Abstract

Background—Controversy exists about the incremental utility of nontraditional lipid biomarkers [e.g., apolipoprotein (apo) B, apo A-I, and non-HDL-C] in improving cardiovascular disease (CVD) risk prediction when added to a conventional model of traditional risk factors (e.g., total cholesterol, LDL cholesterol, HDL cholesterol, sex, age, smoking status, and blood pressure). Here we present a systematic review that was conducted to assess the use of nontraditional lipid biomarkers including apo B, apo A-I, apo B/A-I ratio, and non-HDL-C in improving CVD risk

prediction after controlling for the traditional risk factors in populations at risk for cardiovascular events.

Content—This systematic review used the Laboratory Medicine Best Practices (LMBP™) A-6 methods. A total of 9 relevant studies published before and including July 2015 comprised the evidence base for this review. Results from this systematic review indicated that after the adjustment for standard nonlipid and lipid CVD risk factors, nontraditional apolipoprotein biomarkers apo B (overall effect = relative risk: 1.31; 95% CI, 1.22–1.40; 4 studies) and apo B/apo A-I ratio (overall effect = relative risk: 1.31; 95% CI, 1.11–1.38; 7 studies) resulted in significant improvement in long-term CVD risk assessment.

Summary—Available evidence showed that nontraditional lipid biomarkers apo B and apo B/apo A-I ratio can improve the risk prediction for cardiovascular events after controlling for the traditional risk factors for the populations at risk. However, because of insufficient evidence, no conclusions could be made for the effectiveness of apo A-I and non-HDL-C lipid markers to predict the CVD events, indicating a need for more research in this field.

Cardiovascular disease (CVD)⁸ remains the leading cause of death and inpatient hospital care in the United States (1–4). Research has shown that approximately 50% of population-attributable risk of developing CVD is associated with abnormalities in lipid biomarker profile (5). Most of the existing guidelines have used traditional lipid levels and other risk factors, namely total cholesterol (TC), LDL cholesterol (LDL-C), HDL cholesterol (HDL-C), triglycerides (TG), and nonlipid risk factors, e.g., high blood pressure, cigarette smoking, diabetes, age, sex, diet, and obesity, as risk factor scores for CVD risk prediction (6, 7). Based on recent studies, there is a growing interest to investigate whether nontraditional lipid-related markers add incremental value to standard prognostic models containing information on TC, HDL-C, and other conventional risk factors and can improve the CVD risk prediction (5). The utility of nontraditional markers in risk assessment is best examined by combining them with a model that includes traditional risk factors (8, 9). Non-HDL cholesterol (non-HDL-C), apolipoprotein (apo) B, and apo A-I are among the most investigated nontraditional lipid biomarkers and hence were the focus of this study (10–12).

QUALITY GAP: LIPID BIOMARKERS AND CVD RISK

Traditional risk factors provide estimates of plasma pool sizes and do not necessarily relate to the flux of cholesterol between lipoproteins and tissues, which may be more relevant to the process of atherosclerosis. Controversy exists about the effectiveness of traditional lipid tests to accurately predict risk of cardiovascular events, causing potential for missed opportunities for prevention and leading to suboptimal clinical management because these do not (a) account for the variability in cholesterol subfraction content, (b) measure lipoprotein particle size and number, or (c) provide information suggestive of changes associated with insulin resistance progression. Two major trends may be further compromising the ability of LDL-C to serve as the best surrogate for atherogenic lipoproteins to target CVD risk reduction. First, the prevalence of obesity in the US remains high

⁸**Nonstandard abbreviations:** CVD, cardiovascular disease; TC, total cholesterol; LDL-C, LDL cholesterol; HDL-C, HDL cholesterol; TG, triglycerides; apo, apolipoprotein; LMBP, Laboratory Medicine Best Practices; ATP, Adult Treatment Panel.

