Graphic Atlas of Common Serotypes.	11
Tabular Summary of Serotypes by Year.	178

The *Salmonella* Surveillance System, begun in 1962 at the Centers for Disease Control (CDC), collects reports of isolates of *Salmonella* from human and nonhuman sources from every state in the United States and District of Columbia (1). The reports are sent regularly by State and Territorial Epidemiologists and Public Health Laboratory Directors, who provide demographic data and serotype identification for each isolate from humans; in addition, reports of nonhuman isolates are sent by the U. S. Department of Agriculture. This surveillance system is distinct from the Morbidity and Mortality Weekly Report (MMWR) system, which is a clinically based notifiable disease reporting system. The MMWR system has included typhoid and nontyphoid salmonellosis as separate categories since 1942, but it does not include laboratory confirmation or serotype (2). The *Salmonella* Surveillance System has maintained data about all reported isolates of *Salmonella* on magnetic tape since 1968. This publication is an analysis of data from this system reported during the 19-year period from 1968 through 1986.

Since its beginning, the *Salmonella* Surveillance System has remained essentially unchanged except for fluctuations in reporting interests and priorities. Previously rare serotypes have been introduced into the United States and have spread to a variety of animal reservoirs, established serotypes have changed in frequency, and some once-common serotypes have become rare. We find the richness of the trends and patterns observed for serotypes meaningful and believe they can suggest hypotheses that might be important in understanding the epidemiology of *Salmonella* transmission. Although unknown changes in the reporting system could have affected patterns in an unpredictable way, many of the observed patterns are consistent from year to year. Some patterns are unique for certain serotypes and are consistent with what would be expected as a result of changes in the distribution of known *Salmonella* vehicles associated with particular serotypes.

The nomenclature of the genus *Salmonella* has undergone considerable change in recent years. Previously, the genus was divided into three species: *S. typhi*, *S. choleraesuis*, and *S. enteritidis*. *S. typhi* and *S. choleraesuis* each consisted of a single serotype: the approximately 2000 other serotypes were all classified under *S. enteritidis*, which included the serotype *enteritidis*. Recently proposed nomenclature, reflecting DNA hybridization and other taxonomic studies, classify all *Salmonella* and *Arizona* as a single species, *S. choleraesuis*, with six subgroups (3). To avoid confusion, we have followed the common convention of referring to each serotype as though it were a separate species. Thus, *S. enteritidis* in this report, refers to the serotype *enteritidis*. We have also used the conventions *S. paratyphi* A (formerly known as *S. paratyphi*), *S. paratyphi* B (more recently renamed *S. schottmuelleri*), and *S. paratyphi* C (more recently named *S. hirschfeld*).

Salmonellosis has often been discussed in the context of clinical manifestations as a single disease entity that is usually transmitted by food or water, without regard for the fact that there are many pathogenic salmonellae, each with its own epidemiologic features. Prevention strategies, therefore, have often been couched in terms such as "*Salmonella* prevention," "*Salmonella* in foods and food establishments," and "*Salmonella* in animals or animal feeds." The graphical descriptions presented here illustrate the variety among the serotypes. Examination of the epidemiologic characteristics of individual serotypes suggests that some control recommendations should be tailored to the individual serotype, and that interventions can be directed toward specific vehicles to reduce the risk of disease from those serotypes.

This report presents an epidemiologic summary of the most commonly reported serotypes. Most previous reports based on these surveillance data have necessarily been descriptive, using percentage distributions, and have not related the number of reported isolates to the populations at risk. Part of this analysis relates the frequency of reported

isolates to sex-, age-, or county-specific populations from the 1980 census in a graphical format. We hope that this atlas will serve as a useful reference for those working in public health who want to compare their experience with a particular serotype with the nationwide experience. We also hope that this epidemiologic atlas of *Salmonella* serotypes will stimulate thought, lead to testable hypotheses, and increase our understanding of the epidemiology of the *Salmonella* tribe.

