Current Trends

## Update on Influenza Activity Worldwide and World Health Organization and United States Recommendations for Influenza Vaccine Composition for the 1987-1988 Season

During February or March each year, the World Health Organization (WHO) summarizes availahle data on recently isolated influenza viruses arnund the unorld and issues recemmend tions for vaccine composition. The WHO reports $(1,2)$ and the U.S. recommendations for composition of the 1987-1988 influenza vaccine are summarized below.

## Influenza- Worldwide

From September 1986 through February 1987, influenza A(H1N1) viruses predominated and, in most countries, were the only type of influenza virus isolated. As in previous epidemics since 1977, influenza $A(H 1 N 1)$ outbreaks occurred mainly among children and young adults. Few influenza $A(H 3 N 2)$ or influenza $B$ viruses have been isolated.

Influenza A(H 1N 1). In the Americas, localized outbreaks occurred in the United States in October and November 1986. Influenza activity increased markedly in the United States in December, and, by mid-February, the virus had been isolated from patients in 49 states and the District of Columbia. Canada also reported activity from October through January. In Jamaica, outbreaks were serologically confirmed in both October and November. Brazil reported a single case in October.

In Asia, widespread outbreak activity was reported in the Democratic People's Republic of Korea during October and November and in Japan during November and December. China reported sporadically occurring cases from November through January, and Hong Kong reported them in December. In the Middle East, influenza $A(H 1 N 1)$ virus was isolated during outbreaks in the Islamic Republic of Iran in November and in Israel during November and December.

In Europe, localized outbreaks occurred in the United Kingdom in September and October, with continued activity through January. In both the German Democratic Republic and the USSR, outbreak activity was widespread during November and declined during December. Czechoslovakia, Hungary, Poland, and Yugoslavia also reported widespread influenza activity in December. Elsewhere in Europe (Denmark, the Federal Republic of Germany, Finland, France, Italy, the Netherlands, Norway, Romania, Spain, Sweden, and Switzerland), there was activity between December and February.

Influenza A(H3N2). Influenza $A(H 3 N 2)$ virus was isolated along with influenza $A(H 1 N 1)$ during an outbreak in the Democratic People's Republic of Korea. The virus was also isolated during an outbreak in Ecuador in November. Otherwise, A(H3N2) was detected only in sporadically occurring cases in Canada, China, Italy, Romania, Tunisia, the United States, and the USSR.

Influenza B. Outbreaks of influenza B were reported in Panama in September and October and in Singapore in December. Sporadically occurring cases were also detected in Canada, Chile, the Federal Republic of Germany, Hong Kong, India, Senegal, Singapore, Spain, Sweden, Taiwan, the United Kingdom, the United States, and the USSR.
Antigenic Analysis of Recent Isolates
Influenza $\mathbf{A}(\mathrm{H} 1 \mathrm{~N} 1)$ viruses collected from many parts of the world during the 1986-1987 season have been antigenically characterized. Virtually all of them were indistinguishable from the A/Taiwan/1/86-like strains isolated in Asia early in 1986 (3). Influenza B viruses, which were isolated infrequently during the 1986-1987 season, were antigenically heterogeneous. However, all were closely related to B/Ann Arbor/1/86 (4).

The influenza $A(H 3 N 2)$ viruses isolated from outbreaks in all parts of the world during the 1985-1986 season were antigenically heterogeneous. About two-thirds differed from A/Mississippi/1/85 (H3N2), which was included in the 1986-1987 U.S. trivalent influenza vaccine. More than $25 \%$ of the $\mathrm{A}(\mathrm{H} 3 \mathrm{~N} 2)$ isolates characterized in the United States during the 1985-1986 season were antigenically similar to the A(H3N2) variant, A/Stockholm/8/85. Sera from recipients of the 1986-1987 trivalent vaccine were tested for antibody against both A/Mississippi/1/85 and A/Stockholm/8/85 antigens by hemagglutination inhibition (Table 1). For both young adults and nursing home residents who had received the trivalent vaccine, the geometric mean titers were nearly threefold lower to the A/Stockholm/8/85 virus than to the homologous $\mathrm{A} / \mathrm{Mississippi} / 1 / 85$ virus. Furthermore, for the nursing home residents, $38 \%$ of the post-vaccination sera had titers that were $\geqslant 40$ to $A / S t o c k h o l m / 8 / 85$, whereas $69 \%$ had titers $\geqslant 40$ to A/Mississippi/1/85.