(13), leading to a higher prevalence of mixed dyslipidemia and more discrepancies between LDL-C and other lipoproteins such as apo B, LDL particle number, and non-HDL-C (14–16). Second, evidence suggests that even when LDL-C is within the normal range, significant residual cardiovascular risk remains (17). Because a majority of patients on conventional lipid-lowering treatment have either diabetes or some component of the metabolic syndrome, there is an increasing need to identify the degree of residual cardiovascular risk (14–16, 18–20).

The objective of this review was to evaluate the available evidence to compare the incremental utility of apolipoprotein and non-HDL lipid bio-markers to the traditional lipid measures (e.g., TC, TG, HDL-C) and other nonlipid standard risk factors (e.g., smoking status, high blood pressure, type 2 diabetes) for risk prediction of CVD events. For the purposes of this review, cardiovascular events of interest included ischemic heart disease, congestive heart failure, stable angina, unstable angina, myocardial infarction, and CVD death.

DESCRIPTION OF EVALUATED PRACTICES

This review evaluated the effectiveness of the following 4 biomarkers (practices) to improve the prediction of CVD events when added to traditional lipid biomarkers (e.g., TC, HDL-C): (i) apo B; (ii) apo A-I; (iii) apo B/apo A-I ratio; and (iv) non-HDL cholesterol (non-HDL-C).

Apo B

Apo B is the primary apolipoprotein of chylomicrons, VLDL, intermediate-density lipoprotein, and LDL particles (14, 21, 22). Importantly, there is 1 apo B-100 molecule per hepatic-derived lipoprotein; hence, measurement of apo B can quantify the number of lipoprotein particles by noting the total apo B-100 concentration in the circulation (more specific to LDL particle concentration) (23). Furthermore, high levels of apo B are indicative of a higher risk even when LDL-C or non-HDL-C levels commonly stay low in highly atherogenic states such as the metabolic syndrome and type 2 diabetes (24, 25). Prospective studies suggest that concentrations of apo B are superior indicators of vascular/heart disease and CVD risk prediction than standard lipid profile, e.g., TC and LDL-C (22, 26–31).

Apo A-I

Apo A-I is the major apolipoprotein in the HDL particles (32), accounting for 70% of all HDL-associated proteins (16) and mediates many of the anti-atherogenic functions of HDL (33). HDL-C levels are inversely correlated with risk for CVD, but HDL-C is heterogeneous in composition and size and varies widely across patients; thus, apo A-I is potentially more accurate than HDL-C in reflecting the “atheroprotective” potential of lipid metabolism (16, 18, 32).

Apo B/A-I ratio

The apolipoprotein B/A-I ratio is used as a measure of the proatherogenic to anti-atherogenic cholesterol (34). It was found to be strongly associated with CVD risk, (16, 29, 35, 36) and in some cases more than that of other cholesterol ratios (34, 36). Furthermore,

compared to other lipid ratios, apolipoprotein B/A-I ratio may be more accurate in risk prediction, particularly among high-risk individuals (37).

Non-HDL-C

Non-HDL-C is the difference between the TC concentration and the HDL-C concentration, providing an estimate of cholesterol in the atherogenic particles including intermediate-density lipoprotein, VLDL, lipoprotein(a), and LDL (31, 38). Although the CVD risk prediction is based on the increased concentrations of TC (39, 40), mostly from increased LDL-C, research has shown the utility of non-HDL-C in the prevention of CVD (41) and varying CVD risk prediction across several studies (11, 18, 25, 28, 31, 36, 42). The latest guidelines for both European and American Cardiological Societies emphasize the importance of this parameter for assessing the risk of atherosclerosis and coronary heart disease.

