## International Notes

## Measles - Hungary

Between December 1, 1988, and May 14, 1989, 19,080 measles cases in residents of Hungary were reported to Hungary's National Institute of Hygiene; in the previous 3 years, fewer than 25 cases were reported annually (Figure 1) (1). The overall incidence rate in this epidemic was 186 cases per 100,000 population. Budapest and all 19 counties in Hungary were affected, with county-specific attack rates ranging from 51 to 358 cases per 100,000 population. Six measles-associated deaths occurred (case-fatality rate: $0.03 \%$ ).

Source: National Institute of Hygiene, Hungary.
*Through May 14, 1989.

## Measles - Continued

Age data were available for 11,475 reported case-patients. Seventy-five percent of patients were 16-22 years of age. The highest age-specific attack rates (1723 and 1273 per 100,000 ) occurred in 17 - and 18 -year-olds, respectively (Figure 2). Attack rates for persons $2-15$ years of age ranged from 35 to 165 per 100,000. The attack rate for infants $<1$ year of age was 351 per 100,000.

Preliminary information on vaccine status indicates that an estimated $77 \%$ of 17-21-year-olds with measles had previously received live measles vaccine. Based on approximately $93 \%$ vaccine coverage, vaccine efficacy for persons in this age group (most of whom were vaccinated from 1969 through 1971) was an estimated 83\% (2).

Control measures implemented during the epidemic included mass revaccination of persons $16-22$ years of age regardless of previous vaccination history. During February and March 1989, 650,000 doses of vaccine were administered to this target group; reported cases subsequently declined (Figure 3).

Reported by: A Vass, MD, Head, Public Health and Epidemiology Div, Ministry of Health and Social Affairs; I Domok, MD, Deputy Director-General, I Straub, MD, Head, Dept of Epidemiology, National Institute of Hygiene, Hungary. Expanded Programme on Immunization, WHO Regional Office for Europe, Copenhagen, Denmark. Div of Environmental Hazards and Health Effects, Center for Environmental Health and Injury Control; Div of Immunization, Center for Prevention Svcs, CDC.
Editorial Note: In 1969, Hungary began measles vaccination efforts using the live, attenuated Leningrad-16 strain produced in the Soviet Union. From 1969 to 1974, a single dose of vaccine was administered in mass campaigns to persons 9-27 months of age. However, in 1974, mass campaigns were discontinued, and vaccine was administered during routine health care. The recommended age for vaccination was 10 months until 1978, when it was changed to 14 months. Coverage rates of targeted persons during the campaigns ranged from $93 \%$ to $99 \%$ and have been at least $98 \%$ since routine administration began in 1974 (3).

FIGURE 2. Measles attack rates per 100,000 population, by age in years and birth cohort - Hungary, 1988-1989*

Source: National Institute of Hygiene, Hungary.
*Through March 15, 1989.

## Measles - Continued

The vaccination program has had a major impact on the epidemiology and annual incidence of measles in Hungary (Figure 1). After vaccination was implemented, the incidence rate decreased until 1973-74, when large epidemics occurred primarily in unvaccinated $6-9$-year-olds. The annual incidence rate then decreased until 1980-81, when another epidemic occurred, primarily in 7-10-year-olds. After the epidemic, persons born between 1973 and 1977, who would have received vaccine when the recommended age was 10 months, were revaccinated. Subsequently, the annual incidence rate for measles decreased until 1988 ( 3,4 ).

Investigation of this epidemic has prompted concern about the roles of primary vaccine failure (unsuccessful initial vaccination) and secondary vaccine failure (loss of immunity after successful vaccination). The 1988-89 epidemic mainly affected persons 17-21 years of age, who had been targeted to receive vaccine during mass campaigns in the first years of the vaccination program in Hungary. The high agespecific attack rates in this age group, in which vaccine coverage was at least $93 \%$, suggest that vaccine failure played a major role in this epidemic.

