## Current Trends

## Rubella and Congenital Rubella United States, 1980-1983

## RUBELLA

Although the incidence of reported rubella has fluctuated slightly over the past several years, a downward trend has been observed for most of the United States. A review of data for the period January 1, 1980, through September 24, 1983, indicates that if no sudden change in reporting patterns occurs, the final rubella incidence rate for 1983 should be at an all-time low.

In 1980, a total of 3,904 cases of rubella were reported to CDC; this represents an incidence of 1.7 cases per 100,000 population (Table 1). The 1981 incidence (0.9/100,000) was the lowest reported since rubella became a notifiable disease in 1966 (Figure 1); 2,077 cases were reported in 1981, a decline of $47 \%$ from the 1980 total. In 1982, 2,325 cases of rubella were reported in the United States (incidence 1.0/100,000) - a $12 \%$ increase over the

1981 total. The increased occurrence in 1982 reflected an increase in cases of rubella in California, primarily among adolescent and young-adult populations and particularly in hospitals and universities. California, which reported almost three times as many cases in 1982 ( 1,437 cases) as in 1981 (533), accounted for $62 \%$ of all cases nationwide. In the rest of the nation, the number of reported rubella cases was $42 \%$ lower in 1982 than in 1981. In 1980, only one state reported no cases of rubella. Five states and the District of Columbia reported no cases in 1981, and seven states reported none in 1982. The number of counties reporting rubella declined from 676 ( $21.5 \%$ of all counties) in 1980, to 366 (15.7\%) in 1981, to 494 (11.7\%) in 1982.

During the first 38 weeks of 1983 (ending September 24, 1983), 791 cases were reported, a $61 \%$ decrease from the number reported during the same period in 1982. Sixteen states and the District of Columbia have reported no cases thus far in 1983, twice as many reporting areas as were free of rubella during the same period in 1982. Sixty percent of cases reported thus far in 1983 are from four reporting areas (California, Florida, New York City, Texas). Although the California cases alone currently account for $28 \%$ of the 1983 cases, rubella activity in California is down by $83 \%$ compared with 1982 figures from the same period.

The age-specific incidence rate of rubella in children under 15 years of age decreased over the past 3 years. While children under 5 years of age still had the highest overall incidence rate in 1982 ( 2.7 reported rubella cases per 100,000 population), they accounted for a lower proportion of all cases in 1982 (20\%) than in 1981 (37\%). In contrast, the incidence rate for those 15 years of age and older, noted to have been lower in 1981 (0.4/100,000) than in 1980 (1.0/100,000), increased somewhat in 1982 ( $0.8 / 100,000$ ). Persons 15 years of age and older accounted for a much higher proportion of cases in 1982 (62\%) than in 1981 ( $37 \%$ ). Although between 1981 and 1982 the incidence rates increased for all age groups 15 years of age and older, the greatest increase occurred in the 25- to 29-year age group, which experienced almost a threefold increase in disease (Table 1). The increase in reported incidence rates for adolescents and young adults in 1982 over those reported in 1981 again reflects rubella activity in California; this state accounted for 74\% of all 1982 cases in persons 15 years of age and older. If California cases are excluded, the incidence rates for persons 15 years of age and older decreased by 17\% between 1981 and 1982. When rates for 1980 and 1982 are compared, age-specific incidence rates in 1982 were higher only for persons 25 years of age and older (a 50\% increase); 1982 rates were lower for 15- to 24-year-olds.

