## EFFECTS OF DDT MOSQUITO LARVICIDING ON WILDLIFE

## PART I. THE EFFECTS ON SURFACE ORGANISMS OF THE ROUTINE HAND APPLICATION OF DDT LARVICIDES FOR MOSQUITO CONTROL ${ }^{1}$

By Clarence M. Tarzwell, Senior Assistant Sanitarian (R), United States Public Health Service

This paper is the first of a series by the author and co-workers on the effects of DDT anopheline larviciding on wildlife. Subsequent parts dealing with other phases of the subject will appear at irregular intervals as the studies progress. Investigations of the effects on wildlife of the routine use of DDT as a mosquito larvicide were undertaken by the United States Public Health Service at the Carter Memorial Laboratory late in 1944. The purpose of these studies was to determine at what dosages and in what manner or physical state DDT could be routinely used as an anopheline larvicide without being significantly harmful to other organisms of economic or recreational value.

During the first year of the study, investigations were made on the effects of the routine hand application of DDT dusts, emulsions, and solutions. Experiments were carried on in 22 ponds, using several methods of application, types of larvicides, and dosages of DDT to determine their joint and individual effects on the fish life and the surface, bottom, and plankton organisms. DDT dusts were applied by means of several types of dusters, but air-pressure hand sprayers were generally used for the application of emulsions and solutions. DDT solutions were generally applied at the rate of $1 / 2$ or 1 gallon per acre by means of an atomizing nozzle (1). It became apparent early in the study that tight emulsions and solutions applied at a rate of 0.4 pound, or more, of DDT per acre were detrimental to fish in shallow

[^0]water. Such methods and rates of application were therefore abandoned in favor of dusts or solutions applied at the rate of $0.1,0.05$ or 0.025 pound of DDT per acre. Individual treatments with these latter dosages caused no observed fish mortality. However, routine treatments at 0.1 pound per acre caused fish mortality between the third and tenth treatments. A series of 11 to 18 treatments at this rate significantly reduced the fish population in the ponds studied. Data secured to date indicate that, for small or shallow waters, routine treatments should not exceed 0.05 pound DDT per acre. Routine treatment at the rate of 0.05 pound per acre caused fish mortality in shallow ponds in which the entire area was treated. It is believed that in larger, deeper waters in which only the margins are treated, mortality will not be significant. Tests are to be made in such areas, using 0.05 pound of DDT routinely. No fish mortality was observed in areas routinely treated at $0.025^{\circ}$ pound of DDT per acre.

During the second year (1945) of the investigation, emphasis was laid on a study of the effects of routine treatment at 0.1 pound DDT per acre, applied by airplane. Exhaust sprays or thermal aerosols and sprays from nozzles were the methods of application. Extensive areas on the Savannah River National Wildlife Refuge were treated in these studies. In addition to the effects on fish and fish food (surface, bottom, and plankton organisms), the investigations were expanded, in cooperation with the United States Fish and Wildlife Service, to include studies of the effects of routine treatment on amphibians, reptiles, birds, mammals, and terrestrial insects. -Studies of these latter groups were confined to marginal areas into which there is driftage from treated areas.

During the third season, observations will be made in the Wildlife Refuge to determine the effects of 2 years of routine treatments on the fish population.

Investigations of the effects of the routine hand application of DDT mosquito larvicides on surface organisms other than mosquitoes were undertaken in April 1945. The purpose of these studies was to determine at what concentrations, and in what manner, DDT could be routinely used as an anopheline larvicide, without being significantly harmful to the surface organisms which are of importance as fish food and to wildlife in general. Experiments were conducted on more than 20 ponds, using several different formulae, methods of application, and concentrations of DDT.

## PROCEDURE

All investigations were conducted on ponds in the vicinity of Savannah, Ga. Studies were made in three areas in the Savannah

River National Wildlife Refuge, on natural ponds, and on 14 artificial ponds at the Plant Introduction Laboratory of the Bureau of Plant Industry. Rotary hand dusters, atomizers, and air-pressure hand sprayers, equipped with several types of nozzles, were used for the application of the larvicidal materials. The larvicide was applied as a dust, a tight emulsion, a quick-breaking emulsion, and in solution. The forms most commonly used were a 1 -percent-DDT dust in Electro FD No. $2{ }^{2}$ and a solution of DDT in fuel oil, applied at the rate of 1 gallon or $1 / 2$ gallon per acre. The dosages used varied from 2 pounds to 0.025 pound per acre, those most commonly used being 0.1 pound, 0.05 pound, and 0.025 pound per acre. Treatments were routine at weekly intervals.

