Comparative Genomics of Vibrio cholerae from Haiti, Asia, and Africa

Aleisha R. Reimer, Gary Van Domselaar, Steven Stroika, Matthew Walker, Heather Kent, Cheryl Tarr, Deborah Talkington, Lori Rowe, Melissa Olsen-Rasmussen, Michael Frace, Scott Sammons, Georges Anicet Dahourou, Jacques Boncy, Anthony M. Smith, Philip Mabon, Aaron Petkau, Morag Graham, Matthew W. Gilmour, Peter Gerner-Smidt, and the V. cholerae Outbreak Genomics Task Force

Cholera was absent from the island of Hispaniola at least a century before an outbreak that began in Haiti in the fall of 2010. Pulsed-field gel electrophoresis (PFGE) analysis of clinical isolates from the Haiti outbreak and recent global travelers returning to the United States showed indistinguishable PFGE fingerprints. To better explore the genetic ancestry of the Haiti outbreak strain, we acquired 23 whole-genome Vibrio cholerae sequences: 9 isolates obtained in Haiti or the Dominican Republic, 12 PFGE pattern-matched isolates linked to Asia or Africa, and 2 nonmatched outliers from the Western Hemisphere. Phylogenies for whole-genome sequences and core genome single-nucleotide polymorphisms showed that the Haiti outbreak strain is genetically related to strains originating in India and Cameroon. However, because no identical genetic match was found among sequenced contemporary isolates, a definitive genetic origin for the outbreak in Haiti remains speculative.

The current (seventh) cholera pandemic was caused by serogroup O1 El Tor biotypes of Vibrio cholerae. This biotype first emerged on the Indonesian island of Sulawesi in 1961, then subsequently spread throughout Asia and Africa, where endemic and epidemic disease persists today (1,2). Seventh cholera pandemic biotypes were introduced into Peru in 1991 and subsequently spread across South and Central America, but these biotypes never reached the island of Hispaniola. Recent endemic and epidemic cases in Asia and Africa are increasingly attributed to genetically atypical El Tor variants that share characteristics of classical and El Tor strains (1,3,4).

After the 2010 earthquake in Haiti, an outbreak of cholera emerged that resulted in >385,000 infections and 5,800 deaths as of July 7, 2011 (5). The outbreak strain quickly spread to the neighboring Dominican Republic and globally as travelers returned home from affected regions (6,7). Concurrent cholera cases in the United States, linked by travel to cholera-endemic regions in Asia and Africa, were identified by national surveillance activities of PulseNet USA (Centers for Disease Control and Prevention [CDC], Atlanta, GA, USA.)

Serotyping, biotyping, and pulsed-field gel electrophoresis (PFGE) fingerprinting investigations suggested that the travel-associated cases could be genetically related to the Haiti outbreak strain (8). Because of the historical absence of cholera in Haiti before the 2010 earthquake, speculation abounds that the outbreak strain was imported into Haiti. Although clonality of the Haiti outbreak strain has been inferred by phenotypic characterization and

Parsons, Erfain Ribot, Maryann Turnsek, Shau Tyler, Jean M. Whichard, Anne Whitney, and the authors.
genotypic subtyping, thereby supporting a single foreign source hypothesis (6,8), definitive evidence, e.g., by whole-genome sequencing for the genetic ancestry of the Haitian strain is lacking.

Preliminary comparative analysis of whole-genome sequences from two 2010 Haiti outbreak isolates with genomes from historical cholera cases resulted in speculation that the outbreak originated in southern Asia (9). However, this study lacked recent, globally distributed cholera case isolates and particularly lacked studied genomes from Africa, to which cholera is endemic. We selected contemporary V. cholerae isolates from clinical infections, attributed to geographically distinct locations and sharing PFGE fingerprints with Haiti outbreak strains, from the PulseNet USA database for comparative whole-genome analysis. Although detailed epidemiologic investigations are essential for unequivocally attributing geographic origin(s) and means of cholera introduction into Haiti, genome sequences of these 23 contemporary isolates showed details related to genetic content and diversity that were otherwise missed with lower-resolution PFGE subtyping, thereby providing useful genetic ancestry information for interpreting the outbreak in Haiti.

