METHANE EMISSIONS FROM U.S. COAL MINES IN 1980

By Roy H. Grau III¹ and John C. LaScola²

ABSTRACT

This Bureau of Mines report contains a tabulation of methane emissions during 1980 for all coal mines located in the United States with emissions greater than 0.1 MMcfd. Listed for each mine are methane emission quantity, location, and coalbed. The report also compares records of 1975 and 1980 and describes relationships between emissions in 1980 and the Bureau's coalbed gas content data on 11 mines.

INTRODUCTION

Methane gas is a threat to safety in underground coal mines. Research by Government and industry has led to great gains in reducing methane gas ignitions and explosions. The development of advanced methane control techniques is necessary for the safe operation of more gassy mines and the implementation of rapid mining techniques.

As part of this research, the Bureau of Mines has surveyed total methane emission data from underground bituminous coal mines in the United States and tabulated emissions from mines producing over 0.1 MMcfd of methane. This report is an update of similar studies previously described in Information Circulars 8733, 8659, and 8558 (2-4).³

The data from 1980 were compiled from Mine Safety and Health Administration (MSHA) records of air quality-quantity inspections made quarterly at each mine. The inspections involve measuring airflow and collecting air samples in the main returns. From these data, an average methane emission is calculated and used to represent the daily mine emission for each quarter. The methane emissions given in this report are the averages of the four 1980 quarters and do not include mine emissions from other sources such as degasification projects. Since a previous Bureau study showed that emissions from mines emitting less than 0.1 MMcfd represented only 2 pct of all emissions, 0.1 MMcfd was chosen as a lower limit for data collection (4).

ACKNOWLEDGMENTS

The authors express their appreciation to the district and subdistrict personnel of the Mine Safety and Health Administration throughout the country who

contributed much of the information for this report. The completion of this project would not have been possible without their full cooperation.

DISCUSSION OF RESULTS

METHANE EMISSION STATISTICS

During 1980, 200 underground coal mines in the United States had methane emissions of at least 0.1 MMcfd. These mines are listed in order of highest emissions to lowest in table A-1 in the appendix and alphabetically by coalbed in table A-2. Both tables contain each mine's respective coalbed, State, and county. The emissions from all mines totaled 256.3 MMcfd, and the mines were distributed through 11 States and 64 counties.

A comparison of the emission data for 1975 (2) and 1980 is shown in table 1. Total emissions increased from 216.3 MMcfd in 1975 to 256.3 MMcfd in 1980. The number of mines emitting 0.5 MMcfd or less decreased by 9.0 pct, but the gas emitted from this group remained at 8.0 pct. Also, there was an increase in the number of mines producing between 0.5 and 1.0 MMcfd, as well as those producing over 1.0 MMcfd. However, in both categories, the percentage of emissions they contributed to the total amount in 1975 and 1980 was almost equal. The overall increase in methane emissions from 1975 to 1980 may have been caused by a variety of factors such as new mines in gassier seams, an increase in the size of the

mines, and the fact that 1980 coal production for underground bituminous coal mines in the United States was 337 million short tons compared with 293 million short tons in 1975.

Table 2 gives a comparison of the 10 mines with the highest emissions in 1975 and 1980. The emissions from the 10 highest producing mines increased from 66.8 MMcfd in 1975 to 82.8 MMcfd in 1980. Although the mines that are listed as top gas producers in 1975 were all active operations in 1980, six were replaced in the 1980 list by different mines, all of which were located in Alabama or Virginia. Interestingly, these six mines ranged from 4 to 14 yr old while five of the six mines that were replaced were at least 30 yr old. Although this seems to indicate that a direct relationship exists between emissions and age, a more in-depth observation shows that there is no singular relationship between the two (4). For instance, in 1980 the following mines had these respective ages and emissions:

Blue Creek No. 4.....	6 yr	16.5 MMcfd
Blue Creek No. 5.....	5 yr	6.2 MMcfd
Loveridge No. 22.....	29 yr	8.2 MMcfd

NAP Not applicable.

Previous Bureau studies have reported conflicting data on how emissions are affected by coal mine production (4-6, 8). Data from this report show that no singular relationship exists between emissions and production. This can be confirmed by reviewing the three highest emitting mines in 1980 with their respective emissions and coal production:

Blue Creek No. 4.	16.5 MMcfd	752 Mtpy
Blue Creek No. 3.	11.1 MMcfd	1,015 Mtpy
Loveridge No. 22.	8.2 MMcfd	2,142 Mtpy

If age and production do affect emissions, it is in combination with other factors such as coalbed gas content, geology, permeability, rib length, etc., all of which would combine to alter the emission rate.

Figure 1 compares total emissions, number of mines, and mean and median emissions of all mines for 11 states.