Rubella - Continued

## CONGENITAL RUBELLA SYNDROME

Detailed reports of cases of congenital rubella syndrome (CRS), including clinical signs and laboratory results, are voluntarily submitted by local and state health departments to two different morbidity systems: the National Morbidity Reporting System (the reporting system for the MMWR) and the National Congenital Rubella Syndrome Registry (NCRSR), maintained at the Division of Immunization at CDC. Cases reported to the MMWR are reported without clinical and epidemiologic data and are counted by year of report. In contrast, cases reported to the NCRSR are classified according to specific criteria and are reported by year of birth." Data for a given year are reported as provisional until at least 3 years have elapsed. According to the NCRSR, the incidence rates of confirmed and compatible CRS have declined substantially since 1979 (Figure 2). Fifty-five cases were reported in 1979, 14 were reported in 1980, and nine were reported in both 1981 and 1982. California reported seven of the nine cases in 1982 and is the only state that has reported cases in 1983 (three cases, all with estimated dates of conception in 1982). Almost all CRS cases continue to be reported within the first year of birth (1).
Reported by Surveillance and Investigations Section, Surveillance, Investigations, and Research Br, Div of Immunization, Center for Prevention Svcs, CDC.
Editorial Note: The goal of rubella vaccination programs is to prevent congenital rubella infection.t The vaccination strategy adopted by the United States in 1969, the year rubella vaccine was licensed, was aimed at controlling rubella in preschool and young school-aged children, the known reservoirs for rubella transmission. The intention was to thereby prevent exposure of susceptible, pregnant females to rubella virus (2). Accordingly, the primary target group for vaccine was children of both sexes. Secondary emphasis was placed on vaccinating susceptible adolescents and young adults, especially women. By 1977, vaccination of children 12 months of age and older had resulted in marked declines in reported rubella incidence in children and had interrupted the characteristic 6- to 9-year rubella epidemic cycle; however, this vaccination strategy had less effect on rubella incidence in persons 15 and over (i.e., childbearing age for women) (Table 2). Approximately 10\%-20\% of this latter population continued to be susceptible (3-5), a proportion similar to that of prevaccine years (6). Most importantly, reported endemic CRS continued at a low but constant level (7). When this problem was recognized, public health authorities targeted other groups for vaccination. Increased efforts were made to vaccinate junior and senior high school students and enforcerubella immunization requirements for school entry (8). Also, all susceptible military recruits began to receive rubella vaccine (9).

Published accounts of rubella outbreaks in hospitals have caused concern about the need to screen and/or vaccinate susceptible personnel $(10,11)$. A number of states have considered requiring proof of rubella immunity for college entrance (12). These factors, combined with the 1977 Childhood Immunization Initiative and the 1978 Measles Elimination Initiative (which encouraged use of combined measles and rubella vaccine), have led to decreases in reported rubella cases in all age groups.

[^0]The number of doses of rubella vaccine administered in the public sector to persons 15 years of age and older doubled between 1978 and 1981. By 1981, incidence rates for adolescents and young adults were lower than those for young children (Tables 1 and 2). Compared with rates for prevaccine years, by 1981 the overall reported incidence of rubella had declined by $96 \%$, with a $90 \%$ or larger decrease in cases in all age groups. Predictably, the number of reported CRS cases started to decline further (Figure 2).

Although the increase in reported rubella incidence in older individuals in 1982 was not reported nationwide, outbreaks in this population can still occur. Until the susceptibility rate of postpubertal women is effectively lowered, CRS will continue to occur, each case at an estimated lifetime expenditure of $\$ 221,600$ (13). While CRS will eventually be eliminated as currently young, vaccinated cohorts enter the childbearing years, the process is slow and costly in human life and health resources. Only nine CRS cases were reported in 1982; however, this figure represents only an estimated one-tenth of the total case count (14). The

FIGURE 2. Incidence rate of reported rubella cases and congenital rubella cases, United States, 1966-1982

*Includes proration of $\geqslant 15$-year-olds with unknown ages.
**Rate per 100,000 births of confirmed and compatible cases of congenital rubella syndrome (CRS), by year of birth. Reporting for recent years is provisional, as cases may not be diagnosed until later in childhood.

- Average annual U.S. estimate of rubella incidence in $\geqslant 15$-year-olds, based on data from Illinois, Massachusetts, and New York City for the 3-year periods, 1966-1968, 1969-1971, and 1972-1974. Age-specific data were not available for U.S. totals until 1975.

