

# Lung Cancer Mortality, 1949-51

## Supplemental Tables

"Comparative Mortality Among Metropolitan Areas of the United States, 102 Causes of Death," Public Health Service Publication No. 562, was issued in 1957. Section I of this report, "Ratios of Age-Adjusted Mortality for 163 Metropolitan Areas to Total United States, 102 Causes, White Population by Sex, 1949-51," includes ratios for cancer of the lung (malignant neoplasm of trachea, bronchus, and lung) specified as primary (ISC 162), and for cancer of the lung unspecified as to whether primary or secondary (ISC 163). The separate mortality ratios published for each of these two causes have not been of maximum value because in practice reported deaths from lung cancer unspecified (ISC 163) include varying proportions of deaths from primary lung cancer in different areas.

The supplemental tables presented here fulfill the need for mortality ratios for all reported lung cancer combined (ISC 162 and 163). Table 1 presents lung cancer mortality ratios for white males and white females for each of the 163 standard metropolitan areas. Ratios based on less than 16 deaths are shown in parentheses, in keeping with the selection of 16 as the critical number in the original publication. Table 2 shows the frequency distributions of the mortality ratios presented in table 1.

The mortality ratio in this study is an index of the relationship of the lung cancer mortality of a race-sex group in a standard metropolitan area to the lung cancer mortality of the corresponding race-sex group in the total United States. For example, a ratio of 1.3 for lung cancer for white males in the Detroit metropolitan area means that white male mortality from lung cancer in that area is about 30 per-

*The data were compiled by Miss Rose Sachs, statistician, formerly with the Field Studies Branch, Division of Air Pollution, Public Health Service, under the direction of Dr. Richard A. Prindle, deputy chief of the division. Miss Sachs is now with the Heart Disease Control Branch, Division of Chronic Diseases, Public Health Service.*

cent higher than the corresponding mortality for all white males in the United States in the same years. The approximate nature of these values should be borne in mind.

The number of white male deaths from lung cancer in each standard metropolitan area is usually several times the number of white female deaths (table 1, columns 4 and 5). The magnitude of this difference is not measured by the difference between the mortality ratios (table 1, columns 6 and 7).

The white male lung cancer mortality ratio for all standard metropolitan areas is 1.2 (table 1, column 6). The mortality ratios of the 163 areas range from 0.4 to 2.0 (table 2). More than half of the areas (97) have ratios between 0.8 and 1.2.

The white female lung cancer mortality ratio for all standard metropolitan areas is 1.1. The range, too, is slightly lower than the range for males.

The lung cancer mortality ratios were derived by the same formula and from the same data used in the preparation of section I of the original publication. A shortcut for computing these ratios by machine was developed and used. In both the original formula and the shortcut 10 age groups were used. The original formula, in which mortality means deaths from a specified cause, is shown below.

$$\left. \begin{array}{l} \text{Mortality ratio for} \\ \text{race-sex group of} \\ \text{SMA} \end{array} \right\} = \frac{\left\{ \begin{array}{l} \text{Reported deaths, SMA race-sex group} \\ \text{Sum of 10 products: (SMA race-sex-} \\ \text{age population group} \times \text{U.S. age-} \\ \text{group death rate)} \end{array} \right\}}{\left\{ \begin{array}{l} \text{Sum of 10 products: (U.S. race-sex-} \\ \text{age population group} \times \text{U.S. age-} \\ \text{group death rate)} \\ \text{Reported deaths, U.S. race-sex group} \end{array} \right\}} \times$$

<sup>1</sup> A few standard metropolitan areas are different from those used by the Bureau of the Census: Boston includes Lawrence and Lowell, Mass., New Haven includes Waterbury, Conn.; Hartford includes New Britain-Bristol, Conn.; and Bridgeport includes Stamford-Norwalk, Conn. The New York-Newark-Jersey City standard metropolitan area was divided into two metropolitan areas, New York and Newark-Jersey City.

SOURCE: "Comparative Mortality Among Metropolitan Areas of the United States, 102 Causes of Death," PHS Publication No. 562, October 1957, was based on mortality data from the former National Office of Vital Statistics and detailed population data were supplied by the Scripps Foundation. These data were used in the preparation of this table.

## Radiation as Working Hazard

The widow of a uranium miner was awarded \$11,466 in death benefits by the Colorado Industrial Commission in its first case judging the effects of radiation as a working hazard. Additional sums were provided for medical and funeral expenses under the Workmen's Compensation Act.

The death of 43-year-old Robert D. Johnson in 1958 was attributed to lung cancer caused by exposure to radioactive materials. He had operated three uranium mines near Uravan, Colo., from 1949 until his death.

An autopsy disclosed excessive amounts of radio-lead in bones, kidneys, liver, and muscles. Testimony at the hearing traced the origin of the radio-lead to inhalation of radioactive substances. Radio-lead is the end product of radioactive materials called "radon daughters," which are produced by radon gas emitted by disintegrating radium in uranium mines. Radon gas, which is continually being released by rock containing radium, is the primary health problem in uranium mines, ac-

ording to testimony by Duncan A. Holaday of the Division of Occupational Health, Public Health Service.

Johnson was one of 3,300 uranium miners being studied by the Public Health Service to determine radiation effects in uranium mines. Air samples taken for the study from one of the mines worked by Johnson contained 42 to 72 times the safe working-level concentration of radon gas and radon daughters. Johnson had dug shafts and drifts in each of his mines to reach high-grade ore. These operations took 6 months to 1 year in each case and were done in close quarters without natural or forced ventilation.

Dr. Victor Archer, Public Health Service specialist in radiological health, testified, "I think that our data together with the data from European mines, combined with our basic radio-biological knowledge, make a very strong case that exposure at high levels in such an atmosphere would be very likely to produce or accelerate cancer."
