Syndrome - United States, 1985-1988
183 Influenza Vaccine Composition
Recommendation for the 1989-90
Season

## Current Trends

## Rubella and Congenital Rubella Syndrome United States, 1985-1988

## RUBELLA

A provisional total of 221 cases of rubella was reported in the United States in 1988 ( 0.1 cases per 100,000 population), the lowest since rubella became a nationally notifiable disease in 1966. In 1987, 306 cases of rubella $(0.1 / 100,000$ ) were reported. The incidence of rubella has declined by more than $99 \%$ since 1969, the year rubella vaccine was licensed (Figure 1).

FIGURE 1. Incidence rates of reported rubella and congenital rubella syndrome (CRS) cases - United States, 1967-1988

*1988 provisional data.
${ }^{\dagger}$ Includes proration of patients $\geqslant 15$ years old for whom age was unreported. Average annual U.S. estimate based on data from lllinois, Massachusetts, and New York City for the 3 -year periods 1966-1968, 1969-1971, and 1972-1974.
${ }^{5}$ Confirmed and compatible cases, by year of birth. Provisional data due to delayed diagnosis and reporting.

Rubella and CRS - Continued
In 1987, the last year for which complete data are available, 20 of 52 reporting areas (which comprise the 50 states, District of Columbia, and New York City [NYC]) reported no rubella cases, compared with 18 reporting areas in 1986 and 14 in 1985. One hundred five ( $3.3 \%$ ) counties reported rubella cases in 1987, compared with 152 $(4.8 \%)$ in 1985. The reported age-specific incidence rates of rubella declined for all age groups during these 3 years (Table 1). In 1987, children $<5$ years of age continued to have the highest incidence rate ( 0.5 cases $/ 100,000$ population) and accounted for $28 \%$ of the total number of patients with known ages. The rate for persons $\geqslant 15$ years of age, who accounted for $49 \%$ of the patients with known ages in 1987, declined most dramatically - by $59 \%$ ( $0.19 / 100,000$ in 1985 to $0.08 / 100,000$ in 1987).

Long-term trends of rubella incidence among specific age groups can be assessed by comparing recent data from the total United States with those from three areas for which age-specific data were available before 1975-Illinois, Massachusetts, and NYC (Table 2). In the 3-year period before vaccine licensure (1966-1968), the estimated risk of acquiring rubella was highest in children 5-9 years of age. Of the patients with known ages, children <10 years of age accounted for $60 \%$, while only $23 \%$ of the total was reported among those $\geqslant 15$ years of age. By comparison, the reported incidence rates for 1985-1987 have declined by $\geqslant 95 \%$ for all age groups, with the greatest decreases occurring among persons $<20$ years of age. Persons aged $\geqslant 20$ years accounted for just over half of all patients with known ages. Although the decrease in incidence rates was smallest for this age group, their risk of acquiring rubella still declined more than 95\%, relative to prevaccine licensure years.

Rubella and CRS - Continued

## CONGENITAL RUBELLA SYNDROME

Data on congenital rubella syndrome (CRS) are available from reports submitted weekly to the MMWR and from the National Congenital Rubella Syndrome Registry (NCRSR) maintained at the Division of Immunization, Center for Prevention Services, CDC. The MMWR CRS reports are case counts with no accompanying data and are tabulated by year of report. The NCRSR contains clinical and laboratory information on cases of CRS that are reported by state and local health departments. The NCRSR cases are monitored by year of patient's birth and are classified into six clinical categories (1), the most specific of which are "CRS-confirmed" (i.e., cases with both congenital anomalies and laboratory evidence of rubella infection) and "CRScompatible" (i.e., cases that satisfy selected clinical criteria without laboratory confirmation). Beginning in 1984, information was routinely collected to evaluate whether a CRS case was "indigenous" or "imported."* Since the NCRSR cases are classified by year of patient's birth, data are considered provisional for any given year; delays in diagnosis and/or reporting may result in the updating of figures. This summary updates previous reports on surveillance of CRS in the United States (1).