Two methods were used for detecting kills or changes in the population of surface organisms due to the routine treatments. Gross observations were made 24 to 48 hours after treatment to detect any kill of the larger surface insect forms, such as Gyrinidae, Dytiscidae, Hydrophilidae and Corixidae, and quantitative surface samples were taken before and after treatment to determine any changes in the population of surface organisms due to individual treatments. During the first 2 to 4 weeks of treatment, quantitative samples were taken before and after each treatment, but thereafter they were taken at biweekly intervals. Samples were taken simultaneously in suitable check ponds.

Each surface sample represented the organisms from a surface area of 1 square foot to a depth of 2 inches. Thus, in taking each sample, about $\frac{1 / 6}{}$ cubic foot of water was strained. The samples were taken by means of the screen-dipper and strainer-pan technique, described by Hess and Tarzwell (2). This dipper (fig. 1) has a metal frame 4 inches square, a copper-wire-screen back and an adjustable handle. Since the dipper is 4 inches, or $1 / 3$ foot, wide, pulling it over a distance of 3 feet sampled an area of 1 square foot, from which it strained out and retained all organisms larger than the wire-mesh openings. A mark was placed on the side of the dipper 2 inches above the bottom, so that all samples could be taken at the proper depth. The dipper was moved through the water at a slow uniform rate to allow all the water to pass through, while retaining the organisms. Water was collected in the strainer pan (fig. 2), and the contents of the dipper were washed into it by placing the back of the dipper in the water and then, by a backward motion, causing the water to pass through the screen in the reverse direction, thus washing the organisms out of the dipper and into the pan. The strainer pan was provided with the same mesh of screen as that on the dipper, so that

[^1]water collected in it would be free of those organisms retained in the dipper. After the contents of the dipper were washed into the strainer pan, they were then poured through a concentrator (fig. 3) to remove excess water. After the solid materials were sufficiently concentrated, the plug was removed from the concentrator and the contents were washed into a suitable container, by means of a wash bottle, and preserved for study. In the laboratory, the organisms in each sample were identified and counted by means of a binocular dissecting microscope. Square petri dishes, the bottoms of which were marked off in a grid, each square of which was the size of the microscope field, were used in making the counts. Prepared forms were used for recording the organisms found in each sample. All data were analyzed statistically to determine the significance of -any changes due to treatment.

At the beginning of the study, 25 random samples were taken in a selected area before and after treatment. It soon became apparent, however, that large homogeneous areas suitable for such sampling did not occur in the ponds being studied, and that there was great variation in the numbers of organisms found in the various samples. In most instances this variation was so great that it would have been impossible to detect even large differences due to treatment. Random sampling was therefore abandoned in favor of paired samples. A method of sampling was adopted wherein 10 sampling stations were set up in each of the principal ponds being studied. These stations were marked by numbered stakes, and the richest areas were selected for the stations to insure a large number and variety of organisms in each sample. The stakes were so placed that environmental conditions were as nearly similar as possible on all sides of the stake, for a distance of at least 1 yard. The pretreatment samples were taken on the right side of the stake just previous to the application of the larvicide, and the posttreatment samples were taken on the left, 48 hours thereafter. Before treatment began, the adequacy of the sampling method was tested by comparing samples taken on the right and left sides of the stakes 48 hours apart. Differences between samples taken in this manner without treatment were not significant, indicating that the sampling technique was adequate. Samples were taken before and after the first two treatments and then at biweekly intervals, or at every other treatment. A consistent effort was made to reduce variation by rigidly controlling the sampling technique, so that differences due to the treatment might be detected. Student's $t$ test was used for comparing the samples to determine the significance of the differences, and $P$ values were used to denote levels of significance, a value of 0.05 or less being considered significant.

