Diseases, Centers for Disease Control and Prevention, US Public Health Service, Department of
Health and Human Services, Fort Collins, Colorado

Abstract

IMPORTANCE—Since its introduction in North America in 1999, West Nile virus has produced
the 3 largest arboviral neuroinvasive disease outbreaks ever recorded in the United States.

OBJECTIVE—To review the ecology, virology, epidemiology, clinical characteristics, diagnosis,
prevention, and control of West Nile virus, with an emphasis on North America.

EVIDENCE REVIEW—PubMed electronic database was searched through February 5, 2013.
United States national surveillance data were gathered from the Centers for Disease Control and
Prevention.

FINDINGS—West Nile virus is now endemic throughout the contiguous United States, with 16
196 human neuroinvasive disease cases and 1549 deaths reported since 1999. More than 780 000
illnesses have likely occurred. To date, incidence is highest in the Midwest from mid-July to early
September. West Nile fever develops in approximately 25% of those infected, varies greatly in
clinical severity, and symptoms may be prolonged. Neuroinvasive disease (meningitis,
encephalitis, acute flaccid paralysis) develops in less than 1% but carries a fatality rate of
approximately 10%. Encephalitis has a highly variable clinical course but often is associated with
considerable long-term morbidity. Approximately two-thirds of those with paralysis remain with
significant weakness in affected limbs. Diagnosis usually rests on detection of IgM antibody in
serum or cerebrospinal fluid. Treatment is supportive; no licensed human vaccine exists.

Prevention uses an integrated pest management approach, which focuses on surveillance,
elimination of mosquito breeding sites, and larval and adult mosquito management using
pesticides to keep mosquito populations low. During outbreaks or impending outbreaks, emphasis
shifts to aggressive adult mosquito control to reduce the abundance of infected, biting mosquitoes.

Author Contributions: Dr Petersen had full access to all of the data in the study and takes responsibility for the integrity of the data
and the accuracy of the data analysis.

Study concept and design: All authors.
Acquisition of data: All authors.
Analysis and interpretation of data: Nasci, Petersen.
Drafting of the manuscript: All authors.
Critical revision of the manuscript for important intellectual content: All authors.
Administrative, technical, or material support: Brault, Petersen.
Study supervision: Petersen.

Conflict of Interest Disclosures: All authors have completed and submitted the ICMJE Form for Disclosure of Potential Conflicts of
Interest and none were reported.
Pesticide exposure and adverse human health events following adult mosquito control operations for West Nile virus appear negligible.

**CONCLUSIONS AND RELEVANCE**—In North America, West Nile virus has and will remain a formidable clinical and public health problem for years to come.

West Nile virus has become endemic in all 48 contiguous United States as well as all Canadian provinces since its discovery in North America in New York City in 1999. It has produced the 3 largest arboviral neuroinvasive disease (encephalitis, meningitis, or acute flaccid paralysis) outbreaks ever recorded in the United States, with nearly 3000 cases of neuroinvasive disease recorded each year in 2002, 2003, and 2012.

**Evidence Review**

This review is intended to provide a general overview of West Nile virus to the practicing physician or public health practitioner. Relevant background information was obtained by searching the PubMed electronic database through February 5, 2013, using the search term *West Nile virus*. Surveillance data from patients with disease onset from 1999 through 2012 and reported by May 15, 2013, were gathered from the national ArboNET surveillance system conducted by the Centers for Disease Control and Prevention.

**Ecology**

West Nile virus is maintained in a bird-mosquito-bird transmission cycle. Although West Nile virus has been detected in 65 different mosquito species and 326 bird species in the United States, only a few *Culex* mosquito species drive transmission of the virus in nature and subsequent spread to humans: *Culex pipiens* (northern house mosquito) in the northern half of the United States, the closely related species *Cx quinquefasciatus* (southern house mosquito) in the southern states, and *Cx tarsalis* in many areas of the plains and western states that overlap with the distribution of *Cx pipiens* and *Cx quinquefasciatus*. Numerous passerine birds (perching birds of the order Passeriformes) develop sufficient serum viremia to efficiently infect mosquitoes feeding upon them and thus are competent amplifier hosts. A relatively small subset of the bird community may significantly influence transmission dynamics and certain passerine species such as the American robin (*Turdus migratorius*) are important amplifiers despite their low abundance relative to other West Nile virus–susceptible birds. Humans are unlikely to infect mosquitoes because they only develop a low-level serum viremia and thus are considered dead-end hosts.

