is largely because half the countries listed have either not reported or submitted incomplete data (Table 2). In 18 of the 30 countries listed in this continent, the average annual number of cases in 1961-1965 increased, compared with 1951-1955. Between 1961-1965 and 1966-1969, the average annual number of cases increased substantially in 15 of these countries. A continuous decline over the entire period 1951-1969 is noticed in four countries, but only in Angola is the data sufficiently complete to conclude that there has been a real decrease in the incidence of the disease.

Cameroon, Ghana, Mozambique, and Nigeria registered substantial increases in 1970 over the 1969 total. In each of these countries, except Cameroon, the 1970 provisional totals also exceeded the average annual number of cases for 19661969.

For the period 1951-1969, the average annual number of cases for the 30 countries has been slowly but steadily rising. This to some extent results from improved reporting practices by health administrations, but for the larger part it undoubtedly reflects a steadily increasing incidence of the disease.

In the American Region, a considerable increase in the number of reported cases for 1970 was noted, compared with previous years (Table 3). Of the 26 countries with data available for comparison between 1969 and 1970, 10 showed an increase in the annual number of notified cases, and for one (Bolivia) the 1970 total was higher than for the period 19511969. Local outbreaks were recorded from at least four countries: Bolivia, Paraguay, Colombia, and Argentina. Each of these outbreaks was sufficiently large to justify mass poliomyelitis vaccination programs. In Colombia, the predominant polio virus serotype recovered from laboratory-examined cases was type 1, whereas in Argentina it was type 3. In each of the outbreaks, the cases occurred chiefly in children under the age of 4 years.

Of particular significance has been the decrease of polio in recent years in Canada, Cuba, Dominican Republic, Jamaica, Puerto Rico, Trinidad and Tobago, United States of America, and Uruguay, which has brought the disease under effective control.

The slight rise in the annual number of cases between 1969 and 1970 in the United States should be noted. The increase, though small, is being carefully watched by the U.S.

Health Administration. Attention has been drawn to the fact that there has been a steady decline in the proportion of children completely immunized against polio from 1964 to 1971. Pockets of susceptible children are known to be developing in many of the larger inner-city areas. Also significant is the report that two-thirds of the cases from the United States were from Texas, which borders on Mexico, and that several of these cases were epidemiologically associated with travel across this border.

The combined data from the American Region indicates that in most countries the poliomyelitis situation is still unstable, and the disease is not yet under effective control.

In the Eastern Mediterranean Region, only Iraq, Israel, Jordan, and Lebanon reported complete data. These countries showed a decline in the number of cases recorded in 1970, compared to 1969. This trend is particularly noticeable for Lebanon, which reported a substantial number of cases between 1961 and 1969.

In the European Region, 10 countries out of 22 reporting for 1970 had no cases, and an additional five countries notified three cases or less. A total of 1,077 cases were reported from this Region in 1970. Of the countries for which provisional data is available for 1969 ( 25 countries) and 1970
(23 countries), only France, Portugal, Yugoslavia, and Turkey registered increases in reported cases in 1970. However, in France, Portugal, and Yugoslavia the changes reflect the expected variations in reporting practices or occurrence of the disease.

In the U.S.S.R. in 1958, 22,054 poliomyelitis cases were registered. There were for the individual years 1965 to 1969 only $300,290,140,120$, and 190 cases, respectively.

Poliomyelitis is being well controlled in Europe by systematic use of polio virus vaccines in most countries. The live vaccines are predominantly used, but in Scandinavia, where killed vaccine is used, the decrease in cases of polio is as significant and stable as in other European countries.

In the South-East Asian Region, the overall epidemiologic situation in 1970 is obscured by the absence of data from such populous countries as India and Indonesia. In fact, with only Ceylon reporting for 1969 and 1970, no conclusions can be drawn on the basis of officially submitted data. Throughout most of this Region, the disease remains typical infantile paralysis with over 80 percent of the patients under 3 years of age. In Thailand, an analysis of age distribution of cases admitted to children's hospitals between 1960 and 1966

## POLIOMYELITIS - (Continued from page 31.3)

suggested a slight upward age shift coinciding with a definite increase in the total number of cases.

Data for the Western Pacific Region are shown in Table 4. Australia, Japan, New Zealand, and Singapore present a very favorable epidemiologic situation. In New Zealand only one case of poliomyelitis was reported in 1970, the only case in the last 5 years. Australia had two cases in 1970, and a total of only 10 cases between 1966 and 1969.

Approximately twice the expected number of cases was observed in the Greater Manila area of the Philippines in May 1970. However, the cases were widely distributed geographically, and a localized outbreak was not reported. Only one country officially reported an outbreak of paralytic polio to WHO in 1970: The Australian Territory of Papua and New Guinea, where 44 cases, with one death, occurred in May and June. Polio virus type 1 was isolated from one patient.