The above methods were used for determining the effects of indi-

Figure 1.-Taking a square-foot surface sample with the screen dipper. A yardstick is used to insure accuracy in the distance sampled.

vidual treatments. . Residual or accumulative effects due to routine treatment were shown by comparing graphically the populations in the treated and check ponds throughout the season, or throughout the period of treatment.

## RESULTS AND CONCLUSIONS

Tight or stable emulsions, formed by some organic solvent such as xylene, DDT, an emulsifier, and water, were found to be detrimental to aquatic organisms when sprayed on the water. Tight emulsions, when applied at dosages of 0.2 pound of DDT per acre, killed many aquatic insects and fish. For this reason, they were abandoned in favor of quick-breaking emulsions or solutions of DDT containing a spreading agent. Water emulsions were also abandoned in favor of solutions of DDT in fuel oil or kerosene, applied at the rate of 1 gallon per acre, because of the savings in labor. Thus 1-percent-DDT dusts and solutions of DDT in fuel oil with a spreader were used in most of the tests to determine the effects of DDT on the aquatic biota other than mosquitoes.

## GROSS OBSERVATIONS

Gross observations were made at the time of treatment, and 24 and 48 hours after treatment, to note any kill of the larger forms. In shallow ponds having a sand bottom, individual treatments with fuel-oil solutions, at rates of 1 to 2 pounds of DDT per acre, killed aquatic hemipterons, beetles, dragonflies, damselflies, mayflies, chironomids, tadpoles, crayfish, and fish. Treatment with oil solutions, at dosages of 0.4 pound of DDT per acre also killed many of the aquatic forms, but a single treatment at this rate did not kill fish.

Treatments in all routine studies with fuel-oil and kerosene solutions of DDT were at dosages of $0.1,0.05$, and 0.025 pound per acre. Dusts were generally applied at the rate of 0.1 pound DDT per acre. Little or no kill was noted after individual and routine treatments with dust. From information now at hand, it appears that routine treatments with DDT dusts, in quantities sufficient to give adequate anopheline control, are not harmful to wildlife. Individual treatments with DDT solutions in fuel oil, applied at the rate of 1 or $1 / 2$ gallon per acre and at the above dosages, gave kills of the following forms: Collembola, Corixidae, Notonectidae, Belostomatidae, Naucoridae, Gerridae, Haliplidae, Dytiscidae, Gyrinidae, Hydrophilidae, and Chironomidae. In general, the kills were more pronounced for the larger dosages. There were distinct kills at all dosages after several treatments, but for the first few treatments, very slight mortalities were noted at dosages of 0.025 pound of DDT per acre. The first treatment at 0.1 pound of DDT per acre gave significant kills of the larger
surface insects, and pronounced kills resulted from the second treatment, after which the observed number of dead organisms decreased. This was probably due to a marked reduction in the population due to the first two treatments. Surface forms were not eliminated. however, even by a series of 22 weekly treatments at 0.1 pound of DDT per acre.

Counts of the kill of surface organisms in a series of ponds 24 hours after the eleventh, twelfth and fourteenth treatments clearly show that surface forms were present in considerable abundance after routine treatments extending over a three-month period. The kill of the various forms in these ponds 24 hours after the eleventh, twelfth and fourteenth treatments are tabulated in table 1. These ponds were all about the same size, 5 by 15 feet. As indicated in table 1, a considerable number of aquatic and terrestrial forms were found dead in the ponds. It is probable that the terrestrial forms had been resting near the ponds and were killed at the time the ponds were treated, or that they later came in contact with the oil film containing the DDT. The latter is true for the Orthoptera, and the various adult Diptera and Odonata. The dragonfly and damselfly nymphs were very resistant to the DDT solutions sprayed on the surface of the ponds, but the adults were susceptible, and were killed in considerable numbers. A portion of these probably came to the water surface to lay eggs. In treatment of extensive areas, this kill might become important.

