Summarized in this report is information received from state health departments, university investigators, virology laboratories, and other pertinent sources, domestic and foreign. This summary is intended primarily for the use of those with responsibility for disease control activities. Anyone desiring to quote this report should contact the original investigator for confirmation and interpretation.

Contributions to the Surveillance Report are most welcome. Send them to:

I. SUMMARY

In 1977 a total of 1,536 cases of encephalitis, resulting in 171 deaths, were reported to the Center for Disease Control. This total is $16 \%$ less than the 1976 total and $29 \%$ less than the average total for the preceding 5 years. The average for the preceding 5 years was increased by the 4,308 case total of 1975 , a major epidemic year for St. Louis encephalitis activity. Of the 9 geographic divisions in the United States, the East North Central had the most cases (467), but the highest attack rate was associated with the East South Central. Cases were reported to have occurred in all states except Maine, Nevada, Oregon, Vermont, and Wyoming. In 1977, as in each year except 1975, the majority of cases (70\%) were of indeterminate etiology. of the other cases with known etiology, the majority ( $52 \%$ ) were associated with arboviral infection, including St. Louis encephalitis ( 132 cases), California ( 65 cases), western equine ( 41 cases), and eastern equine ( 1 case); the next largest group consisted of cases associated with childhood infections ( $26 \%$ ), including chickenpox ( 43 cases), mumps ( 43 cases), measles ( 32 cases), and rubella (l case). Sixty-three cases associated with herpes simplex infection accounted for $14 \%$ of the cases with an established etiology. The other cases of determined etiology, accounting for less than $10 \%$, included 17 cases involving enterovirus infection, 14 with herpes zoster, 5 with respiratory virus infections, and 3 with infectious mononucleosis.

## IL. METHODS AND DEFINITIONS

This summary was compiled from data submitted to CDC from all state health departments. Only cases clinically classified as having an encephalitic component (i.e., encephalitis, meningo-encephalitis) were included, regardless of etiology. For each of these cases, information was requested on patient's age, sex, and county of residence, the date of onset and outcome of the illness, pertinent laboratory results, and etiologic evaluation when available. In general, cases were classified according to the degree of etiologic information available. Cases considered to be laboratory-confirmed were associated either with the isolation of a virus from an appropriate site--usually the central nervous system (CNS)--or with diagnostic serologic results, usually involving at least a 4-fold difference in titer between acute- and convalescent-phase paired sera. Presumptive cases included those with enterovirus isolates from non-central nervous system sites without supporting serologic evidence, and cases with serologic evidence not meeting the criteria for a confirmed case. Except for presumptive arboviral infections which were tabulated with other cases of documented arboviral etiology, all presumptive cases were included in the indeterminate category. Similarly, cases with documented evidence for more than 1 etiology (complex) and those cases with either inconclusive or no evidence for a specific etiology were included in the indeterminate category. The physician's clinical diagnosis was accepted as documented evidence for specific etiologies where clinical diagnosis was feasible--for example, childhood exanthems or herpes zoster.

## III. EPIDEMIOLOGY AND MORBIDITY TRENDS

In 1977 there were 460 cases, resulting in 53 deaths, with sufficient evidence to document a specific infectious etiology (Table 1). More than half the total (32\%) involved arboviral encephalitis, and the major arboviral encephalitides were St. Louis encephalitis (SLE) ( $55 \%$ ), California encephalitis (CE) ( $27 \%$ ), and western equine encephalitis (WEE) ( $17 \%$ ). Encephalitis cases following childhood infections (measles, mumps, chickenpox, rubella) accounted for 119 cases, about a quarter ( $26 \%$ ) of those with determined etiology. Encephalitis cases following measles (43) were nearly as numerous as they had been in the preceding year (44) when more cases were reported than had been since 1971, reflecting the recognition of widespread outbreaks of meas les infection. Fatal encephalitis cases differed markedly in their etiologic pattern. The fatality rate for encephalitis cases associated with herpes simplex and zoster were $47 \%$ and $50 \%$, respectively. Although herpes infections accounted for only $17 \%$ of known cases, they were as sociated with $60 \%$ of all fatal cases with determined etiology. In
contrast, cases associated with arboviral and childhood infections represented $78 \%$ of those with determined et iology but only $36 \%$ of those ending fatally.

