## **Abstract**

Within the framework of Registration, Evaluation, Authorization, and restriction of CHemicals (REACH), occupational exposure models are often used to predict the levels of exposure at a workplace. Poor inter-assessor agreement with their use poses a concern that may lead to different and dangerous risk conclusions. TREXMO (v1, 2016), a web tool providing parameter translations between six exposure models under REACH, is expected to improve the inter-assessor agreement. In this study, 18 assessors performed exposure assessment for six exposure situations within and outside the framework of this translation tool. In more than half of the evaluated cases, the results showed better agreement between assessors selecting the exposure parameters within the framework of TREXMO than when manually coding. The most affected were the parameters related to activity (such as "handling types" of Stoffenmanager) and exposure control (such as local controls). Furthermore, the agreement between the estimates calculated by different assessors was also improved when performing the translations between the models. For Stoffenmanager, for example, the relative standard deviation of 70–121%, obtained for vapors without applying the translation system, was 29-94% with the translations from ART. These findings showed a potential of TREXMO to impact the inter-assessor agreement. Because the study was limited to 18 assessors and only six exposure situations were assessed, further investigations are suggested.

**Keywords:** Advanced REACH Tool; ECETOC TRA; inter-rater agreement; occupational exposure models; Stoffenmanager; TREXMO

#### Introduction

Occupational exposure models, within the context of the Registration, Evaluation, Authorization and restriction of CHemicals (REACH) legislation (ECHA, 2016), are often applied by registrants to establish exposure scenarios. However, the different educational backgrounds and levels of experience of assessors evaluating the same set of conditions in an exposure scenario may strongly affect the reliability of their exposure estimates (Kromhout *et al.*, 1987; Cherrie and Schneider, 1999; Friesen *et al.*, 2011).

Inter-assessor agreement presents a degree of concurrence between the assessors evaluating the same exposure situation (ES) (Fleiss, 1971). Previous studies (Schinkel et al., 2014; Landberg et al., 2015; Lamb et al., 2017) have reported variations by several orders of magnitude between the exposure estimates calculated by different assessors. Schinkel et al. (2014) compared assessors' agreement regarding the Advanced REACH Tool (ART) and found that training improved slightly the agreement. However, substantial variation between the assessors was observed in evaluating the same exposure situation, mostly due to the variations in values chosen for activity-related parameters. Landberg et al. (2015) investigated the agreement for Stoffenmanager and reported significant variations for activity-related parameters and personal protection. More recently, a broader study, known as the eteam (Lamb et al., 2017), evaluated the inter-assessor agreement for several models, that is, EMKG-EXPO-TOOL, MEASE, ECETOC TRAv2 (an older version of the model; ECETOC, 2009) and TRAv3 (ECETOC, 2012) and Stoffenmanager. Again, the authors found significant variations between the assessors, particularly when assessing the activity-related parameters in the models (such as PROC in TRA). No systematic trend, however, was observed between less and more experienced participants in the study or between those employed at different types of organizations.

The present work shows the results obtained for the agreement evaluated for several professionals in occupational safety and health when using TREXMO (Savic et al., 2016). By using between-model translations, TREXMO supports parameter selection and it is expected to provide reliable estimates for a wide range of ESs. The agreement results obtained from TREXMO were compared with those found when coding the models' parameters manually. The term "manual" coding is used to refer to the common use of the models outside the framework of TREXMO.

#### Method

Eighteen assessors employed in occupational and safety organizations in Switzerland and the EU participated in this study and completed the exposure assessment. Only those, who were to some extent experienced with the exposure models, were invited. On average, the assessors had 5 years of experience in occupational hygiene. Before this study, nine assessors had applied ART or Stoffenmanager in >10 instances; four were more experienced with TRAv3; three had used one of these models 5–10 times, while the remaining two had conducted only 1–3 exposure assessments by using any of the considered models.