When conditions favor substantial viral amplification within the passerine-*Culex* transmission cycle, increasing numbers of infected mosquitoes present a human infection risk by mid to late summer. The complex and interrelated factors that promote viral amplification and hence human outbreaks are not well quantified and vary among the diverse ecological conditions present in North America. Warmer temperatures correlate with increased human incidence at national or regional (multistate) scales. Increased ambient temperature shortens the incubation time from infection to infectiousness in mosquitoes and increases viral transmission efficiency to birds, both critical factors for arboviral amplification. At smaller scales, urban and agricultural land covers, rural irrigated
landscapes, increased temperature, increased rainfall, decreased rainfall, and several socioeconomic factors such as housing age and community drainage patterns, per capita income, and density of poorly maintained swimming pools relate to higher incidence in some locations. Nevertheless, considerable challenges remain in predicting how, when, and where these factors will combine to produce the focal, intense outbreaks that now characterize West Nile virus ecology in the United States.

Virology and Pathogenesis

West Nile virus is 1 of more than 70 viruses of the family Flaviviridae of the genus Flavivirus. Serologically, West Nile virus is a member of the Japanese encephalitis serocomplex, which includes Japanese encephalitis virus and an endemic North American flavivirus, St Louis encephalitis virus. West Nile viruses can be designated into at least 5 phylogenetic lineages. Only lineage 1 and 2 West Nile viruses have been associated with significant outbreaks in humans.

Lineage 1 can be further subdivided into 3 sublineages: isolates from the western hemisphere, Africa, the Middle East, and Europe constitute lineage 1a; Kunjin virus from Australasia represents lineage 1b; and lineage 1c consists of viruses from India. The initial North American isolates (East Coast genotype) identified in 1999 in New York City have been most closely related to a lineage 1a West Nile virus isolated from Israel in 1998. Since approximately 2002, the East Coast genotype has largely been displaced by a new genotype (WN02 genotype) encompassing several conserved amino acid substitutions that may have increased the efficiency and rapidity of viral transmission in North American mosquito vectors.

Mosquito salivary components introduced at the site of infection in vertebrates modulate initial infection of target cells such as keratinocytes and skin-resident dendritic cells through several mechanisms including focalized suppression of immune effector cell trafficking to the site of inoculation. Infected dendritic cells or keratinocytes migrate to draining lymph nodes from which a serum viremia is generated that then relays infection to visceral organs and potentially to the central nervous system (Figure 1).

West Nile virus is capable of replicating and eliciting pathology in the brain (ie, neurovirulence); however, a critical prerequisite to generating neuroinvasive disease in humans is the virus’ capacity to gain access to the central nervous system (ie, neuroinvasiveness). Postulated West Nile virus neuroinvasive mechanisms include (1) direct viral crossing of the blood-brain barrier due to cytokine-mediated increased vascular permeability; (2) passage through the endothelium of the blood-brain barrier; (3) a Trojan horse mechanism in which infected tissue macrophages are trafficked across the blood-brain barrier; and (4) retrograde axonal transport of the virus to the central nervous system via infection of olfactory or peripheral neurons (Figure 2). Regardless of how the virus enters the central nervous system, murine models of infection have shown persistent viral replication in various tissues, including the central nervous system, suggesting a potential etiology for long-term neurological sequelae observed in patients with neuroinvasive disease.
Distribution and Human Disease Incidence

West Nile virus has an extensive distribution throughout Africa, the Middle East, southern Europe, western Russia, south western Asia, and Australia (Kunjin subtype of West Nile virus), which derives from its ability to infect numerous mosquito and bird species. Until the early 1990s, human outbreaks, mainly associated with mild febrile illnesses, were reported infrequently from Israel and Africa. Since then, new viral strains with likely African origin have increased human disease incidence in parts of Russia and southern and eastern Europe, with large outbreaks of increased clinical severity occurring in Romania, Russia, Israel, and Greece.\textsuperscript{15,22} In the western hemisphere, West Nile virus spread from its 1999 discovery location in New York City\textsuperscript{1} to the Pacific Coast by 2003\textsuperscript{23,24} and Argentina by 2005.\textsuperscript{24} Although West Nile virus now circulates in many countries in the western hemisphere, for unknown reasons only the United States and Canada have experienced substantial human disease incidence.\textsuperscript{24}

