CONTENTS

On December 8, 1965, a 35 -month-old Mexican girl died at the Children's Hospital, San Diego, California, with symptoms indicative of rabies. This diagnosis was confirmed on December 10 by the California State Department of Public Health Viral and Rickettsial Laboratory. The onset of the illness was after an apparent incubation period of only 10 days.

The child came from Ensenada, Baja California, Mexico, where she had been bitten above the right ear by a presumed rabid dog on November 18. This dog subsequently bit other dogs and all the animals involved were destroyed; none of these dogs was examined for rabies. However, because of the history the child was started on

a course of treatment, using an unspecified rabies vac- cine, on November 19, the day after she was bitten. No rabies vaccine was given on November 20 and 21. However, the course of treatment was resumed on November 22 and the rabies vaccine was administered daily thereafter through November 30, when the tenth and last dose was

given. There is no history of hyperimmune serum being given after the child had been bitten.

On November 28 the child began to show evidence of cerebral irritation; on November 29 and 30 her temperature began to rise and she became stuporous. On December 6 she was admitted to San Diego Children's Hospital at the request of officials of the Tijuana Health Department. On admission she was totally unresponsive with a rising temperature, which was $104^{\circ} \mathrm{F}$ on December 7 shortly before death.

A white cell count on admission was 10,500 with 75 percent neutrophils and 20 percent lymphocytes; the hemocrit was 37 . Cerebrospinal fluid pressure was slightly increased; the fluid was clear with a cell count of 24 polymorphs and one lymphocyte. Culture of the fluid for organisms gave negative results.

After the death of the child on December 8 an autopsy was performed and specimens of the brain, using
the fluorescent antibody technique, were positive for rabies. Infant mice were inoculated with the brain tissue and on the 5th day one mouse began to show suspicious symptoms. It was sacrificed and was positive for rabies by the fluorescent antibody technique. Thereafter it was not until the 17 th day that other mice began to show symptoms of rabies. One mouse was sacrificed on that day and another on the 19th day. Both of these mice were also fluorescent antibody positive for rabies. Laboratory studies of other tissues obtained at the autopsy are proceeding.
(Reported by Dr. J. B. Askew, Health Officer, San Diego California; Dr. Philip K. Condit, Chief, Bureau of Communicable Disease; and Dr. George L. Humphrey, Public Health Veterinarian, State of California Department of Public Health.)

## CURRENT TRENDS

POLIOMYELITIS - 1965

Weekly poliomyelitis case reports are received at the Communicable Disease Center from State and local health departments through the National Morbidity Reporting System. Poliomyelitis Surveillance forms are later completed on individual patients and forwarded to CDC; when all of these forms have been received they provide the data for the annual Poliomyelitis Surveillance Report. The following summary has been compiled from the weekly telegraphic reports to CDC and from such Poliomyelitis Surveillance data as are presently available.

Through the 52 nd week of 1965 , a provisional total of 59 cases of poliomyelitis has been reported in the United States; of these, 43 are classified as paralytic cases. This provisional total of paralytic cases is less than one-half of that reported during 1964, the previous record low year.

The dramatic decline in the annual incidence of poliomyelitis is illustrated in Figure 1. The peak of recorded incidence was in 1952 when an estimated total of 21,000 cases of paralytic disease was reported, a rate of 37.2 per 100,000 population. The comparative rate for 1965 is 0.025 per 100,000 .

The occurrence of paralytic poliomyelitis by 4 -week periods during the last 5 years is shown in Figure 2. The seasonal pattern of increased incidence during the early summer is evident in 1961 through 1963; in 1964 this was not a feature. However, during 1965 this early summer incidence is again discernible in very slight degree.

Preliminary information about 34 of the 43 paralytic cases reported in 1965 is available from the Poliomyelitis Surveillance forms submitted by the State Health Departments. The geographic distribution of the 34 cases through out the U.S. is shown in Figure 3 (page 444); 32 percent of them were reported from nine counties in Texas. The only counties to report two cases of paralytic polio in any one month were Scottsbluff County, Nebraska, Cameron County, Texas, and Yuma County, Arizona.

The Communicable Disease Center epidemic reserve oral polio vaccine type I was used in mass vaccination campaigns in children in Pinal and Yuma Counties, Arizona, in February and May 1965 respectively.

Two deaths from bulbar poliomyelitis occurred. One was of a child aged $11 / 2$ years from Wise County, Texas, and the other of a child of 11 years from Scottsbluff County, Nebraska; neither had received any polio vaccine. The paralytic status of the other 32 cases, as assessed after 60 days, was that 8 cases are so severely disabled as to be confined to bed or wheel chair; a further 12 cases have significant disability and 6 cases have only minor residual motor involvement. Data regarding the 60 day status of the remaining six cases are not yet available.

There are two major points of interest and importance illustrated in Table 1 which shows the age and vaccination status of the 34 paralytic cases. The first is that 56

By Date of Report, 1965

percent of them are 4 years of age or younger; the second is that 59 percent had received no polio vaccine whatsoever.

Of the 34 paralytic cases, stool specimens were available for laboratory examination from 29 patients and poliovirus was present in specimens from 24 of them (Table 2, page 445). In one case from New York both type I and type III poliovirus were isolated from the same specimen; in another case from Michigan, type II poliovirus and coxsackie virus type A4 were also isolated from one specimen.

Isolations of poliovirus during 1965 are compared with those in previous years in Table 2. The relative increase in the frequency of recovery of type II poliovirus is believed to be associated with a wider distribution of oral poliovaccine.

According to the Poliomyelitis Surveillance Reports received thus far at $C D C$, there were no paralytic cases reported during 1965 in persons who had received oral polio vaccine less than 30 days before the onset of paralysis. In four individuals, however, paralytic poliomyelitis