METHODS

For each serotype studied, we plotted 8 graphs. Each graph should be interpreted with an understanding of its rationale and limitations as outlined below. Because of the constraints of size and space, the graphs are printed sideways on 2 facing pages and are numbered as follows:

1	2
3	4
5	6
7	8

For each serotype, the first graph (Figure 1) shows the 3-month moving average for reported isolates over the entire 19-year span. The month of report is typically 3-6 weeks after the date of isolation. Data points for each month on this graph were smoothed by taking the mean of the number of isolates from that month, the month before, and the month after. This helped remove some of the erratic fluctuations that tend to obscure real periodic changes in reporting frequency. These fluctuations represent reporting artifacts, random changes, and small outbreaks. Thus, the smoothing reveals more clearly the periodic occurrences that are useful for characterizing some serotypes.

Figure 2 shows the distribution of isolates by reporting month according to whether the isolates came from rural or urban counties. The data presented include all isolates over the 19-year span, summed for each month. These sums are plotted as the percentages of the total number of isolates reported from each type of county. An isolate was labeled "rural" or "urban" if it was reported from a county that had at least 90% of its population defined as either rural or urban in the 1980 U.S. census. The "mixed" category included all isolates that were not classified into the rural or urban categories using this definition.

Figure 3 shows the reported number of isolates by year for each of 3 age-groups. Note that the Y-axis scale varies from serotype to serotype. Because only a few isolates were reported for some serotypes, only 3 age-groups are graphed. We chose the age-groups 0-4 years, 5-29 years, and 30+ years to represent preschool children, school children and young adults, and older adults.

Figure 4 shows the distribution of isolates by reporting month for each of the 3 age-groups. These data are the sums of isolates reported each month over the 19-year span. The sums are plotted as the percentages of the total number of isolates reported for each age-group. The age-groups used are the same as in Figure 3: 0-4 years, 5-29 years, and 30+ years.

Figure 5 shows the median ages of persons from whom the isolates were reported by gender (sex), for each year in the 19-year span. This graph reflects changes in the distribution of the ages of persons at risk. However, a change in the median age must be

interpreted in light of other data presented about frequencies of isolates reported. For example, a rise in the median age over time for a particular serotype may reflect either an increase in the number of older persons or a decrease in the number of younger persons from whom isolates were reported. When no isolates were reported for the gender group during a given year or when ages were not given for the gender group during a given year, no point could be computed; a skip will occur in the line representing that gender group for that year.

Figure 6 shows the distribution of reported isolates by age-group and sex of the person from whom the isolate came. These data are also summed over the entire 19-year span. The graph has 11 age-groups with various spans: <1 year, 1-4 years, 5-9 years, 10-19 years, 20-29 years, 30-39 years, 40-49 years, 50-59 years, 60-69 years, 70-79 years and ≥ 80 years of age. For each age-group, the data are graphed as the percentage of the total number of isolates reported for each gender. These graphs present percentages that are not adjusted for the unequal age-group intervals. This has the effect of diminishing the appearance of differences between percentages for the age-groups under age 10, relative to the older age-groups that are plotted in 10-year intervals. Adjusting the percentages would have made the percentages for 4-, 5-, and 10-year groups appear at one fourth, one fifth, and one tenth of their present heights, respectively. It also has the effect of accentuating the relative differences in the older age-groups.

Figure 7 summarizes reported data on *Salmonella* isolates from nonhuman sources. The reported numbers of isolates from a given nonhuman source can vary considerably because of special studies or intense interest on the part of health officials. This makes the quantitative assessment of these data difficult. For instance, large numbers of reported isolates may have come from a single turkey flock or cattle herd, because of a research project or outbreak investigation. We have chosen to reduce the data to a simple qualitative form: a "+" indicates that the serotype was reported at least once from a particular source in a given year. The reported sources of isolates have been combined into broad categories of related sources.