Very few $A(H 3 N 2)$ viruses have been isolated during the 1986-1987 season; however, several appear similar to the A/Stockholm/8/85 variant. The 1986-1987 variant, A/Leningrad/360/86, an egg isolate suitable for vaccine production, appears closely related to A/Stockholm/8/85 (Table 2). These reference strains are poorly inhibited by ferret serum to the $A / B a n g k o k / 1 / 79$ strain, used ${ }^{2}$ in influenza vaccines during the period 1980-1985. They are also inhibited at significantly reduced titers (compared to the homologous titer) by ferret

antiserum to $A /$ Mississippi/1/85. However, ferret antisera to both A/Stockholm/8/85 and A/Leningrad/360/86 inhibit A/Mississippi/1/85.

## Recommendations for the Composition of Influenza Virus Vaccines

Because of these antigenic variations and the continued isolation of viruses resembling A/Stockholm/8/85, WHO recommends that influenza vaccines for use during the 1986-1987 season contain a representative of this variant in place of $A / M i s s i s s i p p i / 1 / 85$.

The above findings were discussed at a WHO meeting in February. The Public Health Service Vaccine Advisory Panel (PHSVAP) met during the same period to review the data regarding antigenic variations of virus isolates. Consistent with WHO recommendations, the PHS recommends that influenza vaccines for use in the 1987-1988 season be trivalent and contain the following antigens:

A/Taiwan/1/86(H1N1)-like antigen
B/Ann Arbor/1/86-like antigen
A/Leningrad/360/86(H3N2)-like antigen
Recommendations of the Immunization Practices Advisory Committee regarding dosage and schedule of the vaccine will be published in the MMWR later this spring.

## Perspectives in Disease Prevention and Health Promotion

## Sex-, Age-, and Region-Specific Prevalence of Sedentary Lifestyle in Selected States in 1985 - The Behavioral Risk Factor Surveillance System

The Behavioral Risk Factor Surveillance System (BRFSS) is a telephone survey conducted by state health departments to routinely collect risk factor data from adults ( $>18$ years of age). The following analysis examines sedentary lifestyle data from the 25,221 persons interviewed by the 22 states (including the District of Columbia) participating in the BRFSS during 1985.

Participants were asked to provide details of up to two activities performed during the past month. The prevalence of sedentary lifestyle was estimated by the percentage of persons who reported either no physical activity or physical activity less than three times per week and/or less than 20 minutes per occasion. This criterion level is based on the 1990 objectives for the nation regarding physical fitness and exercise (1) and represents the minimum amount of physical activity likely to confer health benefits.

Table 3 presents the sex-specific prevalence of sedentary lifestyle in the 22 states. The distribution of these prevalences is summarized in the "box-plots" in Figure 1. These plots provide the maximum range, the upper and lower quartiles, and the median (50th percentile) of the distribution of state-specific prevalences for the 22 states.

Figure 1 indicates that the median prevalence of sedentary lifestyle is somewhat higher for women than for men; however, the distribution of prevalence estimates for the two genders overlap considerably. This figure also shows that the variation in prevalence estimates of sedentary lifestyle is somewhat greater for women than for men.

Table 4 presents the age-specific prevalence of sedentary lifestyle for adults in the 22 states. In most instances, the prevalence of sedentary lifestyle for adults increased with increasing age. The distribution of these prevalences is summarized in Figure 2, which also indicates that there is considerable overlap between the three age-specific prevalence distributions of adult sedentary lifestyle in the states.

Figure 3 indicates that the median prevalence of sedentary lifestyle by region is somewhat higher for the southeastern states and lowest in the southwestern and mountain states. FIGURE 1. Box-plot summaries of the sex-specific distribution of sedentary lifestyle prevalences from $\mathbf{2 2}$ states participating in the 1985 Behavioral Risk Factor Surveillance System

*Confidence interval.

Northeastern and central states were intermediate in their prevalence of sedentary lifestyle. Again, there is considerable overlap of the region-specific distribution of prevalence estimates for the four regions.

Editorial Note: Eleven of the 1990 objectives for the nation relate to physical fitness and exercise. Most of these 11 objectives emphasize "appropriate physical activity," which is defined as "exercise which involves large muscle groups in dynamic movement for periods of 20 minutes or longer, three or more days per week, and which is performed at an intensity of 60 percent or greater of an individual's cardiorespiratory capacity." This amount of physical activity is rather strenuous, and evidence indicates that less intensive, yet regular, physical activity may also confer health benefits (2). Therefore, the analysis reported here sought to estimate the prevalence of sedentary lifestyle, i.e., physical activity less than three times per week, less than 20 minutes per occasion, or both, regardless of the intensity of participation.

An average of $55 \%$ of the 25,221 persons interviewed by telephone in the 22 states participating in the 1985 BRFSS reported so little physical activity in the past month as to be

[^2]considered sedentary. Rates increased with age and were slightly higher for women than for men. The National Health Interview Survey (3), a representative survey conducted by the Na tional Center for Health Statistics using household-interviews, provided very similar estimates of the prevalence of sedentary lifestyle for 1985. The trends for age, gender, and region have been noted previously in other national surveys (4).