The data for 1970 show no marked variations from previous trends. In Europe, North America, Australia, New Zealand, and a few other countries including the U.S.S.R., the disease has fallen to insignificant proportions. The same trend is observed in a group of countries in Asia and in Central and South America where adequate vaccination programs have been implemented. Throughout much of Africa and Asia, however, a definite increase in the number of cases of
polio was observed. In most countries in Central and South America, the polio situation can be characterized as unstable. There is a slight decrease in morbidity, but the fluctuation in the yearly reported number of cases and the appearance of scattered outbreaks are enough to make the situation disquieting. It can be assumed that further changes in this part of the world depend greatly on efforts to organize vaccination programs. Polio virus type 1 is still responsible for the majority of cases in those countries with endemic disease or frequent outbreaks. On the other hand, in countries where vaccine has been used extensively, an equal distribution of the three polio virus serotypes is often found from the reported or suspected cases.

Tropical and sub-tropical countries with a rising level of community and personal hygiene may expect increasing numbers of paralytic poliomyelitis cases. Large outbreaks, such as those occurring in the temperate countries before polio vaccines were available, should be anticipated. These outbreaks may be averted in part, or even completely, by planning now for the implementation of nation-wide vaccination programs.

## EPIDEMIOLOGIC NOTES AND REPORTS

## HUMAN VENEZUELAN EQUINE ENCEPHALITIS - Rio Grande Valley

On June 23, 1971, a 43-year-old sanitarian with the U.S. Public Health Service in Ft. Collins, Colorado, was sent to Brownsville, Texas, to assist in the studies of the Venezuelan equine encephalitis (VEE) epidemic then occurring only in Mexico. For the next 9 days, he worked in Texas doing mosquito larvae surveys and was occasionally bitten by mosquitoes. On July 3, he went to Mexico and helped collect more than 60,000 mosquitoes; he received several more mosquito bites at this time. Subsequently, more than 100 mosquito pools collected were shown to be infected with VEE virus. On July 3, he also helped separate serum from clotted blood which had been collected from people in Mexico. Some of these blood specimens were found to be positive for VEE virus.

On July 6, the patient had onset of a severe, bilateral, frontal headache, fever with occasional chills, diffuse myalgia, and general malaise. In his return to Ft. Collins, he vomited twice and arrived with a temperature of $103.6^{\circ} \mathrm{F}$. The next day, he also experienced a moderately severe sore throat. A physical examination at that time showed only a low-grade fever and an erythematous throat. There was no exudate or cervical adenopathy. The patient denied any respiratory or gastrointestinal complaints other than the sore throat and the
two episodes of vomiting. He subsequently became afebrile, but a low-grade temperature of $101^{\circ} \mathrm{F}$. recurred and persisted for 2 days. He returned to work the next week but complained of easy fatigability.

Acute blood specimens and throat washings were obtained on July 7. The throat specimen was found positive for virus in monkey-kidney, Hep-2, and Wistar 38 tissue cultures. The isolate was later identified as VEE. The serum specimen was positive for virus in duck-embryo-cell culture. This isolate was also identified as VEE using the hemagglutinationinhibition test. Serologic confirmation of VEE infection was also obtained in the convalescent sera.
(Reported by the Zoonoses Section, and the Arboviral Disease Section, Ecological Investigations Program, CDC, Ft. Collins, Colorado.)

## Editorial Note

The clinical course described above is typical of human VEE illness. The majority of laboratory confirmed human VEE cases reported from the lower Rio Grande Valley of Texas have presented with sudden onset of fever and severe headache with subsequent development of myalgia and general malaise. The illness usually lasts for $2-4$ days.

## BOTULISM FROM HOME-CANNED PEPPERS - Pennsylvania

On Aug. 21, 1971, a man and his wife from Philadelphia, Pennsylvania, became ill with vomiting and diarrhea. The next day, they both had difficulty swallowing and blurred or double vision. On August 23, the woman experienced respiratory distress and was taken to a local hospital. She was apneic and comatose on admission but was successfully resuscitated. Her condition continued to deteriorate, however, and she
died on August 30. Her husband, who was also admitted on August 23, had fixed, dilated pupils, markedly disconjugate lateral gaze, and inability to swallow. He was alert and had no respiratory distress or difficulty talking. Investigation of these two cases led to the discovery of a third case on August 24. This patient, a neighbor, had experienced vomiting and (Continued on page 316)

BOTULISM - (Continued from page 315)
diarrhea on August 21 , weakness and dysphagia the following day, and diplopia on August 24. Her condition and that of the man have subsequently improved.

An epidemiologic investigation by the Philadelphia Health Department revealed that the affected couple frequently ate home-canned peppers. Peppers from a newlyopened jar had been eaten at lunch and supper on August 20 by both husband and wife. Their three children did $p \cdots:$ any. The neighbor also ate these peppers at lunch on August 20; she only had two bites because they tasted bad. No one else is known to have eaten peppers from this jar.