Figure 8 shows the age-standardized rates by state for each serotype. These rates were obtained by computing the age-specific rates (using the same age-groups that were presented in Figure 6) for each state based on the 1980 census estimates for each state. These were standardized by multiplying each age-specific rate by the 1980 census estimate of the U.S. population in that age-group to obtain an expected number of isolates in each age-group that would have occurred in the United States if the age-specific rates for that state had occurred in the age-specific populations of the entire United States, adding the expected numbers over all age-groups, and dividing the total number expected in the U.S. population by the 1980 census estimate of the total population of the United States. For each serotype, the highest age-standardized rate is represented by a peak of a fixed height, and the heights of the other peaks on the map vary in proportion to the relative rates in those states. The maps provide at a glance the characteristic geographic locations of relatively larger and smaller standardized rates. The relative distribution patterns can be compared from map to map, but the maximum height for each map is fixed by the graphics program. Therefore, absolute heights of peaks for one serotype should not be compared with heights of peaks for another serotype. Further, it must be noted that states are smaller in the East, particularly the Northeast, and that a greater density of peaks in the Northeast may not be related as much to geographic distributions of reported isolates as to the greater density of the smaller states.

Graphs were created on an IBM 3083 mainframe computer using SAS software. These were downloaded to a COMPAQ Deskpro 386 microcomputer using Teknigraphics Graph-tek 4105 and CGI, and Freelance Plus software packages. SAS files of standardized rates for each state were computed on the mainframe computer and downloaded to the microcomputer. These points were then used to create the maps using SAS PC. These were printed using a Hewlett-Packard LaserJet Series II Laser Printer.

Limitations of the data: Surveillance data represent only a small fraction of the actual number of *Salmonella* infections in the United States. In determining the proportion of cases that occurred in well-studied outbreaks that were actually reported in the surveillance system, previous reports state that only 1% of cases of salmonellosis are reported (1). An analytic approach using several different methods to estimate the actual number of cases that have occurred similarly suggested that only 1%-5% of infections are reported (4). The national surveillance data base has several other limitations that should be kept in mind. Cases and carriers are not distinguished, except for persons from whom *S. typhi* was isolated. There is considerable variation among physicians, laboratories, and local and state health departments in obtaining cultures and reporting isolates. This makes state-to-state comparisons problematic. Reported isolates represent a mix of outbreak-associated and sporadic cases, and the process of detecting outbreaks is not systematic. Similarly, family clusters of *Salmonella* isolates cannot be accurately identified.

Three-Month Moving Average

The history of reporting patterns is presented on the 3-month moving average graphs. Reports of some new serotypes that have emerged in the surveillance system have increased to a steady and characteristic pattern (*S. agona*, *S. haardt*, and *S. mbandaka*) while *S. hadar* has continued to increase since its emergence in this country in 1976. The future frequency of reporting of *S. hadar* after 1986 may 1) increase, signaling that the pathogen is becoming more common in 1 or more vehicles, that a vehicle for which this organism has a propensity is becoming more widely distributed, that a problem is occurring in the processing, storage, distribution, or other step leading to consumption of the vehicle, or that a new risk group is being increasingly exposed to the vehicle; 2) remain at its present level, indicating that the serotype has established itself in the vehicle(s) that transmit it; or 3) decrease, indicating that transmission from the current reservoirs is not being sustained.

All serotypes exhibit seasonal changes in reporting frequency, with cyclical variation of both yearly and longer periods. The usual pattern includes a peak in reporting during September and October and a low point in frequency in March and April. Many serotypes have consistent 1-year cyclical patterns (e.g., *S. anatum*, *S. cerro*, *S. enteritidis*, *S. heidelberg*, *S. infantis*, *S. javiana*, *S. miami*, *S. mississippi*, *S. montevideo*, *S. muenchen*, *S. newport*, *S. norwich*, *S. oranienburg*, and *S. typhimurium*). Some graphs suggest longer cycles: e.g., *S. schwarzengrund*, with a 2-year cycle; *S. adelaide* with a 4-year cycle; and *S. anatum*, *S. blockley*, *S. infantis*, and *S. reading* with possibly longer periodic cycles in addition to the seasonal cycle. It is difficult to distinguish some baseline or "characteristic" patterns from shifts away from baseline caused by long-lasting outbreaks. For example, the reporting patterns for *S. johannesburg*, *S. london*, *S. manhattan*, *S. schwarzengrund*, and *S. siegburg* may reveal problems that lasted several years and subsided without intervention. On the other hand, the reporting frequencies of some serotypes are so low that patterns are less obvious, although the same factors that influence the patterns of more commonly reported serotypes could affect the patterns of these less commonly reported serotypes (e.g., *S. bareilly*, *S. bovismorbificans*, *S. drypool*, *S. gaminara*, *S. meleagridis*, *S. miami*, and *S. saphra*).