Each assessor was provided with six ESs, which were selected from a NIOSH database (Lee et al., 2019a,b). Among these six ESs, three ESs addressed exposure to vapors, including spreading of liquids over a surface (ES-1), liquid transfer (ES-2), and spraying of liquids (ES-3). The remaining three ESs addressed exposure to dusty products (powders), including powder handling (ES-4), powder transfer (ES-5), and moving/agitation of powders (ES-6). More details on the ESs can be found in Supplementary Tables S1 and S2, available at Annals of Work Exposures and Health online. The assessors were asked to code the most appropriate parameters by interpreting the exposure conditions in the ESs and evaluate exposure by using the three following methods:

- Manual coding, where the models' parameters were coded outside the framework of TREXMO and thus with no parameter translations applied. A Microsoft Office Excel (Visual Basic Application) file was provided, containing all input parameters of the six models including Stoffenmanager, ART, MEASE, EMKG-EXPO-TOOL, EASE, and ECETOC TRAv3.
- 2. Translating from Stoffenmanager (SM), where SM was used as the starting model. This means that the assessors interpreted the information in the provided ESs and selected the corresponding parameters in this model. The established coding was used to get the translation outcomes in the other models. Due to a low translation efficiency to ART (Savic et al., 2016), SM was not used to deliver translation outcomes to ART.
- 3. Translating from ART, where ART was used as the starting model in TREXMO to obtain the parameter sets in the other models.

The study was designed in a way that an assessor did not evaluate an ES more than once. This was done to redistribute the total work amount evenly over the 18 assessors and to make the study more time-efficient. Therefore, based on the backgrounds and experience, the assessors were split into three equal groups to minimize a possible between-group variability. Each group assessed six ESs following a different order of the three methods above. For example, group I evaluated ES-1 (spraying of liquids) and ES-4 (powder handling) by using manual coding, while ES-2 (liquid transfer) and ES-5 (powder transfer) by translating the parameters from ART in TREXMO and ES-3 and ES-6 by translating from SM in TREXMO. Group II, by following a different order, evaluated ES-1 and ES-4 by translating from ART in TREXMO, while group III evaluated these two ESs by translating from SM in TREXMO. Finally, each vapor and dust ES was evaluated by all three methods, but different assessors. This means that every ES-method combination was evaluated six times by six different assessors. The only exception is ES-3 (spraying of liquids), which was not assessed in EMKG-EXPO-TOOL and EASE, because this activity is outside of the domain of two models.

#### **Statistics**

For each assessment method, the agreement between the exposure parameters, which were coded by different assessors, and between the obtained exposure estimates was analyzed in R software (version 3.3.1). The agreement was analyzed for all six models of TREXMO. We, however, present only the results of SM and TRAv3, for which more evaluation studies are available (Schinkel et al., 2010; Landberg et al., 2017; Spinazzè et al., 2017; van Tongeren et al., 2017; Lee et al., 2019a) compared with the other models (supplementary table S1 of Lee et al., 2019a,b), in this short communication with the limited length. The results of MEASE, EMKG-EXPO-TOOL, EASE, and ART (only for manual coding) are presented in Supplementary Tables S3-S8, available at Annals of Work Exposures and Health online.

Different measures were used to quantify the levels of agreement per parameter and between the modeled estimates. For the former, the percentage agreement [Gisev et al., 2013; equation (1)] and S-index [Falotico and Quatto, 2010; equation (2)] were calculated. The percentage agreement is calculated as the ratio between the number of times any two responses (i.e., exposure parameters) were in concordance and the total number of responses. The reasoning for using S-index as an alternative to Cohen's kappa (Cohen, 1960) as the agreement

measure has been explained elsewhere (Falotico and Quatto, 2010).

$$P(\%) = \frac{N(\text{concordant responses})}{N(\text{total})} \times 100$$
 (1)

$$S = \frac{\frac{P}{100} - \frac{1}{N}}{1 - \frac{1}{N}} \tag{2}$$

In equation (2), N is the number of categories (e.g., five dustiness categories in SM) available per given exposure parameter.