Primary vaccine failure may have occurred as a result of poor vaccine handling practices during the early campaigns, vaccination at about 10 months of age when maternal antibody could interfere with successful vaccination, or thermolability of the vaccine used at that time. Secondary vaccine failure has been suspected because persons most affected in this epidemic were vaccinated in the more distant past. Assessing waning immunity may be difficult because virtually all persons 17-21 years of age were vaccinated approximately the same number of years before the epidemic. Few persons 11-16 years of age were single-dose recipients, since they were revaccinated after the 1981 epidemic.

Epidemiologic studies are under way to further assess the epidemic, determine risk factors for vaccine failure, and more accurately determine vaccine efficacy. Data gathered may be of interest to all countries with measles-control programs and elimination goals.

## Current Trends

## Lyme Disease - United States, 1987 and 1988

In 1987 and 1988, CDC surveyed state health departments for reported cases of Lyme disease (LD [Lyme borreliosis]); in 1987, 2368 cases meeting the case definition* of their respective states were reported, and in 1988, 4572 cases were reported. Demographic data were available for $54 \%$ of reported cases: $92 \%$ were white, $4 \%$ Hispanic, $2 \%$ black, and $2 \%$ Asian; $51 \%$ of cases occurred in females. Age-specific incidence rates were highest for children $<15$ years of age and for persons $25-44$ years of age ( 0.2 per 100,000 population). In the Northeast and North Central regions, $64 \%$ of LD patients had onset of illness from May through August; in comparison, in the Pacific region, where 33\% of patients had onset in these months, more cases occurred from January through May.

In 1987 and 1988, cases were reported from all states; however, in nine states, infection was thought to have been acquired out of state (Figure 1). Indigenous cases now have been reported in all states except Alaska, Arizona, Hawaii, Montana, Nebraska, New Mexico, and Wyoming. (Missouri and Nevada did not report indigenous cases in 1987 or 1988 but had done so previously.) In 1987 and 1988, 94\% of U.S. cases were reported from nine states: New York, New Jersey, Wisconsin, Connecticut, Pennsylvania, Rhode Island, California, Massachusetts, and Minnesota; the six states in the upper northeast accounted for $80 \%$ of all cases. In 1988, New York state reported $56 \%$ of all cases, and two suburban counties of New York City (Westchester and Suffolk) reported $44 \%$ of U.S. cases. LD remains rare in the Mountain region, where, in 1987 and 1988, five cases were reported, and nine cases have been reported since 1980.

Estimates of regional incidence (per 100,000 persons) varied approximately 100fold: 6.1 in the Mid-Atlantic region, 3.7 in New England, 0.7 in the North Central states, 0.6 in the Pacific states (1987 data only), 0.2 in 16 Southeast and Southwest states, and $<0.1$ in the Mountain region (2).
Reported by: State and local health departments. Div of Vector-Borne Infectious Diseases, Center for Infectious Diseases, CDC.

[^0]Editorial Note: National surveillance for LD relies on states for reports. Since 1982, when national surveillance began, state surveillance systems for LD have changed considerably. LD has been made a reportable disease in 31 states and the District of Columbia, and surveillance for LD has intensified, especially in areas where the disease is endemic.

Since 1982, 13,825 cases of LD have been reported. From 1982 through 1987, the number of cases increased nearly fivefold from 492 to 2368 ; in 1988, reported cases doubled (4572 cases) (Figure 2). LD is the most commonly reported vectorborne disease in the United States (Figure 3). From 1983 through 1987, LD accounted for $50 \%$ of the vectorborne infections reported to CDC. Tickborne diseases (e.g., LD, Rocky Mountain spotted fever [RMSF]) accounted for $95 \%$ of these infections; fleaborne typhus and plague and mosquitoborne arboviral infections accounted for the remaining 5\%.