Serious attention should be given to those serotypes whose patterns lead us to suspect problems are beginning as a result of gradual increases in reporting frequency or of more abrupt changes that may eventually require intervention. *S. paratyphi* A, *S. stanley*, and *S. typhimurium* all have patterns with upward trends for most of the period of observation. *S. alachua*, *S. berta*, *S. braenderup*, *S. brandenburg*, and *S. enteritidis* all have pattern changes suggesting a recent and continued increase from a previously level baseline.

A separate feature of the seasonal cycle is the amplitude of seasonal variation. Although most serotypes tend to have greater numbers of isolates reported in the warmer months, some show striking seasonal increases (e.g., *S. javiana* and *S. newport*). The general warm season increase in reported isolates could reflect many things, including heat stress on the animal reservoir; higher ambient temperatures permitting greater bacterial growth in the abattoir, transport truck, storage container, or kitchen; and summertime eating settings that may have deficient refrigeration, such as picnics and other outdoor festivities. In addition, some of the seasonal variation of a given serotype may depend on the age spectrum of the persons from whom it is isolated, or on the rural/urban distribution it exhibits (see discussion under Seasonal Distribution by Rural/Urban Category). What remains to be explained, however, is why some serotypes should have such prominent seasonal variation and others less prominent.

Single large peaks mark specific outbreaks. The most dramatic example is the enormous outbreak of milk-associated *S. typhimurium* infections in May 1985 in the Midwest (5). This single large outbreak, with over 17,000 culture-confirmed cases, is visible in many of the analyses of data for this serotype. The outbreak of *S. cubana* infections related to carmine dye in the early 1970s is also very prominent (6). An outbreak of *S. eastbourne* infections in 1974 was related to contaminated holiday chocolate candy (7).

Other known outbreaks about which limited data have been reported through other channels (e.g., through the foodborne outbreak surveillance system and in annual summaries of the *Salmonella* surveillance system [8]) appear in the surveillance data. Some of the most prominent of these peaks represent an outbreak of *S. newbrunswick* infections associated with ham in 1979; 4 outbreaks of *S. thompson* infections reported in 1982, 1 of which was associated with ice cream, 1 with gravy served at a fast-food outlet, and 2 for which no vehicles were identified; 2 outbreaks of *S. poona* infections associated with a supermarket in 1979 and a nursery in 1985; an outbreak of *S. senftenberg* infections in a prison in 1981; 3 outbreaks of *S. sandiego* infections in 1970 and 1972, 1 of which was associated with turkey, while the vehicles were undetermined for 2 others; outbreaks of *S. drypool* infections in 1981 and 1982 with unknown vehicles; an outbreak of *S. manhattan* infections in 1974 associated with chicken salad; an outbreak of *S. stanley* infections in 1977 associated with ice cream; 3 outbreaks of *S. typhimurium* var. *copenhagen* infections associated with beef in 1982, milk in 1978, and an unknown vehicle in 1979; an outbreak of *S. virchow* infections associated with beef in 1973; 2 outbreaks of *S. chester* in 1973 and 1981 associated with beef; and 3 outbreaks of *S. meleagridis* infections reported in 1982 with unknown vehicles.

Seasonal Distribution by Rural/Urban Category

Since most isolates are reported from counties that are in metropolitan areas, the number of isolates from rural counties is relatively small. However, the seasonal distributions suggest the possibility of a mode of transmission or exposure group for isolates reported from rural counties that is different from urban counties for some serotypes. For example, *S. anatum*, *S. braenderup*, *S. bredeney*, *S. drypool*, *S. haardt*, *S. havana*, *S. mbandaka*, *S. montevideo*, *S. muenchen*, *S. newport*, *S. reading*, *S. saintpaul*, *S. sandiego*, *S. tennessee*, and *S. virchow* are among serotypes having peaks of reported isolates in the spring in rural counties.