METHODS

This systematic evidence review was conducted using the Laboratory Medicine Best Practices (LMBP) Initiative's "A-6" systematic review methods, which is reported in detail elsewhere (43) (LMBP™ website). In brief, the process includes formation of a review team that includes a review coordinator, data abstractors, CDC liaison, and subject matter experts (expert panel team) with the expertise in the area of cardiovascular medicine, laboratory management, and evidence review methods. The team worked under the oversight of the LMBP Workgroup. Supplemental Appendix A lists the members of the expert panel team for this review; see the Data Supplement that accompanies the online version of this article at <http://www.jalm.org/content/vol1/issue2>. The results of the evidence-based best practice are presented to and approved by the LMBP Work-group team (Supplemental Appendix B lists the LMBP Workgroup members; see the online Data Supplement).

Ask (A-1): review question and analytic framework

Review question—What practices are effective at improving the risk prediction (or risk estimation) for CVD events among the populations at risk, specifically ischemic heart disease, congestive heart failure, angina, myocardial infarction, and CVD death, when supplemented to the traditional lipid (e.g., TC, LDL, TG, and HDL) and nonlipid (e.g., age, sex, smoking status, and blood pressure) risk factors?

This review question is addressed in the context of an analytic framework as depicted in Fig. 1.

The following were the relevant Population, Intervention/Practice, Comparator, and Outcome (PICO) elements considered for this review.

Population

- Men (>35 years)
- Women (>45 years)

- Younger adults (< 20 years) with multiple cardiovascular risk factors for CVD
- No previously diagnosed CVD or diabetes at baseline
- In ambulatory (including primary, specialty care) and inpatient settings

Interventions: Practices using nonstandard lipo-protein measurements in addition to the existing traditional risk factors (e.g., TC, TG, LDL-C, HDL-C, age, sex, smoking status, and blood pressure) for calculating cardiovascular risk assessment. The following lipid biomarkers were considered for this review:

- Apo B
- Apo A-I
- Apo B/apo A-I ratio
- Non-HDL-C

Comparison: Practices using traditional risk factors (e.g., TC and HDL-C, age, sex, smoking status, and blood pressure) alone to calculate CVD risk prediction.

Outcome: Improvement in the 10-year risk prediction of CVD events (e.g., myocardial infarction, ischemic heart disease, and CVD death) upon adding the nonstandard biomarker. Studies with follow-up period <10 years were still included in the review but were penalized in the study quality rating because of type 1 censoring of the findings (44).

Inclusion/exclusion criteria for studies to be included in this review

Inclusion criteria—To meet the eligibility criteria for this review, a study had to (a) address one or more of the proposed practices of interest in the context of CVD outcomes; (b) target populations in the studies who met the population criteria—that is, at-risk populations described above, with no previously diagnosed CVD or diabetes; (c) report the outcome(s) of interest—that is, improvement in the 10-year risk prediction of CVD events (e.g., myocardial infarction, CVD death) due to the addition of 1 of the 4 practices; and (d) provide comparison data to calculate the effectiveness of practices of interest (e.g., pre- and post-intervention data, concurrent comparison data).

In addition, interventions were considered to be included in this review if the biomarker of interest was added to a model or algorithm of the traditional lipid profile (e.g., TC, TG, HDL-C) and other risk factor (e.g., high blood pressure, cigarette smoking, diabetes, family history of premature heart disease, age, sex, diet, obesity, and physical inactivity) for predicting CVD risk. The practices were considered individually (e.g., the combination of apo B and non-HDL-C simultaneously added into a model was not considered a practice of interest), unless the results for the effectiveness of each practice was reported separately. A practice was considered effective if the fit of a model containing all traditional risk factors was significantly improved through the addition of a practice.

Exclusion criteria—The exclusion criteria were as follows: (a) previously diagnosed CVD or symptomatic coronary artery disease at baseline and (b) previously diagnosed diabetes at baseline.

