## Progress in Chronic Disease Prevention

## Chronic Disease Reports: <br> Mortality Trends - United States, 1979-1986

CDC's National Center for Health Statistics (NCHS) has developed the system by which deaths are reported, coded, and tabulated to produce official U.S. mortality statistics (1). Crude and adjusted mortality rates as reported by NCHS are the standard for reporting mortality statistics. Some alternative approaches may be useful to focus on particular events of epidemiologic importance (2). This report describes U.S. mortality trends from 1979 to 1986 using two departures from standard mortality reporting: the data were age-adjusted to the 1980 total U.S. population, and in some cases, different International Classification of Diseases, Ninth Revision, Clinical Modification (ICD-9-CM) groupings were used to form diagnostic categories (e.g., chronic obstructive pulmonary disease [OPD] included only cases likely to be associated with smoking).

Between 1979 and 1986, the total age-standardized mortality rate in the United States declined by $8 \%$. However, this "average" change obscures considerable diversity in changing mortality rates for specific diseases: nine major chronic disease groupings demonstrated differing trends over this period (Figure 1). The largest decreases occurred for stroke (ICD-9-CM 430-434, 436-438)*, coronary heart disease (CHD) (ICD-9-CM 410-414, 429.2), and cirrhosis (ICD-9-CM 571) (Figure 1). In contrast, the portion of OPD likely to be related to smoking (ICD-9-CM 491, 492, 496) increased by $33 \%$ and lung cancer (ICD-9-CM 162), by $15 \%$. Three cancers showed diverse trends: female breast cancer (ICD-9-CM 174) increased by $5 \%$; colorectal cancer (ICD-9-CM 153, 154) declined by 7\%, and cervical cancer (ICD-9-CM 180) declined by $18 \%$. Diabetes mellitus (ICD-9-CM 250) decreased moderately (3\%) as an underlying cause of death.
Reported by: Office of the Director, Center for Chronic Disease Prevention and Health Promotion; Epidemiology and Surveillance Br, Div of Surveillance and Epidemiologic Studies, Epidemiology Program Office, CDC.
Editorial Note: The diverse trends in mortality for these nine diseases suggest that shared risk factors may have different effects. For example, the overall national prevalence of smoking declined by 13\% (from 33.5\% to 29.1\%) during 1979-1987 (3). During the same period, stroke and CHD mortality decreased substantially; in contrast, smoking-related OPD and lung cancer mortality markedly increased.
*See Chronic Disease Reports: Stroke figure and tables following this article.

## Mortality Trends - Continued

This diversity in the trends for smoking-related disorders may result from a combination of epidemiologic circumstances. Smoking is a stronger risk factor (i.e., is associated with greater relative risks) for lung cancer and this grouping of OPD than for stroke or heart disease (4). In addition, the latency between initiation of smoking and subsequent death is much longer for persons with pulmonary sequelae; recent mortality trends are thus less likely to be associated with recent trends in the risk factor. Finally, smoking may be the primary causative agent in lung cancer and this grouping of OPD, whereas smoking is only one of several interrelated risks for stroke and heart disease. Prevalences of these risks, which include hypertension, hypercholesterolemia, physical inactivity, and obesity, may have changed among the population in recent years (5).

The divergent trends in breast and cervical cancer mortality may also result from a variety of risk factors $(4,6)$, of which few are amenable to direct intervention. Effective screening tests are available for both cancers. The Pap smear for cervical cancer is a well-established clinical tool, and its use may account for some of the decline in cervical cancer mortality. However, efficacy of the Pap smear has never been directly tested nor a systematic national program for its application conducted. The screening mammogram, a more recent development, was effective in a controlled setting (7), but no systematic national program exists for the widespread dissemination of mammographic services. The lack of such a program may not directly contribute to the increase in mortality but could be important in the failure to demonstrate desired decreases. Finally, the age, race, and socioeconomic differences in survival patterns exhibited by persons with cervical or breast cancer, as well as by those with colorectal cancer (8), may also play an important role in current mortality trends.

FIGURE 1. Percent change in mortality and 1986 mortality, by selected chronic diseases - United States, 1979-1986

## Mortality Trends - Continued

Death attributed to a chronic disease results from a series of intertwined biologic and epidemiologic events, including interactions among risk factors, diseases, and coding practices. Although cause-specific mortality trends using nonstandard rubrics are a useful measure of overall effect, they must be interpreted cautiously. Nonstandard use of diagnostic categories provides opportunities for special epidemiologic focus, but care should be taken to make such use explicit.