Although some serotypes have the typical fall peak in reported isolates in both urban and rural counties, the peak for rural counties often occurs about 1 or 2 months before the peak for urban counties. This is true for *S. blockley*, *S. miami*, and *S. thompson*. However, the peak for urban counties precedes the peak for rural counties in the distribution of reported isolates of *S. saintpaul*.

The rural county distributions may actually be tri-modal for some serotypes, with a third peak occurring in May/June in addition to the March/April and September/October

peaks. *S. anatum*, *S. braenderup*, *S. derby*, *S. london*, and *S. saintpaul* have such distributions. Others such as *S. adelaide*, *S. brandenburg*, *S. cerro*, and *S. drypool* have the May/June peak along with either a spring or a fall peak.

It is unclear what the relationship is between these earlier peaks and the epizootology of salmonellae in rural counties, and their relationship to specific seasonal exposures, such as calving.

Frequencies by Age-Group and Year

There has been a general increase in the number of *Salmonella* isolates reported to CDC each year, from 19,740 in 1968 to 42,028 in 1986. Many individual serotypes have been increasing in frequency of reporting since the 1970s; these increases are largely unexplained. Many other serotypes are represented by a somewhat constant number of isolates each year, and a few are becoming less common (Table 1).

Table 1. Mean number of isolates reported annually during 1968-1976 and 1977-1986 of serotypes with changing isolation rates.

INCREASING Serotype	1968-1976	1977-1986	DECREASING Serotype	1968-1976	1977-1986
<i>S. adelaide</i>	5	59	<i>S. californica</i>	17	15
<i>S. alachua</i>	19	51	<i>S. cubana</i>	88	26
<i>S. berta</i>	42	79	<i>S. derby</i>	474	368
<i>S. braenderup</i>	103	292	<i>S. eimsbuettel</i>	17	4
<i>S. brandenburg</i>	8	58	<i>S. java</i>	305	180
<i>S. cerro</i>	22	114	<i>S. manhattan</i>	285	132
<i>S. dublin</i>	27	119	<i>S. miami</i>	73	40
<i>S. enteritidis</i>	1752	3234	<i>S. saintpaul</i>	971	684
<i>S. haardt</i>	2	80	<i>S. siegburg</i>	50	27
<i>S. hadar</i>	<1	369	<i>S. thompson</i>	633	384
<i>S. heidelberg</i>	1472	3108	<i>S. urbana</i>	30	11
<i>S. mbandaka</i>	0	114			
<i>S. montevideo</i>	350	684			
<i>S. muenster</i>	30	89			
<i>S. ohio</i>	22	191			
<i>S. paratyphi A</i>	18	55			
<i>S. schwarzengrund</i>	80	199			
<i>S. virchow</i>	17	56			

Increases in reporting frequencies of a few serotypes can be explained. The dramatic increase in reports of *S. agona* isolates followed its introduction in 1969 in Peruvian fish meal used as an ingredient in poultry feeds (9). It has become widely distributed in many food animals and is presumably maintained by recycling through rendered animal byproducts used in animal feeds.

The increase in reports of *S. dublin* isolates appears to be related to the consumption of raw milk, particularly on the Pacific Coast (10). The organism is found on dairy farms and can cause mastitis. It appears to be adapted particularly to the bovine host, but the cycles of transmission by which it persists there are unclear.

S. enteritidis isolates have increased dramatically in recent years in the Northeastern United States (11). Although this serotype is widespread throughout food-animal reservoirs, the recent increase is strongly associated with shell eggs and appears to be related to a new capacity for transovarian transmission, which permits the intact egg to be contaminated before the shell is formed.

S. hadar was recently introduced into commercial turkey flocks, possibly from a European source; it has been epidemic in the United Kingdom for several years (12). It has appeared in feed products and in chicken flocks in the United States, and reporting of this serotype is rapidly increasing.