Most patients with West Nile virus–related illnesses are unrecognized clinically. A follow-up study of asymptomatic, viremic blood donors who subsequently developed West Nile fever showed that 38% sought medical care and 2% were hospitalized for symptoms attributable to the infection; however, only 5% of those seeking medical care were correctly diagnosed.\textsuperscript{4} Thus, incidence trends are best monitored by the incidence of neuroinvasive disease because reporting of these cases is comparatively complete. Nevertheless, even during a well-publicized outbreak, only 40% of patients with clinically compatible meningitis or encephalitis were tested for West Nile virus.\textsuperscript{25}

A total of 16 196 patients with West Nile virus neuroinvasive disease with onsets from 1999 through 2012 and 1549 deaths have been recorded in the United States. Although the number of patients with neuroinvasive disease fluctuates annually, some regions experience persistently higher incidence (Figure 3). Ninety-four percent of patients with West Nile virus infection have symptom onsets in July through September (Figure 4).\textsuperscript{23} Extrapolations from neuroinvasive disease case reporting in the United States suggest that through 2010 approximately 3 million persons were infected, of whom 780 000 developed West Nile fever.\textsuperscript{26} In Canada, West Nile virus was first detected in southern Ontario in 2001 and by 2009 the virus’ distribution had extended westward to British Columbia. Through October 2012, 975 patients with neuroinvasive disease have been reported in Canada.

Transmission to Humans

Mosquito bites account for nearly all human infections. West Nile virus can also be transmitted via transfused platelets, red blood cells, and fresh frozen plasma\textsuperscript{5} as well as through heart, liver, lung, and kidney transplants.\textsuperscript{27} Transmission via organ transplant has occurred from donors without detectable viremia, suggesting viral sequestration in organs shortly after viremia has cleared.

One possible transplacental transmission following a second trimester infection resulted in an infant with chorioretinitis, lissencephaly, and cerebral white matter loss. Fortunately, fetal abnormalities due to intrauterine infection are uncommon: none of 72 live infants born to 71 women infected during pregnancy had malformations linked to West Nile viral infection or

\textsuperscript{JAMA. Author manuscript; available in PMC 2015 September 09.}
had conclusive laboratory evidence of congenital infection. Nevertheless, 3 neonates born to women infected within 3 weeks’ prepartum developed symptomatic West Nile virus disease at or shortly after birth, indicating the possibility of intrauterine infection or infection at the time of delivery. Other rare or suspected modes of transmission include breast milk transmission, percutaneous or conjunctival exposure to laboratory workers, and by unknown means in patients undergoing dialysis and workers at a turkey breeder farm.

**Infection and Illness**

It is not known what proportion of persons develop West Nile virus infection following an infected mosquito bite. Persons with a genetic defect in the *OAS1* gene (HGNC 8086), which modulates host response to exogenous viral RNA, are more likely to have anti–West Nile virus antibodies than persons without this defect, suggesting that immune response function determines who becomes infected after exposure. Among persons who become infected, approximately 25% develop West Nile fever and 1 in 150 to 250 develops neuroinvasive disease. Risk factors for developing West Nile fever following infection are poorly defined. A follow-up study of asymptomatic, viremic blood donors indicated that increasing viral load and female sex, but not age, subsequently increased the risk of developing West Nile fever. A smaller follow-up study of viremic blood donors suggested that younger persons were more likely to develop West Nile fever. In contrast, advancing age profoundly increases the risk of neuroinvasive disease, particularly encephalitis. The risk may approach 1 in 50 among persons aged at least 65 years, a rate 16 times higher than that for persons aged 16 to 24 years. In addition, a history of cancer, diabetes, hypertension, alcohol abuse, renal disease, and chemokine receptor *CCR5* deficiency as well as male sex may increase the risk of neuroinvasive disease. Persons infected through transplant of infected organs are at extreme risk of developing neuroinvasive disease; however, conflicting data exist regarding risk among previous organ recipients infected via mosquito bite.

**Clinical Illness**

The incubation period for clinical illness generally ranges from 2 to 14 days, but prolonged incubation periods of up to 21 days have been observed among immunocompromised patients. West Nile fever can range from a mild infirmity lasting a few days to a debilitating illness lasting weeks to months. Symptoms are of sudden onset and often include headache, malaise, fever, myalgia, chills, vomiting, rash, fatigue, and eye pain (Box 1). Fever may be low-grade or absent. A rash, which often appears around the time of defervescence, tends to be morbilliform, maculopapular, and nonpruritic, and predominates over the torso and extremities, sparing the palms and soles.