## Hospital Discharge Rates for Cerebrovascular Disease United States, 1970-1986

Despite a nearly $50 \%$ decline in cerebrovascular mortality in the past 30 years, stroke remains the third leading cause of death and continues to be a major public health problem in the United States. The direct health-care costs of stroke were estimated to be approximately $\$ 3.3$ billion annually in 1976 (1). Hospitalizations represent more than one third of those costs.

This report describes national trends in hospital discharge rates from 1970 to 1986 for cerebrovascular disease and its components. The annual number of hospital discharges was determined from the first-listed diagnosis in the National Hospital Discharge Survey (NHDS) (2) of CDC's National Center for Health Statistics (NCHS).* Data for the NHDS are obtained from a multistage, stratified cluster sample of discharges from nonfederal short-stay hospitals in the 50 states and the District of

[^2]Cerebrovascular Disease - Continued
Columbia. The NHDS collects approximately 200,000 records a year. Each year, 3237-4577 patients in the sample were discharged with a first-listed diagnosis of cerebrovascular disease. Population estimates were determined from data provided by the Bureau of the Census (5) and Demo-Detail ${ }^{\dagger}$ (6).

The general category of cerebrovascular disease under both ICDA-8 and ICD-9-CM includes all discharged persons with a first-listed diagnosis of 430 through 438 (3,4). This grouping was subdivided for further analysis as follows: intracranial hemorrhage (ICDA-8: 430-431; ICD-9-CM: 430-432); occlusion of cerebral arteries (ICDA-8: 433-434; ICD-9-CM: 434); transient cerebral ischemia (ICDA-8 and ICD-9-CM: 435); acute ill-defined cerebrovascular disease (ICDA-8 and ICD-9-CM: 436); and other cerebrovascular disease (ICDA-8: 432, 437-438; ICD-9-CM: 433, 437-438) (7).

Observed changes in hospital discharge rates from 1978 to 1979 reflect a mixture of procedural changes in coding practices and real changes in hospitalization rates. ${ }^{5}$ For this reason, the following descriptions of trends from 1970 through 1986 omit changes in rates from 1978 to 1979 (Figures 1 and 2).

From 1970 through 1986, hospital discharge rates per 100,000 population for cerebrovascular disease ranged from a low of 254 in 1970 to a high of 384 in 1985. Hospital discharges per 100,000 population for cerebrovascular disease increased an average of 4.9 per year from 1970 through 1986. Rates increased every year except 1974-1975 and 1985-1986.

[^3]FIGURE 1. Hospital discharge rates per 100,000 persons for cerebrovascular diseases - United States, 1970-1986

Trends in hospital discharges per 100,000 population varied among the components of cerebrovascular disease. For intracranial hemorrhage, rates decreased from 26 in 1970 to 19 in 1976, then increased to 32 in 1986. For occlusion of cerebral arteries, rates remained relatively constant from 1970 through 1983, then rose from 45 in 1983 to 81 in 1986. For transient cerebral ischemia, rates increased from 12 in 1970 to 22 in 1978 and from 76 in 1979 to 88 in 1986 (with a peak of 94 in 1983). For acute ill-defined cerebrovascular disease, rates climbed from 97 in 1970 to 119 in 1978 and from 99 in 1979 to 121 in 1984; they declined to 104 in 1985 and to 92 in 1986. For other cerebrovascular diseases, hospital discharge rates increased from 75 in 1970 to 87 in 1972, fluctuated between 87 and 93 through 1984, then declined to 76 in 1986. Reported by: Office of Surveillance and Analysis, Center for Chronic Disease Prevention and Health Promotion, CDC.
Editorial Note: This report uses data on hospitalizations to identify trends for one important aspect of the health-care burden of cerebrovascular disease. Hospital discharge rates reflect a variety of influences and often do not correspond to trends in incidence or mortality rates (8). Since 1970, stroke mortality in the United States has declined. This change has been attributed in part to declining incidence resulting

FIGURE 2. Hospital discharge rates per 100,000 persons for components of cerebrovascular disease - United States, 1970-1986

from improvements in the detection and control of hypertension (9-11). The data in this report showed an increase in cerebrovascular disease hospitalization rates from 1970 through 1984. Additional evidence suggests that an increased detection of milder strokes may have contributed to increasing hospitalization rates (12,13). Declining hospitalization rates after 1984, together with declining mortality and case-fatality rates, may indicate a declining prevalence of disease.