An outbreak of *S. newbrunswick* infections in a nursing home in 1972 appears as a peak restricted to the 30+ age group. Other unusual peaks are not easy to explain, but they probably reflect common-source outbreaks. Examples of these include *S. berta* in 1971 and 1981, *S. inverness* in the 0-4 age-group in 1973 and 1983, *S. kottbus* in the 5-29 and 30+ age-groups in 1985, *S. paratyphi* B in the 0-4 and 5-29 age-groups in 1971, and *S. senftenberg* in the 0-4 age-group in 1975.

Important decreases in reports of some serotypes are also understood; they followed the epidemiologic detection of specific vehicles and their successful control. For example, the formerly high isolation rate of *S. cubana* was associated with the use of carmine dye to study gastrointestinal motility (6). This dye, made of pulverized insects, is no longer used for that purpose. The number of reported isolates of 3 serotypes associated with turtles, *S. java*, *S. urbana*, and, to a lesser extent, *S. litchfield*, decreased following the successful efforts to reduce and ultimately to ban the distribution of small pet turtles in the early 1970s (13). The reduction was most prominent in the 0- to 4-year age-group, the group most likely to have been exposed to the pet turtles.

Seasonal Distribution by Age-Group

Examination of the seasonal distribution of isolates within specific age-groups reveals several interesting patterns. If a particular serotype is transmitted via a common source, such as a food item consumed by all age-groups, then the seasonal distribution should be similar for the age-groups. However, if persons of different ages acquire their infections from different vehicles or as a result of transmission from older or younger persons, then the peaks in reporting incidence may occur at different times for different ages. Some serotypes showing simultaneous seasonal peaks in all age-groups are *S. bareilly*, *S. hadar*, *S. havana*, *S. heidelberg*, *S. mississippi*, *S. montevideo*, *S. norwich*, and *S. weltevreden*. Other serotypes show nonsimultaneous peaks among different age-groups. For example, the peak in isolates from younger persons follows that of older persons for *S. newport*, *S. anatum*, *S. javiana*, and *S. thompson*.

Median Age by Sex and Year

The graphs of median age should be interpreted along with the graphs of frequency of reported isolates by age in order to better understand the meaning of changes in the medians. Some apparently large changes are a result of the small numbers of reported isolates. For example, the graph for *S. adelaide* presents high median ages before 1974 and low medians for the years after 1973. However, the graph of frequencies of reported isolates shows that during 1968-1973 very few isolates were reported for this serotype.

Many changes in median age occurred during the 19-year period analyzed. In 1982 the median age of persons from whom isolates of *S. agona* were reported began to rise. This rise in median age can be attributed to a decrease in the frequency of reported isolates from the 0- to 4-year age-group and a slight increase in isolates from the older age-group. Similarly, the frequencies of reported isolates for each age-group should be examined to

explain changes in the median ages for other serotypes, such as *S. blockley*, *S. enteritidis*, *S. infantis*, *S. java*, *S. manhattan*, *S. montevideo*, *S. muenchen*, *S. newport*, *S. oranienburg*, *S. panama*, *S. saintpaul*, and *S. thompson*. However, the change in median ages of males differs from that of females for certain serotypes, such as *S. reading* and *S. schwarzengrund*. These changes in reporting frequencies need explanation. Possible reasons include 1) an increase in the population in the age-group for which an increase occurred; 2) introduction of a new subpopulation into the country (e.g., refugees); 3) introduction of new food items popular among a particular age or sex group; and 4) new contamination of an existing food item popular among a particular age or sex group.

Distribution of Isolates by Age-Group and Sex

Three common features pertain to most serotypes. First, the largest percentage of isolates is reported for the <1- and 1- to 4-year age-groups. Second, a rise occurs in the percentages of reported isolates from the 10-19, 20-29, and 30-39 age-groups, and among these, a peak occurs in the 20-29 age-group (e.g., *S. chester*, *S. montevideo*, *S. muenchen*, *S. muenster*, *S. paratyphi A*, *S. sandiego*, *S. typhi*, and *S. virchow*). Generally, the percentages decline successively after the 30- to 39-year age-group, although a slight rise in percentage appears in the 60- to 69-year or 70- to 79-year age-groups for many serotypes. Three serotypes are notable exceptions to this: *S. choleraesuis*, *S. choleraesuis* var. *kunzendorf* and *S. dublin*, for which there is a general increase in percentage after the 10- to 19-year age-group. Third, the distributions for males and females differ slightly. Usually the percentage is higher for males in the <1- and 1- to 4-year age-groups and higher for females 20-29 (and, although less often, 30-39 and 40-49). Among the older age-groups the percentages for males and females are somewhat more similar with inconsistent fluctuations.