For the agreement between the modeled estimates, the relative standard deviation (RSD) (equations (3) and (4)) was calculated.

$$\sigma = \sqrt{\frac{\sum (X_i - \bar{X})^2}{N - 1}} \tag{3}$$

$$RSD = \frac{\sigma}{\bar{X}} \times 100\% \tag{4}$$

where,  $\sigma$  is the standard deviation of the modeled estimates and  $\overline{X}$  is their average value. The higher RSD, the smaller agreement is between the assessors, and vice-versa. For each coding method, a mean (with its standard deviation) and a median were calculated for the six RSD obtained for the six ESs.

#### Results and discussion

Table 1 shows the agreement per input parameter for SM and TRAv3. The parameters are classified into source, activity, control, and time group, describing different aspects of exposure. The same classification has been already applied in Savic et al. (2016). Table 2 contains the calculated RSD for the estimates of the two models. The results for the other four investigated models (i.e., ART, MEASE, EMKG-EXPO-TOOL, and EASE) are given in Supplementary Tables S3-S8, available at Annals of Work Exposures and Health online. Although somewhat lower, the RSD values for MEASE were similar to those of TRAv3. The translations from ART were the least efficient for EMKG-EXPO-TOOL and EASE (Supplementary Table S6, available at Annals of Work Exposures and Health online), for which the RSD values were often even lower compared with the manual coding. Also, when coding manually, the lowest RSD was obtained for EMKG-EXPO-TOOL (median = 71; Supplementary Table S6, available at Annals of Work Exposures and Health online). MEASE and ART showed slightly higher RSD (both with median = 75; Supplementary Tables S6 and S8, available at Annals of Work Exposures and Health online) than

Mean RSD		104	82	97	108	48
SD <sup>a</sup> RSD		33	67	26	81	46
Median		101	62	93	69	43.5

<sup>+ (</sup>or –) means that the agreement of exposure estimates using TREXMO-SM or TREXMO-ART was improved (or decreased) compared with the using the manual coding.

EMKG-EXPO-TOOL. This might indicate the best level of agreement for the three given models. Since, however, only 18 assessors participated in the study, this statement cannot be considered reliable enough.

Since no translations were performed from other models to ART, only the results for manually coding were calculated (Supplementary Tables S7 and S8, available at Annals of Work Exposures and Health online). Compared with the manual coding in the other models, the agreement per parameter for ART was considerably better. Probably, this might be because ART provides supporting information using pictures and/or detailed description with examples for exposure parameters. Excluding dustiness, for which the agreement was the lowest (S = 0.33), the S-index for other parameters was within the range of 0.51–1.00. The better starting agreement for ART may explain why it resulted in better results, as compared with SM as the starting models. In addition, the corresponding RSD found for ART were similar to those of SM and TRAv3. Compared with SM and TRAv3, Riedmann et al. (2015) have shown that the estimates in ART are more sensitive to the changes in input parameters. This could explain why the better agreement per parameter did not result also in a better agreement between the estimates of ART.

## Stoffenmanager

Compared with the manual coding, translations from ART improved the agreement for *type of handling* (S-index from 0.03 to 0.31 for powders; only slight for vapors), *evaporation*, *drying*, *or curing* (i.e., presence of the far-field exposure source; S-index from 0.15 to 0.62), and somewhat less for *localized controls* (S-index from

0.69 to 0.78) (Table 1). These parameters have previously found to be most decisive factors in estimating exposures for SM (Riedmann et al., 2015; Savic et al., 2018). This is also obvious from the results shown in Table 2, where the RSD was smaller for two out of three ESs for both vapors and dusts when translating from ART. Excluding inspections and maintenance, which has almost no impact on estimating exposures, the other parameters in the source group were not altered by the translations from ART. This was an expected outcome, since SM and ART share similar descriptions of the parameters used to model the source group. For example, the five dustiness categories (such as fine dust) are the same in both models.