For infants born in 1987, six CRS cases were reported to the NCRSR, of which three were considered indigenous. All three were confirmed CRS cases, and one of them occurred in a mother who had had at least one previous pregnancy. Only one CRS case has been reported thus far for 1988. Recent declines in rates of CRS recorded by NCRSR have paralleled the decline in overall rubella incidence and, more specifically, in the incidence for persons $\geqslant 15$ years of age (Figure 1). During 1970-1987, the reported rate of rubella among persons in this age group declined $97 \%$, from 2.3 to 0.1 cases/100,000 population. In 1970, 67 CRS cases occurred (1.80/100,000 live births),
*Based on definitions approved by the Council of State and Territorial Epidemiologists, an imported case of CRS is defined as CRS in a U.S. or non-U.S. citizen whose mother was outside the United States during her presumed exposure to rubella. If the timing of exposure to rubella cannot be determined, the mother must have been outside the United States throughout the 21 days before conception and the first 20 weeks of her pregnancy.

TABLE 2. Age distribution of reported rubella cases and estimated incidence rates* - Illinois, Massachusetts, and New York City, 1966-1968, ${ }^{\dagger}$ and total United States, 1985-1987 ${ }^{\dagger}$

[^0]Rubella and CRS - Continued
and three have been reported as of March 22, 1989, for 1987 ( $0.08 / 100,000$ live births), representing a $96 \%$ decline (Table 3). This downward trend was interrupted in 1986, when 12 CRS cases were reported (2). In that year, eight of these cases were reported to the NYC Department of Health 8-10 months after the peak of a rubella outbreak in NYC (3).
Reported by: Surveillance, Investigations, and Research Br, Div of Immunization, Center for Prevention Svcs, CDC.
Editorial Note: As part of the 1990 health objectives for the nation, the Public Health Service set a goal to reduce the number of rubella cases to $<1000$ and to reduce CRS to $<10$ cases annually (4). The former goal was achieved for the first time in 1983, when 970 rubella cases were reported (5). Although the goal for CRS has also been reached, unacceptable morbidity is still occurring. The primary aim of rubella vaccination programs is to prevent congenital rubella infection, which can result in miscarriages, abortions, stillbirths, and CRS in infants. When rubella vaccine was licensed in 1969, the United States adopted a policy of universal immunization of children of both sexes. The focus of this rubella vaccination strategy was to control rubella in preschool-aged and young school-aged children, the primary sources of rubella transmission. This strategy was designed primarily to reduce and interrupt circulation of the virus, thereby reducing the risk of exposure to susceptible pregnant women. Also, vaccinated children would be protected immediately, and their immunity was expected to persist at least through their childbearing years (6). Secondary emphasis was placed on vaccinating susceptible adolescents and adults, especially women.

The success of the rubella control program is apparent. In 1966-1987, the reported incidence rates of CRS and of rubella among persons $\geqslant 15$ years of age declined in parallel by $95 \%-96 \%$ to all-time low levels. Meanwhile, incidence rates of rubella in children $<15$ years of age have continued their downward trend. As the highly immune cohorts of young children enter the childbearing years, CRS should disappear from this country.

However, concern continues despite the dramatic success of the U.S. rubella immunization program. In 1987, 48\% of reported rubella cases were in persons $\geqslant 15$ years of age ( $32 \%$ of all cases were in persons 15-29 years of age). Most serologic surveys of various postpubertal populations carried out during the 1970s and early 1980s found rates of rubella susceptibility comparable to the prevaccine years: $10 \%-20 \%$ of persons still lacked serologic evidence of immunity to rubella (7-9). Updated population-based serologic surveys are needed to fully characterize the magnitude and extent of risk for this adolescent and young adult population. The NYC experience during 1985-1986 (2,3) and several recent college outbreaks (10) highlight the possible risk of disease in postpubertal women. The continued occurrence of rubella in childbearing-aged populations suggests that potentially preventable cases of CRS may continue to occur during the next 10-30 years. Such concerns led CDC to announce an initiative in February 1985 to hasten elimination of rubella and CRS by targeting susceptible childbearing-aged populations for vaccination (11).