Rubella - Continued
only effective means to rapidly eliminate CRS is to intensify efforts to vaccinate susceptible, postpubertal individuals.

Immunizing this population, especially women of childbearing age, will require a multifaceted approach (15). Some recommended activities include: (1) making the general public and health-care providers more aware of the dangers of rubella infection; (2) ensuring that patients are vaccinated as part of routine medical and gynecologic care; (3) ensuring vaccination of all women visiting family planning clinics; (4) ensuring vaccination of unimmunized women immediately after they undergo childbirth, miscarriage, or abortion; (5) vaccinating susceptible women identified by premarital serology; (6) vaccinating hospitalized women before discharge; (7) requiring proof of immunity (a positive serologic test or documented rubella vaccination) for college entry; and (8) requiring proof of immunity for all hospital personnel who might be exposed to patients with rubella or who might have contact with pregnant patients. These strategies, along with continued immunization of all school-aged children, will hasten the elimination of rubella and CRS in the United States.

[^2]Streptococcal Infections - Continued
14 of the patients has been identified as a group C $\beta$-hemolytic streptococcus-species Streptococcus zooepidemicus; the species of the remaining two isolates have not yet been determined. Ages of the 16 patients ranged from 19 to 89 years (median 74); 10 were male. All patients were Hispanic.

In general, the clinical syndrome was characterized by fever, chills, and vague constitutional symptoms. However, five patients had localized signs of infection, including pneumonia, endocarditis and meningitis, pericarditis, and abdominal pain that led to a cholecystectomy for one patient and an appendectomy for another patient. Two patients with multiple underlying medical problems died.

A case-control study was undertaken to identify possible risk factors for contracting group C streptococcal infections. Patients and controls were matched for age, sex, ethnicity, and neighborhood of residence. Some of the possible risk factors investigated included underlying illnesses, immunosuppressive medications, animal exposure, group activities, restaurants visited, and food items consumed. Initial questionnaires identified eating "queso blanco," a homemade white cheese, as the only risk factor associated with illness (10 of 15 case patients versus 7 of 45 controls, $p<0.001$ ). During subsequent discussions, four of the five patients who did not report in the case-control study that they had eaten the homemade cheese later remembered that they had consumed the cheese before the onset of illness. Thus, only one patient did not recall having eaten the cheese before becoming ill.

The sole source of the homemade cheese consumed by the patients was an ungraded, small (seven cows), family dairy farm in northern New Mexico. At the farm, the cheese was made from raw cows' milk and was not subsequently aged. It was distributed to several stores in northern New Mexico within 24-48 hours after preparation in the family kitchen. Milk samples from the cows and cheese samples from the stores were obtained for microbiologic analysis. Group C $\beta$-hemolytic streptococci, species $S$. zooepidemicus, have been isolated from multiple samples of each.

Public health control measures included closing the dairy operation, removing the cheese from the stores, and advising the public to dispose of any "queso blanco" purchased from the stores that sold the implicated product. No new cases of group $C$ streptococcal infections have been identified since these interventions were implemented.
Reported by FH Espinosa, MD, WM Ryan, MD, PL Vigil, MD, Espanola Hospital, Espanola, DF Gregory, MD, RB Hilley, MD, DA Romig, MD, RB Stamm, MD, ED Suhre, MD, PS Taulbee, MD, LH Zucal, MD, St. Vincent Hospital, Santa Fe, RW Honsinger Jr, MD, PJ Lindberg, MD, Los Alamos Medical Center, Los Alamos, M Barcheck, JA Miller, R Mitzelfelt, JM Montes, LJ Nims, OJ Rollag, DVM, State Public Health Veterinarian, N Weber, JM Mann, MD, State Epidemiologist, New Mexico Health \& Environment Dept; Div of Bacterial Diseases, Center for Infectious Diseases, CDC.
Editorial Note: Group C streptococci are a common cause of infection in several animal species but are generally considered to be a rare cause of infection in humans (1). Of the four species of group C streptococci, S. equisimilis has been reported to cause most human illnesses, including bacteremia, endocarditis, meningitis, pneumonia, epiglottitis, puerperal sepsis, and wound infections. However, S. zooepidemicus has been associated with two outbreaks of pharyngitis and nephritis in Europe $(2,3)$. While pharyngitis was not a part of the clinical syndrome in the outbreak reported here, it is too early to tell if poststreptococcal glomerulonephritis will develop.