West Nile meningitis, similar to that of other viral meningitides, is characterized by abrupt onset of fever and headache along with meningeal signs and photophobia. Headache may be severe, and associated gastrointestinal disturbance may result in dehydration (Box 2). West Nile encephalitis ranges in severity from a mild, self-limited confusional state to severe encephalopathy, coma, and death. Extrapyramidal disorders are frequently observed, and features of Parkinsonism may be seen. Patients with West Nile encephalitis frequently develop a coarse tremor, particularly in the upper extremities.
tremor tends to be postural and may have a kinetic component. Myoclonus, predominantly of the upper extremities and facial muscles, may occur and may be present during sleep. Cerebellar ataxia, increased intracranial pressure, cerebral edema, and seizures have been described but are uncommon.

West Nile virus–associated paralysis most commonly results from destruction of the anterior horn cells of the spinal cord. Asymmetric weakness usually develops rapidly within the first 48 hours after symptom onset, although patients with extensive spinal cord involvement develop a more symmetric dense quadriplegia. Central facial weakness, frequently bilateral, may occur. Respiratory failure requiring emergent intubation may result from diaphragmatic and intercostal muscle paralysis. Sensory loss or numbness is generally absent though some patients experience intense pain in the affected limbs just before or during the onset of weakness. Other causes of weakness associated with West Nile virus infection include Guillain-Barre syndrome and other demyelinating neuropathies, motor axonopathy, axonal polyneuropathy, involvement of ventral spinal roots, myasthenia gravis, and brachial plexopathies.

Other manifestations described in the setting of West Nile virus infection include multifocal choroiditis, vitritis, myocarditis, pancreatitis, fulminating hepatitis, rhabdomyolysis, stiff-person syndrome, and autonomic instability.

**Clinical Outcome**

Full recovery is the norm for patients with uncomplicated West Nile fever or meningitis; however, initial symptoms, particularly extreme fatigue, may be prolonged. West Nile fever may precipitate death among persons of advanced age or with underlying medical conditions. Outcomes of West Nile encephalitis are variable and may not correlate with severity of initial illness. Patients hospitalized with West Nile virus encephalitis frequently require assistance with daily activities following acute care discharge and often report substantial functional and cognitive difficulties for up to a year following acute infection. Only 37% of patients in the 1999 New York City outbreak achieved full recovery at 1 year and 53% of patients in Idaho reported symptoms lasting at least 6 months, mostly fatigue, muscle aches, and difficulties with memory and concentration.

Although some studies have documented neurocognitive deficits on standardized testing for as long as 1 year after acute illness, others have failed to confirm this finding. Nevertheless, self-reported fatigue, somatic, and cognitive complaints lasting months or years are common among persons recovering from West Nile virus illness. Neuropsychiatric symptoms, including depression, anxiety, and apathy, have been reported. One investigator reported West Nile virus RNA in urine in patients up to 7 years following acute illness and implied an association with chronic renal failure; however, 2 other studies failed to substantiate this finding.

Among patients with acute flaccid paralysis due to poliomyelitis-like syndrome, roughly one-third recover strength to near baseline, one-third have some improvement, and one-third have little or no improvement. Little functional improvement has been documented 6 months after onset.
Case fatality rates among patients with neuroinvasive disease generally approximate 10%. Advanced age is the most important risk factor for death, ranging from 0.8% among those aged less than 40 years to 17% among those aged at least 70 years. Encephalitis with severe muscle weakness, changes in the level of consciousness, diabetes, cardiovascular disease, hepatitis C virus infection, and immunosuppression are possible risk factors for death. Patients discharged from the hospital following acute West Nile virus illness experience a 2- to 3-fold increase in long-term, all-cause mortality compared with age-adjusted population norms, although not all of this increase may be attributable to West Nile virus.

**Diagnosis**

Detection of IgM antibody in serum or cerebrospinal fluid (CSF) using the IgM antibody-capture enzyme-linked immunosorbent assay (MAC-ELISA) forms the cornerstone of West Nile virus diagnosis in most clinical settings. Because IgM antibody does not cross the blood-brain barrier, its presence in CSF indicates CNS infection. At least 90% of patients with encephalitis or meningitis have demonstrable IgM antibodies in CSF within 8 days of symptom onset. The West Nile virus–specific IgM antibody may not be detected initially in serum or plasma; 1 study showed that only 58% of patients with West Nile fever had a positive MAC-ELISA result at clinical presentation. Nevertheless, MAC-ELISA testing of acute- and convalescent- phase sera will provide definitive diagnosis. Testing for IgG antibodies has no utility in the acute clinical diagnostic setting.