Dead adult chironomids were found on the water surface in great numbers, many of which were probably killed while attempting to emerge. In several instances, they were present in such large numbers that it was impractical to count them. In the counts made on these ponds, dead dytiscids and hydrophilids ranked next in abundance after chironomids. In the ponds treated at the rate of 0.1 pound of DDT per acre, the average kill per treatment, exclusive of chironomids, was 113 organisms, or 1.5 per square foot; in the ponds treated at the rate of 0.05 pound DDT per acre it was 10 organisms, or 0.13 per square foot; and in those treated at the rate of 0.025 pound per acre, the average kill was 35 organisms, or about 0.5 per square foot. Treatment with fuel oil alone, at the rate of 1 gallon per acre, resulted in an average kill for the three treatments of 12 organisms, exclusive of chironomids. The average number of dead insects found in the dusted pond was five, whereas the average for the check ponds was slightly more than two. These results indicate that treatment with dust at the rate of 0.1 pound of DDT per acre kills very few surface insects. The over-all results suggest that 0.05 pound and 0.025 pound of DDT per acre in fuel oil kills only a fraction as many surface forms as do applications at 0.1 pound per acre, and that fuel oil in itself kills numerous forms. It may be that 0.025 to 0.05 pound of DDT applied

Table 1.-Summary of the kill of large surface and other organisms in 1 'f experimental ponds due to the use of DDT larvicides at specified dosages and times

735426-47 (face p. 530)
in 1 gallon of fuel oil per acre will kill considerably less insect life than the regular routine oiling at 15 to 40 gallons per acre which has been used for mosquito control in the past.

The surface forms found dead in the treated and check ponds at the Wildlife Refuge after the eighteenth treatment are summarized in table 2. These results also indicate that oil solutions cause a con-

## Table 2.-Summary of the kill of surface forms by the eighteenth routine larvicidal treatment at the Wildlife Refuge

${ }^{1}$ Too numerous to count.
siderable kill, whereas the dust has little effect. They further indicate that although each treatment kills a considerable number of surface forms, it does not exterminate them, for there was a marked kill after the eighteenth treatment. The apparently large kill at 0.05 pound of DDT per acre in the refuge pond is due to the fact that this pond is many times larger than those dealt with in table 1.

The mortalities of organisms noted after the fifth and seventh treatments on three ponds in the Camp Stewart area are tabulated in table 3. Average mortalities per treatment were 258 organisms for 0.1 pound DDT per acre and 81 organisms for 0.05 pound. Two dead

Table 3.-Kill of surface organisms 24 hours after the routine fifth and seventh treatments in experimental ponds at Camp Stewart

[^2]organisms were found in the check pond. Forms most prominent in the kill were the same as those found in the other ponds, namely, Dytiscidae, Gyrinidae, Hydrophilidae, Corixidae, and adult Anisoptera and Zygoptera.

Several series of studies were made to determine the relative effect of various solvents when used alone. It was found that kerosene was less toxic than fuel oil and that alcohol, acetone, and Aro-sol ${ }^{3}$ killed very few insects. However, when combined with DDT, which is much more toxic than any of the solvents tested, indications are that the effect of the solvent is masked and that mortalities resulting from the various DDT solutions do not differ significantly. This phase of the problem needs more study, especially on those solvents which evaporate quickly, or which may affect final distribution of the DDT. When used alone, at the rate of 2 gallons per acre, fuel oil and Velsicol NR-70 ${ }^{4}$

[^3]caused a considerable kill of surface insects. Velsicol gave a distinct scumlike film and was the most toxic solvent tested.

## QUANTITATIVE SURFACE SAMPLES

Square-foot surface samples were taken in a number of treated and check ponds to determine the effect of individual treatments with DDT larvicides on surface organisms. In each group or series of ponds, samples were taken from both treated and check ponds on the same day so that conditions would be comparable. Thus, for each series of samples taken before and after treatment from the sprayed areas, similar series were taken from the check area, with the usual 48 -hour interval between samplings. Both permanent and temporary watered areas were studied in this manner.