Laboratory studies have demonstrated type B botulinum toxin in the sera of the first two patients, as well as in the
leftover peppers. The peppers contained an unusually high concentration of toxin, 12,000 mouse LD50's per gram. Toxin was also present in low titer in the neighbor's serum, though there was not enough pre-treatment serum available to determine its type.
(Reported by Bonnie Dorwart, M.D., Miles Sigler, M.D., Michael Manko, M.D., private physicians, Lankenau Hospital, Philadelphia, Pennsylvania; David G. Farris, M.D., Chief, Communicable Disease Control, Philadelphia Department of Health; W. D. Schrack, Jr., M.D., Director, Division of Communicable Diseases, Pennsylvania Department of Health; and an EIS Officer.)

## INTERNATIONAL NOTES <br> CHANGES IN <br> VACCINATION CERTIFICATE REQUIREMENTS FOR INTERNATIONAL TRAVEL

Vaccination Certificate Requirements for International Travel was published as a Supplement to Morbidity and Mortality Weekly Report in Vol. 19, No. 21, for the week ending May 30, 1970. Since that time, some countries have modified their requirements according to the evolution of the cholera outbreak; some have also made changes in smallpox and yellow fever certificate requirements.

The Vaccination Certificate Requirements of May 30, 1970, with changes as indicated in the following list, represent the current status of requirements for all countries updated through Aug. 13, 1971.
NOTE: This supersedes the list of changes published in MMWR, Vol. 20, No. 14, week ending April 10, 1971.
(Reported by the Foreign Quarantine Program, CDC.)

## EPIDEMIOLOGIC NOTES AND REPORTS <br> FOLLOW-UP ON VENEZUELAN EQUINE ENCEPHALITIS - Texas

Since the last report on Venezuelan equine encephalitis (VEE) (MMWR, Vol. 20, No. 34), a total of $88^{*}$ equine viral isolates have been reported from Texas (Table 5) (Figure 1). There have been 84 laboratory confirmed human cases of VEE reported from the following counties: Cameron and Hidalgo (68), Nueces (5), San Patricio (5), Kleberg (3), Aransas (2), and Refugio (1).
(Reported by M. S. Dickerson, M.D., Chief, Communicable Diseases Services, J. E. Peavy, M.D., Commissioner, Texas State Department of Health; Richard E. Omohundro, D.V.M., Coordinator of Regional VEE Eradication Program, U.S. Department of Agriculture; the Laboratory Division, and the Epidemiology Program, CDC.)
*This week's total is one less due to duplicate submissions of specimens from one horse which were counted twice.

In June 1971. an outbreak of salmonellosis due to Salmonella berra occurred in Red Bluff, California. Approximately 200 ill persons were identified. Fifteen were hospitalized, and two elderly patients died. $S$. berta was isolated from 51 of 67 persons who submitted stool specimens.

Epidemiologic investigation revealed the vehicle of infection to be custard-filled pastries, particularly maple bars, processed and sold at a single bakery. The contaminated ingredient was unpasteurized, frozen turkey eggs supplied only to that bakery. $S$. berta was isolated from several maple bars and other pastries, and from previously unopened containers of the turkey eggs. Three bakery employees and the owner of the turkey breeding farm supplying the eggs were among those persons with stools positive for $S$. berta. Environmental swabs of the turkey farm, including turkey droppings and eggshell scrapings, were negative for $S$. berta.

The bakery was temporarily closed for thorough cleaning. disinfection, and for recommended remodeling. Subse-
quent environmental swabbing revealed no evidence of persisting $S$. berta surface contamination. Stool specimens negative for salmonellae are being required of all bakery workers before they return to work. The bakery will not use unpasteurized bulk eggs, and the turkey breeding farm is no lopger processing bulk eggs.
(Reported by Doreen M. Wysocki, P.H.N., John Scott, Sanitarian, Lynn E. Wolfe, Jr., M.D., Health Officer, Tehama County Health Department, California; Catherine Powers, B.A., Associate Microbiologist, Ronald Wood, Ph.D., Director, Microbial Diseases Laboratory, and S. Benson Werner, M.D., Medical Epidemiologist, Infectious Disease Element, California State Department of Public Health.)

## Editorial Note

Since June 1, 1966, the California Agricultural Code has required that all egg products for human consumption be pasteurized.

The Morbidity and Mortality Weekly Report, circulation 24,600, is published by
for Disease Control, Atlanta, G David J. Sencer, M.D. Philip S. Brachman, M.D
Director, Epidemiology Program, CDC PhilipS. Brachman, M.D.
Editor, MMWR Michael B. Gregg, M.D.
The data in this report are provisional, based on weekly telegraphs to CDC by state health departments. The reporting week concludes at close of business on Friday; compiled data on a national basis are officially released to the public on the succeeding Friday
n addition to the established procedures for reporting morbidity and mortality nadion to current interest to health officials.