In both of the European outbreaks, unpasteurized milk was suspected as the source of infection. The outbreak reported here is the first epidemic of group $C$ streptococcal infections in the United States and is the first such reported outbreak in which the vehicle-cheese made from unpasteurized cows' milk - has been epidemiologically implicated. Although $S$. zooepidemicus and S. equisimilis are rarely reported causes of mastitis in cows, the cause of
this outbreak was contaminated milk from cows with mammary infections due to $S$. zooepidemicus.

Because few laboratories routinely determine the species of group $C$ streptococci, the number of human infections due to $S$. zooepidemicus is not known. Furthermore, group $C$ streptococci may be mistakenly identified as group A strains if only bacitracin susceptibility testing is done to differentiate group A streptococci from other $\beta$-hemolytic streptococci. It is impractical for clinical laboratories to routinely determine the serogroup and species of all $\beta$ hemolytic streptococci isolated from all sites. However, serogroups of $\beta$-hemolytic streptococci and species of group $C$ strains isolated from blood and other normally sterile sites should be identified if further information is to be gained about the epidemiology of such infections.

## Interstate Outbreak of Drug-Resistant Tuberculosis Involving Children - California, Montana, Nevada, Utah

As of September 30, six cases of tuberculosis (TB) and an additional 53 persons with significant reactions* to the tuberculin skin test have been identified in an outbreak of TB in California, Montana, Nevada, and Utah.

In November 1982, a 19-month-old child in Missoula, Montana, was diagnosed as having TB based on hilar adenopathy on chest radiograph and a significant tuberculin skin test reaction. The child's only known contact with a person having a history of TB was with a 30-year-old woman who was a close family friend and the child's babysitter.

The woman submitted to diagnostic evaluation in February 1983. Her chest film showed a $5-\mathrm{cm}$ right apical cavity. A sputum culture yielded Mycobacterium tuberculosis; 50\% of the organisms were resistant to isoniazid (INH). Subsequently, this patient's husband was found to have a large lesion in the right pleura and was sputum-culture positive for $M$. tuberculosis sensitive to INH. M. tuberculosis isolates from both the woman and her husband were identified as phage type $2(7,12,13)$.

The woman had many social contacts. Besides working as a babysitter and having parttime jobs that brought her into frequent contact with the public, she was extremely active in a variety of church, community, and school activities. As part of the investigation, over 1,000 persons have been skin tested in Montana. These include over 200 persons who had identifiable contact with the woman, as well as over 500 persons who belonged to groups potentially exposed to her.

Three other cases were identified. All were in children 3-4 years of age who had significant tuberculin skin test reactions and pulmonary infiltrates and/or respiratory symptoms. For these three cases, the exposure to the woman was either through babysitting or family visits.

[^3]All patients are being treated with multiple drugs to which the INH-resistant organisms are susceptible.

To date, 37 reactors (persons with significant tuberculin skin test reactions) have been identified in Montana. Of these, 31 had identifiable contact with the 30 -year-old woman. The remaining six reactors had contact with the other cases. All reactors are taking rifampin as preventive therapy. Nine other reactors in Nevada and Utah and one reactor in California have been identified, all among relatives and friends of the woman. Contacts have also been identified in Illinois, Oklahoma, Washington, and Wyoming; to date none of these contacts who have been skin tested have shown a significant reaction.