Acquire (A-2): search for evidence

A comprehensive electronic literature search was conducted to retrieve the relevant evidence published before and including July 2015. Three databases were used for a formal literature search: PubMed, CINAHL, and EMBASE (focusing on international biomedical literature). Details of the formal literature search strategy can be found in Supplemental Appendix C (see the online Data Supplement). In addition, the systematic review team used other sources to locate relevant studies including hand searches (e.g., the citations from retrieved studies, Google scholar) and referrals from the experts in the field (e.g., expert panel team). To collect relevant unpublished data, researchers in the field, laboratories, and institutions were invited through personal requests and the LMBP website, but the review team did not receive any relevant unpublished data to be included in this review.

Appraise (A-3): screening, data abstraction, and quality scoring of individual studies

During the initial screening process, studies were excluded if they did not satisfy the inclusion criteria for this review as described in a previous section. Each eligible study was abstracted and assessed for quality of execution by 2 independent reviewers. Data abstraction was conducted by using the standardized LMBP abstraction methods and abstraction form. All differences were resolved through consensus. After the full abstraction, each study was evaluated for quality scoring to minimize any issue related to internal and external validity using LMBP quality assessment methods (43).

Details on the rating process of individual studies can be found elsewhere (43). Each study was classified into 1 of 3 quality ratings: good (8–10 score), fair (5–7 score), and poor (4 score). Studies with poor quality ratings were excluded from the effect size metaanalyses and the overall practice evidence base. See Supplemental Appendix D (in the online Data Supplement) for the Evidence Summary Tables containing quality ratings for each study.

Analyze (A-4): summarization of results and strength of the effect magnitude

Results from all included studies were variously reported risk ratios: odds ratios, relative risks, or hazard ratios. For the analyses purposes, these ratios were assumed to approximate the same measure of relative risk. Metaanalysis was performed to calculate the overall grand mean effect recommended by Borenstein et al. (45). A random-effects model was used for these statistics to perform meta-analysis because (a) not all the studies compared the same mixture of nontraditional lipid biomarkers to the traditional risk factors to improve the CVD risk prediction and (b) the long-term CVD risk prediction was based on different clinical CVD events in individual studies. To evaluate the effectiveness of these interventions, pooled point estimates across studies were expressed as an overall grand mean with CIs. When possible, all metaanalysis results were presented as forest plots, where the vertical line labeled “1” equals “no/minimal” difference between practices, and estimates to the right of the line favor the tested practice, i.e., improved risk prediction of CVD events due to the assessed practice. However, as apo A-I levels inversely correlate with risk for CVD (i.e.,

high apo A-I levels are protective against future cardiovascular events), the effect estimates less than 1 were considered favorable for development of CVD risk prediction.

For the effectiveness strength rating, the point estimate from each study between 1 and 2.0 was considered as a “moderate” magnitude of effectiveness; and any point estimate >2.0 was considered a “substantial” magnitude of effect. Final conclusions and recommendations for the overall effectiveness were based on the criteria including number of studies, quality of available evidence, consistency of results, and magnitude of effect estimates. Criteria for these ratings are described in greater detail elsewhere (43).

RESULTS

A total of 5575 bibliographic records were retrieved from the literature search, of which 106 were identified from other sources (e.g., hand searches, referrals). A total of 5305 studies were excluded (2044 duplicates and 3261 were not relevant to the topic). The remaining 270 published studies were screened further, and 179 were excluded. The remaining 91 studies were subjected to full abstraction and quality assessment; finally, 9 independent published studies (34, 46–53) met the inclusion criteria and comprised the total body of evidence (Fig. 2).

Apo B

Four eligible studies (48, 49, 51, 52) examined the associations between the plasma apo B levels when added to other traditional lipids with CVD risk prediction. The combined evidence from all included studies indicated that the risk assessment to develop long-term CVD events was significantly improved by adding apo B marker to the traditional risk factors (overall effect = relative risk: 1.31, 95% CI, 1.22–1.40, Fig. 3). The total evidence showed consistently favorable association of apo B lipid marker with the better long-term CVD risk prediction. The effect estimates for the CVD risk prediction were statistically significant from all included studies (48, 49, 52) but 1 study (51). The overall evidence was derived from 3 good quality studies (49, 51, 52) and 1 “fair” quality study (48) (Fig. 3).