Test ponds 1, 2, and 3 were permanent water areas at the Savannah Migratory Waterfowl Refuge. Pond 1 was routinely treated with a DDT-fuel-oil solution at the rate of 0.05 pound of DDT and 1 gallon of fuel oil per acre. Pond 2 was dusted at the rate of 0.1 pound of DDT per acre, and pond 3 was an untreated check for the other two ponds. The DDT-fuel-oil solution proved much more toxic to the surface Hemiptera and Coleoptera than the DDT-pyrophyllite dust mixture. Changes in the population of surface organisms in pond 1, due to the individual applications, as indicated by the 190 quantitative surface samples taken during the period of treatment, are summarized in table 4. Samples were taken before and after the first, second, fourth, sixth, eighth, tenth, eleventh, thirteenth, and fifteenth treatments, and after the seventeenth in each of the ponds. The total number of the various organisms found in the 10 samples taken before and after the indicated treatments are shown in table 4, as well as the mean difference of the number taken before and after treatment. A decrease in the number of organisms found after treatment is indicated by a minus sign, and a significant change by an asterisk. Few significant changes were noted in the population of surface organisms due to individual treatments, and most of those which did occur were not consistent.

Pond 2 was treated with a 1-percent-DDT dust in pyrophyllite at the rate of 0.1 pound of DDT per acre, but demonstrated less damage than pond 1, treated with 0.05 pound of DDT in fuel oil. A total of 190 square-foot surface samples were taken in this pond. The organisms taken in these samples are tabulated in table 5. Only one significant decrease in the total number of organisms was found. Changes in the numbers of organisms in the different groups were not consistent and are therefore not considered important.

The check pond, number 3, showed two significant changes in the total number of organisms found. The samples collected on Sep-

tember 20 showed an increase, whereas those collected on October 19 showed a decrease. Significant changes in the various groups of organisms were not consistent and may be largely due to sampling error. In general, the population in the check area followed what appeared to be a fairly normal seasonal trend (table 6). The 570 surface samples taken before and after individual treatments in the three ponds, throughout a series of 18 applications, indicate very little significant change in the population of surface organisms due to individual larvicidal treatments with DDT. A comparison of the data in tables 4,5 , and 6 shows no consistent change due to the individual treatments.

Some accumulative or seasonal changes in the population of the various groups of surface organisms were indicated by these studies. The seasonal trend of the total population of the surface organisms and of various groups of organisms in the treated ponds are compared with those in the check pond in figures 4 through 8. These graphs show the average number of organisms per square-foot sample from each of the three ponds at each sampling date. Figure 4 shows the

FIGURE 4.-A seasonal comparison of the population of surface organisms in an untreated pond with those in ponds routinely treated with DDT larvicides for 17 weeks. Pond 1 treated at the rate of 1 gallon fuel oil and 0.05 pound of DDT per acre, pond 2 dusted at the rate of 0.1 pound of DDT per acre, and pond 3 untreated. Graph based on 570 quantitative square-foot surface samples taken to a depth of 2 inches.
average number of all organisms pel square foot found in each pond throughout the season. This graph indicates an increase in the total number of surface organisms in the treated ponds, with the greatest increase occurring in the pond treated with the DDT-oil solution.

Figure 5 shows the seasonal abundance of Cladocera in the check and treated ponds. Although the average number of Cladocera per square foot was somewhat greater in the treated ponds, it is not believed that the differences are significant. On the whole, the Cladocera

populations in the check and treated areas remained remarkably similar throughout the season. It is therefore concluded, on the basis of these data, that routine treatment at the rates of 0.1 pound of DDT

FIGURE 5.-A comparison of the seasonal abundance of Cladocera in an untreated pond with that in ponds routinely treated with DDT larvicides for 17 weeks. Treatments as indicated in figure 4. Graph based on 570 quantitative square-foot surface samples.
dust or 0.05 pound of DDT in fuel oil per acre have little or no effect on these organisms.