This analysis showed the greatest decline in discharge rates after 1983 in the less specific disease categories (other cerebrovascular disease, acute ill-defined cerebrovascular disease, and transient cerebral ischemia) and the largest increases in discharge rates in the more specific diagnostic categories (intracranial hemorrhage and occlusion of cerebral arteries). Thus, the introduction of diagnostic related groups, which became widely used after 1983, may have stimulated increased use of more specific diagnoses. Increases in the use of computerized tomography and in elective hospitalization for endarterectomy may also have contributed to increased recognition of intracranial hemorrhage and occlusion of cerebral arteries from 1983 through 1986.

## School Policies and Programs on Smoking and Health United States, 1988

In 1988, the National School Boards Association (NSBA), in collaboration with the American Cancer Society, the American Heart Association, and the American Lung Association, conducted a random sample mail survey of 2000 of the more than 15,000 public school districts in the United States to gather information on school smoking policies and programs (1); 1310 ( $66 \%$ ) of the districts responded. A similar study was done in 1986 (2). Topics covered in the survey were districts' policies on tobacco smoking, development of school smoking policies, antismoking education programs in schools, assistance given to districts by voluntary health organizations, and demographics of each school district. Two hundred of the 690 nonrespondents were contacted and questioned by telephone; they were similar to respondents demographically and in their responses. Not all respondents answered all questions.

In 1988, 1239 (95\%) of all responding school districts had a written policy or regulation on tobacco smoking in schools; in 1986, 622 ( $87 \%$ ) of 714 school districts had a written policy or regulation. All the written policies addressed smoking by students, 1189 ( $96 \%$ ) addressed smoking by faculty/staff/administration, and 1140 ( $92 \%$ ) addressed smoking by other adults (e.g., parents, school visitors). Of the 71 (5\%) responding districts with no written policy, 31 (44\%) are considering developing such policies. Of the 1310 districts responding, 226 (17\%) totally banned smoking (no smoking allowed by anyone on school premises or at school functions). From 1986 to 1988, the proportion of districts prohibiting adults from smoking in school buildings, on school grounds, and at school-related functions more than doubled. For example, the proportion prohibiting smoking by faculty/staff/administrators in school buildings increased from $11 \%$ in 1986 to 289 (24\%) of 1188 in 1988.

Of the 1169 districts with written policies, 802 ( $69 \%$ ) had enacted these policies within the last 6 years. Health hazards of tobacco use continued to be the reason most respondents ( $914 / 1188$ [77\%]) cited for instituting a nonsmoking policy, followed by belief in adult role models (574/1188 [48\%]) and state or local antismoking legislation (525/1188 [44\%]). Smoking policies were initiated by school boards (307/1203 [26\%]), district administrations (226/1203 [19\%]), teachers (156/1203 [13\%]), building administration staff (143/1203 [12\%]), parents (69/1203 [6\%]), community (69/1203 [6\%]), students (63/1203 [5\%]), and other (48/1203 [4\%]).

Most districts (1078/1239 [87\%]) reported excellent or good compliance among faculty, and 1062 ( $86 \%$ ) of 1239 reported similar compliance among students. Reported compliance was much higher in districts with total smoking bans than in districts with some restrictions.

In 1988, 942 ( $75 \%$ ) of 1254 school districts had antismoking educational programs at the elementary school level, 1016 ( $81 \%$ ) at the middle school level, and 982 ( $78 \%$ ) at the high school level; in 1986, the corresponding proportions were $61 \%$ for elementary schools, $64 \%$ for middle schools, and $62 \%$ for high schools. Voluntary health organizations were involved in providing antismoking education in 74\% of the school districts.