11.0

There were 1,076 cases included in the indeterminate category: 1,026 with no indication of evidence for a specific etiology, and 50 with inconclusive evidence ( 23 with an enterovirus demonstrated from an anatomical site not in the CNS, and 27 other viral agents associated with either presumptive serologic evidence or isolation from a peripheral anatomic site).

Although the total number of arboviral cases reported for 1977 continued the declining trend that has followed the extraordinary epidemic activity in 1975, 1977 was a year of substantial epidemic arboviral encephalitis activity, as shown in $T a b l e$ 2. With the exception of 1975 and 1976, the total of 239 cases of arboviral encephalitis for 1977 is the highest total reported since 1966. A major contribution to the arboviral total for 1977 resulted from the late-seas on outbreak of SLE in Florida
detailed in the special report section of this report (Section IV). Only 17 cases of encephalitis were considered associated with a confirmed enteroviral etiology. Nevertheless, enteroviral infections are a likely cause of many of the cases of indeterminate etiology in the summer season, and enteroviral cases are probably the most underreported because of the difficulty of laboratory confirmation and the relative mildness of most cases. Cases associated with childhood infections continued the secular decline that began in 1966; the total of 119 cases is the lowest annual total recorded since the encephalitis surveillance system began in 1960 .

${ }^{*} \mathrm{Cl}$ - Childhood infections: measles, mumps, chickenpox, rubella

The pattern of seasonal activity for 1977 (Figure 1) differs somewhat from that of other years characterized by epidemic arboviral activity in that the Florida SLE activity occurred late in the year. The monthly distribution of cases for other etiologic groups is also similar to the patterns of previous years (Figure 2). Arboviral and enteroviral activity occurred predominantly in the summer and early fall; August was the month of peak activity for cases of arboviral and enteroviral encephalitis and for those of indeterminate etiology. Childhood infection-associated cases occurred more frequently from January through May. The monthly occurrence of cases in the indeterminate category suggests a composite of the seasonal distribution of cases as sociated with documented etiologies. The late summer peak of cases with unknown etiology may reflect undiagnosed arboviral or enteroviral cases.

Encephalitis cases for 1977 are tabulated by state and etiologic group in Table 3; fatal cases are tabulated in Table 4. Almost half of all cases ( $49 \%$ ) were reported from 6 states: California (191), Ohio (171), Florida (109), Illinois (108), Indiana (93), and Mississippi (87). The incidence of encephalitis is displayed by state in Figure 3. The geographic division with the highest rate was East South Central. Variations in attack rate from state to state are greatly influenced by epidemic patterns; however, dissimilar rates may also reflect dissimilar reporting practices and emphases on epidemiologic and laboratory investigations.

Fig. 3 CASES OF ENCEPHALITIS PER I,OOO,000 POPULATION, UNITED STATES, 1977

A. Arboviral Encephalitis (Arthropod-borne Encephalitis)

The total of 239 cases of arboviral encephalitis reported for 1977 (Figure 4) is only $57 \%$ of the total reported for 1976 and only $11 \%$ of the 1975 total. Nevertheless, with the exception of 1975 and 1976, the 1977 total is the highest since 1966, when 438 cases were reported (Table 5). The 132 SLE cases (Figure 5) accounted for $55 \%$ of the total, and $61 \%$ of the SLE cases were associated with the outbreak in Florida (see Section IV). Other states reporting SLE cases were: Illinois (13), Indiana (10), Texas (10), Mississippi (5), Ohio (4), Louisiana (3), Kentucky (2), and Alabama, New Jersey, and Tennessee ( 1 each). SLE activity, including the Florida outbreak, was generally not associated with urban concentrations of cases. The Florida outbreak, the first time SLE cases were reported from Florida since 1962, involved 110 laboratory-documented cases of SLE, including cases manifested as aseptic meningitis; these cases were widely scattered over 19 counties. The 65 cases of CE were all reported by North Central states except for 1 case from Connecticut and another from North Carolina. Cases from the North Central states were reported by Wisconsin (17), Illinois (15), Ohio (13), Minnesota (11), Indiana (5), and Iowa (2). The total of 41 cases of WEE was, with the exception of 1975 when 133 cases were reported, the largest total reported since 1966. WEE was reported by 10 states, with Colorado (11), Minnesota (9), and Texas (7) reporting the most cases. The only other case of arboviral encephalitis reported involved eastern equine encephalomyelitis (EEE) in Louisiana. Arboviral encephalitis cases in 1977 are shown by age group, sex, and etiologic agent in Table 6 . SLE is predominantly a disease of older persons; of the 132 cases in which age was specified, $72 \%$ occurred in persons 40 years or older. In contrast, CE is recognized largely in younger persons; $85 \%$ of these cases involved persons younger than 20 years old. More than 20 cases of SLE and several cases of CE were reported as aseptic meningitis. These cases are included in the 1977 Aseptic Meningitis Surveillance Report.