Conclusions—Applying the LMBP criteria (43), the overall strength of evidence is considered moderate to conclude that the addition of apo B bio-marker to the traditional risk factors can improve the risk prediction for cardiovascular events for populations at risk (Table 1).

LMBP working group (WG) recommendation (apo B)—Based on the moderate evidence of effectiveness, lipoprotein apo B measure is recommended to improve the risk prediction for cardiovascular events when added to other traditional risk factors for the populations at risk (e.g., men >35 years, women >45 years, and younger adults 20 years old with multiple risk factors for CVD, in ambulatory and inpatient settings). This recommendation is based on consistently favorable results from 3 “good” quality and 1 fair quality studies.

Apo A-I

Two studies (48, 49) qualified to be included in the evidence that reported the impact of the measures of apo A-I in CVD risk prediction. One study was rated good quality of execution (49) and the other study was of fair quality (48). Combined results from both studies showed the favorable association of apo A-I marker with the CVD risk prediction—that is, the participants with the higher apo A-I levels tended to have lower risk of developing CVD events (overall random effect: 0.85; 95% CI, 0.79–0.92) (Fig. 4).

Conclusions—Applying the LMBP criteria, due to the limited available evidence, the overall strength of evidence is considered “insufficient” to conclude that the addition of apo A-I to the traditional risk factors can improve the risk prediction for cardiovascular events for populations at risk.

LMBP WG recommendation (apo A-I)—Because of the insufficient available evidence, no recommendations could be made for or against the effectiveness of apo A-I practices to predict the CVD events.

Apo B/apo A-I

Seven studies provided evidence for the effectiveness of apo B/A-I ratio. Results from 4 included studies (46, 47, 50, 51) were presented as hazard ratios, 2 as relative risk (34, 48), and 1 as odds ratio (53); the results from these studies were combined to calculate overall grand mean estimate of effectiveness. The combined results from the total evidence showed a consistent and positive association of apo B/A-I ratio marker to the development of long-term CVD events [overall grand mean estimate: 1.31 (95% CI, 1.11–1.38)] (Fig. 5). The results were statistically significant from all but 2 studies (47, 51). Of 7 studies, 4 studies (34, 47, 50, 51) had a quality rating of good, and 3 (46, 48, 53) were of fair quality. One study (50) showed a substantial effect estimate but had a large CI, indicating a less precise estimate. Six studies (34, 46–48, 51, 53) showed moderate effect for the CVD risk prediction (Fig. 5).

Conclusions—Applying the LMBP criteria, the overall strength of evidence is considered moderate to conclude that the addition of apo B/apo I ratio to the traditional risk factors can improve the risk prediction for cardiovascular events for populations at risk (Table 2).

LMBP WG recommendation (apo B/apo A-I ratio)—According to the LMBP methods, based on the moderate evidence of effectiveness the lipo-protein apo B/apo A-I ratio is recommended to improve the risk prediction for cardiovascular events when added to other traditional risk factors for the populations at risk (e.g., men >35 years, women >45 years, younger adults < 20 years old with multiple risk factors for CVD, in ambulatory and inpatient settings). This recommendation is developed based on evidence from 4 good and 3 fair quality studies (Table 2).

Non-HDL-C

Only 1 fair quality study (48) was identified investigating the association of non-HDL-C with CVD outcomes after controlling for traditional risk factors. The results from this

prospective cohort study showed that non-HDL-C lipid marker when adjusted for nonlipid (e.g., age, sex) and lipid (e.g., triglycerides) risk factors were associated with better CVD risk prediction at the 7.9-year follow-up period (hazard ratio: 1.25; 95% CI, 1.11–1.41).