In addition, the reported figure for CRS cases is believed to underestimate the actual total, perhaps capturing only $10 \%$ of the actual total (12). The NCRSR is a passive reporting system that, by its nature, results in underreporting of actual disease incidence and selective reporting of infants with severe and obvious CRS recognized and reported early in life. The limitations of current CRS surveillance

## Rubella and CRS - Continued

underscore the need for all specialists who treat children with congenital anomalies compatible with CRS to continue to consider it in the differential diagnosis and to report all suspected cases to their state health departments.

As with other adult immunizations, creative approaches are necessary to enhance rubella immunization levels in the childbearing-aged population. Adopting and enforcing comprehensive kindergarten through 12th grade school immunization laws (especially for postpubertal elementary and secondary school students) and requiring proof of immunity to rubella as a condition for college entry can minimize the risk of rubella outbreaks in these populations (13). Another way to reach susceptible postpubertal women is to offer rubella vaccine at any encounter with the health-care system. After excluding patients who say they may be pregnant and counseling about the advisability to avoid conception for 3 months after vaccination, practitioners should not hesitate to vaccinate childbearing-aged women against rubella. No CRS-like defects have been detected in 212 infants born to susceptible mothers inadvertently vaccinated with RA27/3 live rubella virus vaccine during pregnancy (14; CDC, unpublished data). NCRSR surveillance data indicate that one third to one half of mothers delivering CRS infants had had a previous live birth, suggesting that both postpartum vaccination and use of rubella vaccine in family-planning clinics could have an important impact on the overall occurrence of reported CRS. Physicians and other health-care personnel should offer rubella vaccine whenever they encounter a potentially susceptible woman lacking contraindications for vaccination. Susceptible persons identified through preemployment, premarital, or prenatal screening should be offered vaccine at follow-up visits.

## Influenza Vaccine Composition Recommendation for the 1989-90 Season

During the 1988-89 influenza season, influenza type $B$ has predominated in the United States but has cocirculated with type $A(H 1 N 1)$ and $A(H 3 N 2)$. Elsewhere in the Northern Hemisphere, type A influenza has generally predominated, with both influenza $A(H 1 N 1)$ and $A(H 3 N 2)$ cocirculating.

Antigenic analysis of type $\mathrm{A}(\mathrm{H} 1 \mathrm{~N} 1)$ viruses from outbreaks indicates that most strains are closely related to the U.S. vaccine strain, A/Taiwan/1/86. The antibody induced by this vaccine component reacts well with the recently circulating type $\mathrm{A}(\mathrm{H} 1 \mathrm{~N} 1)$ viruses.

As in last season, type $A(H 3 N 2)$ viruses continue to be heterogeneous. Some isolates resemble the current vaccine strain $A / S i c h u a n / 2 / 87$, but most are better inhibited by antiserum to the A/Shanghai/11/87 reference virus (Table 1). In addition, patients vaccinated with A/Sichuan/2/87 vaccine consistently had lower antibody responses to the A/Shanghai/11/87 strain (Table 2) than to the vaccine strain.

Most influenza $B$ strains isolated this season, particularly in the United States, are similar to the current vaccine component, B/Nictoria/2/87. However, a new variant was identified in Asia; B/Yamagata/16/88 is an example of the variant (Table 3). This strain was first seen in the People's Republic of China in August 1987 and circulated in Japan, Hong Kong, Singapore, Taiwan, and Thailand from February 1988 to January 1989. The antibody induced by the current BNictoria/2/87 vaccine component is poorly reactive with the $B /$ Yamagata/16/88 strain (Table 4).

Based on these and other data, the World Health Organization (WHO) has recommended that the trivalent influenza vaccine for use in the 1989-90 season

Influenza Vaccine - Continued
contain the following components: type A(H3N2), A/Shanghai/11/87-like antigen, and type $B /$ Yamagata/16/88-like antigen and retain the type $\mathrm{A}(\mathrm{H} 1 \mathrm{~N} 1)$ component of the current vaccine. This decision has been ratified by the Food and Drug Administration's Vaccine Advisory Panel.