B. Enteroviral Encephalitis

Only 17 cases of encephalitis were associated with confirmed enteroviral infection, i.e., an enterovirus was isolated from some CNS location or was serologically confirmed by a diagnostic rise in appropriately collected acute- and convalescent-phase paired sera (Table 7). There were 23 presumptive cases associated with an enterovirus isolated from throat or stool specimens without accompanying serologic confirmation. These cases were tabulated as encephalitis of indeterminate etiology. Confirmed enterovirus cases were reported by 7 states and involved echovirus 6, 9 , and 14 and coxsackievirus A9, B3, and B5. As in previous years, most cases (all with specified age for 1977) were in persons less than 40 years old (Table 8). The only fatal case involved a Georgia resident with serologically confirmed coxsackie B3 infection. In the 10 -year period 1968-1977, a total of 859 echovirus and 87 coxsackievirus encephalitis cases have been reported.

C. Encephalitis Associated with Childhood Infections

The 1977 total of 119 cases of encephalitis associated with childhood infections was the lowest annual total in United States records. The secular decline of cases associated with childhood infections has followed the decline in the national incidence of measles, mumps, and rubella infections that began with the effective vaccination against these diseases (Tables 9 and 10). Five of the 32 cases of reported meas les encephalitis resulted in death. Although the 32 case total is lower than the 44 cases reported for 1976 , it is markedly higher than the totals reported for 1974 and 1975. The increase in reported cases following measles for 1976 and 1977 may be associated with scattered outbreaks of measles and with closer surveillance resulting from increased interest. Mumps encephalitis was reported from a total of 18 states; 3 cases were fatal. There is no vaccine approved to prevent chickenpox infection, and the number of chickenpox-associated encephalitis cases has not declined to the extent that the number associated with vaccine-preventable childhood exanthems has. Only l of the 43 cases of encephalitis following chickenpox infection was fatal. One case of encephalitis was associated with rubella infection, reflecting the relatively small number of rubella cases and the consistently low rate of encephalitic involvement. In the 10-year period 1968-1977, the following totals of encephalitis cases associated with childhood infections have been reported: mumps, 2,030; chickenpox, 605; meas les, 321 ; and rubella, 26.

[^0]Encephalitis cases caused by childhood infections occurred primarily in the younger age groups (Table 11). Of those cases for which age-specific data are available, most occurred in persons younger than 20 years old: $88 \%$ of the cases associated with chickenpox, $93 \%$ associated with measles, and $81 \%$ associated with mumps. The numbers of reported cases of childhood infection-associated encephalitis were too small to allow representative observations regarding sex distribution.

## D. Encephalitis with Other Documented Etiology

The other 85 cases of encephalitis with documented etiology are shown by age group, sex, and etiologic agent in Table 12. Herpes simplex encephalitis accounted for $74 \%$ of these cases and 25 ( $76 \%$ ) of the 33 associated fatalities, with a case-fatality ratio of $40 \%$. Herpes simplex cases occurred in persons of all ages and were not associated with any recognized outbreaks or particular season. The 14 herpes zoster cases were associated with a $50 \%$ case-fatality ratio, the highest for any etiologic group. Six of the 14 zoster cases involved patients aged 70 or older. The other cases of encephalitis with a determined etiology involved infectious mononucleosis (3), adenovirus (1), parainfluenza (1), respiratory syncytial virus (1), and Mycoplasma pneumoniae (1).

E. Encephalitis of Indeterminate Etiology

The 1,076 cases of indeterminate etiology represent $70 \%$ of all encephalitis cases reported for 1977 . Cases of unknown etiology have represented the majority of reported cases every year except for 1975, when arboviral cases were in the majority. Encephalitis cases of indeterminate etiology and associated deaths are shown by age group and sex in Table 13. Cases involved males (55\%) somewhat more frequently than females, but no single age group predominated. The fatality rate was higher for persons less than 1 year of age or 40 years of age or older; the highest rate (39\%) involved persons 60 or older. Although cases of indeterminate etiology occurred through 1977, the incidence peaked in late summer about the same time that cases of arboviral and enteroviral etiology peaked.