The effects of the two types of treatment on the population of surface insects in the ponds at the Wildlife Refuge are shown in figure 6. A comparison of the standing populations in the three ponds throughout the 17 weeks of treatment indicates a reduction in the number of surface insects in the treated ponds, with the larger reduc-

Figure 6.-A comparison of seasonal trends in the population of surface insects in check and treated ponds. Treatment for the various ponds as indicated in figure 4. Data from 570 quantitative square-foot suciace samples.
tion occurring in the pond treated with a DDT-fuel-oil solution at the rate of 0.05 pound of DDT per acre. Most of this reduction occurred among the following orders of insects: Diptera, Coleoptera, Hemiptera, and Ephemeroptera. However, none of the orders were eliminated, and although individuals of these groups were not as abundant in the treated areas as they were in the check areas, the population in the treated areas did show a seasonal increase. From this data, it is concluded that the population of surface insects is kept at a level below their natural abundance by routine treatment, and that oil solutions are more toxic than dust.

The effect of the routine laviciding on surface aquatic insects was most pronounced on the chironomid population. Seasonal trends in the population of chironomids in the check and treated ponds are shown in figure 7, which indicates the average number of organisms taken per square foot in each of the ponds throughout the season. As in other instances, the greatest reduction occurred in the pond treated with a DDT-oil solution.

Figure 7.-The effects of routine larviciding with DDT on the population of Chironomidae as indicated by a comparison of the populations in check and treated areas throughout the period of treatment. Treatment as indicated in figure 4. Data based on 570 quantitative square-foot surface samples.

As has been shown previously (figure 4), the total population of surface forms increased in treated areas. This increase occurred in spite of a considerable decrease in the aquatic insects and was largely due to a significant increase in a few forms. In the treated ponds at the Wildlife Refuge, there was a considerable increase in thenematodes, oligochaetes and copepods. The seasonal abundance of oligochaetes in the check and treated ponds is compared in figure 8. Their increase in abundance in the treated ponds was rapid and significant, and suggests the limiting of some other forms of life by the DDT. It is
probable that the DDT reduced the predators or competitors of the oligochaetes nematodes, and copepods. The significance of this change from the standpoint of fish production is not definitely known,

Figure 8.-A comparison of the abundance of Oligochaeta in untreated and treated areas during the period of 17 routine treatments with DDT larvicides. Treatments for the ponds as indicated in figure 4. Data based on $\mathbf{6 0 0}$ quantitative square-foot surface samples.
since data are not available on the relative value of chironomids, in contrast to oligochaetes and nematodes, as fish food. Although chironomids are much larger forms, the others occur in great numbers, and the total volume of food produced may not be greatly modified by the change in the composition of the population.

Studies made in other ponds indicated much the same changes as those observed in the Refuge ponds. In general, there was an increase in nematodes, oligochaetes, and copepods, a decrease in chironomids, surface Hemiptera, Coleoptera, and Ephemeroptera, while other forms remained about the same.

Test pond 4 was routinely dusted by a crew regularly engaged in mosquito control. Treatment began on April 4, 1945, and continued into October. A total of 26 applications were made with a dust containing 1 percent DDT and 99 percent pyrophyllite, applied at the average rate of about 0.2 pound of DDT per acre. The effects of the first 4 applications on the population of surface organisms, as indicated by some 120 random square-foot surface samples taken before and after the individual treatments, are summarized in table 7. In this table, the average number of each group of organisms taken before treatment, and the mean difference between the number taken before and after treatment, are shown. Decreases in the average number found after treatment are indicated by a minus sign. The standard error of the mean difference has been calculated for those groups judged to be of importance, and the $t$ and $P$ values determined.

A 5-percent level of significance has been selected as significant for changes after treatment. It will be noted (table 7) that although there was considerable variation in the numbers of the various groups of organisms taken before and after treatment, very few of the changes were significant and these were not consistent changes.

Changes due to the eighth, tenth, and sixteenth treatment in pond 4, as indicated by paired surface samples, are summarized in table 8. The mean numbers of organisms taken in 10 samples before and after treatment are shown, along with the differences between these means and the standard error of this difference, for those groups judged to be the most important or having the largest numbers of individuals. No significant changes were noted. Sampling was discontinued after the sixteenth treatment, due to the entrance of brackish water through a newly constructed drainage ditch.