Recent vaccination with yellow fever or Japanese encephalitis vaccines or recent infection with a related flavivirus (eg, St Louis encephalitis or dengue) may produce a positive West Nile virus–IgM antibody test result. The plaque-reduction neutralization test can help distinguish serologic cross-reactions among the flaviviruses, but the test is only available in reference laboratories. In 1 study, 17% of patients had demonstrable West Nile virus–specific IgM antibodies a year after initial infection; thus, persistent IgM antibody from a previous infection may be unrelated to current illness.

Nucleic acid amplification testing has utility in certain clinical settings as an adjunct to MAC-ELISA. Among patients presenting with West Nile fever, 1 study showed that 45% of cases were identified with nucleic acid testing; 58% with serology, or 94% with a combined approach of these 2 methods. Nucleic acid amplification testing—may prove useful in immunocompromised patients when antibody development is delayed or absent and its use in blood donor screening in the United States and Canada has nearly eliminated the risk of West Nile virus transfusion transmission.

Total leukocyte counts in peripheral blood typically are normal or slightly elevated. Examination of CSF of patients with neuroinvasive disease shows normal glucose, elevated protein (generally <150 mg/dL) and moderate pleocytosis (generally <500 cells/µL) usually with a predominance of lymphocytes; however, neutrophils may predominate in early infection. Imaging studies are usually normal, but focal lesions in the pons, basil ganglia, thalamus, and anterior horns and enhancement of the leptomeninges, the periventricular
areas, or both are occasionally seen. These lesions may appear hyperintense on T2-weighted magnetic resonance and fluid-attenuated inversion recovery images.\(^6^8\)

**Treatment and Prevention**

Treatment of West Nile virus infection remains supportive. Several investigated therapeutic approaches include immune \(\gamma\)-globulin, West Nile virus–specific neutralizing monoclonal antibodies, corticosteroids, ribavirin, interferon \(\alpha\)-2b, and antisense oligomers.\(^6^9,^7^0\) No study has documented efficacy, in part due to difficulty in recruiting sufficient numbers of patients. Case reports or uncontrolled clinical series suggesting efficacy should be interpreted with extreme caution due to West Nile virus’s highly variable clinical course.

Novavaccine is licensed for humans. Despite 4 licensed equine vaccines and promising preliminary results from several phase 1 and 2 human vaccine candidates, phase 3 efficacy trials have not been attempted due the unknown market potential of a West Nile virus vaccine and logistical difficulties in conducting phase 3 clinical trials for this sporadic and widely dispersed disease.\(^6^9\) Preliminary analysis suggested that universal West Nile virus vaccine coverage would not be cost-effective;\(^7^1\) however, the cost-effectiveness of vaccination of specific target groups such as elderly individuals has not yet been established. Because humans are dead-end hosts, a human vaccination program would not influence viral amplification in nature.

West Nile virus prevention relies in part on methods to reduce the numbers of West Nile virus–infected mosquitoes. Community-based mosquito control programs using integrated pest management principles proactively identify the sources of vector mosquitoes and use several methods such as elimination of breeding sites, larviciding, and targeted adult mosquito control to prevent adult mosquito populations from achieving levels that increase human infection risk.

When increasing human case incidence or surveillance of vector mosquito populations indicates an impending human epidemic, the immediate goal is to reduce rapidly the number of infected adult mosquitoes by widespread ultra-low volume application of organophosphate or synthetic pyrethroid insecticides. Organophosphates irreversibly block the enzyme acetylcholinesterase; pyrethroids open sodium channels of neuronal membranes, paralyzing the mosquito, and are usually combined with piperonyl butoxide, preventing the mosquito’s microsomal oxidase enzymes from metabolizing pyrethroids.

Although the efficacy of these control measures is difficult to measure, strategically timed early-season control of adult mosquitoes in the Coachella Valley of California using ultra-low volume insecticide applications decreased subsequent West Nile virus transmission.\(^7^2\) In addition, aerial ultra-low volume insecticide application decreased infected mosquito abundance and reduced human-case incidence during a West Nile virus outbreak in the Sacramento area.\(^7^3\) Human health risks associated with ultra-low volume organophosphate or synthetic pyrethroid use appear negligible, largely because the timing of application and low volume of pesticide used result in minimal human exposure.\(^7^4,^7^5\)
Insect repellent use has been associated with reduced West Nile virus risk. Unfortunately, few people report regular repellent use even during well-publicized outbreaks. Commercially available insect repellents containing DEET, IR3535, oil of lemon eucalyptus, and picaridin are registered by the US Environmental Protection Agency on the basis of their excellent safety profiles and proven efficacy in reducing or preventing mosquito biting. Many other commercially available unregistered products, such as those containing citronella oil, cedar oil, geranium oil, peppermint oil, and soybean oil, have unproven efficacy.