Outbreak of St. Louis Encephalitis in Florida
No St. Louis encephalitis (SLE) had been reported from Florida since 1962, when an outbreak occurred in the urban counties of Pinellas, Hillsborough, Manatee, and Sarasota, located on the west coast of Florida. The 1962 outbreak culminated a period of extensive SLE activity marked by outbreaks in the Tampa Bay area in 1959 and 1960. Except for some scattered cases in animals, no SLE had been detected in Florida from 1963 through 1976.

By October 25 , 1977, approximately 20 SLE cases had been diagnosed in Florida. An investigation team consisting of epidemiologists and ecologists from the Florida State Department of Health and Rehabilitative Services, assisted by CDC workers, began to search for SLE in humans and animals in late October. The investigation team established a surveillance program for clinical cases of SLE throughout Florida, with emphasis on the central and southern counties where cases had been reported. The infection control nurse, nurse epidemiologist, or chief of the infection control board for each hospital was instructed to report cases of encephalitis, aseptic meningitis, or febrile headache to the county health department once a week. The county, in turn, notified the state of all suspected cases of SLE. Mosquito abatement programs, which were already in effect, were intensified in affected areas. The person in the hospital responsible for reporting cases also encouraged the collection and shipment of proper serologic specimens to the state laboratory so that the diagnosis of SLE could be confirmed or ruled out.

In the counties reporting cases of SLE, hospital records were examined to detect possible additional cases. All cases were categorized as confirmed or presumptive SLE based on laboratory testing.

From August 8 through December 5, 1977, 110 laboratory-presumptive or laboratoryconfirmed cases were reported from central and south Florida (Figure 6). In 65 instances the clinical syndrome of encephalitis was documented; in the other 45 cases the illness was less severe (e.g., aseptic meningitis), or the clinical status was not available. The 69 confirmed and 41 presumptive cases, which reached a peak the week of October 21 , were reported from 19 counties (Figure 7). The highest attack rates occurred in central Florida counties that had not reported human cases of SLE in the 1962 outbreak.

The attack rate for the area outside standard metropolitan statistical areas (SMSAs) was 5.10 per 100,000 population, and the attack rate within SMSAs was 1.25 per $100,000(p<.001)$. The attack rates both for rural areas outside SMSAs (3.8) and for other urban areas outside SMSAs (5.8) were significantly higher than the at tack rate for central cities within SMSAs (1.2).

In this outbreak cases did not appear to spread from a central focus as they did in the outbreak of 1962 ; instead they occurred in the counties involved concurrently, with no evidence of spread from 1 area to another.

Analysis of age distribution revealed that overall there was a significant correlation between advancing age and clinical attack rate; however, the rate for persons aged $15-24$ was somewhat higher than the rate for those aged $35-44$, and approximately the same as for the age group 55-64. The overall high rate in the age group $15-24$ was attributable to the elevated attack rate in males aged $15-24$ (3.46 cases/100,000).

Limited occupational data were available on cases in this outbreak. Fifty-four percent of the persons aged $15-24$ had outdoor occupations or avocations, but only $16 \%$ of other age groups had outdoor occupations or avocations; this was statistically significant ( $\mathrm{p}<.05$ ). In addition, all patients with SLE in the 15-to-24-year age group with a history of work or recreation outdoors resided in noncentral city areas, and all but 1 in non-SMSA areas.

No significant difference occurred in attack rates by race. This is in contrast to the Florida outbreak in the early 1960 s when the attack rate for whites was significantly higher than the rate for blacks.

Fig. 6
ST. LOUIS ENCEPHALITIS CASES, BY WEEK OF ONSET, FLORIDA, 1977*

As seen in other outbreaks of SLE, the severity of clinical presentation was agedependent. A significant correlation of .76 was present between advancing age and clinical encephalitis. A significant negative correlation of -.84 was present between aseptic meningitis and advancing age. No correlation was found between age and febrile headache; however, the numbers were too small to be adequately evaluated.

The case-fatality ratio for this outbreak was $7.2 \%$, far below the case-fatality ratio in 1962 of $19.2 \%$. It may have been related to the greater number of young people seen in this outbreak, to lower virulence, or to higher case ascertainment. The trend of age-specific case-fatality ratios was typical for SLE, and all persons who died were over age 55.