The increased incidence of reported LD probably is due to improved awareness and recognition of the disease, as well as to an actual increase in incidence and geographic spread. Other factors may also contribute to the increase. For example, because the clinical and laboratory diagnosis of LD may be imprecise (3), other conditions possibly may be misdiagnosed and reported as LD. In addition to differences in clinical interpretation of erythema migrans (EM), misdiagnosis may also result from the lack of standardization of serologic testing and from crossreactivity with Treponema and with other Borrelia (3). In areas with endemic LD, persons with illnesses other than LD-but who previously have been infected with B. burgdorferi (the causative agent for LD) - also may be misdiagnosed (4). Conversely, several factors may be responsible for failure of a case of LD to be diagnosed and/or to meet the case definition. These include early treatment of symptoms resulting in abrogation of the specific antibody response (3), the low sensitivity of

FIGURE 1. Number and average annual incidence rates of reported Lyme disease cases, per 100,000 population - United States, 1987-1988*

*Data for Oregon and California are for 1987 only.

Lyme Disease: United States - Continued
serologic tests in early LD (3), and the failure of approximately $25 \%$ of LD patients to manifest EM $(4,5)$. The extent of underreporting of LD is unknown.

Until more sensitive and specific laboratory diagnostic tests become available, diagnosis of LD relies predominantly on clinical features. Serologic testing may be of greatest diagnostic utility in patients who have symptoms compatible with late-stage LD. The validity of serologic test results depends largely on the experience of the diagnostic laboratory and its quality-control procedures. No published data exist on the diagnostic utility of antigen-detection assays in the laboratory diagnosis of LD. A comparative study of licensed LD diagnostic kits is planned by the Association of State and Public Health Laboratory Directors.

FIGURE 2. Reported cases of Lyme disease, by year - United States, 1982-1988

FIGURE 3. Reported cases of vectorborne diseases - United States, 1983-1987

## Lyme Disease: United States - Continued

State- and community-based epidemiologic studies have documented an increase in human cases and an expansion of affected areas (5-8). Entomologic surveys have detected local increases of Ixodes dammini, the principal tick vector in northeastern and central states, and its spread to new areas ( $7-10$ ). However, because the risk for acquiring LD varies widely by locality, the disease appears to be of public health consequence only in certain regions-specifically, coastal counties on both seaboards and in certain counties in the upper Midwest. In the southeastern, southwestern, and Mountain states, RMSF remains the leading vectorborne disease: from 1983 through 1987, 3160 RMSF and 658 LD cases were reported from the Southeast and Southwest, and 37 RMSF and seven LD cases were reported from the Mountain states.

Data concerning risk factors for acquiring LD are limited. In suburban areas where LD is endemic, infection may be acquired principally around patients' residences $(11,12)$, and risk of exposure may be continuous during the transmission season. Under these circumstances, certain personal protection measures (e.g., the daily application of repellents) may not be practical. Further efforts are needed to evaluate the effectiveness of environmental modifications and focal application of acaricides (chemicals effective against ticks) for the control of vector ticks in these circumstances. Where LD is transmitted sporadically through occasional or brief exposures during recreation or work, personal protection measures are most appropriate for prevention.

Measures recommended to reduce exposure to ticks include avoiding areas endemic for LD; using repellents; wearing long-sleeved shirts and long pants, and tucking pants into the top of socks; wearing light-colored clothing; and inspecting clothing and skin frequently for ticks. Animal studies suggest that I. dammini may not efficiently transmit infection until after 48 hours of attachment and that prompt removal of attached ticks may limit transmission (13). However, it is unknown how long a tick must attach to human hosts before infection occurs.
$\mathrm{N}, \mathrm{N}$-diethyl-m-toluamide (DEET) is effective in repelling I. dammini and other vector ticks. In view of the possible risk for toxicity (14), the use of DEET-containing repellents solely to prevent LD may be inappropriate in areas without endemic LD. Permethrin $(0.5 \%)$ sprayed onto clothing also is effective in reducing the numbers of adherent ticks, including I. dammini and others ( 15,16 ). However, permethrin aerosols are available only in certain states that have obtained Environmental Protection Agency approval for their distribution.