## Smoking and Health - Continued

Editorial Note: Tobacco use by students remains a major public health problem. Approximately 3000 persons-most <21 years of age-begin to smoke each day in the United States $(3,4)$. The findings that $95 \%$ of school districts now have a written policy regarding smoking and that this proportion has been increasing are encouraging. Smoking bans in schools accomplish several goals: 1) they discourage students from starting to smoke; 2) they reinforce knowledge of the health hazards of cigarette smoking and exposure to environmental tobacco smoke; and 3) they promote a smoke-free environment as the norm. It is particularly important that smoking policies are now directed at adults as well as students. School policies that restrict smoking have always applied to the students, but from 1986 to 1988, the proportion of districts having smoking restrictions for faculty/staff/administrators and other adults attending school functions increased substantially.

The 1990 health objectives for the nation include as a target that all 50 states enact laws that prohibit smoking in enclosed public places (5). Based on the present survey, a completely smoke-free environment for schools has been achieved in 17\% of school districts. In accordance with its goal of eliminating smoking in the public schools, NSBA has published No Smoking: A Board Member's Guide to Nonsmoking Policies for the Schools (2), which includes the entire 1986 survey report, outlines implementation steps and guidelines concerning nonsmoking policies, and describes several antismoking school programs across the country.

The increase in antismoking instruction in schools is also encouraging. Studies show that such instruction, as part of a comprehensive school health education curriculum, is effective in preventing initiation of smoking among children and adolescents (6). A National Cancer Institute advisory panel on smoking and school health has developed recommendations for the essential elements of a school-based smoking prevention program (7). These elements include: emphasizing the social and short-term physiologic consequences of tobacco use; training students in refusal skills; involving parents, trained teachers, and peers in smoking-prevention activities; and designing a curriculum that reflects the needs of the community. The public health community has also identified the need to develop cessation programs for children and adolescents addicted to nicotine (4).

FIGURE I. Reported measles cases - United States, Weeks 8-11, 1989

The Morbidity and Mortality Weekly Report is prepared by the Centers for Disease Control, Atlanta, Georgia, and available on a paid subscription basis from the Superintendent of Documents, U.S. Government Printing Office, Washington, D.C. 20402, (202) 783-3238.

The data in this report are provisional, based on weekly reports to CDC by state health departments. The reporting week concludes at close of business on Friday; compiled data on a national basis are officially released to the public on the succeeding Friday. The editor welcomes accounts of interesting cases, outbreaks, environmental hazards, or other public health problems of current interest to health officials. Such reports and any other matters pertaining to editorial or other textual considerations should be addressed to: Editor, Morbidity and Mortality Weekly Report, Centers for Disease Control, Atlanta, Georgia 30333; telephone (404) 332-4555.

[^0]:    *Diagnoses for 1970-1978 are based on the International Classification of Diseases (ICD), Eighth Revision, Adapted (ICDA-8) (3); those for 1979-1986, on the ICD, Ninth Revision, Clinical Modification (ICD-9-CM) (4).

[^1]:    *Because AIDS cases are not received weekly from all reporting areas, comparison of weekly figures may be misleading.
    ${ }^{\dagger}$ Five of the 152 reported cases for this week were imported from a foreign country or can be directly traceable to a known internationally imported case within two generations.

[^2]:    *Mortality data in this table are voluntarily reported from 121 cities in the United States, most of which have populations of 100,000 or more. A death is reported by the place of its occurrence and by the week that the death certificate was filed. Fetal deaths are not included.
    **Pneumonia and influenza.
    $\dagger$ Because of changes in reporting methods in these 3 Pennsylvania cities, these numbers are partial counts for the current week.
    Complete counts will be available in 4 to 6 weeks.
    $\dagger \dagger$ Total includes unknown ages.
    §Data not available. Figures are estimates based on average of past available 4 weeks.

[^3]:    ${ }^{\dagger}$ Use of trade names is for identification only and does not imply endorsement by the Public Health Service or the U.S. Department of Health and Human Services.
    ${ }^{5}$ To assess the effects of changes in coding practices from ICDA-8 to ICD-9-CM, NCHS calculated comparability ratios for various diseases, including cerebrovascular diseases. The comparability ratio of a disease entity is defined as the ratio of the number of cases coded to a set of ICD codes under the old coding procedures to the number of cases coded to a set of codes (not necessarily identical) under the new coding procedures, when the coding procedures are applied to the same cases. To obtain its comparability ratios, NCHS recoded data from 1975 using ICD-9-CM procedures. Even the adjusted rates seem to be affected by changes in coding procedures from ICDA-8 to ICD-9-CM and therefore are not used in this report.