Methods

Patients and Isolates

V. cholerae isolates and travel histories from cholera case-patients in the United States were referred to CDC. A strain from an outbreak in Cameroon in 2010, isolated from a specimen received at CDC, and an isolate from South Africa likely linked to an outbreak in Zimbabwe in 2009 were also included in this study (10). Isolates C6706 and 3569–08 were acquired during the outbreak in Latin America in 1991 and from the US Gulf Coast in 2008, respectively. All strains were characterized as V. cholerae O1 on the basis of standard biochemical, cholera toxin, and serologic testing performed as described (11,12). PFGE was performed according to the PulseNet standardized protocol with restriction enzymes SfiI and NotI; PFGE patterns were designated by using BioNumerics version 5.10 (Applied Maths Inc., Sint-Martens-Latem, Belgium) and compared by unweighted pair group method with arithmetic mean analysis (DICE coefficient 1.5% tolerance and optimization). Strain designations and other information are shown in Table 1.

Whole-Genome Data Acquisition, Assembly, and Annotation

Single-end pyrosequencing reads (GS FLX-Titanium; Roche Diagnostics, Indianapolis, IN, USA) and single-end 36-bp or 76-bp Illumina reads (GAIIe sequencer; Illumina, San Diego, CA, USA) were acquired and yielded >99% genome coverage and 32× and 240× average coverage depths, respectively (Table 2). Pyrosequencing reads were first assembled de novo by using Newbler version 2.5.3 (Roche Diagnostics). To correct potential base-calling errors attributed to homopolymers, Illumina GAIIe reads (average 14 million reads/genome) were mapped to the Newbler contigs by using CLC Genomics Workbench version 4.5 (www.clcbio.com/index.php?id=1042) and yielded an average combined coverage depth of 270× per genome.

Both chromosomes of Haiti outbreak isolate 2010EL-1786 were sequenced to full closure by using PCR and Sanger sequence-based bridging of contigs and a fosmid library of templates. Optical mapping also supported the contig ordering derived for 2010EL-1786. For all remaining isolates, Illumina-supplemented, homopolymer-corrected, Newbler-assembled contigs were prepared as pseudogenomes by first linking contigs with a linker sequence containing stop codons in all 6 translation reading frames. These high-coverage pseudogenomes were used for downstream analyses. Identification of coding sequences was achieved by using Glimmer3 (14). Genome annotation was achieved by using an automated, in-house, modified version of GenDB version 2.2 (15) and manual curation for regions of interest.

Comparative Genomics

Whole-Genome Alignment and Core Genome Phylogeny

Whole-genome alignments of all study isolates and 5 available reference V. cholerae genomes (Table 1) were performed by using Progressive Mauve (16) and visualized by using PhyML 3.0 (17). To determine vertical inheritance patterns, study genomes were analyzed with historical V. cholerae genomes (isolates M66–2, MJ-1236, CIRS101, and N16961) by using phylogenetic analysis of high-quality single-nucleotide polymorphisms (hqSNPs) contained in core genes. Coding region predictions were analyzed by using parallelized BLASTn (http://blast.ncbi.nlm.gov/Blast.cgi) to identify highly similar orthologs in all strains. Highly similar orthologs were defined as those containing a high-scoring segment pair >400 bp and identity ≥97%. Each orthologous loci set was multiply aligned by using ClustalW (18). Multiple alignments were manually inspected to remove erroneously aligned regions; indel-associated SNPs and loci containing ≥30 SNPs were also excluded. Each SNP column from each multiple nucleotide alignment was analyzed for hqSNPs, defined as those containing no gaps or ambiguous basecalls, and having an adjusted quality score >90 (of a maximum score of 93). A total of 4,376 hqSNPs were identified from 632 orthologous loci and extracted from the alignments to prepare a compressed
pseudoalignment composed of hqSNPs (online Technical Appendix 1, www.cdc.gov/eid-static/spreadsheets/11-0794- Techapp1.xls). This pseudoalignment was used to build a maximum-likelihood phylogenetic tree by using PhyML 3.0 (17). Branch confidences were estimated by using the approximate likelihood-ratio test (19).