## International Notes

## Lyme Disease - Canada

From 1977 through May 1989, 30 cases of Lyme disease (LD [Lyme borreliosis]) were reported to Canada's Laboratory Centre for Disease Control (LCDC). Ontario is the only province in which LD is a reportable condition; however, active laboratory surveillance for LD is conducted in other provinces. In Ontario, the diagnosis of LD is based on recognition of erythema migrans (EM), with involvement of at least two of the three organ systems usually affected by LD (joints, nervous system, and cardiovascular system), or EM and an indirect immunofluorescence antibody titer $\geqslant 1: 128$ or an enzyme-linked immunosorbent assay optical density $\geqslant 0.40$, or EM and isolation of Borrelia burgdorferi. Without EM, diagnosis is based on involvement of at least one organ system and positive serology or isolation (C. LeBer, Ontario Ministry of Health, personal communication, 1989).

For 25 ( $83 \%$ ) of the 30 cases, exposure probably occurred in Canada. Four patients had a documented history of tick bite during travel to the southeastern United States before onset of symptoms; one case was acquired in Germany. Seventeen (68\%) of the 25 indigenous cases were reported in Ontario, and five (20\%), in Manitoba (Figure 1). The areas in Canada with the highest number of cases border on the American states with the highest reported incidence of LD.

Sixteen ( $53 \%$ ) of the 30 cases occurred in 1988. Of the 25 cases for which month of onset was reported, cases occurred most commonly in July (28\%) and June (16\%). The mean age of LD patients was 40 years (range: 18 months to 70 years). Males accounted for $53 \%$ of all cases.

A tick bite was documented for $47 \%$ of the patients; the remainder had either no history of a bite or no available information. For $48 \%$ of LD patients, EM was documented. The most frequently documented presenting symptom was rash (38\%),

FIGURE 1. Distribution of indigenous Lyme disease cases, by province - Canada, 1977-1989

Lyme Disease: Canada - Continued
followed by arthralgia/arthritis (28\%) and influenza-like illness (13\%). Most had multiple symptoms; five patients had neurologic involvement. Five (17\%) of the 30 LD patients were hospitalized.
Comment: In several provinces, studies are being planned to determine the prevalence of infected vectors in Canada. The Department of Entomology, University of Manitoba, identified, and the Smithsonian Institution in Washington, D.C., confirmed, two female lxodes dammini ticks collected in Gunton and Winnipeg, Manitoba, in May and June 1989. These are the first reports of this vector species in Manitoba. The only other Canadian reports are from Long Point, Ontario. Intensive sampling efforts for l. dammini in other regions of Manitoba in 1989 found only Dermacentor variabilis (American dog tick).

To acquire more complete incidence data for Canada, LCDC is interested in receiving reports of any additional cases through provincial/ territorial epidemiologists.
Adapted from: Canada Diseases Weekly Report 1989;15:135-7 and 1989;15:185, as reported by: MJ Todd, MHSc, AO Carter, MD, Disease Surveillance, Bureau of Communicable Disease Epidemiology, Laboratory Centre for Disease Control, Ottawa, Ontario; TD Galloway, PhD, Dept of Entomology, Univ of Manitoba, Winnipeg.

## Epidemiologic Notes and Reports

## Seizures Temporally Associated with Use of DEET Insect Repellent New York and Connecticut

In August 1989, epidemiologists from the New York State Department of Health (NYSDH) investigated five reports of generalized seizures temporally associated with topical use of N,N-diethyl-m-toluamide (DEET). Three of the case-patients, one from New York and two from Connecticut, were reported by a pediatric neurologist who practices in both states. One case was reported initially to an entomologist in New York, and one was reported directly to the NYSDH. The cases occurred in June through August 1989.