Conclusions—Applying the LMBP criteria (43), the overall strength of evidence is considered insufficient to conclude at the time that the measures of non-HDL-C can improve the risk prediction for cardiovascular events for populations at risk.

LMBP WG recommendation (non-HDL-C)—Because of the insufficient available evidence, no recommendations could be made for or against the effectiveness of non-HDL-C practices to predict the CVD events (Table 3).

DISCUSSION

Best practices recommendations

Based on the findings from this systematic review, below are the LMBP workgroup recommendations for 4 evaluated practices in this review.

Lipoprotein apo B and apo B/apo A-I ratio measures are recommended to improve the risk prediction for cardiovascular events when added to other traditional risk factors for the populations at risk (i.e., men >35 years, women >45 years, and younger adults 20 years old with multiple risk factors for CVD, in ambulatory and inpatient settings).

Because of the insufficient evidence, no recommendations could be made for or against their effectiveness of apo A-I and non-HDL-C practices to improve the prediction of CVD events. This result does not discount the utility of these lipid markers in this context, but points to the lack of sufficient and consistent evidence in the literature. This is partly driven by the fact that many studies had to be excluded from the analyses because they did not include or adjust for all of the traditional risk factors included in this review.

This review examined 4 nontraditional lipid bio-markers, namely apo B, apo A-I, apo B/A-I ratio, and non-HDL-C, for improving CVD risk assessment. In contrast to previous guidelines, to date, some published reviews focus on 1 biomarker (22, 54) whereas others examine several biomarkers (3, 31, 55). The intent of the current review was not to determine how well the lipid biomarkers predict the risk of CVD in comparison to or as a replacement to traditional lipid and nonlipid risk factors, but rather, how do these emerging lipoproteins improve the risk prediction for CVD when added to traditional cardiovascular risk factors.

The lipid biomarkers examined in this review have great potential utility in the field of cardiovascular health and have been investigated for at least 2 decades. Undoubtedly, the literature is available to answer different types of review questions in this field. Based on the existing evidence, major Canadian guideline groups have concluded that specific apolipoproteins should be included into CVD screening biomarkers as an alternative to the traditional cholesterol indices to estimate risk and to guide therapy (56, 57). Yet, limited evidence was available to answer our review question, “Did the lipid biomarker provide

additional benefit beyond traditional risk factors?” Our findings are consistent with current national guidelines in the use of apo B (55). We extend and add to those findings by investigating the use of other lipid biomarkers (apo A-I, apo B/A-I ratio, and non-HDL-C), which, to the best of our knowledge, have not been assessed in the same review and subjected to the same rigorous review criteria. It is important to acknowledge that the practices and outcomes used in this systematic review agree with the general principles of, but do not necessarily mimic, the current (ATP [Adult Treatment Panel] IV) (55) and past (ATP III) (58) guidelines for CVD risk prevention in the general population. The approach for this review was intended to be independent and stand alone and was thoroughly evaluated with guidance from the expert panel. This review was initiated while ATP III guidelines were enacted; the ATP IV guidelines were published towards the end. The traditional risk factors used in this review are in common with those assessed in both guidelines and are considered standard practice. For the applicability of the review, substantial and moderate findings were reported from Sweden (50), the US (46, 47, 50, 51), Canada (49, 52), the Netherlands (48, 53), and Denmark (58). In contrast, ATP IV guidelines (55) report risk equations from a pooled population of non-Hispanic African Americans and whites. Several studies reviewed herein provided promising results.