§This isolate does not contain ctxB.
indistinguishable SfiI and NorI PFGE patterns designated PulseNet USA patterns KZGS12.0088 and KZGN11.0092, respectively (Table 1). Also sequenced were a hemolytic variant and a nonhemolytic variant that harbored a minor variation of the main Haiti outbreak PFGE pattern and were derived from an isolate from 1 patient in Haiti (Table 1). Twelve contemporary *V. cholerae* isolates from global sources with matched PFGE fingerprints were also sequenced. Infections for these 12 contemporary isolates originated (by documented patient travel) from regions of Pakistan, India, or Nepal. Two additional isolates were from patients in outbreaks in Cameroon and South Africa likely connected to the cholera outbreak in Zimbabwe in 2009 (21). Although all sequenced clinical isolates were serogroup O1, Inaba and Ogawa serotypes were observed among PFGE pattern-matched isolates (Table 1). All strains were biotype El Tor and all produced cholera toxin.

**Phylogenetics of Strains**

Haiti outbreak isolates and 12 global PFGE pattern-matched *V. cholerae* isolates belong to phylogroup 1 of the seventh pandemic clade. The phylogenetic tree based on whole-genome sequencing showed clustering of the 9 Hispaniola isolates (8 from Haiti and 1 related isolate from the Dominican Republic) with 12 other PFGE pattern-matched isolates. All 21 isolates were in 1 cluster relative to non-PFGE–pattern-matched outliers (Figure 1). When compared with historical reference genomes, the closest ancestors for Haiti genome sequences (2010–2011; derived herein) were isolates CIRS101 from Dhaka, Bangladesh (2002) and MJ-1236 from Matlab, Bangladesh (1994). These data confirm the genetic relatedness also inferred by PFGE subtyping and further support inclusion of the Haiti outbreak isolates in phylogroup 1 of the seventh pandemic clade (Figure 1). The whole-genome sequencing dataset showed that additional underlying genetic diversity was present across PFGE pattern-matched isolates (including 9 isolated from Hispaniola) not observed by PFGE subtyping.

**Common Mobile Elements and Genes of Haiti Outbreak Strain and PFGE Pattern-matched Isolates**

*V. cholerae* macrodiversity is commonly attributed to presence or absence of mobile genetic elements (22). The contiguous genome derived for Haiti isolate 2010EL-1786 was used as the outbreak type strain and harbored 2 circular chromosomes of 3.03 Mbp (chromosome I) and 1.05 Mbp (chromosome II), which encoded 2,920 and 1,051 predicted coding sequences, respectively. Pairwise comparisons of all coding sequences from each study genome with all coding sequences from reference isolate 2010EL-1786 (all vs. all comparison) showed congruent gene content and low overall diversity on larger chromosome I (Figure 2). One noteworthy exception was the absence of *Vibrio* pathogenicity island 1 in the 2005 isolate 3582–05 from Pakistan. This island contains essential cholera virulence factors, including the tcp gene cluster, which encodes toxin-
coregulated pilus involved in \textit{V. cholerae} colonization of the human intestine and necessary for horizontal transfer of the cholera toxin bacteriophage. This finding was the only macroscopic difference observed between isolate 3582–05 and PFGE matches. All Haiti outbreak and PFGE pattern-matched isolates contain an integrated conjugative element belonging to the SXT/R391 family (SXT-ICE) that carries genes conferring antimicrobial drug resistance. No macroscopic differences were observed in SXT-ICE among Haiti outbreak and PFGE pattern-matched isolates (Figure 2; online Technical Appendix 2 Figure 1). Conversely, historical isolates (1970–2005) from Pakistan, Bangladesh, the US Gulf Coast, and South America, and recent clinical isolates (2009–2010) from cases linked to Pakistan or South Africa independently clustered away from Haiti outbreak isolates (online Technical Appendix 2 Figure 2). Clade analysis of outbreak isolates and highly related isolates 2009V-1085, 2009V-1096, and 2010EL-1749, identified 25 hqSNPs in 24 conserved loci that distinguish members of this clade (online Technical Appendix 2 Figure 3; online Appendix Table, wwwnc.cdc.gov/EID/article/17/11/11-0794-TA1.htm). Resulting distances suggest that the outbreak isolates have a closer genetic relationship with 2009V-1085 and 2009V-1096 from India (7–10 hqSNPs) than with 2010EL-1749 from Cameroon (10–13 hqSNPs).