The translations from ART, however, reduced the level of agreement for some parameters, such as breathing zone (i.e., the parameter that determines the presence of a near-field source), general ventilation, and room size. A detailed analysis of the assessors' selections showed that this outcome originates from the coding provided in the starting model, that is, ART. The two coding methods (i.e., manual and translating from ART) were not performed by the same group of assessors. In this case, it was found that the assessors who were translating from ART were less concordant when selecting the parameters in this starting model. This later resulted in different translation outcomes in SM. In addition, in a few cases related to general ventilation, the assessors did not apply the translation outputs obtained from ART, but rather selected other ventilation categories available in SM. If the assessors applied the obtained translations, the inter-assessor agreement for general ventilation would not be different for the different coding methods.

aSD, standard deviation for RSD.

#### **ECETOC TRAv3**

Translations into TRAv3 were obtained from both ART and SM as the starting models. When translating form ART slightly better results were found than when translating from SM. For example, translations from SM did not alter the agreement for PROC (S-index = 0.10, for powders), while with ART, the S-index was increased meaningfully (=0.28). Compared with the manual coding, the smaller RSD was obtained for only three ESs when translating from SM, while the agreement was improved for five out of six ESs with the translations from ART.

In a few cases, again, the translations led to lower agreement. The most important was for PROCs coded for vapors, where S-index of 0.88 found when manually coding was reduced to 0.60 and 0.63 when translating from SM and ART, respectively. The reason for this outcome was the definition of the translation rules (Savic et al., 2016) in case of the spraying ES. Since neither ART nor SM have sector of use defined as industrial and professional use, the translation of the spraying activity/ handling from these models results in two translation outcomes in TRAv3, that is, PROC 7-industrial spraying and PROC 11-professional spraying. One might believe that the assessors' choice between two PROCs in TRAv3, which followed the translations, was rather random. However, all the assessors, who coded the given ES manually in TRAv3, selected PROC 7, as the corresponding ES report stated clearly that the ES addresses industrial use.

Overall, the translations from ART led to better results than those from Stoffenmanager. The explanation for this might be found in the concept behind the translation rules (Savic et al., 2016). ART is a more complex model than any other tools and often has more options in an exposure parameter (e.g., five categories of dustiness). Since lower-level models (such as TRAv3) have less number of options in exposure parameters, it is often a case that two or more options in exposure parameters of ART share the same translation path by leading to a single outcome in another model. The simplest example would be dustiness, where for example, both "fine dust" and "extremely fine dust" are translated as "high dustiness" in TRAv3. This means that if two assessors select different options for dustiness parameter in ART, the translations might still result in the same outcome in TRAv3. Regarding the inter-assessor agreement preceded by a translation from ART, the translation of multi options in a parameter into a single option in the lower-level models (n→1 translation) might compensate the complexity of ART.

### Conclusion

In this study, we evaluated the inter-assessor agreement for six different ESs when assessed within and outside the framework of TREXMO. The study was limited to a small number of ESs (i.e., six) and only 18 occupational professionals. The findings of this study might have also been biased by various factors, outside of the tools or the methods used, leading to between-assessor variability in terms of, for example, their backgrounds, their subjective judgment (such as whether they prefer middle values or extremes), and their motivation for performing the assessments. This impact, however, stays unknown due to the small number of the assessors. It would be thus difficult to generalize the obtained results and draw straightforward conclusions. The results, however, imply a potential of TREXMO to affect the assessors' agreement and suggest further investigations to be conducted. Another limitation of the study was the use of TREXMO 1.0, which was not offering a user-friendly graphical environment. The study should be thus repeated with the most recent version of the tool and with a greater number of volunteers and ESs. Finally, it should be noted that TREXMO integrates version 4.0 of Stoffenmanager and that some differences, regarding the inter-assessor agreement, might exist with newer versions (Heussen and Hollander, 2017; Savic et al., 2017).

## Supplementary Data

Supplementary data are available at Annals of Work Exposures and Health online.