The patients, four boys aged 3-7 years and one 29 -year-old man, had few prodromal symptoms and recovered quickly. All five had unremarkable medical histories, and none had had a previous seizure or neurologic event. All had normal nonfocal neurologic examinations after their seizures, and four had normal complete laboratory examinations and normal computerized tomography and/or magnetic resonance imaging examinations. Each had had topical cutaneous exposure to varying concentrations of DEET; four had had fewer than three applications. The interval between last use of DEET and onset of seizures ranged from 8 to 48 hours. One patient developed urticaria before his seizure; he was one of two patients who developed an urticarial reaction to phenytoin administered to control seizures.

While reinforcing the importance of DEET in preventing Lyme disease (LD [Lyme borreliosis]), health officials in New York, Connecticut, and New Jersey issued a health alert on August 22 advising caution in the use of DEET-containing repellents. The NYSDH is planning to conduct epidemiologic studies to evaluate the association between DEET and neurologic events.

DEET - Continued
Reported by: S Oransky, MD, Hudson Valley Poison Control Center, Nyack; B Roseman, MD, Pediatric Neurologic Associates, White Plains; D Fish, PhD, Medical Entomology Laboratory, New York Medical College, Valhalla; T Gentile, MS, Center for Environmental Health, J Melius, MD, State Environmental Epidemiologist, New York State Dept of Health. ML Cartter, MD, JL Hadler, MD, State Epidemiologist, Connecticut State Dept of Health Svcs. Div of Environmental Hazards and Health Effects, Center for Environmental Health and Injury Control; Div of Vector-Borne Infectious Diseases, Center for Infectious Diseases; Div of Field Svcs, Epidemiology Program Office, CDC.
Editorial Note: For health officials in New York and Connecticut, two of the states where LD is of growing concern, inquiries about the potential adverse effects of insect repellents have increased. Recent anecdotal reports of seizures temporally associated with the use of DEET have heightened public awareness of DEET's potential adverse effects.

DEET has been marketed in the United States since 1956 and is used by an estimated 50-100 million persons each year. Since 1961, at least six cases of toxic systemic reactions from repeated cutaneous exposure to DEET have been reported (1-6). Six girls, ranging in age from 17 months to 8 years, developed behavioral changes, ataxia, encephalopathy, seizures, and/or coma after repeated cutaneous exposure to DEET; three died. Another six systemic toxic reactions have been reported following ingestion of DEET (7). Additionally, episodes of confusion, irritability, and insomnia have been reported by Everglades National Park employees following repeated and prolonged use of DEET (8).

DEET is partially absorbed through the skin and has been used to enhance dermal delivery of other drugs (9). Adverse reactions include allergic responses, direct neurotoxicity, and dermatitis. One of the girls who died after dermal exposure was partially deficient in the enzyme ornithine carbamoyltransferase (3); DEET may interfere with the urea cycle metabolic pathway (10).

Anecdotal reports of seizures are difficult to interpret. None of the recent cases in New York and Connecticut have been clearly established as DEET toxicity. In contrast to cases described in the medical literature, the New York and Connecticut patients were all male, DEET exposure was less intense, few prodromal symptoms or encephalopathy were seen, and recovery was more rapid and complete. With the dramatic increase in the prevalence of DEET use in areas with endemic LD, the reported cases of seizures temporally related to DEET use may be coincidental. However, these cases may represent a different, previously unreported spectrum of toxic reactions. Careful toxicologic and epidemiologic studies must be conducted, including adequate documentation of DEET levels in affected and unaffected persons.

Clinicians evaluating patients with unexplained seizures should consider the possibility of exposure to DEET. However, since the exact circumstances under which DEET-related neurotoxicity may occur are unclear, DEET should not be accepted as the cause of a seizure until appropriate evaluation has reliably excluded other possible etiologies.