\section*{Comparison of Haiti Outbreak Genomes}

Across the 18 described hypervariable \textit{V. cholerae} mobile genetic elements sequences (representing >300 kb
of the total genome), no macroscopic differences were observed among the 9 Hispaniola isolate sequences (Figure 2; online Technical Appendix 2 Figure 1), and as stated, only 2 hqSNPs were identified in the core genome. Pairwise alignment of the complete genome of study reference 2010EL-1786 with available genome data for 2 sequenced Haiti 2010 outbreak isolates, designated H1 and H2 (9), showed only 3 polymorphisms across the entire genome. However, because the available H1 and H2 consensus sequences contain ambiguous basecalls, these nucleotides were excluded from our comparative analyses. Nonetheless, these data confirm the clonal nature of the Haiti outbreak strain.

**Structural and Allelic Profiles of Isolates Carrying a Hybrid Cholera Toxin Prophage**

Structure and allelic profiles of the CTXφ prophage have been used for *V. cholerae* lineage analysis (23). Chromosome I of Haiti isolate 2010EL-1786 harbors 1 hybrid CTXφ characterized by a 1-nt variant of the classical ctxB allele (ctxB-7) and El Tor rstR flanked by a toxin-linked cryptic element and El Tor–type RS1 element with an intact rstC locus (Figure 3). The SNP at ctxB codon19 results in replacement of the classical cholera toxin B histidine residue with asparagine, and this ctxB-7 allele was observed among all Hispaniola isolates (Table 1). Five of the 12 PFGE pattern-matched isolates from other locations (2008–2010) also shared this variant ctxB allele. The remaining 7 PFGE pattern-matched isolates encoded classical ctxB alleles.

**Discussion**

Public health investigators use PFGE, the current standard technique for subtyping most bacterial enteric pathogens, to link patients infected with a particular pathogen to a specific infection source(s) by fingerprint matching to pathogens isolated from environmental samples. Whole-genome sequencing has recently emerged as an enhanced laboratory tool for high-resolution analysis of microbial diversity and has been successfully used to investigate bacterial disease outbreaks (24–26). Because whole-genome sequencing can provide pathogen genetic fingerprints at single-nucleotide resolution, it should revolutionize the diagnosis, surveillance, and control of microbial diseases.

For molecular epidemiologic investigations using whole-genome sequencing, an expansive number of isolates from an outbreak would ideally be selected to ensure broad coverage for possible genotype variants within that population that might otherwise be masked with lower-resolution typing methods. In addition, outlier isolates from different locations that are indistinguishable or related by several diverse subtyping methods should also be subjected to whole-genome sequencing to contextualize the diversity seen within the outbreak population and to find other clonal relationships. In this study, a temporal and
A geographic distribution of outbreak isolates was selected to confirm clonality of the outbreak strain and to gain insight into the microevolution of *V. cholerae* during an outbreak. Additionally, minor PFGE and nonhemolytic variants observed among outbreak isolates were also sequenced to confirm their clonal relationships with isolates exhibiting the main outbreak pattern and phenotype.

The PulseNet USA database substantially contributed to this work by identifying genetically related (using PFGE typing) and epidemiologically relevant isolates for whole-genome sequencing analyses. Notably, one 2008 isolate from a traveler from the United States to Nepal was identified and included in this study, although we acknowledge that the evolutionary relationship of the Haiti strain to strain(s) circulating in Nepal during 2010 may not be ideally represented by this 2008 isolate. Microbial evolution will have occurred during 2008–2010, and global travel may have introduced additional strains into Nepal in the interim, such that the 2008 isolate from Nepal may differ substantially from a strain circulating in Nepal in 2010, the suggested progenitor of the outbreak strain. Unfortunately, 2010 isolates from Nepal were not available for analysis.

Also identified in the PulseNet USA database was 1 PFGE pattern-matched isolate from western Africa. The close genetic relationship of this isolate from Cameroon to the Haiti strain suggests that a potential link between western Africa and the Haiti outbreak cannot be ignored. Further studies on additional isolates from western Africa are required to confirm or refute this possibility. Similarity of whole-genome sequences for Haiti isolates, PFGE pattern-matched isolates, and other seventh pandemic strains confirmed the clonal nature of the 2010–2011 cholera outbreak strain and the close genetic relationships for the studied strains initially suggested by PFGE subtyping (Figure 1). Previous *V. cholerae* studies have reported that seventh pandemic strains are clonal, sharing near identical gene content on a highly related genome backbone but containing variable mobile genetic elements or gene cassettes (27). Despite dynamic horizontal gene transfer (22), we identified only a few nucleotide differences among mobile sequences of the 9 sequenced 2010–2011 outbreak-related Hispaniola isolates and the 12 recent PFGE-pattern-matched clinical isolates (Figure 2).