Results of treatments in ponds 5 and 6 are summarized in table 9. These ponds were located in the Camp Stewart area and were small, temporary sand-bottom ponds, resulting from the overflow of the Canoochee River. Pond 5 was treated with a DDT-fuel-oil solution, to which was added 0.5 percent of $\mathrm{B}-1956^{5}$ in order to improve the spreading properties of the fuel oil. Some significant changes appear to have resulted from the three treatments. There was a significant decrease in total organisms after the first treatment, and a general decrease in the mayflies and midges, whereas the copepods, ostracods, and nematodes showed a distinct increase after the third treatment.

Emulsions were used for the larviciding in pond 6. The first application consisted of an emulsion made by adding 1 gallon of fuel oil, containing 0.1 pound of DDT and 0.5 percent of a spreading agent, to 14 gallons of water. Treatment was at the rate of 15 gallons of emulsion per acre for both the first and second treatments, but the amounts of oil and DDT were doubled for the second application. Surface Hemiptera and Coleoptera were killed by both treatments, and there was a marked decrease in the mayflies and chironomids. However, other forms, such as nematodes, oligochaetes, and copepods, increased to such an extent that there was a significant increase in the total population after the first treatment, and a considerable increase after the second.

Test pond No. 7 had a permanent inflow of water from a nearby artesian well. It was given weekly routine treatments at the rate of 0.1 pound of DDT and 1 gallon of fuel oil per acre. Treatment began early in July and was discontinued in December. The effects of the various individual treatments are summarized in table 10. Gross observations indicated that the first two applications killed a large number of Coleoptera and Hemiptera. Members of these

${ }^{1}$ Exceeds 5－percent level of signiffcance．
orders were found dead after each of the 22 applications applied to the pond, indicating a reduction but not an elimination of surface forms. Surface sampling was discontinued after the seventeenth treatment. As indicated in table 10, few significant changes occurred due to individual treatments. However, long-term or cumulative effects were noted after treatment had continued for a number of weeks. The larger members of the families Gyrinidae, Dytiscidae, Haliplidae, Hydrophilidae, Corixidae and Gerridae became quite scarce after several treatments. Further, the quantitative surface samples indicated a reduction in Chironomidae and Ephemeroptera, whereas there was an increase in Oligochaeta. The seasonal trends of the population of oligochaetes, insects, and chironomids in a treated pond are shown graphically in figure 9 . All insects, and chironomids in particular, were drastically reduced by the treatments with DDT, whereas the oligochaetes steadily increased. This change was observed in all ponds treated routinely.

Figure 9.-Trends in the population of Oligochaeta, Chironomidae, and Insecta in a pond routinely treated for 17 weeks at the rate of 1 gallon fuel oil and 0.1 pound of DDT per acre. Graph based on 200 quantitutive square-foot surface samples.

## SUMMARY

Quantitative sampling of the surface forms and counts of dead organisms on the water surface 24 hours after treatment were the methods used for determining the effects of routine treatment with DDT larvicides.

Routine applications of DDT as a dust caused little apparent damage to the surface organisms, as indicated by gross observations. Paired square-foot surface samples, taken before and 48 hours after treatment, indicated few significant changes due to treatment. The seasonal trend of the population of surface organisms was somewhat affected by routine treatments with dust at the rate of 0.1 pound of DDT per acre, but the changes were not as great as those caused by treatments with solutions of DDT in fuel oil.

DDT-fuel-oil solutions killed the large surface insects, such as Dytiscidae, Gyrinidae, Hydrophilidae, and Corixidae, at concentrations as low as 0.025 pound of DDT per acre. However, the kills resulting from applications of 0.05 or 0.025 pound of DDT per acre were proportionately much less than those resulting from applications at the rate of 0.1 pound per acre. As was true for treatments with dust, few significant cbanges occurred due to any single treatment. The seasonal effects of routine DDT treatments, as indicated by a comparison of the population of surface organisms in the treated and check ponds, were quite marked. There was an increase in the number of Oligochaeta, Nematoda, and Copepoda, and a decrease in the Chironomidae, Hemiptera, Coleoptera, and Ephemeroptera. Insects as a group decreased in number in the treated ponds, with the largest decrease occurring among the Chironomidae.
The net results of these changes are difficult to evaluate, but it appears that there is some reduction in the available supply of fish food. Although the forms which increase in numbers often occur in great abundance, they are much smaller than the forms which are reduced in number, and in general they are not as readily taken by the fish. Reductions noted to date, however, have not been sufficient to affect the breeding stock, and since treatment is in localized areas, it is probably not sufficient to seriously limit the fish population by restriction of the food supply.