Considerations for implementation

Apo B is measured mainly by immunonephelometric or immunoturbidimetric assays. Efforts to improve variability among these assays have been made by harmonizing measurements using a thoroughly characterized immunoassay. Because apo B is a well-characterized analyte, it has the potential of being standardized and linked to the International System of Units (SI system), which is not possible with LDL-C, which is often only indirectly measured and harmonized to a thoroughly characterized ultracentrifugation method (16, 33, 60, 61). Like apo B, apo A-I is mainly measured with immunonephelometric or immunoturbidimetric assays. These assays are being harmonized to a thoroughly characterized immunoassay, while HDL-C (2) assays are standardized to a thoroughly characterized ultracentrifugation method (23, 33, 61). Non-HDL-C is simply calculated as the difference between total plasma cholesterol and HDL-C. Since it can be calculated directly from routine lipid tests, it does not incur additional cost, making it more readily available (54, 62). Since non-HDL-C does not depend on triglycerides, it can be calculated from nonfasting samples.

Economic evaluation

No eligible economic evaluations were identified for analysis of cost-effectiveness.

Potential harms

The use of additional lipid biomarkers could require an additional venipuncture. All venipuncture procedures pose a minimal risk to clinical staff of needle stick injury and exposure to infectious or other harmful agents. In addition, patients identified at intermediate risk to develop CVD events may become candidates for unnecessary additional testing to better stratify risk and for aggressive medical therapy (e.g., lipid lowering, blood pressure control) for secondary CVD prevention (63).

Study limitations

The scope and clinical relevance of this review is confined to CVD events and excludes stroke, which has been included in the outcome for CVD risk assessment in the recent national guidelines for assessment of cardiovascular risk (55). Most of the evidence for this review is from prospective studies with populations having a single race/ethnicity, thus limiting generalizability. However, across the studies, there was a variety of findings supporting the need to develop population-specific risk prediction systems. In some cases, the follow-up period was <10 years, which may introduce bias into the case ascertainment process. However, this concern was compensated during the quality scoring of these studies. Differences in inherent or baseline risk status may arise from the type of population used in the studies (community based vs clinic based), which may affect study results. In addition, the restriction to English language studies may also introduce bias.

Several studies summarized in this review did not control for variations in measurement method and interindividual variation—for example, this review assumed that all biomarker tests used in individual studies performed at the same level of analytical quality. The impact of these differences on the outcome of this review is not known.

Future research needs

There was sufficient evidence to make recommendations for 2 risk biomarkers based on the moderate strength of evidence. However, more research is needed to strengthen the evidence rating and also to make recommendations for the other 2 biomarkers (e.g., apo A-I and non-HDL-C). Examination of the literature revealed several deficits that need to be highlighted as best practices for high-quality studies examining the added benefit of nontraditional lipid biomarkers to predicting CVD events. Several studies did not adjust for all the traditional risk factors and provided incomplete information about the demographics of the population. Model descriptions varied, and in some cases, it was difficult to understand the model selection criteria, model specifications, and what factors were included in the model. Several studies lacked sufficient raw data eliminating the ability to replicate findings. Finally, many studies used different analytical methods to calculate the effectiveness of evaluated practices; thus, we were not able to combine the result from those studies to perform metaanalysis to produce an overall grand mean of effectiveness. It is desirable for future studies to use common standardized analytical methods.

The aim of this study was to assess the additive benefits obtained by adding the lipid biomarkers to a panel of traditional risk factors. Thus, the potential benefits of replacing the traditional risk factors with the new biomarkers, especially in patients with conditions known to have highly altered lipid particle profiles, was not assessed and requires further investigation.

IMPACT STATEMENT

The findings from this study are beneficial for the population at risk of developing adverse cardiovascular events, including men (>35 years), women (>45 years), and younger adults (< 20 years) with multiple cardiovascular risk factors for cardiovascular disease (CVD). Existing guidelines mainly used traditional lipid levels and other risk factors—namely total cholesterol, LDL, HDL, triglycerides, high blood pressure, smoking, diabetes, age, and sex—as risk factor scores for CVD risk prediction. This study evaluated the incremental utility of nontraditional lipid biomarkers (e.g., apo B, apo A-I, and non-HDL-C) in improving CVD risk prediction to a conventional model of traditional risk factors.