Extensive recombination in *V. cholerae* genomes may confound evolutionary relationship analyses as strains and lineages undergo reassortment (1). However, base substitutions acquired horizontally as recombination segments generally occur with localized density (28). Although we cannot guarantee that recombinant segments were absent from the core genome phylogeny (online Technical Appendix 2 Figure 2), the even spatial and genome-wide distribution of core genome hqSNPs suggests that they were vertically inherited. While we cannot guarantee that recombinant segments were absent from the core genome phylogeny (online Technical Appendix 2 Figure 2), the even spatial and genome-wide distribution of core genome hqSNPs suggests that they were vertically inherited. We have derived a useful phylogenetic approximation of isolate relatedness on the basis of hqSNPs, which supports shared ancestry for the Haiti outbreak isolates and 12 recent clinical isolates sharing PFGE patterns (online Technical Appendix 2 Figure 2). Sequenced isolates from India and Cameroon (2009–2010) were shown to be the closest genetic relatives among the non-Hispaniola isolates (isolated in 1991–2010; this study) and 4 other available reference *V. cholerae* genomes (isolated in 1937–2002). The ctxB allele variant (ctxB-7) of the Haiti strain (and its genetic relatives) was first observed among isolates from a cholera outbreak in Orissa, India, in 2007 (29), but the ctxB-7 allele has since also been observed in isolates from southern Asia and more recently from western Africa (8,30).

The genetic makeup of the Haiti outbreak strain will likely have substantial public health implications for Haiti and other susceptible locations. Our reasoning is that the atypical O1 El Tor *V. cholerae* strains (CIRS101 and CIRS101-like variants) have already emerged as the predominant clone causing cholera in Asia and Africa and have displaced prototypical O1 El Tor strains (3,4,29). Unfortunately, atypical O1 El Tor *V. cholerae* strains appear to have retained the relative environmental fitness of their prototypical O1 El Tor ancestors while acquiring enhanced virulence traits, such as classical or hybrid CTX prophage and SXT-ICE (4). Thus, with higher relative fitness and virulent and antimicrobial drug–resistant phenotypes, the Haiti outbreak strain harbors infectivity and ecologic persistence advantages over other seventh pandemic strains. Consequently, the Haiti outbreak strain
(or its genetic ancestor) may easily replace current El Tor *V. cholerae* strains circulating in the Western Hemisphere to become endemic (like other atypical El Tor strains) and will likely cause future outbreaks. Such dire predictions warrant enhanced epidemiologic surveillance and renewed priorities aimed at cholera prevention.

Absence of cholera in Haiti over the past century; the clonal nature of the outbreak strain; and a massive influx of international travelers, aid workers, and supplies after the 2010 earthquake suggest an outside infection source for the 2010–2011 outbreak. Our core genome phylogeny (online Technical Appendix 2 Figure 2) suggests that the Haiti outbreak strain most likely derived from an ancestor related to isolates from within or near the Indian subcontinent. However, concurrent identification of a 2010 isolate from Cameroon as a close genetic relative of the Haiti outbreak strain illustrates that whole-genome sequencing on such a relatively small number (n = 27) of *V. cholerae* isolates is insufficient to exclude other plausible ancestral geographic locations.

Our study results are consistent with recent findings of Chin et al. (9), who concluded that two 2010 Haiti outbreak isolates shared ancestry with variant O1 El Tor strains isolated in Bangladesh in 2002 and 2008 and a more distant relationship with an isolate from an outbreak in Latin American in 1991. The vertical inheritance pattern of hqSNPs in our study provide unequivocal genetic evidence for introduction of the outbreak strain into Haiti from an external source as opposed to local aquatic emergence. However, the specific geographic source and mode of entry of the outbreak strain into Haiti cannot be proven by microbiological investigations. Only large-scale epidemiologic studies and microbiological data can provide conclusive evidence of how cholera was introduced into Haiti. This whole-genome sequencing study provides expanded evidence that variant O1 El Tor *V. cholerae* appeared in Haiti by importation and has generated a whole-genome sequencing dataset for future study.

This study was supported in part by Transformational Medical Technologies Program Contract B1042551 from the Department of Defense Chemical and Biological Defense Program through the Defense Threat Reduction Agency.