## ACKNOWLEDGMENTS

Several members of the staff of Carter Memorial Laboratory were engaged in the study of the effects of DDT larviciding on the surface organisms. Mr. William Lynn assisted in the taking of the surface samples. Miss Kate Purvis, Mrs. B. B. Whitmarsh, Miss Marjorie Chaplin, and Mrs. Dorothy Coleman counted and recorded the various groups of organisms in the laboratory. Miss Rosetta Davis made the calculations and assisted in the preparation of the tables. The author wishes to express his appreciation to other members of the staff who have assisted in numerous ways, and especially to Dr. S. W. Simmons who made the study possible and actively encouraged and expedited the investigations.

# INCIDENCE OF DISEASE 

No health department, State or local, can effectively prevent or control disease without knowledge of when, where, and under what conditions cases are occurring

## UNITED STATES

## REPORTS FROM STATES FOR WEEK ENDED MARCH 22, 1947

## Summary

A total of 52,115 cases of influenza was reported for the week (exclusive of Kentucky, where special surveys showed 20,515 cases of upper respiratory infection), as compared with 42,997 last week, 3,477 for the corresponding week last year, and 14,953 for the week in 1939, the last named figure being the largest number reported for any corresponding week of the past 12 years. Declines were rəported in only the West North Central and Mountain areas, resulting from decreased numbers reported in Kansas, Colorado, and Arizona. Of 19 States reporting more than 200 cases each, 16 showed an increase of 14,841 , and 3 reported a decline of 5,436 . Reports of 12 States, showing for the current week 565 or more cases each and aggregating 48,032, are as follows (last week's figures in parentheses): IncreasesIowa 2,321 (970), Virginia 1,439 (1,151), West Virginia 2,589 (2,099), South Carolina 1,814 (1,518), Georgia 1,019 (482), Alabama 1,847 (328), Arkansas 6,859 (5,306), Oklahoma 7,624 (1,083), Montana 565 (193); decreases-Kansas 1,947 (6,260), Texas 19,087 (19,527), Colorado 921 ( 1,604 ). The total for the year to date is 157,694 , as compared with 173,413 for the same period last year and a 5-year (1942-46) median of 57,807 . During the 4 weeks ended with the current week, a total of 125,077 cases has been reported, as compared with 18,400 for the corresponding period last year, a 5-year median of 17,615, and 63,297 , the largest number for any corresponding period of the past 12 years (in 1939).

Of 31 cases of poliomyelitis, 2 less than reported for last week (which was the average week of lowest seasonal incidence) $12 \mathrm{oc}-$ curred in California. The total for the year to date is 656, as compared with 493 for the same period last year and a 5 -year median of 320 .

Both the current and cumulative figures for diphtheria, measles, meningococcus meningitis, scarlet fever, smallpox, typhoid and paratyphoid fever, and typhus fever are below the respective corresponding 5-year medians.

Deaths recorded for the week in 93 large cities of the United States totaled 10,225 , as compared with 10,310 last week, 9,569 and 9,640 , respectively, for the corresponding weeks of 1946 and 1945 , and a 3 -year (1944-46) median of 9,605 . The cumulative figure is 120,684 , as compared with 123,115 for the corresponding period last vear.

Telegraphic morbidity reports from State health officers for the week ended Mar. 22, 1947, and comparison with corresponding week of 1946 and 5 -year median
In these tables a zero indicates a definite report, while leaders imply that, although none was reported, cases may have occurred.

[^6]${ }^{2}$ Period ended earlier than Saturday.
${ }^{3}$ Dates between which the approximste low week ends. The specific date will vary from year to year.
420,515 cases of upper respiratory infection were reported, some of which werc probably influenza.

## WEEKLY REPORTS FROM CITIES ${ }^{1}$

City reports for week ended March 15, 1947
This table lists the reports from 88 cities of more than 10,000 population distributed throughout the United States, and represents a cross section of the current urban incidence of the diseases included in the table.