Investigation of the woman's medical history revealed that in January 1979 in Nevada, she had been diagnosed as having TB; at the time, she had a $3-\mathrm{cm}$ right apical cavity and a sputum culture that yielded M. tuberculosis sensitive to INH. She was treated with INH and ethambutol. After diagnosis of her illness, an additional 11 persons in Utah and Nevada were identified as having significant tuberculin skin test reactions; all reactors were relatives or friends of the woman. Eight months after diagnosis, she moved to Missoula, Montana, with a 3 -month supply of medicine. However, she did not complete her course of treatment.

Of the six cases in the outbreak, four patients (67\%) are under 15 years of age. Of the 53 reactors who have also been identified, $25(47 \%)$ are under 15 years of age. Thus, nearly half (29/59) of the infected persons are children.

Still pending is an analysis to determine reactor rates for persons in different exposure categories and reactor rates by duration of exposure to the presumed source of infection.
Reported by HA Renteln, MD, J Chin, MD, State Epidemiologist, California Dept of Health Svcs; Y Bradford, H Ezell, B Finley, D Lang, E Montgomery, W Newcomer, M Taylor, J Veleber, Missoula CityCounty Health Dept, D Bean, B Desonia, E Kelly, R Nelson, R Paulsen, F Sweeney, J Gedrose, State Epidemiologist, Montana State Dept of Health and Environmental Sciences; J Brophy, C Hess, D Knesek, M Meador, G Reynolds, MD, Acting State Epidemiologist, Nevada State Dept of Human Resources; D Forster-Burke, MA Miller, Tooele County Health Dept, E Butler, B Holmes, BL Larson, A Nelson, RE Johns Jr, MD, State Epidemiologist, Utah State Dept of Health; Div of Tuberculosis Control, Center for Prevention Sves, CDC.
Editorial Note: This outbreak has several important facets. The first is that of drug resistance. While it is difficult to pinpoint the reason why INH resistance developed in the woman presumed to be the source of infection, probably the most important factor was that the patient failed to complete her treatment. Patients being treated for TB should be carefully monitored for compliance until the recommended course of therapy is completed.

Of note was the fact that both the woman and her husband had the same M. tuberculosis phage type, while only the woman had INH-resistant organisms. Her husband may have been infected before her organisms became resistant. Although only the woman has bacteriologically confirmed INH-resistant TB, there is a high probability that the four children with TB were infected with INH-resistant organisms. Therefore, they were placed on therapy with a combination of drugs to which the INH-resistant organisms are sensitive.

Since there is also a relatively high probability that reactors without disease have been infected with INH-resistant organisms, these individuals have been given rifampin as preventive therapy. Although the efficacy of preventive therapy with rifampin has not been demonstrated in controlled trials, the results of a study using the Delphi technique and decision analysis to determine the choice of preventive treatment for INH-resistant tuberculous infection support the use of rifampin (2). This outbreak is the largest in which rifampin has been used as an alternative regimen to prevent TB.

Another notable aspect of this outbreak is the large number of infected children, including four with TB and 25 reactors. This illustrates that TB in children is still a problem in this country.

Tuberculosis - Continued
A final aspect of this outbreak is the interstate transmission of tuberculous infection. Infected persons have been identified in four states; contacts have been identified in eight. Since transmission occurred across state lines, efficient communication between local, state, regional, and federal health authorities has been an essential part of efforts to control the outbreak.

## Neonatal Gonococcal Ophthalmia - California

A case of neonatal gonococcal ophthalmia has been reported to CDC from San Diego, California. The ophthalmia occurred even though the neonate received ocular prophylaxis with erythromycin.

In late June, a male infant, of normal weight for gestational age, was born to a primiparous mother after a full-term, uncomplicated pregnancy. The mother had received prenatal care at a local health center since the end of the first trimester. She had been seen nine times during the pregnancy. Specimens for VDRL and gonorrhea cultures had been obtained in February 1983; both tests were reported as negative. The father had been seen at the clinic of a naval air station, diagnosed as having gonorrhea, and treated 9 days before the infant's birth. The mother was not contacted for either evaluation or treatment at that time.