Future Perspectives

The resurgence of West Nile virus in 2012 after several years of decreasing incidence in the United States suggests that West Nile virus will continue to produce unpredictable local and regional outbreaks. These outbreaks are associated with considerable long- and short-term morbidity from West Nile virus neuroinvasive disease and West Nile fever, respectively. Thus, sustainable, community-based surveillance and vector management programs are critical, particularly in metropolitan areas with a history of West Nile virus and large human populations at risk. Community response plans must include provisions for rapidly implementing large-scale adult mosquito control interventions when surveillance indicates such measures are necessary. Further evaluation of target populations and cost-efficacy of a vaccine will help determine the need for continued human vaccine development. Practical pathways and paradigms for testing and approval of vaccines and therapeutics adapted to the sporadic outbreak nature of West Nile virus are required. These measures will not only help address the risks associated with West Nile virus but will add to our preparedness for all domestic and exotic mosquito-borne pathogens.

REFERENCES

JAMA. Author manuscript; available in PMC 2015 September 09.

Box 1

Characteristics of West Nile Fever

Abrupt onset, usually July through September

Occurs in approximately 25% of those infected by mosquito bite

All ages affected, but no strong age predilection

Symptoms present in more than 50% of patients:

- Headache, generalized weakness, morbilliform or maculopapular rash (often at time of defervescence), fever (often low grade), myalgia

Less common symptoms:

- Joint pain, chills, painful eyes, vomiting or diarrhea, lymphadenopathy

Diagnosis most readily made by detection of West Nile virus–specific IgM antibody in serum, although a convalescent-phase sample may be required because the antibody often is not present at the time of clinical presentation

Treatment is supportive

Illness duration days to weeks, generally with complete recovery, although prolonged fatigue may occur
Box 2

Characteristics of West Nile Neuroinvasive Disease

Abrupt onset, usually July through September

Occurs in less than 1% of those infected via mosquito bite

All ages affected, although very strong predilection with advancing age

Clinical Syndromes

Meningitis characterized by clinical signs of meningeal inflammation, including nuchal rigidity, Kernig or Brudzinski sign, or photophobia or phonophobia

Encephalitis characterized by depressed or altered level of consciousness, lethargy or personality change lasting more than 24 hours

Acute flaccid paralysis characterized by acute onset of limb weakness with marked progression over 48 hours, which is usually asymmetric, are flaccid or hyporeflexic, and without sensory abnormalities. Four-fifths of persons with acute flaccid paralysis occur in conjunction with encephalitis or meningitis

May be commonly accompanied by other symptoms and signs:

Nausea and vomiting, myalgia, chills, rash (less commonly reported than patients with West Nile fever), arthralgia, ataxia, visual disturbance, tremors, myoclonus, bulbar dysfunction (dysarthria, dysphagia)

Diagnosis most readily made by detection of West Nile virus–specific IgM antibody in cerebrospinal fluid or serum; in immunocompromised patients, development of IgM antibody may be delayed or absent, and nucleic acid amplification tests may be required

Cerebrospinal fluid generally shows normal glucose, elevated protein, pleocytosis (>5 leukocytes/µL)

Treatment is supportive

Illness duration weeks to months; long-term functional and cognitive difficulties common in patients with encephalitis, paralysis, or both
Figure 1. Schematic of Pathogenesis of West Nile Virus Infection
Following the bite of an infected mosquito, infection begins in keratinocytes and immune cells in the epidermis and spreads to draining lymph nodes. Viremia originating in the lymph nodes disseminates infection to peripheral organs.
Figure 2. West Nile Virus Neuroinvasive Mechanisms

Potential mechanisms for neuroinvasion of West Nile virus include (1) direct infection of the vascular endothelium and subsequent entry to the central nervous system, (2) viral passage through the vascular endothelium due to disruption of the blood-brain barrier integrity by vasoactive cytokines, (3) a Trojan horse mechanism through which infected monocytes are trafficked into the central nervous system, or (4) retrograde axonal transport to the central nervous system following infection of peripheral neurons.