The optimal concentration of DEET for prevention of tick bites is unknown. However, repellents containing $20 \%-30 \%$ DEET applied to clothing are approximately $90 \%$ effective in preventing tick attachment (11). To minimize the possibility of adverse reactions to DEET, the following precautions are suggested:

- Apply repellent sparingly only to exposed skin or clothing.
- Avoid applying high-concentration products to the skin, particularly of children.
- Do not inhale or ingest repellents or get them into the eyes.
- Wear long sleeves and long pants, when possible, and apply repellent to clothing to reduce exposure to DEET.
- Avoid applying repellents to portions of children's hands that are likely to have contact with eyes or mouth.
- Never use repellents on wounds or irritated skin.
- Use repellent sparingly; one application will last 4-8 hours. Saturation does not increase efficacy.
- Wash repellent-treated skin after coming indoors.
- If a suspected reaction to insect repellents occurs, wash treated skin, and call a physician. Take the repellent can to the physician.

Specific medical information about the active ingredients in insect repellents is available from the National Pesticide Telecommunications Network, telephone (800) 858-7378.

## Deaths Associated with Hurricane Hugo - Puerto Rico

At 9 a.m. eastern daylight time on Monday, September 18, 1989, the eye of Hugo, the North Caribbean's strongest hurricane (a category four on a scale of five) in a decade, struck the northeast corner of Puerto Rico. Hugo's path extended from the Lesser Antilles and the Virgin Islands (where it struck on September 17) to South Carolina and areas of North Carolina (where it came ashore during the late evening and early morning of September 21-22). Wind velocities in San Juan were measured at up to 100 mph ; wind gusts elsewhere measured as high as 140 mph . These winds

## Hurricane-Related Deaths - Continued

damaged nearly $25 \%$ of homes on Puerto Rico, left approximately $75 \%$ of the island without power, and created 30 -foot swells off the east coast. Heavy rains accompanying the hurricane caused some flash flooding.

From September 18 to September 29, the medical examiner in Puerto Rico investigated nine deaths considered to be related to the hurricane. One death (case 1) occurred before the storm (preimpact phase); two (cases 2 and 3), during the storm (impact phase); and six (cases 4-9), after the storm (postimpact). The medical examiner categorized the manner of death for all cases as "accident."*

Case 1. A 57 -year-old man was electrocuted while trying to remove an outside television antenna before the storm.

Case 2. A 94 -year-old woman drowned while waiting out the storm in her home.
Case 3. A 60 -year-old man drowned on his boat during the storm.
Cases 4-8. Five electric company workmen, ages 28, 30, 35, 37, and 42 years, were electrocuted in five separate incidents while attempting to repair downed power lines after the storm.

Case 9. A 35 -year-old man was electrocuted when he contacted an electric cable lying on the ground where he was chopping a tree.
Reported by: PRechani, PhD, Director, Instituto de Sciencias Forenses de Puerto Rico, San Juan; JV Rullan, MD, State Epidemiologist, Div of Epidemiology, Puerto Rico Dept of Health. Div of Field Svcs, Epidemiology Program Office; Div of Environmental Hazards and Health Effects, Center for Environmental Health and Injury Control; Div of Safety Research, National Institute for Occupational Safety and Health, CDC.
Editorial Note: In the past, hurricane-related mortality has occurred primarily as a result of drownings during the impact phase. Most of these drownings have been associated with storm surges rather than heavy rains (1). For most parts of the world, however, this pattern may be changing. This decrease in impact-phase drownings may be a consequence of improved forecasting and early warnings about approaching hurricanes, as well as increased compliance of persons potentially at risk with effective evacuation programs.

The principal public health response to Hurricane Hugo was early warning and a coordinated evacuation plan. By the evening of Sunday, September 17, Puerto Rican officials had evacuated $>18,000$ persons who were residing in low-lying, flood-prone areas. Cases 2 and 3 were the only impact-phase deaths in Puerto Rico. Despite repeated pleas from government authorities, these persons refused to leave their property and move to temporary shelters.