The 1990 physical fitness and exercise objectives are also concerned with the regular monitoring of national trends, the use of community recreation programs and facilities, public and professional awareness of the benefits of regular physical activity, worksite fitness programs, and the evaluation of the short- and long-term effects of physical activity (5). Recent reports have summarized progress in these areas $(5,6)$.

Specific health reasons for promoting physical activity stem from a wide variety of research findings. Increased levels of physical activity have been associated with reduced risk of coronary heart disease (7), enhanced weight control (8), reduced symptoms of anxiety and mild to moderate depression, and an enhanced sense of well-being derived from feeling and looking better (9). Further, there is emerging evidence that physical activity may have important beneficial effects on non-insulin-dependent diabetes mellitus, hypertension, and osteoporosis (6). In addition, physical activity is helpful in managing and treating many chronic diseases (10).

In spite of the fact that physical activity is a complex behavior (11) and difficult to assess (12), progress has been made in the ability to characterize national levels of physical activity. Unfortunately, these results indicate that less than half of the American population is physically active at a level likely to confer health benefits. Because of the multiple health benefits of physical activity and because of the high prevalence of sedentary lifestyle documented among the U.S. population, the promotion of prudent physical activity should be a national priority for the Public Health Service.

Epidemiologic Notes and Reports

## Update: Salmonella enteritidis Infections in the Northeastern United States

New England and the Middle Atlantic region* experienced a fivefold increase in the reported isolation rate of Salmonella enteritidis between 1976 and 1985 (1). Consequently, a regional S. enteritidis Working Group was established in 1986 to coordinate investigations of S. enteritidis outbreaks. Investigations of recent outbreaks and related studies suggest that many S. enteritidis infections in the Northeast are associated with eggs.

Fourteen S. enteritidis outbreaks have been reported to CDC from the Northeast since October 1, 1986. The vehicles of transmission have been identified for 10 of the outbreaks. At least six of these vehicles were either eggs or foods which contained raw or undercooked eggs (homemade eggnog prepared with store-bought eggs, Monte Cristo sandwiches made of sliced cooked meat and cheese on bread dipped in raw egg and grilled, and Caesar salad dressing made with raw eggs). The outbreak-associated eggs were all USDA grade A shell eggs, and, in each instance, the food preparation history suggested the eggs were eaten raw or undercooked. The outbreak-associated eggs were not available for culture. However, in an outbreak associated with riceballs (made with eggs) in September 1986, S. enteritidis was cultured from an egg-breaking machine in the restaurant involved.

[^3]Salmonella - Continued
Editorial Note: Salmonellosis associated with eggs is not a new problem. Large outbreaks of salmonellosis associated with bulk egg products and cracked shell eggs $(2,3)$ led to the passage of the Egg Products Inspection Act in 1970. This law required pasteurization of all bulk egg products and federally-supervised inspection of shell eggs for "checks" or cracks. Since enactment of this legislation, there have been fewer egg-associated outbreaks of salmonellosis, and CDC has not received any reports of outbreaks associated with bulk egg products (4).

These recent outbreaks suggest that egg-associated $S$. enteritidis is an emerging public health problem and show the importance of routine serotype-specific surveillance. Eggs can become contaminated with Salmonella in several ways. Fecal soiling may contaminate egg shells, and the internal contents of the egg may occasionally be contaminated by organisms entering through hairline cracks in the shell (5). In addition, if there is an ovarian infection in the hen, an egg yolk may become infected by certain serotypes of Salmonella before the shell is formed ( 6 ). It is not known whether $S$. enteritidis is one such serotype.

As is true for meat, poultry, raw milk, and other raw foods of animal origin, proper handling and cooking of eggs can minimize the risk of salmonellosis. Thorough cooking kills Salmonella. Consumers concerned about the proper handling of egg-containing foods should contact their county extension home economist or call the USDA Meat and Poultry Hotline (800-535-4555). Further research is needed to understand the ecology of Salmonella colonization in poultry and other food-animal species and to determine ways to further reduce the contamination of eggs and other foods derived from animals.

Clinicians are encouraged to report cases of salmonellosis to their state health department. Isolates of Salmonella can be submitted to state laboratories for serotyping to support epidemiologic investigations.

## Progress in Chronic Disease Prevention

## The Prevalence of Cancer - Connecticut, January 1, 1982

Incidence and follow-up data from the Connecticut Tumor Registry were analyzed in order to estimate the prevalence of cancer (1). A case was included in this analysis if the patient was alive on January 1, 1982, and had been diagnosed with cancer at any time during the study period, 1935 through 1981. Cases of basal- and squamous-cell cancer of the skin were not included. During the study period, 288,221 residents of Connecticut were diagnosed with invasive cancer. Of these, 53,628 ( $18.6 \%$ ) were known to be living on January 1, 1982; $19,881(6.9 \%)$ were lost to follow-up (i.e., reported alive with a date of last contact prior to January 1, 1982). The life-table method was used to estimate the number of patients among those lost to follow-up who were alive on January 1, 1982 (2).