One day before delivery, the mother visited the health center with uterine contractions but was not considered to be in active labor. A yellow-green, slightly odorous discharge was noted at the vaginal introitus. Cultures were taken, and she was referred to the affiliated hospital, with a diagnosis of possible rupture of membranes. No antibiotics were administered.

She was admitted on the following day to the obstetric ward in active labor, with spontaneous rupture of membranes and a copious green vaginal discharge. Two hours later, an internal fetal monitor was applied. Six hours and 35 minutes later, a lightly meconium-stained infant was delivered vaginally, vertex posterior presentation. Apgar scores were 6 at 1 minute and 9 at 5 minutes. The infant's eyes were treated with erythromycin ophthalmic ointment about 5 minutes after delivery. The newborn examination was described as normal.

Approximately 24 hours after birth, the results of the cultures obtained from the mother the day before delivery were reported as positive for a gram-negative, oxidase-positive organism, eventually confirmed as Neisseria gonorrhoeae. The mother was treated with procaine penicillin, 4.8 million units intramuscularly (IM) and probenecid 1 g orally. Blood and cerebrospinal fluid for culture were obtained from the infant, and he was treated with 200,000 units of benzathine penicillin ( 50,000 units $/ \mathrm{kg}$ ). Both cultures were subsequently negative. At 2 days of age, the infant developed a copious yellowish discharge from both eyes, along with ocular swelling and redness. Gram-stain smear of the exudate revealed gramnegative diplococci, subsequently confirmed as $N$. gonorrhoeae, $\beta$-lactamase negative. He was treated with aqueous penicillin, 50,000 units $/ \mathrm{kg}$ intravenously (IV), for 7 days. In addition, his eyes were washed with saline every 30 minutes to 1 hour, and tetracycline eye ointment was instilled after each saline irrigation. The infant's eyes gradually improved over the next 2-3 days. Topical therapy was maintained for 5 days. Examination by an ophthal-
mologist revealed no corneal damage. The infant was subsequently seen as an outpatient; he had no apparent eye damage. One week after delivery, the mother was readmitted for endometritis culture-positive for $\boldsymbol{N}$. gonorrhoeae, $\beta$-lactamase negative, demonstrating the severity of her infection. She responded to treatment with IV antibiotics.
Reported by R Coen, MD, Dept of Pediatrics, University of California at San Diego, Venereal Disease Control Unit, Infectious Disease Section, California Dept of Health Svcs; Operational Research Br, Div of Venereal Disease Control, Center for Prevention Svcs, CDC.
Editorial Note: This is the first case brought to the attention of CDC of gonococcal ophthalmia caused by nonpenicillinase-producing $N$. gonorrhoeae that occurred despite the use of erythromycin ophthalmic ointment. Recent reports have shown that penicillinase-producing N. gonorrhoeae can cause gonococcal ophthalmia despite prophylaxis with erythromycin or with silver nitrate (1).

Several risk factors associated with this case may have reduced the efficacy of prophylactic use of erythromycin ointment. Prolonged rupture of membranes is more frequently associated with gonococcal ophthalmia than with other forms of ophthalmia (2). The interval between rupture of membranes and delivery may have been anywhere from 7 to 24 hours. The description of "yellow-green, slightly odorous discharge" on the day before the delivery is compatible with an established infection. The lower 1 minute Apgar score and light meconium staining noted after birth may have indicated mild distress before delivery, suggesting that an infection was already present. The incubation period of gonorrhea in neonates is 1-5 days. Therefore, the newborn examination within 24 hours after birth would not normally be expected to detect an early infection. In fact, documented cases of gonococcal eye infection have occurred even with minimal inflammatory responses (3).