Analogous to the large portion of emissions produced by a small percentage of mines, a large percentage of emissions occur in a few select States and counties. Although mines were located in 11 States, West Virginia, Alabama, Pennsylvania, and Virginia together had emissions that totaled 215.3 MMcfd or 84 pct of total emissions. Additionally, these 4 States contain 11 counties with the highest emission rates of all counties, greater than 7.2 MMcfd each. Although these counties represent only 17 pct of the 64 counties listed, they contain mines that produce 72 pct of all emissions. Figure 1 also shows that depending upon location, total emissions can be largely dependent upon either the number of mines or the average emission per mine. Noteworthy is Alabama, which has only 14 listed mines yet produces the second highest total emissions and has the highest mean and median emission per mine for any State.

FIGURE 1. - Emissions, number of mines, and mean and median emissions per mine for 11 States.

During 1980, 17 of the total 48 coalbeds had total emissions greater than 1.0 MMcfd. Total emissions, number of mines, and mean and median emissions per mine for the 10 largest methane producing coalbeds are shown in figure 2. The Pittsburgh, Mary Lee, and Pocahontas No. 3 Coalbeds accounted for 67 pct of all emissions. The Pittsburgh Coalbed has the most mines and highest total emission, but the Mary Lee Coalbed is second in emissions and is the highest in gas emissions per mine.

FIGURE 2. - Total emissions, number of mines, and mean and median emissions per mine for the 10 highest emitting coalbeds.

EMISSION TREND ANALYSIS

Since the early 1970's, Bureau research has focused on creating a methodology for predicting methane emissions. Irani (4) showed a relationship between methane emissions and the product of depth and coal production for four major coalbeds. During the same time period, the Bureau developed a direct method of determining the methane content of coal samples

obtained from vertical exploration cores (9). Diamond (1) gives a complete description of the direct method, including 583 test results from 125 coalbeds in 15 States. The final product of this methodology is gas content per unit weight of coal, which can be used as an indicator of the coalbed gas content. Although Kissell (9) has shown a relationship between measured gas content and methane emissions, additional data on gas content, presented in this report, provide a new insight into the relationships between total gas content, depth, and methane emission.

Total gas content is not the only factor affecting the rate at which methane will enter a mine airway. Parameters such as production, mining methods, methane drainage, mine size, geologic conditions, permeability, porosity, and water saturation are also important aspects affecting methane emissions. Although these factors could not be evaluated for this report, the *general* relationships between total mine emissions, total gas content, and depth for 1980 data can be shown.

Table 3 shows 11 mines from which the Bureau has both 1980 emission records and at least one coal core taken on mine property. These mines had emissions between 0.4 and 7.3 MMcfd, not including emissions from degasification programs or

FIGURE 3. - Total gas content versus depth of coal. ($\hat{Y}$ = estimated total gas content; X = depth; R^2 = coefficient of determination.)

vertical borehole gob drainage. The mines were located in seven different coalbeds with coal core depths from 427 to 2,185 ft. Production ranged from 372 to 1,448 Mtpy. Figure 3 shows the graph of gas content versus depth for the mines listed and indicates that gas content will increase with depth (7). It is true to some extent that the higher the gas content, the higher the emissions; however, the gas content data do not take into account that coalbed permeabilities generally decrease in deeper coalbeds and thus restrict methane emissions (11).

¹U = Upper; L = Lower.

FIGURE 4. - Methane emissions versus total gas content. ($\hat{Y}$ = estimated emissions; X = total gas content; R^2 = coefficient of determination.)

The relationship of methane emissions to methane gas content can be observed in figure 4, which may denote that gas content should be used only as an indicator of the relative gassiness of the coalbed and not to predict the exact methane quantities emitted. A similar relationship is presented in figure 5, which

FIGURE 5. - Emissions versus depth of coal. ($\hat{Y}$ = estimated emissions; X = depth; R^2 = coefficient of determination.)

shows methane emission versus depth. A slightly better relationship appears for emissions compared with depth than for emissions compared with gas content, possibly because with deeper mines permeability decreases and gas content increases (7, 11).

CONCLUSION AND SUMMARY

In 1980, there were 200 bituminous coal mines within the United States emitting at least 0.1 MMcfd, with total emissions equaling 256.3 MMcfd. Methane emissions increased by 40.0 MMcfd since the last Bureau survey in 1975. Seventy mines had emissions of 1.0 MMcfd or more, which accounted for 80 pct of the total daily emissions. The mines listed in this report are located in 48 coalbeds, 17 of which have total emissions greater than 1.0 MMcfd. The Pittsburgh, Mary Lee, and

Pocahontas No. 3 Coalbeds accounted for 67 pct of all methane emitted. Although the mines were located in 11 States, West Virginia, Alabama, Pennsylvania, and Virginia accounted for 84 pct of the total emissions.

Coal core gas content data were available for 11 mines. Relationships were established between gas content and depth, emissions and gas content, and emissions and depth.