## Fig. 7

ST. LOUIS ENCEPHALITIS CASES, BY COUNTY, FLORIDA, 1977

The extent and type of control effort was dependent on resources of individual counties. When a county was notified of a case of SLE, control emphasis was switched to adulticiding for Culex nigripalpus, and efforts were made to educate the population regarding the best methods for avoiding contact with mosquitoes: wearing long-sleeved garments, using mosquito repellent, and avoiding outdoor activity at dusk.

In 1977 changes in control efforts were made in Florida when a county was notified that a human case of SLE had occurred there. Since documentation of cases required laboratory confirmation, counties received this information late in the outbreak. In the 5-county area of Polk, Pinellas, Hillsborough, Manatee, and Sarasota, for example, the first case in the 1977 outbreak was not reported until October 27 , although the clinical onset had occurred in early October. In $74 \%$ of the cases clinical onset had occurred before October 27 . Of the 11 persons who had onset after October 27 , only 1 had onset
of clinical symptoms later than November 2, and all onsets occurred within the estimated 2-week incubation period for SLE, i.e., between October 27 and November 10 . Thus, if the decrease in cases had been due to control methods, it would mean that immediately upon notification of SLE cases, the counties in this area were able to prevent the occurrence of additional infections through aggressive mosquito control. This appears highly unlikely.

This outbreak of SLE presents several features that distinguish it from typical outbreaks of SLE described east of the Mississippi (1-3). Previous reports have described outbreaks in the eastern states that were urban-centered, with the epidemic period extending from June through September, and an increasing clinical attack rate being associated with advancing age. The epidemiology of SLE in the western part of the United States is somewhat different (4, 5): the vector, Culex tarsalis, is a rural mosquito, SLE affects males more than females, and clinical attack rates are often higher in persons aged $20-30$ years. These factors may reflect the occupational exposure of persons working around the irrigated fields where $\underline{C}$. tarsalis breeds (5). The outbreak in Florida did not follow either of these patterns exactly. The epidemic period was late in the season, extending into December. Although this is unusual, it has occurred previously in outbreaks in Florida. A significant feature was the lack of an urban focus. Attack rates were lowest in the heavily populated urban areas and highest in the small towns of rural, central Florida. This difference may have been due to the vector involved. Culex pipiens mosquitoes are primarily urban and are the responsible vectors for SLE in eastern outbreaks ( $6, \underline{7}$ ). The vector in Florida is historically, and in this outbreak, the semitropical species Culex nigripalpus, found in rural and urban surroundings (8). Moreover, it is interesting to note that urban birds used for surveillance hād a very low conversion rate to SLE, but sentinel and backyard chicken flocks located in areas outside the city had relatively high conversion rates to SLE. Indirectly, this may reflect the activity of the vector, and it corresponds to the nonurban distribution of human cases seen in this outbreak.

The significantly higher attack rate in males aged $15-24$ closely paralleled the experience of SLE in the west and may have been related to occupational exposure. Although we had limited data on patients' occupations, there did seem to be a higher percentage of persons aged 15-24 with outdoor occupations.

No significant difference was noted between the attack rates in blacks and whites. This is in contrast to the outbreak in Florida in the 1960 s when whites had a signifi$\mathrm{c} a n t \mathrm{ly}$ higher attack rate than blacks (1). In previous outbreaks of SLE, race-specific attack rates varied, depending on whether or not the racial groups lived in areas of high mosquito density $(\underline{9}, 10)$. Since the distribution of cases in this outbreak was different from that of $\overline{19} \overline{62}$, one might expect to see a different relationship in the SLE attack rates between blacks and whites.

It appears that control measures were initiated too late in this outbreak to have had much effect on the number of clinical cases. In instances like this, cases are not defined until laboratory-confirmed, particularly when acute-phase serum specimens are not being tested independently of convalescent-phase specimens and control measures are not instituted until $3-4$ weeks into the outbreak, a time when the number of cases may have peaked and may be diminishing spontaneously.

After the outbreak, many of the techniques developed to monitor mosquito, animal, and human infection with SLE and other arboviruses were incorporated into a statewide plan for arboviral surveillance and control. The procedures now in operation give promise of ensuring the most rapid and effective control if another arboviral outbreak should develop.