Prophylaxis against ophthalmia with either silver nitrate or erythromycin ointment is not adequate for treatment of an already established gonococcal infection. In one study (2), 44 of 46 cases of gonococcal ophthalmia occurred despite silver nitrate prophylaxis. Investigators in this study also found that chlamydia ophthalmia was the most common specific type of ophthalmia neonatorum in their study, occurring in 86 of 302 cases. Silver nitrate is not effective prophylaxis for chlamydia ophthalmia, but erythromycin ophthalmic ointment has been proven to prevent that disease (4).

In this case, gonococcal ophthalmia developed despite the use of topical erythromycin ointment and IM benzathine penicillin. Current CDC recommendations are to treat infants born to mothers with gonococcal infection with aqueous crystalline penicillin $G(5): 50,000$ units IM or IV for full-term infants, or 20,000 units IM or IV for low-birth-weight infants. Documentation of prenatal care, cultures done during pregnancy, circumstances around labor and delivery, knowledge of the incidence of gonococcal infection in the local population, and other factors may help to delineate the choice of agents to be used under high-risk circumstances. The Division of Venereal Disease Control, CDC, encourages reporting of any known cases of neonatal gonococcal ophthalmia for further evaluation of the efficacy of the current recommendations for prophylaxis.

## Notice to Readers

## Relocation of CDC's Division of Hepatitis and Viral Enteritis

CDC's Division of Hepatitis and Viral Enteritis, Center for Infectious Diseases, has moved its operation from Phoenix, Arizona, to Atlanta, Georgia. Epidemiologic assistance and consultation were transferred to Atlanta on August 29, 1983. The new telephone number is (404) 321-2342 (FTS 236-2342).

The Morbidity and Mortality Weekly Report is prepared by the Centers for Disease Control, Atlanta, Georgia, and available on a paid subscription basis from the Superintendent of Documents, U.S. Government Printing Office, Washington, D.C. 20402, (202) 783-3238.

The data in this report are provisional, based on weekly reports to CDC by state health departments. The reporting week concludes at close of business on Friday; compiled data on a national basis are officially released to the public on the succeeding Friday.

The editor welcomes accounts of interesting cases, outbreaks, environmental hazards, or other public health problems of current interest to health officials. Such reports and any other matters pertaining to editorial or other textual considerations should be addressed to: ATTN: Editor, Morbidity and Mortality Weekly Report, Centers for Disease Control, Atlanta, Georgia 30333.

[^0]:    - A confirmed case has at least one defect in A or B and laboratory confirmation of rubella infection. A compatible case has any two complications listed in $A$ or one from $A$ and one from $B$.
    A. Cataracts/congenital glaucoma (either or both count as one); congenital heart disease, loss of hearing, pigmentary retinopathy.
    B. Purpura, splenomegaly, jaundice (with onset beginning within 24 hours of birth), microcephaly, mental retardation, meningoencephalitis, radiolucent bone disease.
    $\dagger$ Intrauterine infection that can result in miscarriages, abortions, stillbirths, and CRS in infants. Congenital rubella syndrome refers to infants born with defects secondary to intrauterine infection or who manifest symptoms or signs of intrauterine infection sometime after birth.

[^1]:    *Reported number of cases per 100,000 population
    ${ }^{\dagger}$ Cases of unknown age excluded
    §Yearly averages
    ${ }^{\text {IR }}$ Represents prevaccine years

[^2]:    - Mortality data in this table are voluntarily reported from 121 cities in the United States, most of which have populations of 100,000 or more. A death is reported by the place of its occurrence and by the week that the death certificate was filed Fetal deaths are not included.
    - Pneumonia and influenza
    $\dagger$ Because of changes in reporting methods in these 4 Pennsylvania cities, these numbers are partial counts for the current week. Complete counts will be available in 4 to 6 weeks.
    t† Total includes unknown ages.
    § Data not available. Figures are estimates based on average of past 4 weeks

[^3]:    *A significant reaction to the tuberculin skin test is one accepted by the American Thoracic Society and CDC as indicating tuberculous infection (1). In this outbreak, reactions of $\geqslant 5 \mathrm{~mm}$ induration among contacts of a patient with tuberculosis were considered to be significant.