On January 1, 1982, the age-adjusted* prevalence rate among males for all sites of cancer combined was $1,789 / 100,000$ compared with $2,222 / 100,000$ among females. In contrast, the age-adjusted cancer incidence rate for all sites among males diagnosed during the period 1978-1981 was almost one-third higher than among females (463/100,000 compared with $342 / 100,000$ ). The mortality rate among males was about $50 \%$ higher than among females ( $246 / 100,000$ compared with $154 / 100,000$ ) (3). The relatively favorable survival rate for women with cancer affecting many of the common sites (e.g., breast and gynecological malignancies) and the poor survival rate for patients with lung cancer (the most common cancer in males) resulted in an age-adjusted prevalence rate among females that was about $25 \%$ higher than that among males.

The five most prevalent malignant diseases among males were prostate cancer (372/100,000), colon cancer (249/100,000), bladder cancer (233/100,000), rectal cancer (145/100,000), and lung cancer ( $135 / 100,000$ ). The most prevalent cancer site in females was the breast $(848 / 100,000)$, followed by corpus uteri $(273 / 100,000)$, colon (224/100,000), cervix ( $138 / 100,000$ ), and rectum $(98 / 100,000)$.

The age-specific prevalence rates for all sites of cancer combined among females 20 to 59 years of age were about twice the rates for males (Figure 4). The rates for all sites combined for males $>70$ years of age were higher than those for females, partly because of the high prevalence of prostate cancer in elderly males. For females, prevalence rates for all sites combined ranged from 1,170/100,000 for those 30 to 49 years of age to 10,635/100,000 for those $>70$. For males, the rates for all sites combined increased from 598/100,000 for those 30 to 49 years old to $11,810 / 100,000$ for those $>70$.

Editorial Note: The magnitude of the cancer problem has been measured traditionally by incidence and mortality statistics. The knowledge of cancer prevalence rates adds a new dimen-

## Cancer - Continued

sion to the assessment of this problem. While incidence reflects only the rate of occurrence of newly diagnosed cancer cases in one particular year, prevalence estimates include patients diagnosed during previous years who survived to the point in time of interest. Because most patients with cancer survive more than one year, prevalence is a useful indicator of the cancer burden on the health care system.
"Cured" and "uncured" cases were included in this study because, in many cases, the determination of cure is ambiguous. It has been suggested that even for so-called cancer survivors, the experience of cancer leaves a long-lasting impression (4). Problems of employment, insurance, second malignancies, and reproduction linger long after the patient's treatment is completed and probably justify including all patients with a history of cancer in the prevalence calculations.

Approximately $2 \%$ of the population of the state of Connecticut had a history of cancer on January 1, 1982. Perhaps even more surprising is the fact that $11 \%$ of females and $12 \%$ of males $\geqslant 70$ years of age had a history of cancer. Applying the age-specific prevalence rates to the estimated 1986 U.S. population (5) results in an estimate of approximately 5 million persons with a history of cancer in the United States. With the anticipated aging of the U.S. population, the number of individuals with a history of cancer can be expected to increase. Calculations using projected populations (5) and assuming constant prevalence rates yield prevalence estimates of 6.2 million for the year 2000 and 9.6 million for 2030 . These projections should be viewed cautiously since the racial and ethnic composition of Connecticut is different from that of the United States as a whole and since incidence and survival patterns among blacks, whites, and other races are known to differ.

Advances in cancer treatment that improve patient survival will almost certainly increase the prevalence rates of cancer over time. With more and more patients living with a history of cancer, an increase in resources will be required to help patients with their medical problems, physical limitations, and social adjustments. However, the successful application of cancer prevention strategies, including smoking cessation and diet modification programs, should decrease the incidence of cancer and thereby lower cancer prevalence.

FIGURE I. Reported measles cases - United States, weeks 09-12, 1987

The Morbidity and Mortality Week/y Report is prepared by the Centers for Disease Control, Atlanta, Georgia, and available on a paid subscription basis from the Superintendent of Documents, U.S. Government Printing Office. Washington, D.C. 20402, (202) 783-3238.

The data in this report are provisional, based on weekly reports to CDC by state health departments. The reporting week concludes at close of business on Friday; compiled data on a national basis are officially released to the public on the succeeding Friday.

The editor welcomes accounts of interesting cases, outbreaks, environmental hazards, or other public health problems of current interest to health officials. Such reports and any other matters pertaining to editorial or other textual considerations should be addressed to: ATTN: Editor, Morbidity and Mortality Weekly Report, Centers for Disease Control. Atlanta, Georgia 30333.