Editorial Note: Influenza type A viruses are classified into subtypes on the basis of two antigens: hemagglutinin $(\mathrm{H})$ and neuraminidase $(\mathrm{N})$. Three subtypes of hemagglutinin (H1, H2, H3) and two subtypes of neuraminidase (N1, N2) are recognized among influenza $A$ viruses that have caused widespread human disease. Immunity to these antigens, especially the hemagglutinin, reduces the likelihood of infection and the severity of disease if infection occurs. However, over time there may be enough antigenic variation (antigenic drift) within the same subtype that infection or vaccination with one strain may not induce immunity to distantly related strains of the same subtype. Antigenic variation occurs with influenza B viruses, although no subtypes are known to exist. For these reasons, major epidemics of respiratory disease caused by new variants of influenza continue to occur. The antigenic characteristics of current strains provide the basis for selecting virus strains included in each year's vaccine.

The manufacturing, quality control, and distribution process involved in producing about 30 million doses of influenza vaccine in the United States require many months to complete. Therefore, the decisions on which strains to include in the vaccine formulation for the 1989-90 influenza season must be completed by late March to early April of 1989. Specific recommendations by the Immunization Practices Advisory Committee will be available later this spring.

## Erratum: Vol. 38, No. 10

p. 153 In the fourth line of the first paragraph, unintentional poisoning is reported as the fifth leading cause of unintentional injury deaths in the United States. This is incorrect. Unintentional poisoning is the third leading cause of unintentional injury deaths.

FIGURE I. Reported measles cases - United States, Weeks 7-10, 1989

The Morbidity and Mortality Weekly Report is prepared by the Centers for Disease Control, Atlanta, Georgia, and available on a paid subscription basis from the Superintendent of Documents, U.S. Government Printing Office, Washington, D.C. 20402, (202) 783-3238.

The data in this report are provisional, based on weekly reports to CDC by state health departments. The reporting week concludes at close of business on Friday; compiled data on a national basis are officially released to the public on the succeeding Friday. The editor welcomes accounts of interesting cases, outbreaks, environmental hazards, or other public health problems of current interest to health officials. Such reports and any other matters pertaining to editorial or other textual considerations should be addressed to: Editor, Morbidity and Mortality Weekly Report, Centers for Disease Control, Atlanta, Georgia 30333; telephone (404) 332-4555.

[^0]:    *Reported cases $/ 100,000$ population. Patients with unknown age excluded.
    ${ }^{\dagger}$ Average annual figures over 3 -year period.
    ${ }^{5}$ 'Represents prevaccine years. National age data were not available before 1975 and were not consistently reported (i.e., >75\% of cases) until 1980.
    ${ }^{〔}$ Total U.S. data ( 1986 population projections) are used for 1985-1987; because the overall number of reported rubella cases is currently small, fluctuations (such as the epidemic in NYC in 1985) in only these three reporting areas skewed the data for this period.
    **Based on actual rates.

[^1]:    *Confirmed and compatible cases only, reported by year of birth. Data are provisional because of delayed reporting.
    ${ }^{\dagger}$ Excluded are the following imported cases: 1984 (1 case), 1985 (1), 1986 (2), and 1987 (3). No imported cases have been reported for 1988.
    ${ }^{5}$ Cases/100,000 live births/year.

[^2]:    *Because AIDS cases are not received weekly from all reporting areas, comparison of weekly figures may be misleading.
    ${ }^{\dagger}$ Fifty of the 435 reported cases for this week were imported from a foreign country or can be directly traceable to a known internationally imported case within two generations.

[^3]:    *Mortality data in this table are voluntarily reported from 121 cities in the United states, most of which have populations of 100,000 or more. A death is reported by the place of its occurrence and by the week that the death certificate was filed. Fetal deaths are not included.
    **Pneumonia and influenza.
    †Because of changes in reporting methods in these 3 Pennsylvania cities, these numbers are partial counts for the current week. Complete counts will be available in 4 to 6 weeks.
    $\dagger \dagger$ Total includes unknown ages.