There is a possible link between infections in infants and young children and infections in parents and grandparents. This link could be common exposure, but the observation of age-related lags between the seasonal peaks suggests that the link could also be transmission from 1 age-group to another for some serotypes. For example, the seasonal distributions (previously described in Seasonal Distribution by Age-Group section) for *S. javiana* and *S. newport* suggest that the isolates for adults in the 30+ age-group precede those for the 5-29 age-group, which possibly precede those for the 0-4 age-group. This, along with the percent distributions for these serotypes, showing the characteristic rise in the 10-19, 20-29, and 30-39 age-groups and a preponderance of isolates from females in all age-groups beginning with the 20-29 year age-group, suggests the possibility of transmission from parents and grandparents (especially mothers and grandmothers) to children.

Geographic Distribution

The geographic distribution of the serotypes can be informative, since the occurrence of *Salmonella* in specific regions of the country may signal regional contamination of a food item, contamination of a food that is consumed primarily in those regions, or the presence of a regional subpopulation that is highly susceptible to *Salmonella*. Serotype-specific differences in the regional distribution of isolation rates are apparent for several serotypes. The high and increasing rate of *S. enteritidis* in the northeastern part of the United States, noted above, is related at least in part to a regional contamination of shell eggs (11). The concentration of *S. dublin* on the West Coast is presumably related to the popularity and availability of raw milk there. Other serotypes exhibit geographic concentrations that are harder to explain: *S. choleraesuis* has the highest rates in the eastern third of the country; *S. hartford* has the highest rates in the southeastern quarter of the country and along the Atlantic coast; *S. javiana* rates are highest in the South, particularly among the Gulf states; *S. mississippi* rates are highest in the Southeast; *S. norwich* rates are highest in the southcentral states; *S. saphra* rates are highest in Texas and Louisiana; and *S. weltevreden* is confined almost exclusively to Hawaii. Explanation of these distributions would require data on local reservoirs and on local exposures to potential food vehicles or other sources.

CONCLUSION

Specific epidemiologic characteristics distinguish categories of serotypes and are unique for some serotypes. The distinctive features of some serotypes probably reflect underlying cycles of transmission. Interpretation of much of the richness of these patterns remains elusive. We do not know the predominant vehicles of transmission for most serotypes, and we can only guess at the underlying complexity of the epidemiology. Devising successful control measures depends on understanding the routes of transmission well enough to interrupt them. The variety of epidemiologic observations presented here makes it clear that it is difficult to consider the "control of salmonellosis" as a single subject. Serotype-specific understanding has been the key to successful control efforts, and the laboratory-based surveillance system has made this possible. The regular appearance of new serotypes and the changes in the epidemiologic patterns of established ones point up the continued need for vigilance.

We presume that most salmonellosis is foodborne in origin and that specific serotypes tend to have specific vehicles, which are usually of animal origin. It would be instructive to compare these data with estimates of the amount of beef, pork, dairy products, and poultry consumed by state of residence, age, and time of year. These data are not currently available and would require carefully designed studies of human food consumption. Introduction of new food items, changes in marketing strategies, changes in the availability of foods to new subgroups of the population, such as fast-food availability to children and teenagers or diet foods to dieters, that could account for sudden increases or decreases in several serotypes may also be fruitful areas of inquiry. It would be interesting to know which serotypes are perpetuated through the use of inadequately treated rendered animal byproduct, which may have its characteristic epidemiologic pattern. Finally, these data could be compared with systematic data on the occurrence of specific *Salmonella* serotypes in animals in the food chain.

We hope that this graphic presentation of the epidemiology of *Salmonella* serotypes in the United States will stimulate further research into the persistence and transmission of these organisms, which will lead to a better understanding and control of the *Salmonella* tribe.