The contribution to mortality of causes other than impact-phase drownings was highlighted by Tropical Storm Isabelle, which struck Puerto Rico in 1985. Of the 95 deaths investigated by the medical examiner, $21(22 \%)$ resulted from drowning; the rest resulted from other traumatic injuries, primarily associated with a landslide and collapsed bridges (CDC, unpublished data, 1987).

Public health officials and health-care providers must recognize that the mortality and morbidity risks associated with hurricanes extend beyond the impact phase. Efforts to minimize injury and other health risks for both disaster-relief workers and the general population are crucial. These risks include electric hazards, floodwaters, lacerations from storm debris and unfamiliar equipment (e.g., chain saws), operation

of motorized vehicles, use of sump pumps and generators in confined spaces, and exacerbation of existing or unknown medical conditions as a result of fatigue, stress, or unavailable medical support.

CDC and other Public Health Service agencies are providing assistance to the Virgin Islands, Puerto Rico, South Carolina, and other areas affected by Hurricane Hugo. At least five of the seven electrocutions reported here were work-related. A Fatal Accident Circumstance and Epidemiology (FACE) team from the National Institute for Occupational Safety and Health, CDC, has arrived in Puerto Rico to assist local health officials in the investigation of the occupational fatalities that occurred during the postimpact phase.

FIGURE I. Reported measles cases - United States, weeks 35-38, 1989

The Morbidity and Mortality Weekly Report is prepared by the Centers for Disease Control, Atlanta, Georgia, and available on a paid subscription basis from the Superintendent of Documents, U.S. Government Printing Office, Washington, D.C. 20402, (202) 783-3238.

The data in this report are provisional, based on weekly reports to CDC by state health departments. The reporting week concludes at close of business on Friday; compiled data on a national basis are officially released to the public on the succeeding Friday. The editor welcomes accounts of interesting cases, outbreaks, environmental hazards, or other public health problems of current interest to health officials. Such reports and any other matters pertaining to editorial or other textual considerations should be addressed to: Editor, Morbidity and Mortality Weekly Report, Centers for Disease Control, Atlanta, Georgia 30333; telephone (404) 332-4555.

[^0]:    *The surveillance case definition for LD varies among states and between states and CDC. Some states use the CDC case definition adopted in 1988, i.e., physician-diagnosed erythema migrans (EM) in a person who acquired infection in a county with endemic LD or, for persons who acquired infection in a county without endemic LD, laboratory evidence of infection in addition to the presence of EM. Other states (e.g., New York, Wisconsin, Connecticut) use a previous, more inclusive, CDC case definition for LD, which counts as cases persons with appropriate systemic manifestations and laboratory evidence of infection (1). Differences in the case definitions used by states must be considered when state and regional incidences are compared.

[^1]:    *Because AIDS cases are not received weekly from all reporting areas, comparison of weekly figures may be misleading.
    ${ }^{\dagger}$ One of the 160 reported cases for this week were imported from a foreign country or can be directly traceable to a known internationally imported case within two generations.

[^2]:    *Mortality data in this table are voluntarily reported from 121 cities in the United States, most of which have populations of 100,000 or more. A death is reported by the place of its occurrence and by the week that the death certificate was filed. Fetal deaths are not included.
    **Pneumonia and influenza.
    tBecause of changes in reporting methods in these 3 Pennsylvania cities, these numbers are partial counts for the current week. Complete counts will be available in 4 to 6 weeks.
    $\dagger \dagger$ Total includes unknown ages.

[^3]:    *"Manner of death" and "accident" are medicolegal terms used on death certificates that refer to the circumstances under which a death occurs; "cause of death" refers to the injury or illness responsible for the death. When a death occurs under "accidental" circumstances, the preferred term within the public health community for the cause of death is "unintentional injury."
